ABSTRACT

The issue of power in exploratory single group repeated measures analysis of variance is explored under the condition of heterogeneous correlations across the repeated measures trials. Tables developed from 13 real and hypothetical data sets (70 cells) show how well both univariate and multivariate power is estimated under a variety of conditions of non-sphericity and effect sizes. It was shown that a reasonable estimate of power could be obtained based on the mean off-diagonal population correlation and J. Cohen's (1965) estimate of effect size for a one-way analysis of variance. It was recommended that researchers base their estimates of this mean population correlation on what they know about their instrument's test/retest reliability under treatment conditions. One data table and nine figures are included. One appendix lists the sources of the data sets, and another appendix provides a computer program for estimating power. (Author/SLD)

Research Association, Boston, April, 1990.

Abstract

The study explores the issue of power in exploratory single group repeated measures analysis of variance under the condition of heterogeneous correlations across the repeated measures trials. Tables developed from real and hypothetical data sets show how well both univariate and multivariate power is estimated under a variety of conditions of non-sphericity and effect sizes. It was shown that a reasonable estimate of power could be obtained based on the mean off-diagonal population correlation and Cohen's estimate of effect size for a one-way analysis of variance. It was recommended that researchers base their estimate of this mean population correlation on what they know about their instrument's test/retest reliability under treatment condition.

Power Analysis in Repeated Measures Analysis of Variance with Heterogeneously Correlated Trials

Introduction

The study explores the issue of power in repeated measures analysis of variance under the condition of heterogeneous correlations between the repeated measures trials. Tables developed from real and hypothetical data sets show how well both univariate and multivariate power is estimated under a variety of conditions of non-sphericity and effect sizes. The question of interest is: How well is the repeated measures effect size estimated when a single correlation coefficient is used as a population parameter to represent the correlations among the repeated measures when the correlation matrix is heterogeneous in a single group exploratory design? This question breaks into two main points: (a) If we use a single estimate for ρ , will it provide a good estimate of population power?, and (b) What should be used for the single estimate? The paper continues with background perspectives on the findings, methods, results, the development of the question of interest, conclusions, the importance of the study, and tables supporting the findings.

Background and Perspectives

Power analysis has been studied for several statistical procedures. However, the importance of a *a priori* determination of the probability that a statistical test will yield statistically significant results has not been in evidence in the literature (Cohen, 1988). Cohen's text gives many examples of power calculations for various search designs. However, it does not include power computations and tables for repeated measures analysis of variance designs except in its most basic form, the dependent t test. This area has been

explored in part (Barcikowski & Robey, 1985, 1984a, 1984b, and Robey & Barcikowski, 1984), yet the impact on power under the specific condition of heterogeneity of the occasions correlation matrix has not been thoroughly addressed. This study will attempt to determine whether a single representative estimate of a heterogeneous trials matrix will be adequate for use with current power analysis methods.

Under valid assumptions (sphericity/circularity and more stringently, under uniformity, or constant correlations among the repeated measures trials) the exploratory single-group univariate F test is always more powerful than the multivariate F test, due to the greater number of denominator degrees of freedom in the univariate test when epsilon, ϵ , is equal to one. Under most circumstances, in an exploratory design, the assumption that sphericity is tenable is unlikely to be upheld. In univariate repeated measures analyses, a routine method to compensate for the violation of the sphericity assumption is the use of an adjusted univariate F test to control the risk of type I error. The adjustment consists of estimating the sphericity parameter, ϵ , and then multiplying the numerator and denominator degrees of freedom by the estimated ϵ . The critical F value is then found using the adjusted degrees of freedom. Of the two estimates of ϵ , ϵ^{\wedge} recommended by Greenhouse and Geisser (1959), and ϵ^{\sim} recommended by Huynh and Feldt (1976), ϵ^{\wedge} is the more conservative and therefore is well put to exploratory designs in which the value of ϵ is probably unknown.

