## Abstract

---

In this paper, I analyze the behavior of public schools facing vouchers. The literature on the effect of voucher programs on public schools typically focuses on student and mean school scores. This paper tries to go inside the black box to investigate some of the ways in which schools facing the threat of vouchers in Florida behaved. Under the 1999 Florida program, schools getting an “F” grade for the first time were exposed to the threat of vouchers, but did not face vouchers unless and until they got a second “F” within the next three years. Exploiting the institutional details of this program, I analyze the incentives built into the system and investigate the behavior of the threatened public schools facing these incentives. There is strong evidence that they did respond to incentives. Using highly disaggregated school level data, a difference-in-differences estimation strategy as well as a regression discontinuity analysis, I find that the threatened schools tended to focus more on students below the minimum criteria cutoffs rather than equally on all, but interestingly, this improvement did not come at the expense of higher performing students. Second, consistent with incentives, they focused mostly on writing rather than reading and math. These results are robust to controlling for differential pre-program trends, changes in demographic compositions, mean reversion and sorting. These findings have important policy implications.

# 1 Introduction

The concern over public school performance in the last two decades has pushed public school reform to the forefront of policy debate in the United States. School accountability and school choice, and especially vouchers, are among the most hotly debated instruments of public school reform. Understanding the behavior and response of public schools facing these initiatives is key to an effective policy design. This paper takes an important step forward in that direction by analyzing public school behavior under the Florida voucher program.

The Florida voucher program, known as the “opportunity scholarship” program, is unique in that it embeds a voucher program within a school accountability system. Moreover, the federal No Child Left Behind (NCLB) Act is similar to and largely modeled after the Florida program, which makes the latter all the more interesting and relevant. Most studies to date, studying the effect of vouchers on public schools, have looked at the effect on student and mean school scores. In contrast, this study tries to go inside the black box to investigate some of the ways in which schools facing the voucher program behaved in the first three years after program.<sup>1</sup> Exploiting the institutional details of the Florida program during this period, it analyzes the incentives built into the system, and investigates public school behavior and response facing these incentives.

The Florida voucher program, written into law in June 1999, made all students of a school eligible for vouchers if the school got two “F” grades in a period of four years. Thus, the program can be looked upon as a “threat of voucher” program—schools getting an “F” grade for the first time were directly threatened by vouchers, but vouchers were implemented only if they got another “F” grade in the next three years. Vouchers were associated with a loss in revenue and also media publicity and visibility. Therefore, the threatened schools had a strong incentive to try to avoid the second “F”, and thereby avoid vouchers. This paper studies some alternative ways in which the threatened schools responded, facing the incentives built into the system.

Under the 1999 Florida grading criteria, certain percentages of a school’s students had to score above some specified cutoffs on the score scale for it to escape the second “F”. Therefore the threatened schools had an incentive to focus more on students expected to score just below these high stakes cutoffs

---

<sup>1</sup> Under the Florida voucher program (described below), schools getting an “F” grade in 1999 were directly threatened by vouchers, but this threat remained valid for the next three years only. Therefore, I study the behavior of the 1999 threatened schools during these three years.

rather than equally on all students. Did this take place in practice? Second, to escape an F grade, the schools needed to pass the minimum criteria in only one of the three subject areas of reading, math and writing. Did this induce the threatened schools to concentrate more on one subject, rather than equally on all? If so, which subject area did the schools choose to concentrate on? One alternative would be to concentrate on the subject area closest to the cutoff.<sup>2</sup> But subject areas differ in the extent of difficulties, so it is not immediately obvious that it is easiest to pass the cutoff in the subject area closest to the cutoff. Rather, schools are likely to weigh the extent of difficulties of the different subjects and their distances from the cutoffs, and choose the subject that is least costly to pass the cutoff. In addition to analyzing the above questions, this study also tries to look at a broader picture. If the threatened schools concentrated on students expected to score just below the high stakes cutoffs, did their improvements come at the expense of higher performing ones?

Using highly disaggregated school level Florida data from 1993 through 2002, and a difference-in-differences analysis as well as a regression discontinuity analysis, I investigate the above issues. There is strong evidence that public schools responded to the incentives built into the system. First, I find that the threatened schools concentrated more on students below and closer to the high stakes cutoffs, rather than equally on all students. Note that, as discussed in detail later, this improvement of the low performing students does not seem to have come at the expense of the higher performing students. Rather, there seems to have been a rightward shift of the entire score distribution, with improvement concentrated more in the score ranges just below the high stakes cutoff. This pattern holds in all the three subjects of reading, math and writing. Second, I find that the threatened schools indeed focused more on one subject area. They did not focus more on the subject area closest to the cutoff. Rather, they concentrated on writing, irrespective of the distances of the subject areas from the high stakes cutoffs. This is consistent with the perception among Florida administrators that writing scores were considerably easier to improve than scores in reading or math. These results are quite robust in that they withstand several sensitivity tests, and the results from the difference-in-differences analysis are qualitatively similar to those obtained from the regression discontinuity analysis. They are robust to controlling for pre-program trends, mean reversion, sorting, changes in demographic compositions and other observable characteristics of schools.

---

<sup>2</sup> The cutoffs differ across subjects (as will be detailed below). Here “cutoff” refers to the cutoff in the corresponding subject area.

This study is related to two strands of literature. The first strand investigates whether schools facing accountability systems and testing regimes respond by gaming the system in various ways. This relates to the moral hazard problems associated with multidimensional tasks under incomplete observability, as pointed out by Holmstrom and Milgrom (1991). Cullen and Reback (2006), Figlio and Getzler (2006) and Jacob (2005) show that schools facing accountability systems tend to reclassify their low performing students as disabled in an effort to make them ineligible to contribute to the school's aggregate test scores, ratings or grades. Jacob (2005) also finds evidence in favor of teaching to the test, preemptive retention of students and substitution away from low-stakes subjects, while Jacob and Levitt (2003) find evidence in favor of teacher cheating. Reback (2005) finds that schools in Texas facing accountability ratings have tended to relatively improve the performance of students who are on the margin of passing. Figlio (2006) finds that low performing students are given harsher punishments during the testing period than higher performing students for similar crimes, once again in an effort to manipulate the test taking pool. Figlio and Winicki (2005) find that schools faced with accountability systems increase the caloric content of school lunches on testing days in an attempt to boost performance.

While these papers study the response of public schools facing accountability systems, the present paper studies public school response and behavior facing vouchers. Although there is considerable evidence relating to the response of public schools facing accountability regimes, it would be instructive to know how public schools behave facing vouchers, an alternative form of public school reform. This study also uses a different estimation strategy than that used in the above literature. In addition to a difference-in-differences strategy, this paper also uses a regression discontinuity analysis unlike that in the above literature.

The second strand of literature that this paper is related to analyzes the effect of vouchers on public school performance. Theoretical studies in this literature include McMillan (2004) and Nechyba (2003). Modeling public school behavior, McMillan (2004) shows that under certain circumstances, public schools facing vouchers may find it optimal to reduce productivity. Nechyba (2003) shows that while public school quality may show a small decline with vouchers under a pessimistic set of assumptions, it will improve under a more optimistic set of assumptions.

Combining both theoretical and empirical analysis, Chakrabarti (2004) studies the impact of two alternative voucher designs—Florida and Milwaukee—on public school performance. She finds that voucher design matters—the “threat of voucher” design in the former has led to an unambiguous im-

provement of the treated public schools in Florida and this improvement is larger than that brought about by traditional vouchers in the latter. Other empirical studies in this literature include Greene (2001, 2003), Hoxby (2003a, 2003b), Figlio and Rouse (2006), Chakrabarti (2007) and West and Peterson (2006).<sup>3</sup> Greene (2001, 2003) finds positive effects of the Florida program on the performance of treated schools. Figlio and Rouse (2006) find some evidence of improvement of the treated schools under the program in the high stakes state tests, but these effects diminish in the low stakes, nationally norm-referenced test. West and Peterson (2006) study the effects of the revised Florida program (after the 2002 changes) as well as the NCLB Act on test performance of students in Florida public schools. They find that the former program has had positive and significant impacts on student performance, but they find no such effect for the latter. Based on case studies from visits to five Florida schools (two “F” schools and three “A” schools), Goldhaber and Hannaway (2004) present evidence that F schools focused on writing because it was the easiest to improve.<sup>4</sup> Analyzing the Milwaukee voucher program, Hoxby (2003a, 2003b) find evidence of a positive productivity response to vouchers after the Wisconsin Supreme Court ruling of 1998. Following Hoxby (2003a, 2003b) in the treatment and control group classification strategy, and using data for 1987-2002, Chakrabarti (2007) finds that the shifts in the Milwaukee voucher program in the late 1990’s led to a higher improvement of the treated schools in the second phase of the Milwaukee program than that in the first phase.

