Preface

For this 15th iteration of the International Conference on Educational Data Mining (EDM 2022), the conference returned to England, this time to Durham, with an online hybrid format for virtual participation as well. EDM is organized under the auspices of the International Educational Data Mining Society. The conference, held July 24th through 27th, 2022, follows fourteen previous editions (fully online in 2021 and 2020, Montréal 2019, Buffalo 2018, Wuhan 2017, Raleigh 2016, Madrid 2015, London 2014, Memphis 2013, Chania 2012, Eindhoven 2011, Pittsburgh 2010, Cordoba, 2009 and Montréal 2008).

The theme of this year's conference is Inclusion, Diversity, Equity, and Accessibility (IDEA) in EDM Research and Practice. This theme emphasizes the importance of considering and broadening who is included – or not included – in EDM, and why. Furthermore, the theme speaks to the importance of IDEA considerations in all stages of the research process, from participant recruitment and selection, data collection, methods, analysis, results, to the application of research results in the future. The conference features three invited talks: Jennifer Hill, Professor of Applied Statistics at New York University, USA; René Kizilcec, Assistant Professor of Information Science at Cornell University, USA; and Judy Robertson, Professor of Digital Learning at the University of Edinburgh, Scotland. As in the past few years of EDM, this year's conference also includes an invited keynote talk by the 2021 winner of the EDM Test of Time Award. The talk is delivered by Tiffany Barnes, Distinguished Professor of Computer Science at North Carolina State University, USA.

This year's EDM conference continued the double-blind review process that started in 2019. The program committee was once again extended, this time using an interest survey process, to better reflect the community presenting works and to keep the review load for each member manageable. EDM received 90 submissions to the full papers track (10 pages), of which 26 were accepted (28.9%), while a further 12 were accepted as short papers (6 pages) and 14 as posters (4 pages). There were 56 submissions to the short paper track, of which 17 were accepted (30.4%) and a further 20 were accepted as posters. The poster and demo track itself accepted 10 contributions out of 20 submissions.

The EDM 2022 conference also held a Journal of Educational Data Mining (JEDM) Track that provides researchers a venue to deliver more substantial mature work than is possible in a conference proceeding and to present their work to a live audience. The papers submitted to this track followed the JEDM peer review process. Five papers were submitted and two papers are featured in the conference's program.

The main conference invited contributions to an Industry Track in addition to the main track. The EDM 2022 Industry Track received six submissions of which four were accepted. The EDM conference also continues its tradition of providing opportunities for young researchers to present their work and receive feedback from their peers and senior researchers. The doctoral consortium this year features nine such presentations.

In addition to the main program, there are six workshops and tutorials: *Causal Inference in Edu-*

ational Data Mining (Third Annual Half-Day Workshop), 6th Educational Data Mining in Computer Science Education (CSEDM) Workshop, FATED 2022: Fairness, Accountability, and Transparency in Educational Data, The Third Workshop of The Learner Data Institute: Big Data, Research Challenges, & Science Convergence in Educational Data Science, Rethinking Accessibility: Applications in Educational Data Mining, and Tutorial: Using the Open Science Framework to promote Open Science in Education Research.

We thank the sponsors of EDM 2022 for their generous support: DuoLingo, ETS, Durham University Department of Computer Science, and Durham University School of Education. We are also thankful to the senior program committee and regular program committee members and reviewers, without whose expert input this conference would not be possible. Finally, we thank the entire organizing team and all authors who submitted their work to EDM 2022. And we thank EasyChair for their infrastructural support.

<i>Antonija Mitrovic</i>	University of Canterbury	Program Chair
<i>Nigel Bosch</i>	University of Illinois Urbana–Champaign	Program Chair
<i>Alexandra I. Cristea</i>	Durham University	General Chair
<i>Chris Brown</i>	Durham University	General Chair

July 23rd, 2022
Durham, England, UK

Organizing Committee

General Chairs

- Alexandra I. Cristea (Durham University, UK)
- Chris Brown (Durham University, UK)

Program Chairs

- Antonija Mitrovic (University of Canterbury, NZ)
- Nigel Bosch (University of Illinois Urbana–Champaign, US)

Workshop & Tutorial Chairs

- Angela Stewart (Carnegie Mellon University, US)
- Steven Bradley (Durham University, UK)

Industry Track Chairs

- Carol Forsyth (Educational Testing Service, US)
- Stephen Fancsali (Carnegie Learning, Inc., US)

Doctoral Consortium Chairs

- Neil Heffernan (Worcester Polytechnic Institute, US)
- Craig Stewart (Durham University, UK)
- Armando Toda (Durham University, UK)
- Carol Forsyth (Educational Testing Service, US)