When the sphericity assumption is violated, then the power of the adjusted univariate test varies from being more powerful than the multivariate test to being severely less powerful than the multivariate test (Barcikowski and Robey, 1984a; Jensen, 1982). Therefore, Barcikowski and Robey recommend the use of both tests.

Cohen (1965) describes power as a function of the significance criterion, α ; sample size, n ; and effect size, f , the degree to which a phenomenon is specific and nonzero in the population. Barcikowski & Robey (1985) modified Cohen's effect size categories (small, medium, large), based on an equation involving a single estimate of the intercorrelations among repeated measures trials. Barcikowski and Robey suggest when heterogeneous correlations are found among the occasions in repeated measures designs, that the intraclass correlation coefficient might be used to represent the population trials correlation matrix in the calculation of effect size to estimate power (1985, p. 7).

Stevens defines the intraclass correlation, ρ , as dependence among observations, which increases type I error rate (1986, p. 202). Haggard (1958) defines ρ as the correlation between every pair of members in the group. Others similarly defining intraclass correlation are Pearson (1901), Harris (1913), Fisher (1950), and Winer (1971).

Two other measures of a single estimate to represent the trials correlation matrix are the mean of the off-diagonal of the correlation matrix, and the median off-diagonal. While not the same as an intraclass correlation, central tendency measures are routinely used to represent sets of numbers. Here, these two measures are determined from the correlations between the occasions.

Development

Mean Vectors and Variance-Covariance Matrices

The development of the analysis began with contrived data from Willhoft and Schafer (1989). They combined five patterns of mean vectors, representing models of growth and learning

over time, with variance-covariance matrices with three levels of sphericity: spherical ($\epsilon^{\wedge} = 1.00$), nearly spherical ($\epsilon^{\wedge} = 0.95$), and moderately spherical ($\epsilon^{\wedge} = .75$). Willhoft and Schafer state that one factor affecting both univariate and multivariate power in repeated measures designs is the "interaction between the way in which the . . . repeated-factor means are ranked, that is, the 'shape' of the mean vector, μ , and the way in which the . . . elements of Σ [the variance-covariance matrix] are arranged" (p. 2).

Extending some of the examples of Willhoft and Schafer (excluding the three "no growth" patterns of all zeros in the mean vector), 58 other pattern combinations of mean vectors and variance-covariance matrices from real and hypothetical data sets (Appendix A) were examined. Those sets of raw data were first analyzed using the Repeated Analyzer SAS language program (SAS Institute Inc., 1985) created by Barcikowski and Robey (1990). From this program, mean vectors, μ ; variance-covariance matrices, Σ ; sample sizes, n ; number of trials, k ; and the non-singular matrix of $(k - 1)$ by k contrast coefficients, C were catalogued. This information was entered into the SAS language program Rho Effect (Appendix B) based on equations in Barcikowski and Robey (1984a, 1985).

Effect Size

In their paper (1985), Barcikowski and Robey show that when the condition of uniformity¹ is met, Cohen's effect size index, f , may be written in both the univariate (f_u) and multivariate (f_m) form as:

$$(1) f_u = f_m = f/\sqrt{1 - \rho}$$

where ρ is a population correlation, such as the intraclass correlation coefficient. Specifically, the univariate and multivariate effect sizes under uniformity are:

$$(2) f_u = f_m = \sqrt{\frac{K \sum_{i=1} (\mu_i - \mu.)^2}{K \sigma_m^2 (1 - \rho)}}$$

This equation is Cohen's (1988, p. 275) effect size for a one-way analysis of variance with K independent groups divided by $\sqrt{1 - \rho}$. For the purpose of repeated measures analysis of variance, K equals the number of trials in a single group design. The numerator of this formula can be found as the sum of squares between measures in a one-way analysis of variance. In the denominator, σ_m^2 can be found as the population variance for any given measure. In practice, σ_m^2 and ρ are estimated from norm information or from past research/pilot work.