Most of the above studies analyze the effect of different voucher programs on student and mean school scores and document an improvement in these measures. This study, on the other hand, tries to delve deeper so as to investigate where this improvement comes from. Analyzing the incentives built into the system, it seeks to investigate some of the alternative ways in which the threatened schools in Florida behaved. Chakrabarti (2004) and Figlio and Rouse (2004) analyze the issue of teaching to the test, but they do not examine the forms of behavior that are of interest in this paper. Evidence on the alternative forms of behavior of public schools facing vouchers is still sparse. This study seeks to fill this important gap.

---

<sup>3</sup> For a comprehensive review of this literature as well as other issues relating to vouchers, see Howell and Peterson (2005), Hoxby (2003b) and Rouse (1998).

<sup>4</sup> Schools that received a grade of “A” in 1999 are referred to as “A” schools. Schools that received a grade of “F” (“D”) in 1999 will henceforth be referred to as “F” (“D”) schools.

## 2 The Program and its Institutional Details

The Florida Opportunity Scholarship Program was signed into law in June 1999. Under this program, all students of a public school became eligible for vouchers or “opportunity scholarships” if the school received two “F” grades in a period of four years. A school getting an “F” grade for the first time was exposed to the threat of vouchers, but its students did not become eligible for vouchers unless and until it got a second “F” within the next three years.

To understand the incentives created by the program, it is important to understand the Florida testing system and school grading criteria.<sup>5</sup> In the remainder of the paper, I refer to school years by the calendar year of the spring semester. Following a field test in 1997, the FCAT (Florida Comprehensive Assessment Test) reading and math tests were first administered in 1998. The FCAT writing test was first administered in 1993. The reading and writing tests were given in grades 4, 8 and 10 and math tests in grades 5, 8 and 10. The FCAT reading and math scores were expressed in a scale of 100-500. The state categorized students into five achievement levels in reading and math that corresponded to specific ranges on this raw score scale.<sup>6</sup> The FCAT writing scores, on the other hand, were expressed in a scale of 1-6. The Florida Department of Education reports the percentages of students scoring at 1, 1.5, 2, 2.5, ..., 6 in FCAT writing. For simplicity, as well as symmetry with reading and math, I divide the writing scores into five categories and call them levels 1-5. Scores 1 and 1.5 will together constitute level 1; scores 2 and 2.5 level 2; 3 and 3.5 level 3; 4 and 4.5 level 4; 5, 5.5 and 6 level 5. (The results in this paper are not sensitive to the definitions of these categories.)<sup>7</sup> In the remainder of the paper, for writing, level 1 will refer to scores 1 and 1.5 together; level 2 scores 2 and 2.5 together etc.; while 1, 2, 3, ..., 6 will refer to the corresponding raw scores.

The system of assigning letter grades to schools started in the year 1999,<sup>8</sup> and they were based on the FCAT reading, math and writing tests. The state designated a school an “F” if it failed to attain the minimum criteria in all the three subjects of FCAT reading, math and writing, and a “D” if it failed the minimum criteria in only one or two of the three subject areas. To pass the minimum criteria

---

<sup>5</sup> Since I am interested in the incentives faced by the threatened schools and this mostly depends on the criteria for “F” grade and what it takes to move to a “D”, I will focus on the criteria for F and D grades. Detailed descriptions of the criteria for the other grades are available at <http://schoolgrades.fldoe.org>.

<sup>6</sup> Levels 1, 2, 3, 4 and 5 in grade 4 reading corresponded to score ranges 100-274, 275-298, 299-338, 339-385 and 386-500 respectively. Levels 1, 2, 3, 4 and 5 in grade 5 math corresponded to score ranges of 100-287, 288-325, 326-354, 355-394 and 395-500 respectively.

<sup>7</sup> Defining the categories in alternative ways or considering the scores separately do not change the results.

<sup>8</sup> Before 1999, schools were graded by a numeric system of grades, I-IV (I-lowest, IV-highest).

in reading and math, at least 60% of the students had to score at level 2 and above in the respective subject, while to pass the minimum criteria in writing, at least 50% had to score 3 and above. In the remainder of the paper, I will use the word “cutoff” and “minimum criteria cutoff” interchangeably to refer to these minimum criteria cutoffs (level 2 in reading and math and score 3 in writing).

### 3 Theoretical Discussion

This section and subsections 3.1-3.3 explore some alternative ways of response of public schools facing a Florida-type “threat of voucher” program and the 1999 grading system. Assume that there are  $n$  alternative ways in which a public school can apply its effort. Quality  $q$  of the public school is given by  $q = q(e_1, e_2, \dots, e_n)$  where  $e_i, i = \{1, 2, \dots, n\}$ , represents the effort of the public school in alternative  $i$ . Assume that  $e_i$  is non-negative for all  $i$  and that the function  $q$  is increasing and concave in all its arguments. Any particular quality level  $q$  can be attained by multiple combinations of  $\{e_1, e_2, \dots, e_n\}$ —the public school chooses the combination that optimizes its objective function. Public school cost is given by  $C = C(e_1, e_2, \dots, e_n)$ , where  $C$  is increasing and convex in its arguments.

The Florida “threat of voucher” program designates a quality cutoff  $\bar{q}$  such that vouchers are implemented if and only if the school fails to meet the cutoff. A school deciding to meet the cutoff can do so in a variety of ways—its problem then is to choose the best possible way. More precisely, it faces the following problem:

$$\text{Minimize } C = C(e_1, e_2, \dots, e_n) \text{ subject to } q(e_1, e_2, \dots, e_n) \geq \bar{q}$$

The public school chooses effort level  $e_i^*, i = \{1, 2, \dots, n\}$  such that  $e_i^*$  solves  $\frac{\delta C(e_i^*)}{\delta e_i^*} \geq \lambda \frac{\delta q(e_i^*)}{\delta e_i^*}$  and  $e_i^* [\frac{\delta C(e_i^*)}{\delta e_i^*} - \lambda \frac{\delta q(e_i^*)}{\delta e_i^*}] = 0$ , where  $\lambda$  is the Lagrange multiplier and  $q(e_1^*, e_2^*, \dots, e_n^*) = \bar{q}$ . If  $e_i^*$  is strictly positive,  $e_i^*$  solves  $\frac{\delta C(e_i^*)}{\delta e_i^*} = \lambda \frac{\delta q(e_i^*)}{\delta e_i^*}$ .

Thus the amounts of effort that the public school chooses to expend on the various alternatives depend on the marginal costs and marginal returns from the alternatives. While it delegates higher efforts to alternatives with higher marginal returns and/or lower marginal costs, the effort levels in alternatives with lower marginal returns and higher marginal costs are lower. It can choose a single alternative  $l$  (if  $\frac{\delta C(e_l^*)}{\delta e_l^*} - \lambda \frac{\delta q(e_l^*)}{\delta e_l^*} = 0 < \frac{\delta C(e_k^*)}{\delta e_k^*} - \lambda \frac{\delta q(e_k^*)}{\delta e_k^*}$  for all  $k \neq l$ ) or it can choose a mix of alternatives. In the latter case the net marginal returns ( $\frac{\delta q}{\delta e_i} - \frac{1}{\lambda} \frac{\delta C}{\delta e_i}$ ) from each of the alternatives in the mix are equal (and in turn equal to zero) at the chosen levels of effort. This paper empirically analyzes

the behavior of public schools and investigates what alternatives the public schools actually chose when faced by the 1999 Florida “threat of voucher” program.

### **3.1 The Incentives Created by the System and Alternative Avenues of Public School Responses**

#### **3.1.1 Focusing on Students below the Minimum Criteria Cutoffs**

Given the Florida grading system, threatened public schools striving to escape the second “F” would have an incentive to focus on students expected to score below the minimum criteria cutoffs.<sup>9</sup> Marginal returns from focusing on such students would be expected to be higher than that on a student expected to score at a much higher level (say, level 4). If marginal costs were not too high, the threatened schools should be expected to resort to such a strategy.