JEDM Track Chairs

- Sharon Hsiao (Santa Clara University, US)
- Luc Paquette (University of Illinois Urbana–Champaign, US)

Poster & Demo Track Chairs

- Frederick Li (Durham University, UK)
- Michelle P. Banawan (Arizona State University, US)
- Hassan Khosravi (University of Queensland, AU)

Publication/Proceedings Chairs

- Andrew M. Olney (University of Memphis, US)
- Tahir Aduragba (Durham University, UK)

Accessibility Chairs

- JooYoung Seo (University of Illinois Urbana–Champaign, US)
- Paul Salvador Inventado (California State University Fullerton, US)

Diversity, Equity, and Inclusion Chair

- Agathe Merceron (Beuth University of Applied Sciences, DE)

Online/Hybrid Experience Chairs

- LuEttaMae Lawrence (University of California Irvine, US)
- Stephen Hutt (University of Pennsylvania, US)

Publicity and Sponsorship Chair

- Effe Law (Durham University, UK)

Web Chair

- Lei Shi (Durham University, UK)

Local Organisers

- Jim Ridgeway
- Peter Tymms
- Suncica Hadzidedic
- Stamos Katsigiannis
- Elaine Halliday
- Georgina Sales
- Judith Williams
- Jingyun Wang
- Dorothy Monekosso
- Nelly Bencomo
- Jindi Wang

IEDMS Officers

Tiffany Barnes, President North Carolina State University, USA

Best Paper Selection

The program committee chairs discussed and nominated four full papers and four short papers for best paper and best student paper awards, based on reviews, review scores, and meta-reviews. The papers and reviews (both anonymous) were then sent to a best paper award committee who ranked the papers. The highest-ranked paper was awarded the best paper award, while the next-highest ranked paper with a student first author was awarded the best student paper award.

Best paper committee

- Luc Paquette
- Kalina Yacef
- Kenneth Koedinger
- Anna Rafferty

Best paper nominees

(Full) Jiayi Zhang, Juliana Ma, Alexandra L. Andres, Stephen Hutt, Ryan S. Baker, Jaclyn Ocumpaugh, Caitlin Mills, Jamiella Brooks, Sheela Sethuraman and Tyron Young. *Detecting SMART Model Cognitive Operations in Mathematical Problem-Solving Process*

(Full) Vinthuy Phan, Laura Wright and Bridgette Decent. *Addressing Competing Objectives in Allocating Funds to Scholarships and Need-based Financial Aid*

(Full) Yuyang Nie, Helene Deacon, Alona Fyshe and Carrie Demmans Epp. *Predicting Reading Comprehension Scores of Elementary School Students*

(Full) Guojing Zhou, Robert Moulder, Chen Sun and Sidney K. D’Mello. *Investigating Temporal Dynamics Underlying Successful Collaborative Problem Solving Behaviors with Multilevel Vector Autoregression*

(Short) Lea Cohausz. *Towards Real Interpretability of Student Success Prediction Combining Methods of XAI and Social Science*

(Short) Juan Sanguino, Ruben Manrique, Olga Mariño, Mario Linares and Nicolas Cardozo. *Log mining for course recommendation in limited information scenarios*

(Short) Zhikai Gao, Bradley Erickson, Yiqiao Xu, Collin Lynch, Sarah Heckman and Tiffany Barnes. *Admitting you have a problem is the first step: Modeling when and why students seek help in programming assignments*

(Short) Anaïs Tack and Chris Piech. *The AI Teacher Test: Measuring the Pedagogical Ability of Blender and GPT-3 in Educational Dialogues*

JEDM Presentations	3

Long Papers

Insta-Reviewer: A Data-Driven Approach for Generating Instant Feedback on Students’ Project Reports	5
<i>Qinjin Jia, Mitchell Young, Yunkai Xiao, Jialin Cui, Chengyuan Liu, Parvez Rashid and Edward Gehringer</i>	
Sparse Factor Autoencoders for Item Response Theory	17
<i>Benjamin Paaßen, Malwina Dywel, Melanie Fleckenstein and Niels Pinkwart</i>	
Exploring Common Trends in Online Educational Experiments	27
<i>Ethan Prihar, Manaal Syed, Korinn Ostrow, Stacy Shaw, Adam Sales and Neil Heffernan</i>	
Optimizing Representations and Policies for Question Sequencing using Reinforcement Learning	39
<i>Aqil Zainal Azhar, Avi Segal and Kobi Gal</i>	
Code-DKT: A Code-based Knowledge Tracing Model for Programming Tasks	50
<i>Yang Shi, Min Chi, Tiffany Barnes and Thomas Price</i>	
Building a Reinforcement Learning Environment from Limited Data to Optimize Teachable Robot Interventions	62
<i>Tristan Maidment, Mingzhi Yu, Nikki Lobczowski, Adriana Kovashka, Erin Walker, Diane Litman and Timothy Nokes-Malach</i>	
Detecting SMART Model Cognitive Operations in Mathematical Problem-Solving Process	75
<i>Jiayi Zhang, Juliana Ma, Alexandra L. Andres, Stephen Hutt, Ryan S. Baker, Jaclyn Ocumpaugh, Caitlin Mills, Jamiella Brooks, Sheela Sethuraman and Tyron Young</i>	
SQL-DP: A Novel Difficulty Prediction Framework for SQL Programming Problems	86
<i>Jia Xu, Tingting Wei and Pin Lv</i>	
Evaluating the Explainers: Black-Box Explainable Machine Learning for Student Success Prediction in MOOCs	98