In an exploratory analysis, ρ is an unknown quantity, and difficult to estimate if homogeneity between the repeated measures trials correlation matrix cannot be assumed. Under the limitation of compound symmetry, formula (2) can be used to calculate effect size which is used to calculate power. Actual power is calculated using σ_{uxm}^2 , the interaction of units and measures, or the error, variance, which can be estimated as the mean square within residual in a reliability program analysis (e.g., SPSS^X RELIABILITY). Under the condition of circularity,

$$(3) \sigma_{uxm}^2 = \sigma_m^2 (1 - \rho)$$

Formula (2) employs the estimate of $\alpha_m^2 (1 - \rho)$ in the denominator. The effect size calculated may be over- or underestimated using a single estimate of ρ . The answer to the question of interest rests on the magnitude of the over- or underestimation.

Methods

Data Sets

Seventy cells were catalogued from 13 data sets. Six data sets came from published sources, some real, some hypothetical. The remaining data sets were collected from practitioners at Ohio University in Athens, OH, and were all real data. The studies came from a wide variety of disciplines, such as hearing and speech sciences, botany, interpersonal communication, curriculum and instruction, and osteopathy. While most of the practitioners' data sets were exploratory, only two were single group designs. The analyses were performed on each group separately, as if each were a single group. The same procedure was followed when there was more than one measure per occasion. Only one measure was analyzed at a time. The hypothetical data sets were separated the same way.

Procedure

The Rho Effect program was used to calculate the parameters of interest. Using information from the Repeated Analyzer program, among the measures that were calculated are the following: (a) RBAR, the average of the lower triangular half of the trials correlation matrix; (b) RMED, the median of the lower triangular half of the trials correlation matrix; (c) MES_POP, the multivariate effect size in the population; (d) UES_POP, the population univariate effect size;

(e) ES_MEAN, the effect size estimate based on RBAR;
(f) ES_MED, the effect size estimate based on RMED;
(g) MPOP_POW, multivariate population power; (h) UPOP_POW, univariate population power; (i) MEAN_POW, multivariate power estimated from RBAR; (j) MED_POW, multivariate power estimated from RMED; (k) UMEANPOW, univariate power estimated from RBAR; and (l) UMED_POW, univariate power estimated from RMED.

Intraclass correlation coefficients were not included in the final Rho Effect program. Several intraclass correlation coefficient formulas were investigated (Harris, 1913; Fisher, 1950; and Winer, 1971), but the resulting effect sizes tended to be so large, both in absolute terms and in comparison to population values, as to be useless and so were discarded.

As there was a varied mixture of real and hypothetical data sets, the analysis of how well power is estimated was descriptive in nature. The Microsoft Works for Apple Macintosh Systems spreadsheet (Productivity Software Inc., 1988) was used to build the database of the variables. Comparisons were made of population parameters vs. derived estimates for ρ , f , and power. Statpro (Penton Software Inc., 1985) was used for graphics.

Results

Table 1 lists comparisons of ρ , f , and power. The comparisons over the 70 data set cells are: (a) |SUM|, the sum of the absolute value of the differences to detect the magnitude of the deviation; (b) μ , the mean of the absolute value of the deviations; (c) σ , the standard deviation of the absolute value of the deviations; (d) % OVER, the percentage of analyses that overestimated the population parameter; (e) % SAME, the percentage of analyses that exactly estimated the population parameter; and, (f) % UNDER, the percentage of

analyses that underestimated the population parameter.

The first entry in Table 1 compares the ρ (RPOP) of the population (which was calculated from formula 4) with the mean r of the correlation trials matrix. The second entry compares ρ to the median r of the correlation matrix. The comparison of these two entries shows that the mean r is a better estimator of ρ , in that the difference of $|\rho - r|$ has a smaller mean and variance. Both the mean r and the median r tend to overestimate ρ . Figure 1 depicts the range of deviations of RBAR and RMED from RPOP. It is easy to see that RMED deviated from RPOP much more than did RBAR. The range bar plot for the mean r deviation shows it to be the more accurate estimator of ρ , with checkpoints at the minimum deviation score, 25th percentile, median, and maximum deviation score.