If schools did indeed behave according to this incentive, then the percentage of students scoring at level 1 in reading and math would be expected to fall after the program as compared to the pre-program period. In writing, the cutoff level is 3 (rather than level 2 in reading and math). Therefore, while the threatened schools would have an incentive to focus on students expected to score below 3, they would be induced to focus more on students expected to score in level 2, since they were closer to the cutoff and hence easier to push over the cutoff. So while a downward trend would be expected in both the percentages of students scoring in levels 1 and 2, the fall would be more prominent in level 2.

#### **3.1.2 Choosing between Subjects with Different Extents of Difficulties Versus Focusing on Subject Closer to the Cutoff**

As per the Florida grading criteria, the threatened schools needed to pass the minimum criteria in only one of the three subjects to escape a second F grade. Therefore the schools had an incentive to focus more on one particular subject area, rather than equally on all. Note that it is unlikely that the concerned schools will focus exclusively on one subject area and completely neglect the others because there is an element of uncertainty inherent in student performance and scores, the degree of difficulty of the test, etc. and schools surely have to answer to parents for such extreme behavior. But if they behave according to incentives, it is likely that they will concentrate more on one subject area. The question that naturally arises in this case is: which subject area will the threatened schools focus on?

---

<sup>9</sup> Some ways to do this would be to target curriculum to low performing students, put more emphasis on the basic concepts rather than advanced topics in class or repeating material already covered rather than moving quickly to new topics.

One possibility is to focus more on the subject area closest to the cutoff i.e. the subject area for which the difference between the percentage of students scoring below the cutoff in the previous year and the percentage required to pass the minimum criteria is the smallest.<sup>10</sup> However, the subject areas differ in terms of their extent of difficulties, and hence the schools may find it more worthwhile to focus on a subject area farther from the cutoff, which otherwise is easier to improve in. In other words, the distance from the cutoff has to be weighed against the extent of difficulty or ease in a subject area, and the effort that a school decides to put in will depend on both factors.

## 4 Data

The data for this study were obtained from the Florida Department of Education. These data include school-level data on mean test scores, grades, percentages of students scoring in different levels, grade distribution of schools, socio-economic characteristics of schools and school finances. In spite of being school level data, these data are highly disaggregated—in addition to data on mean school scores, data are available on percentages of students scoring in different ranges of the score scale for each of reading, math and writing.

School level data on the percentage of students scoring in each of the five levels are available from 1999 to 2002 for both FCAT grade 4 reading and grade 5 math. In addition, data are available on percentages of students scoring in levels 1 and 2 in 1998 for both reading and math. Data are also available on mean scale scores and number of students tested for each of reading and math from 1998-2002.

In grade 4 writing, data are available on the percentage of students scoring at 1, 1.5, 2, 2.5, 3, 3.5, 4, 4.5, 5, 5.5 and 6. These data are available from 1994 to 1996 and again from 1999 to 2002. In addition, data on mean scale scores in writing and number of students tested are available from 1994-2002. Data on school grades are available from 1999 to 2002.

School level data on grade distribution (K-12) of students are available from 1993-2002. Data on socio-economic characteristics include data on sex composition (1994-2002), race composition (1994-2002) and percent of students eligible for free or reduced-price lunches (1997-2002). School finance data consist of several measures of school level and district level per pupil expenditures and are available for

---

<sup>10</sup> As outlined earlier, the required percentage of students below cutoff that would allow the school to pass the minimum criteria in the respective subject is 40% in reading and math and 50% in writing.

the period 1993-2002.

## 5 Empirical Strategy

Under the Florida opportunity scholarship program, schools that received a grade of “F” in 1999 were directly threatened by the program in that all their students would be eligible for vouchers if the school received another “F” grade in the next three years. These schools will constitute my treated group of schools and will be referred to as “F schools” from now on. The schools that received a “D” in 1999 were closest to the F schools in terms of grade, but were not directly threatened by the program. They will constitute my control group of schools and will be referred to as “D schools” in the rest of the paper. Given the nature of the Florida program, the threat faced by the 1999 F schools would be applicable for the next three years only. Therefore, I study the behavior of the F schools (relative to the D schools) during the first three years of the program (that is, upto 2002).

### 5.1 Focusing on Students below the Minimum Criteria

As discussed above, if the treated schools tend to focus more on students anticipated to score below the minimum criteria cutoffs, the percentage of students scoring in level 1 in F schools in reading and math should exhibit a decline relative to D schools. In FCAT writing, although relative declines are likely in both levels 1 and 2, the relative decline in level 2 would be larger than in level 1, if the treated schools responded to incentives.

To investigate whether the F schools resorted to such behavior, I look for shifts in the percentages of students scoring in the different levels (1-5) for the F schools relative to the D schools in the post-program period. Using data from 1999 to 2002, I estimate the following model:

$$P_{ijt} = \sum_{j=1}^5 \alpha_{0j} L_j + \sum_{j=1}^5 \alpha_{1j} (F * L_j) + \sum_{k=2000}^{2002} \sum_{j=1}^5 \alpha_{2kj} (D_k * L_j) + \sum_{k=2000}^{2002} \sum_{j=1}^5 \alpha_{3kj} (F * D_k * L_j) + \alpha_{4j} X_{ijt} + \varepsilon_{ijt} \quad (1)$$

where  $P_{ijt}$  denotes the percentage of students in school  $i$  scoring in level  $j$  in year  $t$ ;  $F$  is a dummy variable taking the value of 1 for F schools and 0 for D schools;  $L_j, j = \{1, 2, 3, 4, 5\}$  are level dummies that take a value of 1 for the corresponding level, 0 otherwise;  $D_k, k = \{2000, 2001, 2002\}$  are year dummies for years 2000, 2001 and 2002 respectively. The variables  $(D_k * L_j)$  control for post-program common year effects and  $X_{ijt}$  denote the set of control variables. Control variables include race, sex, percentage of

students eligible for free or reduced-price lunches, real per pupil expenditure and interaction of the level dummies with each of these variables. The coefficients on the interaction terms ( $F * D_k * L_j$ ) represent the program effects on the F schools in each of the five levels and in each of the three years after the program. I also run the fixed effects counterpart of this regression which includes school by level fixed effects (and hence does not have the level and level interacted with treated dummies). These regressions are run for each of the subject areas—reading, math and writing.

### 5.1.1 Existence of Pre-Program Trends

The above estimates of the program effects will be biased if there are differential pre-program trends between F and D schools in the various levels. Using pre-program data, I next investigate the presence of such pre-program trends. In FCAT writing, pre-program data on percentage of students scoring in each of the different levels are available for the years 1994-1996. In FCAT reading and math, data on percentage of students scoring in levels 1 and 2 are available for the pre-program years 1998 and 1999.<sup>11</sup> To investigate the issue of pre-existing trends, I estimate the following regression as well as its fixed effects counterpart (that includes school by level fixed effects) using pre-program data:

$$P_{ijt} = \sum_j \beta_{0j} L_j + \sum_j \beta_{1j} (F * L_j) + \sum_j \beta_{2j} (L_j * t) + \beta_{3j} \sum_j (F * L_j * t) + \beta_{4j} X_{ijt} + \varepsilon_{ijt} \quad (2)$$

where  $t$  denotes time trend,  $j = \{1, 2, 3, 4, 5\}$  for writing and  $j = \{1, 2\}$  for reading and math. The coefficients of interest here are  $\beta_{3j}$ .

### 5.1.2 Mean Reversion

Another concern here is mean reversion. Mean reversion is the statistical tendency whereby high and low scoring schools tend to score closer to the mean subsequently. Since the F schools were by definition the lowest scoring schools in 1999, it is natural to think that any decrease in the percentage of students in these levels (level 1 in reading and math; levels 1 and 2 in writing) after the program is contaminated by mean reversion. However, since I do a difference-in-differences analysis, my estimates of the program effect will be contaminated only if the F schools revert to a greater extent towards the mean than the D schools.

I use the following strategy to check for mean reversion in level 1. The idea is to measure the extent of decline, if any, in the percentage of students scoring in level 1 (in reading and math) in the schools

<sup>11</sup> Data on percentage of students in all the five levels are available only from 1999.

that received an F grade in 1998 relative to the schools that received a D grade in 1998, during the period 1998-99. Since this was the pre-program period, this gain can be taken as the mean-reversion effect in level 1 for F schools relative to the D schools, and can be subtracted from the program effects previously obtained to arrive at mean reversion corrected effects. A similar strategy can be used to check mean reversion in the other levels.