The third through sixth entries in Table 1 compare univariate and multivariate population effect sizes with estimates of effect size based on mean r and median r . Comparison of the third and fourth entries show that univariate effect size calculated using mean r is a closer estimate of the population parameter than using median r . As in estimating ρ , both estimates tend to overestimate the population effect size. Visual support for these findings are in Figures 2 and 3. These figures contain histogram frequency categories with ten range intervals. The tenth interval on Figure 2 and the eighth interval on Figure 3 contain zero (indicating the closest estimation of a parameter). ES_MEAN (Figure 2) as an estimator falls into this "best fit" interval surrounding zero 74% of the time compared to ES_MED which fits into the interval (Figure 3) 52.8% of the time. Both figures are negatively skewed, indicating that both ES_MEAN and ES_MED tend to overestimate UES_POP.

Entries five and six in Table 1 show first that mean r and median r estimate univariate effect size at least 300% better than they estimate multivariate effect size. In other words, the deviations of $|SUM|$, μ , and σ , of mean and median effect size from multivariate population effect size are over three times greater than the univariate comparisons. However, within this category, the median r is the better estimator. Again, both tend to overestimate the parameter.

Entry seven compares two population parameters, and indicates which has more power: univariate or multivariate. Forty-three percent of the time, univariate population power is greater, compared to the 24% of the time that multivariate power is greater.

Entries eight through 13 compare population power parameters to estimated power. Entry eight vs. nine shows that univariate power based on mean r deviates from population power less than that based on median r . Univariate mean power also over- and underestimates less often than univariate median power. Figures 4 and 5 show the overestimation in the negatively skewed histograms. In the univariate mode, $UMEANPOW$ fits into the interval containing zero 90% of the time (Figure 4) compared to the $UMED_POW$'s 85.7% (Figure 5). The deviations of the multivariate calculations tend to be larger than the deviations of the univariate calculations. Figures 6 and 7 show that while $MEAN_POW$ and MED_POW tend to more equally over- and underestimate multivariate power, i.e., the frequency graphs show a more "normal" distributional shape, that neither fits into the interval containing zero as often as the univariate estimators do. That is, $MEAN_POW$ fits into the "zero" interval 75.5% of the time (Figure 6) and MED_POW (Figure 7) fits into the interval 65.7% of the time. In Table 1, the multivariate comparisons (entries 10 and 11) likewise support the evidence that the mean r is a more

accurate estimator than the median r in deriving power. Deviations of the median r are several times greater than deviations of the mean r . Entries 12 and 13 show that crossovers between univariate and multivariate parameters and estimates fare less well than non-crossover deviations.

Entry 14 compares the multivariate and univariate mean r power estimates. The sample shows univariate mean power as the greater 63% of the time, and the lesser only 1% of the time. This comparison echoes that of entry seven showing the same balance of results as the population values.

Entries 15 and 16 compare the maximum population power per cell (multivariate or univariate, whichever is greater) with univariate mean power and multivariate mean power. `UMEANPOW` appears to approximate maximum population values more closely. Figures 8 and 9 show that 82.8% of the time `UMEANPOW` estimates the parameter within the interval containing zero (Figure 8). In Figure 9, `UMED_POW` fits into that interval only 54% of the time.

Conclusions

Admittedly, a weakness of the analysis is that with 70 cells stemming from 13 data sets, cells are related. However, this exploratory analysis of the question of interest turned up very consistent results, despite the wide variation in the nature of the studies across data sets. The first main point: if we use a single estimate for ρ , will it provide a good estimate of population power?, can be answered affirmatively, based on the small magnitude of many of the deviation scores and other information in Table 1 and the corresponding figures. As to the second main point: What should the estimate be (e.g., mean r , median r)?, in this sample of cells, it was shown that the mean r is the better estimator of

ρ , f , and power, particularly in the univariate mode. A caution in the use of mean r as an estimator is that it tends to overestimate the parameters. However, this single estimate can be used with Barcikowski and Robey's (1985) sample size tables for a single group repeated measures analysis of variance.