The system of assigning letter grades to schools started in Florida in 1999. However, using the 1999 state grading criteria and the percentages of students scoring below the minimum criteria in the three subjects (reading, math and writing) in 1998, I was able to assign F and D grades in 1998. These schools will henceforth be referred to as 98F and 98D schools respectively.<sup>12</sup> Using this sample of 98F and 98D schools, I investigate the relative changes, if any, in the percentage of students scoring in levels 1 and 2 for the 98F schools (relative to the 98D schools) during 1998-99.<sup>13</sup>

### **5.1.3 Using Regression Discontinuity Analysis to Examine the Differential Focus on Students below Minimum Criteria**

The issue of mean reversion arises here from the concern that the F schools may revert towards the mean to a greater extent than D schools just by virtue of their relatively low performance in 1999. Therefore regression discontinuity analysis, comparing schools in a narrow range on either side of the cutoff between F and D schools provides a useful way to get around the problem of mean reversion. The Florida program created a highly non-linear and discontinuous relationship between the percentage of students scoring above a pre-designated threshold and the probability that the school's students become eligible for vouchers in the near future which enables the use of such a strategy.

Consider the sample of F and D schools where both failed to meet the minimum criteria in reading and math in 1999. In this sample, only F schools failed the minimum criteria in writing also, while D schools passed it. Therefore, in this sample the probability of treatment varies discontinuously as a function of the percentage of students scoring at or above 3 in 1999 FCAT writing. There exists a sharp

---

<sup>12</sup> Note that the mean percentages of students in the different levels in F and D schools in 1999 are very similar respectively to the corresponding mean percentages in 98F and 98D schools in 1998, which attests to the validity of this approach.

<sup>13</sup> Note that mean reversion in only levels 1 and 2 (in reading and math) can be assessed using this method, since data on percentages in the other levels are not available for 1998. Data on percentages in the different levels in writing are not available for 1998, which precludes the use of this method in writing. While data are available for the pre-program years 1994-97 in writing, the FCAT reading and math tests were not given then. Therefore, there is no way to impute F and D grades to schools in those years using the 1999 grading criteria. However, I also do a regression discontinuity analysis which serves to get rid of this problem (if any).

cutoff at 50%—while schools below 50% faced a direct threat, those above 50% did not face any such direct threat.

Using the sample of F and D schools that fail minimum criteria in both reading and math in 1999, Figure 5 Panel A illustrates the relationship between assignment to treatment (i.e. facing the threat of vouchers) and the schools' percentages of students scoring at or above 3 in FCAT writing. The figure shows that except one, all schools in this sample that had less than 50% of their students scoring below 3 received an F grade. Similarly, all schools (except one) in this sample that had 50% or a larger percentage of their students scoring at or above 3 were assigned a D grade. Note that many of the dots correspond to more than one school,—Figure 5, Panel B illustrates the same relationship where the sizes of the dots are proportional to the number of schools at that point. The smallest dot corresponds to one school. These two panels show that in this sample, percentage of students scoring at or above 3 in writing uniquely predicts (except two schools) assignment to treatment and there is a discrete change in the probability of treatment at the 50% mark.

Ranking schools in terms of percentage of students scoring at and above 3 in FCAT writing, I first consider schools that lie within  $\pm 7$  percentage points of the 50% threshold and refer to it as discontinuity sample 1. Next, I further shrink the sample and pick schools that lie within a  $\pm 5$  percentage point range of the cutoff and call it discontinuity sample 2. Using each of these samples, I investigate whether the F schools exhibit differential shifts in the percentage of students scoring in the various levels in the post program period. For this purpose, I estimate model (1) and its fixed effects counterpart (that includes school by level fixed effects) using each of these samples. The OLS regressions also include a smooth polynomial<sup>14</sup> in the selection variable, percentage of students scoring at or above 3 in FCAT writing.

I also consider two corresponding discontinuity samples where both F and D schools fail the minimum criteria in reading and writing (math and writing). F schools fail the minimum criteria in math (reading) also, unlike D schools. In these samples, the probability of treatment changes discontinuously as a function of the percentage of students scoring at or above level 2 in math (reading) and there is a sharp cutoff at 60%.

---

<sup>14</sup> The regressions reported in this paper include a cubic in the selection variable. Results remain very similar with other orders of the polynomial (quadratic, quartic, quintic) as well as inclusions of these polynomials along with their interactions with a dummy that takes a value of 1 if the school is below the threshold and 0 otherwise.

### 5.1.4 Compositional Changes of Schools and Sorting

School level data brings with it the hazards of potential compositional changes of schools. In the presence of such changes, the program effects will be biased if the F schools were characterized by different compositional changes than the D schools. I investigate this issue further by examining whether the F schools exhibited differential shifts in demographic compositions after the program.

Another related issue is student sorting which can, once again, bias the results. None of the threatened schools received a second “F” grade in 2000 or 2001, therefore none of their students became eligible for vouchers. Therefore the concern about vouchers leading to sorting is not applicable here. However, the F and D grades can lead to a differential sorting of students in these two types of schools.<sup>15</sup> If there is evidence of a decline in percentage of students in lower levels in F schools relative to D schools, this would be driven by sorting only if the F schools faced a relative flight of low performing students and a relative influx of high performing students in comparison to the D schools. There is no a priori reason as to why this might happen.

However, to investigate this issue further as well as to directly address the potential problem of changes in school composition, I examine whether the demographic composition of the F schools saw a relative shift after the program as compared to the pre-program period. Using data from 1994-2002, I estimate the following regression (as well as its fixed effects counterpart):

$$y_{it} = \phi_0 + \phi_1 F + \phi_2 t + \phi_3 (F * t) + \phi_4 v + \phi_5 (v * t) + \phi_6 (F * v) + \phi_7 (F * v * t) + \varepsilon_{it} \quad (3)$$

where  $y_{it}$  represents the demographic characteristic of school  $i$  in year  $t$  and  $v$  is the program dummy,  $v = 1$  if year > 1999 and 0 otherwise. This regression investigates whether there has been any relative shift in demographic composition of the F schools in the post-program period after controlling for pre-program trends and post-program common shocks. The coefficients in the interaction terms ( $F * v$ ) and ( $F * v * t$ ) capture the relative intercept and trend shifts of the F schools.

### 5.1.5 Stigma Effect of Getting the Lowest Performing Grade

Another concern is that there might be a stigma effect of getting the lowest performing grade F. If there was such a stigma, then F schools would try to improve merely to avoid this stigma rather than

---

<sup>15</sup> Figlio and Lucas (2004) find that following the first assignment of school grades in Florida, the better students differentially selected into schools receiving grades of “A”, though this differential sorting tapered off over time.

in response to the program. I use the following strategies to investigate this issue. First, although the system of assigning letter grades to schools started in 1999, Florida had an accountability system in the pre-1999 period which categorized schools into four groups 1-4 (1-low, 4-high) based on FCAT writing, and reading and math norm referenced test scores. Using FCAT writing data for two years (1997 and 1998), I investigate the performance of schools that were categorized in group 1 in 1997 relative to the 1997 group 2 schools during the period 1997-98. The rationale is that if there was a stigma effect of getting the lowest performing grade, group 1 schools should improve in comparison to the group 2 schools even in the absence of the threat of voucher program. While data on percentage of students in the different levels separately are not available for these two years, data on mean scores as well as data on percentage of students scoring in levels 1 and 2 together (that is, % of students below 3) are available for both years. I investigate trends in both mean scores and percentage of students below 3 for group 1 schools (relative to group 2 schools) during 1997-98 and compare these patterns with the post-program patterns. It should be noted here that the minimum criteria for writing in the pre-program period was exactly the same as in the post-program period and the cutoff in the pre-program period was also 3 (same as in the post-program period). So stigma effect (if any) would induce similar responses in both pre- and post-program periods,—fall in percentage of students below 3.<sup>16</sup>

Second, all schools that received an F in 1999 received higher grades (A,B,C,D) in the years 2000, 2001. Therefore although stigma effect on F schools might have been operative in 2000, this was not likely to have been the case in 2001 or 2002 since none of the F schools got an F in the preceding year. However the F schools would face threat of vouchers till 2002, so if the patterns described above for the different levels are observed in 2001 and 2002 also, then this would provide evidence in favor of the threat of voucher effect and against the stigma effect.

Third, I also use another strategy to investigate this issue. This strategy exploits the relationship between private school distribution around threatened schools and its relationship with threatened

---

<sup>16</sup> I do not use the pre-1999 reading and math norm referenced test (NRT) scores because different districts used different NRTs during this period, which varied in content and norms. Also districts often chose different NRTs in different years. Thus these NRTs were not comparable across districts and across time. Moreover, since districts could choose the specific NRT to administer each year, the choice was likely related to time varying (and also time-invariant) district unobservable characteristics which also affected test scores. Also note that this discussion assumes that if there is a stigma effect associated with getting an F, this would induce a relative improvement of F schools relative to D schools. However, it is not clear that this would be the case in the first place. Stigma is the “bad” label that is associated with getting an F. Since D schools were very close to getting F (more so, in the regression discontinuity analysis), and if F grade carries a stigma, then D schools should be threatened by the stigma effect also. In fact, one might argue that since D schools were unscarred while F schools were already scarred, the former might have a larger inducement to improve to avoid the scar.

school response.<sup>17</sup> F schools that had more private schools in their near vicinity would likely lose more students if vouchers were implemented, and hence would face a greater threat of vouchers than those that had less. However, since stigma was a “bad” label associated with F, these schools would face the same stigma. Therefore if the response was caused by “threat of vouchers”, then one would expect to see a higher response from F schools that had more private schools in their near vicinity. This, however would not be the case if the response was driven by stigma.<sup>18</sup> To investigate this issue, I exploit the pre-program distribution of private schools,<sup>19</sup> and investigate whether threatened schools that had more private schools in their immediate vicinity showed a greater response.

Using data from 1999 to 2002, I run the following fixed effects regression and its corresponding OLS counterpart (which also includes relevant lower level interactions and variables). The variable *number* represents the number of private schools within a one mile radius and  $f_{ij}$  denotes school by level fixed effects. The coefficients of interest here are  $\theta_{4j}$ ,—they show the differential effects on F schools of having an additional private school within its one mile radius in the various levels.

$$P_{ijt} = f_{ij} + \sum_{k=2000}^{2002} \sum_{j=1}^5 \theta_{1kj}(D_k * L_j) + \sum_{k=2000}^{2002} \sum_{j=1}^5 \theta_{2kj}(F * D_k * L_j) + \sum_{j=1}^5 \theta_{3j}(v * L_j * number) + \sum_{j=1}^5 \theta_{4j}(F * v * L_j * number) + \theta_{5j} X_{ijt} + \varepsilon_{ijt} \quad (4)$$

### 5.1.6 The Problem of Underestimation: Are D Schools Untreated?

The computation of treatment effects above assumes that the D schools are not treated by the program. Although D schools do not directly face the threat of vouchers, they are close to getting an “F” and hence are likely to face an indirect threat. In such a case, the program effects shown above (both difference-in-differences and regression discontinuity estimates) would be underestimates. Note that

<sup>17</sup> I would like to thank David Figlio for suggesting this strategy.

<sup>18</sup> Whether or not the stigma effect varies with the concentration of private schools around F schools depends on how one defines the stigma effect. If stigma effect is defined as only the disutility or shame associated with getting an F, then distribution of private schools would not affect the perception of stigma. However, if an F school perceives that this “bad” label is likely to make the school more unattractive and is likely to lead to a flight of students or hinder entry of students, then F schools with more nearby private opportunities will face a greater threat of loss of students (greater stigma effect or stigma is more “real”) and hence will respond to a greater extent. In such a case, this strategy will not be able to differentiate between the threat of voucher effect and the stigma effect. In spite of this, the threat faced from vouchers will be greater and more functional than that faced from stigma, since vouchers do not require payment of any tuition (unlike in the case of stigma) and hence are likely to lead to a greater flight of students. Even though this stigma effect may induce those F schools with more private schools nearby to respond more, this effect will be lower than the corresponding threat of voucher effect. However, still it will be empirically difficult to disentangle the two effects separately using this strategy—as both the stigma effect and the threat of voucher effect will be associated with a higher improvement of F schools with more private schools nearby.

<sup>19</sup> Since the post-program distribution of private schools is likely to be endogenous, I exploit the pre-existing distribution of private schools. However, even though I am looking at pre-existing competition, it could still be argued that location of private schools is not completely exogenous to the quality of neighboring public schools.

this problem is likely to be more prominent in the regression discontinuity analysis.

To get around this problem, I rescale the effects obtained in the previous analyses by the difference in the probabilities of treatment of F and D schools, that is by calculating the corresponding Wald estimator.<sup>20</sup> I use pre-program data to calculate the probabilities that these schools would fall into treatment the next year. These scaling factors are calculated both for the full sample of F and D schools and the discontinuity samples.

A problem here is that the system of assigning letter grades started in 1999. However, as described in section (5.1.2), I was able to assign F and D grades in 1998 using the state grading criteria and 1998 school scores. Using this sample of schools and data on school grades in 1999, I calculate the above probabilities.<sup>21</sup> To calculate these probabilities for the discontinuity samples, I consider the set of schools that failed the minimum criteria in all three subject areas in 1998, and the set of schools that failed the minimum criteria in reading and math in 1998, but passed the minimum criteria in writing. Ranking these schools in terms of their percentages of students scoring at and above 3 in 1998 FCAT writing, I consider the schools within a range of  $\pm 5$  ( $\pm 7$ ) percentage points of the 50% cutoff for discontinuity sample 2 (discontinuity sample 1), and calculate the probabilities that the corresponding groups of schools would fall into treatment.

## **5.2 Choosing between Subjects with Different Extents of Difficulties Versus Focusing on Subjects Closer to the Cutoff**

For each F school, I first rank the subject areas in terms of their distances from the respective subject cutoffs. Distance of a subject from the respective subject cutoff is defined as the difference between the percentage of students scoring below the cutoff in that subject in 1999 and the percentage required to pass the minimum criteria in that subject. Next, based on the ranks of the subjects, I generate three dummies, “low”, “mid” and “high”. “Low” takes a value of 1 if the subject is closest to the cutoff, 0 otherwise; “mid” takes a value of 1 if the subject is second in terms of distance from the cutoff, 0 otherwise; “high” takes a value of 1 if the subject is farthest from the cutoff, 0 otherwise. The analysis in this section will combine the reading, math and writing scores (percent scoring below minimum criteria) in a single model. Therefore, for purposes of analysis in this section, I standardize the reading, math

---

<sup>20</sup> I would like to thank Caroline Hoxby for suggesting this strategy.

<sup>21</sup> Note that 1998 is the first year that such grades can be calculated. This is because (after a field test in 1997) the FCAT reading and math tests were first administered in 1998.

and writing scores by grade, subject and year to have means of 0 and standard deviations of 1.

Using the sample of F schools and data from 1999 and 2000, I estimate the following model:

$$y_{ist} = \gamma_0 read + \gamma_1 math + \gamma_2 write + \gamma_3 low + \gamma_4 mid + \gamma_5 (read * D00) + \gamma_6 (math * D00) + \gamma_7 (write * D00) + \gamma_8 (low * D00) + \gamma_9 (mid * D00) + \gamma_{10} X_{ist} + \varepsilon_{ist} \quad (5)$$

where  $y_{ist}$  represents the percentage of students below minimum criteria cutoff (standardized by grade, subject and year) in school  $i$  subject  $s$  in year  $t$ ;  $read$ ,  $math$  and  $write$  are subject dummies that take a value of 1 for the corresponding subject and 0 otherwise; and  $X_{ist}$  denotes the set of control variables. Control variables include race, sex, percentage of students eligible for free or reduced-price lunches, real per pupil expenditure and interactions of the subject dummies with these variables. *High* is taken to be the omitted category. The coefficients  $\gamma_5 - \gamma_9$  capture the program effects. If the F schools focused on subject areas on the basis of their distances from the cutoff then  $\gamma_8, \gamma_9 < 0$  and  $|\gamma_8| > |\gamma_9|$ . On the other hand, if the schools choose to focus on a certain subject area, then the coefficient of the interaction term between that subject and 2000 year dummy will be negative and larger in magnitude than the other corresponding interaction terms. I also estimate the fixed effects counterpart of this model that includes school by subject fixed effects (and hence does not have subject and distance rank dummies which are absorbed).