Another option to the question of the second main point on the choice of the estimate lies in the type of correlation coefficient used. An applicable correlation coefficient for the purpose of determining a single estimate of the correlations among heterogeneous trials might be test/retest reliability estimates. This type of correlation coefficient is based on testing the same examinees twice with the same test and then correlating the results. Repeated measures designs and test/retest reliabilities share "hazards" such as carry-over and practice effects, changes in subjects' degree of information and/or ability between trials, and time-interval effects (Allen and Yen, 1979).

In practice, a researcher may have *a priori* access to a measure of the test/retest reliability of an instrument. There are two serious cautions to this suggestion, however. First, these "hazards" may result in an over- or underestimation of the true ρ . Second, actual test/retest reliabilities are not subject to treatment effects as might be applied in a repeated measures design. Any type of systemic treatment employed between trials might have the effect of lowering ρ .² The reported test/retest reliability might, *a priori*, be viewed, conservatively as an upper bound of ρ , the degree to which rests on the effects of the treatments on the subjects.

Recommendations

When a researcher is trying to determine *a priori* which r to use to estimate power, there are three routes that may assist:

1. Use Barcikowski and Robey (1985, Table 1, p. 7) effect sizes alone. This route is best employed when the researcher has little or no information about the characteristics of the population from which the sample was drawn, such as in an exploratory design. One can conservatively chose a small effect size assuming a small correlation between measures, or try any of eight other effect sizes based on small, medium, and large correlations for use in Barcikowski and Robey's sample size for power tables. When no other information is available *a priori*, the most conservative effect size will afford the largest sample size in order to detect significant differences.

2. Use Formula (1) with Cohen's effect sizes and a reliability estimate for ρ . This route works best when, although the researcher may not know much about the actual characteristics of the population, the researcher is cognizant of issues that may affect the estimate of ρ . Perhaps the researcher has a reliability coefficient from a test reviewer reference, but plans to sample a very small group. Then the researcher would consider the referenced reliability coefficient as an upper bound for that sample. The researcher would also need to assimilate information about administration and sampling error into the determination of an estimate for ρ .

3. Use Formula (2) with norm. information for σ_m^2 and ρ and consider different mean patterns. This route requires

knowledge about the population characteristics as well as issues concerning reliabilities. In an exploratory analysis, it would not be usual for the researcher to have this much information prior to conducting the study.

For an exploratory single group repeated measures analysis of variance design, when some knowledge about the instrument's test/retest reliability under treatment conditions can be obtained, the researcher will have reasonable results estimating power using route #2. For all the routes, a researcher using a single estimate of ρ will also need to make a knowledgeable decision about which degrees of freedom to employ. This study shows that the univariate test using an estimate of ρ is more powerful than the multivariate test. Using the univariate degrees of freedom with the univariate test would give more accuracy in estimating population univariate power. However, an informed researcher may choose to use the multivariate denominator degrees of freedom, i.e., $(N-K+1)$ vs. the univariate $(N-1)(K-1)$, to arrive at a conservative sample size.

Importance of the Study

The development of sample size/power tables in exploratory single group repeated measures analysis of variance when the trials correlation matrix is heterogeneous addresses an issue not thoroughly researched. In exploratory designs it is most likely the case that correlation matrices are heterogeneous rather than uniform. A method for estimating effect size in single group repeated measures analyses will assist researchers and practitioners in estimating *a priori* the power of their designs.

Footnotes

¹Using a single estimate of ρ is tantamount to assuming uniformity. However, this does not change the basic question of whether or not a reasonable estimate of power can be found using a single representation of a heterogeneous correlation trials matrix.

²However, if the treatment has a linear effect between measures, i.e., no interaction between treatments and subjects, then the use of the reliability as an estimate seems reasonable.