I next explore these issues further by disaggregating the above effects. If the F schools choose to focus on the subject closest to the cutoff, then do they concentrate on the “low” subject irrespective of whether it is reading, math or writing or does the response in the “low” subject depends on the specific subject area? On the other hand, if they choose to focus on one subject area because of its relative ease, do they focus on it irrespective of its rank? To investigate these questions, I estimate the following model as well as the fixed effects counterpart of it that includes school by subject fixed effects. The coefficients of interest here are  $\delta_5 - \delta_{13}$ .

$$y_{ist} = \delta_0 read + \delta_1 math + \delta_2 write + \delta_3 low + \delta_4 mid + \delta_5 (low * D00 * read) + \delta_6 (low * D00 * math) + \delta_7 (low * D00 * write) + \delta_8 (mid * D00 * read) + \delta_9 (mid * D00 * math) + \delta_{10} (mid * D00 * write) + \delta_{11} (high * D00 * read) + \delta_{12} (high * D00 * math) + \delta_{13} (high * D00 * write) + \delta_{14} X_{ist} + \varepsilon_{ist} \quad (6)$$

**Regression Discontinuity Analysis:** A problem with the above analysis is that it cannot rule out the fact that focus on any subject area (either the one considered to be the easiest or the one closest to the cutoff) is due to a year specific shock to that subject area (or other subject areas). For example, one can argue that the F schools chose to concentrate on a subject area because it suddenly became easier.

A way out of this problem is to do a regression discontinuity analysis that compares the effect on schools just below the cutoff to those just above the cutoff between F and D. I use the regression discontinuity strategy discussed above for this purpose and also use the above discontinuity samples. The argument here is that if there was indeed some year specific shocks to one or more subject areas, they would be faced by both the F and D schools in the discontinuity samples, especially because they were so close to each other. Using the above discontinuity samples, I estimate the following model as well as its fixed effects counterpart that includes school by subject fixed effects.  $m(s)$  represents a polynomial in the selection variable. The results reported here include a cubic in the selection variable. Results remain very similar with other orders of the polynomial (quadratic, quartic, quintic) as well as inclusions of these polynomials along with their interactions with a dummy that takes a value of 1 if the school is below the threshold and 0 otherwise.

$$y_{ist} = \psi_0 read + \psi_1 math + \psi_2 write + \psi_3(F * read) + \psi_4(F * math) + \psi_5(F * write) + \psi_6(read * D00) + \psi_7(math * D00) + \psi_8(write * D00) + \psi_9(F * read * D00) + \psi_{10}(F * math * D00) + \psi_{11}(F * write * D00) + m(s) + \psi_{12} X_{ist} + \varepsilon_{ist} \quad (7)$$

## 6 Results

### 6.1 Did the Threatened Schools Focus on Students Expected to Score below the Cutoffs? Investigating Shifts in Percentages Scoring below the Cutoffs

This section looks for post-program shifts in the percentages of students scoring in the various levels for F schools in comparison to D schools. Figure 1 shows the distribution of percentage of students scoring below the minimum criteria cutoffs in F and D schools in 1999 and 2000 in the three subject areas of reading, math and writing. 1999 is the last pre-program year and 2000 the first post-program year. Panels A and B (C and D) look at the distributions in level 1 reading (level 1 math) in the two years respectively, while panels E and F look at the distributions in level 2 writing in 1999 and 2000 respectively. In each of reading, math and writing, the graphs show a relative leftward shift of the F school distribution in comparison to the D school distribution in 2000. This suggests that the F schools were characterized by a greater fall in the percentage of students scoring in level 1 reading, level 1 math and level 2 writing after the program.

Figure 2 shows the distribution of reading, math and writing scores by treatment status in 1999 and

2000. In each of reading and math, there is a fall in the percentage of students scoring in level 1 in F schools relative to D schools in 2000. In writing, on the other hand, while there are relative falls in both levels 1 and 2 in F schools, the fall in level 2 is much more prominent than the fall in level 1. Another important feature—seen in all reading, math and writing—is that there is a general relative rightward shift in the F distribution in 2000, with changes most concentrated in the crucial levels.

I next investigate whether these patterns continue to hold in a more sophisticated regression analysis also. Table 1 presents results on the effect of the program on percentages of students scoring in levels 1-5 in FCAT reading, math and writing. Using model 1, columns (1)-(2) look at the effect in reading, columns (3)-(4) in math and columns (5)-(6) in writing. For each set, the first column reports the results from OLS estimation and the second column from fixed effects estimation. All regressions are weighted by the number of students tested and control for race, sex, percentage of students eligible for free or reduced-price lunches, real per pupil expenditure and interactions of each of these variables with level dummies.

In reading, both OLS and FE estimates show relative decline in percentage of students in level 1 in F schools in each of the three years after the program.<sup>22</sup> On the other hand, there are increases in the percentage of students scoring in levels 2, 3 and 4. The level 1, 2 and 3 effects are always statistically significant (except level 2 in first year), while level 4 effects never are. The level 5 percentages saw a statistically significant decline, but the magnitudes never exceeded 1%. Moreover, the changes in level 1 percentages always economically (and in most cases, statistically) exceed the changes in each of the other levels in each of the three years after the program. These patterns are consistent with the hypothesis that in reading schools chose to focus more on students they expected to score below the minimum criteria cutoff.

The results in math (columns (3)-(4)) are similar. There is a steep and statistically significant decline in the percentage of students scoring in level 1, in each of the three years after the program. Levels 2, 3 and 4 percentages increase, most of which are statistically significant. Level 5 on the other hand saw a small decline, though the effects are not statistically significant in most cases. Once again,

---

<sup>22</sup> Although the state still continued to grade the Florida schools on a scale of A through F, the grading criteria underwent some changes in 2002. So a natural question that arises here is whether the 2002 effects (that is, the effects in the third year after program) were induced by the 1999 program or were also contaminated by the effect of the 2002 changes. However, these new grading rules were announced in December 2001 and were extremely complicated combining student learning gains in addition to level scores. Since the FCAT tests were held in February and March 2002, just a couple of months after the announcement, it is unlikely that the 2002 effects were contaminated by responses to the 2001 announcement. Moreover, the results are very similar if the year 2002 is dropped and the analysis is repeated with data through 2001.

the decline in the level 1 percentages exceed the changes in the other levels, both economically and statistically.

Columns (5)-(6) present the results for writing. The percentages of students scoring in both levels 1 and 2 saw a decline after the program. But interestingly, the decline in level 2 is larger (both economically and statistically) than in level 1, as would be dictated by the incentives created by the program. In writing, there is no evidence of a fall in the percentage of students scoring in level 5. Figures 3, 4 and 5 show the trends in the percentages of students scoring in levels 1-5 in reading, math and writing respectively. Consistent with the results obtained above, there is a large decline in the percentage of students scoring in level 1 in each of reading and math which exceeds the changes in the other levels. In writing, on the other hand, the decline is considerably larger in level 2 than in level 1, once again in conformity with the above regression results.

The patterns in reading, math and writing support the hypothesis that the F schools chose to focus more on students expected to score below the minimum criteria cutoffs. More importantly, consistent with the incentives created by the program, while the declines in reading and math were concentrated in level 1, the decline in writing was most prominent in level 2, rather than level 1. The cutoffs in reading and math were level 2, which justify the declines in level 1. On the other hand, the writing cutoff of 3 induced the F schools to concentrate more on students expected to score in level 2 (i.e. closer to the cutoff) than in level 1. These evidences strongly suggest that the threatened schools focused on students expected to score below and close to the high stakes cutoffs.

A question that naturally arises in this context is whether the improvements of the lower performing students came at the expense of the higher performing ones. There is no evidence of such a pattern in math or writing (except in the first year after program in math). In reading and in first year math there was a statistically significant decline in the percentage of students in level 5, but the effects were very small, always less than 1% in magnitude. I later investigate whether this pattern continues to hold under a more precise regression discontinuity analysis.

### **Looking for Pre-Existing Trends**

The results in Table 1 would be biased if there were pre-existing trends in the percentage of students scoring in the different levels in F schools relative to D schools. Table 2 investigates this issue. As discussed earlier, while pre-program data on the percentage of students in various levels are available for all levels in writing (1994-96), they are available for only levels 1 and 2 in reading and math (1998-

99).<sup>23</sup> Columns (1)-(2) report the results in reading, (3)-(4) in math and (5)-(6) in writing. The first column in each set reports the results from OLS estimation, the second from fixed effects estimation. There is no evidence of any differential trends in F schools relative to D schools in any of the levels and in any of the subject areas. Therefore it is unlikely that the previous results are biased by pre-program trends.

### **Mean Reversion**

This section addresses the concern that the results reported in Table 1 may be biased by mean reversion. Using the strategy described in section 5.1.2, Table 3 reports the results for mean reversion in reading (columns (1)-(3)) and math (columns (4)-(6)).

Relative to the 98D schools, there is no evidence of mean reversion of the 98F schools in either reading or math and in either level 1 or level 2. As discussed earlier, the absence of relevant data in writing precludes the examination of mean reversion in writing using this method. However, the regression discontinuity analysis in the next section serves to get rid of this problem, if any.

### **Regression Discontinuity Analysis: Examining Focus on Students below Cutoffs**

I use the two discontinuity samples described in section 5.1.3, - discontinuity sample 1 ( $\pm 7$ ) and discontinuity sample 2 ( $\pm 5$ ). The summary characteristics of the F and D schools in these samples are reported in Table 4. All these numbers pertain to the pre-program year, 1999. The F and D schools are strikingly similar to each other in terms of various demographic characteristics (race, sex and percentage of students eligible for free or reduced-price lunches), ESE categorization (percentage of enrollment in all ESE categories together, percentage in excluded ESE categories (categories whose scores were not included in the computation of grade), percentage in included ESE categories), real per pupil expenditure, mean scores (FCAT reading, math and writing) and number of students tested. Using discontinuity sample 2, Figure 6, panels C-E show the effects of the program on percentage of students scoring in levels 1, 3 and 5 in reading, one year after the program. Panels F-H show the corresponding effects in reading two years after program. In both years, the percentage of students scoring in level 1 dropped sharply around the 50% cutoff (panels C and F) implying that the program led to a decline in the percentage of students scoring in level 1. Breaks are also visible in level 3 for both years 2000 and 2001 (Panels D and G), but these are considerably smaller in magnitude than the level 1 breaks. There is no evidence of any break in the relationship in level 5 around the 50% cutoff.

---

<sup>23</sup> Data on percentage of students in all the five levels in reading and math are available in 1999, but not before that.

Figure 7, Panels A-C show the effect of the program on percentage of students scoring in levels 1, 3 and 5 in math one year after program. Panels D-F show the corresponding effects in math two years after program. Panels G-I show the effect of the program on percentage of students scoring in levels 1, 2 and 3 in writing one year after the program (2000). (The graphs for 2002 in reading and math and for 2001 and 2002 in writing are similar to those in the other years for the corresponding subject and hence are omitted.)<sup>24</sup>

In math, there is a sharp drop in the percentages of students scoring in level 1 close to the 50% cutoff in both the first and second years after program. Once again, breaks are visible in level 3 in both years in math, though they are much smaller than the corresponding level 1 breaks. While there is no evidence of any discontinuity in level 5 in 2000, there is evidence of a small break in relationship in 2001. (Note that the scales in the level 5 graphs are different from those in levels 1 and 2.) In writing, on the other hand, while drops are visible in both levels 1 and 2 around the 50% cutoff, the drop in level 2 is substantially larger than that in level 1.

I next examine whether these patterns continue to hold in a more rigorous analysis. Using discontinuity sample 2, Table 5 looks at the effect of the program on percentage of students scoring in different levels in F schools relative to D schools.<sup>25</sup> In each of reading and math and in each of the three years after program, the F schools show a relative decline in the percentage of students scoring in level 1. These effects are statistically significant in all cases (except first year reading) and these effects always exceed the effects in the other levels. In addition, these effects are similar to the corresponding level 1 effects in the full sample of F and D schools. In writing, although the effects are somewhat smaller than that in the full sample, they are still economically large and statistically significant. The pattern also remains the same—the level 2 effects in each of the three years after the program and for each of the discontinuity samples exceed the corresponding level 1 effects. Moreover, the level 2 effects always exceed the changes in the other levels. These patterns confirm the earlier results and provide additional evidence that the threatened public schools concentrated more on the students expected to score below and close to the minimum criteria cutoffs.

A related question here is whether the improvement of the low performing students came at the

---

<sup>24</sup> The figures for the other levels are omitted for lack of space, they tally with the results reported in Table 5. All these graphs pertain to discontinuity sample 2, those for discontinuity sample 1 are qualitatively similar and correspond to the results in Table 5.

<sup>25</sup> The results for discontinuity sample 1 as well as other samples mentioned in section 5.1.3 are similar and are available on request.

expense of the higher performing ones. The previous difference-in-differences analysis showed some evidence of a small (less than 1%) decline in percentage of students scoring in level 5 reading and first year math, but there was no such evidence in writing or in the other years in math. But, as seen in table 5, the declines in reading and first year math no longer survive in the more precise regression discontinuity analysis. Here there is no evidence that the improvements of the low performing students came at the expense of the higher performing ones and there is even some evidence of a small increase in percentage of students in level 5 writing.

To sum up, there is strong evidence that the threatened schools concentrated more on low performing students (i.e., students expected to score below and close to the minimum criteria cutoffs) and the declines in the percentages of students just below the minimum criteria cutoffs exceeded the changes in percentages at all other ranges of the score scale. This pattern holds in all the three subjects—reading, math and writing. But there is no evidence that the increased focus of attention on the lower performing students adversely affected the higher performing ones. Rather, there seems to have been a rightward shift of the entire score distribution in each of reading, math and writing, although the improvements were concentrated in score ranges just below the respective minimum criteria cutoffs.

### **Sorting**

Another factor that might potentially bias the results is sorting. To investigate this issue, I analyze the trends in the demographic composition of schools and investigate whether the program led to a shift in the demographic composition of the F schools relative to the D schools. Table 6 presents the estimation results for specification (3). The results reported include school fixed effects, the corresponding results from OLS are very similar and hence omitted. There is no evidence of any shift in the various demographic variables except for a modest positive intercept shift for Hispanics. However, if anything, this would lead to underestimates of the program effects. Moreover, the regressions in the paper control for any change in demographic composition. To sum, it is unlikely that the patterns seen above are driven by sorting.

### **Stigma Effect**

Table 7 investigates whether there is a stigma effect of getting the lowest performing grade using pre-program FCAT writing scores. The logic, as outlined earlier, is that if there is such a stigma effect, then the lowest performing schools (group 1) would improve relative to the group 2 schools and there would be a relative fall in the percentage of students scoring below 3 (that is, levels 1 and 2) in the

pre-program period 1997-98. Columns (1)-(3) find that there is no evidence of any improvement in mean scores. In contrast, there was a large improvement in FCAT writing mean scores in the post-program period (Chakrabarti 2004). Columns (4)-(6) look at the effect on percentage of students scoring in levels 1 and 2. Once again, there is no evidence of any stigma effect. Not only are the effects not statistically significant, but the magnitudes are also very small compared to the post-program patterns (table 1). This implies that threat of vouchers rather than stigma was the driving factor behind the post-program patterns.

Second, as seen above, the patterns in the different levels were not specific to 2000 only, but similar patterns prevailed in 2001 and 2002 also. As discussed earlier (section 5.1.5), the stigma effect is not likely to have operated in 2001 and 2002, since the prior-year grade was not an F. Since F schools continued to face the threat of vouchers till 2002, this provides further evidence in favor of the threat of voucher effect and against the stigma effect.

Third, table 8 investigates whether F schools that had more private schools in their near vicinity responded more to the program. Both OLS and fixed effects results in each of reading, math and writing indicate that this indeed has been the case. In reading and math, F schools with greater public school presence showed a higher fall in their percentages of students scoring in level 1, while in writing these schools showed a higher fall in level 2. This indicates that F schools that had more private school presence around them tended to focus more on students expected to score just below the high stakes cutoffs. As discussed in section 5.1.5, this likely indicates that the effects above were driven by threat of vouchers rather than stigma. However the caveats mentioned in footnotes 18 and 19 should be remembered here. So while the results of this analysis exploiting private school distribution are instructive and suggestive, I do not want to push them too far.

### **Addressing the Problem of Underestimation**

A concern here is that the above estimates may be underestimates as the D schools are likely to be affected by the program to some extent. (Note, though, that the direction of the above effects are correct, but presumably the effects are even larger than the estimates presented in the above analysis.) Using the strategy described in section 5.1.6, the correct difference-in-differences and regression discontinuity estimates can be obtained by scaling up the corresponding estimates above by factors of 1.06 for the full sample and 1.2 for discontinuity sample 2. (The factor is 1.19 for discontinuity sample 1.)

## 6.2 Do Threatened Public Schools Focus on the Subject Closest to the Cutoff? Role of Differences in the Extent of Difficulties between Subjects

This section investigates whether the threatened schools facing the “threat of voucher” program chose to focus on a certain subject area. Table 9 presents the results from estimation of model 5. While columns (1)-(2) present the results without controls, columns (3)-(4) present those with controls. Controls include race, sex, percentage of students eligible for free or reduced-price lunches, real per pupil expenditures and interactions of the subject dummies with these variables. The first column of each set reports results from OLS estimation and the second column from fixed effects estimation.

There is no evidence that the threatened schools concentrated most on the subject closest to the cutoff. The coefficients of the relevant interaction terms are actually positive and are never different from zero statistically. Nor are they statistically different between themselves, as seen in the last row of table 7.

In each of the columns, the first three coefficients indicate a decline in the percentage of students scoring below the minimum criteria cutoffs in each of the three subjects. However, the decline in writing by far exceeds the corresponding declines in the other two subjects. As the p-values indicate, this decline in writing exceeds the declines in reading and math statistically also. To summarize, this table finds no evidence in favor of the hypothesis that the threatened schools concentrated most on the subject closest to the cutoff. Rather the schools seem to have disproportionately favored FCAT writing. While there are improvements in each of the three subject areas, the improvement in writing is substantially larger than that in the other two subject areas both economically and statistically.

Table 10a investigates whether the F schools chose to focus on writing irrespective of its distance from the cutoff (relative to the other subjects). It presents results from estimation of model 6. Columns (1)-(2) report results from specifications without controls, while columns (3)-(4) include controls. There are declines in the percentage of students scoring below the cutoffs in each of the three subjects, irrespective of their distances from the cutoffs. However, these declines are largest in magnitude for writing and holds irrespective of whether writing has a rank of “low”, “mid” or “high”. For example, the decline in writing for “F” schools which were closest to the cutoff in writing (“low” in writing) exceeded the decline in reading (math) for schools that were “low” in reading (math), “mid” in reading (math) or “high” in reading (math). The scenario is exactly the same when writing ranks “mid” or “high”. Note that these improvements are not only economically larger, but as table 10b shows, they are statistically

so too. Moreover, the improvements in the different subjects do not have a definite hierarchy or a one-to-one relationship with distances from the cutoff.

While the above analysis shows that the schools tended to concentrate on writing (irrespective of its distance from the cutoff), the question still remains whether this was due to some year specific shocks, for example,—writing suddenly became easier. As discussed above, to address this issue I use a regression discontinuity analysis where I compare the schools that just barely missed the cutoff to those that barely made the cutoff. Any subject specific shocks to writing (or to any other subject area for that matter) would be differenced out by this analysis. The results of this analysis are reported in table 11. The results in this table are consistent with those above and confirm the above findings. The F schools in the discontinuity sample just below the cutoff tended to focus by far more in writing than in the other subject areas (relative to schools just above the cutoff), ruling out the fact that the focus on writing was due to year specific shocks.<sup>26</sup>

To sum, the F schools chose to concentrate on writing not because of any year specific shocks and irrespective of its distance from the cutoff, presumably because it was easiest to improve in. Case studies reported in Goldhaber and Hannaway (2004) are very much consistent with this picture: *‘Writing came first “because this is the easiest to pass”... “With writing there’s a script; it’s pretty much first we did this, then we did this, and finally we did that, and using that simple sequencing in your writing you would get a passing grade.”’*

Telephone interviews conducted by me with school administrators in several F schools in different Florida districts also show a similar picture. They reveal widespread beliefs among school administrators that writing scores were much easier to improve in than reading and math scores. They say that they focused on writing in various ways after the program. They established a “team approach in writing” which introduced writing across the curriculum. This approach incorporated writing components in other subject areas also such as history, geography, etc. to increase the students’ practice in writing. They also introduced school wide projects in writing, longer time blocks in writing, and writing components in lower grades.

---

<sup>26</sup> While the results reported here are for discontinuity samples 1 and 2, results are similar (and available on request) for the other discontinuity samples mentioned above (section 5.1.3) where both F and D schools fail the minimum criteria in reading and writing (math and writing) and F schools fail the minimum criteria in math (reading) also, unlike D schools.

## 7 Conclusion

This paper analyzes the behavior of public schools facing vouchers. It focuses on the 1999 Florida opportunity scholarship program. Utilizing the institutional details of the program, it analyzes the incentives built into the system, and examines the behavior of public schools facing these incentives.

It focuses on two alternative ways in which the program incentives might have induced the threatened schools to behave. First, certain percentages of a school's students had to score above some pre-designated thresholds on the score scale to escape the second F grade and hence vouchers. As a result, did the threatened schools tend to focus more on students below these cutoffs rather than equally on all students? Second, as per the program details, to avoid an F grade, schools needed to pass the minimum criteria in only one of the three subjects. Did this induce the threatened schools to focus more on one subject area rather than equally on all? If so, did they choose to focus on the subject area closest to the high stakes cutoffs? Alternatively, did they choose to focus on a specific subject that was perceived to be the easiest irrespective of the distances of the subject areas from the thresholds?

I find robust evidence that the threatened schools concentrated more on students expected to score just below the high stakes cutoffs and focused much more on writing compared to reading and math. The latter is consistent with the notion among Florida administrators that writing scores were considerably easier to improve than scores in reading and math. Moreover, although the threatened schools focused more on students expected to score below the minimum criteria cutoffs, the improvement of the lower performing students does not seem to have come at the expense of the higher performing ones. Rather, there seems to have been a rightward shift of the entire score distribution in each of reading, math and writing with improvements more concentrated in score ranges just below the minimum criteria cutoffs.

These findings are informative from a policy point of view. They strongly suggest that the F schools responded to the incentives built into the system. This implies that policy can be appropriately targeted to affect public school behavior and to induce schools to behave in desirable ways. For example, if more attention on reading and math is warranted, it calls for a change in grading rules to give less weight to writing and more to reading and math. If more attention on comparatively higher performing students is desired, in addition to emphasis on low performing students, this calls for an inclusion of higher performing student scores in computation of F and D grades. Interestingly, two of the major elements of the grading criteria changes that went into effect in 2002 were to reduce the weight of writing and

to increase those of reading and math; and extension of emphasis to scores of comparatively higher performing students also.

Effective policy making calls for an understanding of the responses of agents to specific rules of the policy, so that the lessons learnt can be used to create a more effective and stronger policy. This paper has contributed to this learning process and the findings promise to be valuable from the point of view of public school reform.

Observations	1565	1565	1565	1565	1565	1565

\*, \*\*, \*\*\*: significant at the 10, 5, and 1 percent level, respectively. Robust standard errors adjusted for clustering by school district are in parentheses. The dependent variable is percentage of students in school  $i$  scoring in level  $j$  in year  $t$ . This table reports results for discontinuity sample 2. Results for discontinuity sample 1 are similar. Controls include race, sex, percentage of students eligible for free or reduced-price lunches, real per pupil expenditures and interactions of level dummies with each of these variables. OLS regressions include level dummies, interactions of level dummies with treated dummy and year dummies respectively, and a cubic in the selection variable (percentage of students scoring at or above 3 in writing). Results are similar with other orders of the polynomial and their interactions with a dummy that takes a value of 1 below the threshold and 0 otherwise. The FE columns include school by level fixed effects and interactions of level dummies with year dummies.

\*, \*\*, \*\*\*: significant at the 10, 5, and 1 percent level, respectively. Robust standard errors adjusted for clustering by school district are in parentheses. This table uses percentage of students below minimum criteria in reading, math and writing, each standardized by grade, subject and year to have a mean of zero and standard deviation of 1. The dependent variable is percentage of students below minimum criteria cutoff (standardized by grade, subject and year) in school  $i$  in subject  $s$  in year  $t$ . All regressions are weighted by the number of students tested. The regression results are obtained from the estimation of model 5 and its fixed effects counterpart. The OLS columns include the three subject dummies, low and mid dummies. The FE columns include school by subject fixed effects. Controls include race, sex, percentage of students eligible for free or reduced-price lunches, real per pupil expenditure and interactions of the subject dummies with these variables.

Education and Social Policy

The Institute for Education and Social Policy of the Steinhardt School of Culture, Education, and Human Development and Robert F. Wagner School of Public Service at NYU conducts non-partisan scientific research about U.S. education and related social issues. Our research, policy studies, evaluations, seminar series, and technical assistance inform and support policy makers, educators, parents and others in their efforts to improve public schooling. More information is available on our website at <http://steinhardt.nyu.edu/iesp>.