<i>Vinitra Swamy, Bahar Radmehr, Natasa Krco, Mirko Marras and Tanja Käser</i>	
Addressing Competing Objectives in Allocating Funds to Scholarships and Need-based Financial Aid	110
<i>Vinthuy Phan, Laura Wright and Bridgette Decent</i>	
Automatic Short Math Answer Grading via In-context Meta-learning	122
<i>Mengxue Zhang, Sami Baral, Neil Heffernan and Andrew Lan</i>	
Investigating Multimodal Predictors of Peer Satisfaction for Collaborative Coding in Middle School	133
<i>Yingbo Ma, Gloria Ashiya Katuka, Mehmet Celepkolu and Kristy Elizabeth Boyer</i>	
Going Deep and Far: Gaze-based Models Predict Multiple Depths of Comprehension During and One Week Following Reading	145
<i>Megan Caruso, Candace Peacock, Rosy Southwell, Guojing Zhou and Sidney D’Mello</i>	
Predicting Reading Comprehension Scores of Elementary School Students	158
<i>Yuyang Nie, Helene Deacon, Alona Fyshe and Carrie Demmans Epp</i>	
Enhancing Stealth Assessment in Game-Based Learning Environments with Generative Zero-Shot Learning	171
<i>Nathan Henderson, Halim Acosta, Wookhee Min, Bradford Mott, Trudi Lord, Frieda Reichsman, Chad Dorsey, Eric Wiebe and James Lester</i>	
Generalisable Methods for Early Prediction in Interactive Simulations for Education	183
<i>Jade Mai Cock, Mirko Marras, Christian Giang and Tanja Käser</i>	
Toward Better Grade Prediction via A2GP - An Academic Achievement Inspired Predictive Model	195
<i>Wei Qiu, S. Supraja and Andy W. H. Khong</i>	
Individual Fairness Evaluation for Automated Essay Scoring System	206
<i>Afrizal Doewes, Akрати Saxena, Yulong Pei and Mykola Pechenzkiy</i>	
Combining domain modelling and student modelling techniques in a single automated pipeline	217
<i>Gio Picones, Benjamin Paaßen, Irena Koprinska and Kalina Yacef</i>	
Neural Recall Network: A Neural Network Solution to Low Recall Problem in Regex-based Qualitative Coding	228
<i>Zhiqiang Cai, Cody Marquart and David Shaffer</i>	
Towards Including Instructor Features in Student Grade Prediction	239
<i>Nathan Ong, Jiaye Zhu and Daniel Mosse</i>	
Item Response Theory-Based Gaming Detection	251
<i>Yun Huang, Steven Dang, J. Elizabeth Richey, Michael Asher, Nikki G. Lobczowski, Danielle Chine, Elizabeth A. McLaughlin, Judith M. Harackiewicz, Vincent Alevin and Kenneth Koedinger</i>	
Exploring Cultural Diversity and Collaborative Team Communication through a Dynamical Systems Lens	263

Mohammad Amin Samadi, Jacqueline G. Cavazos, Yiwen Lin and Nia Nixon

[Predicting Cognitive Engagement in Online Course Discussion Forums](#) 276
Guher Gorgun, Seyma Nur Yildirim-Erbasli and Carrie Demmans Epp

[Investigating Temporal Dynamics Underlying Successful Collaborative Problem Solving Behaviors with Multilevel Vector Autoregression](#) 290

Deep Down, Everyone Wants to be Causal

Jennifer Hill, Professor of Applied Statistics at New York University, USA

Most researchers in the social, behavioral, and health sciences are taught to be extremely cautious in making causal claims. However, causal inference is a necessary goal in research for addressing many of the most pressing questions around policy and practice. In the past decade, causal methodologists have increasingly been using and touting the benefits of more complicated machine learning algorithms to estimate causal effects. These methods can take some of the guesswork out of analyses, decrease the opportunity for “p-hacking,” and may be better suited for more fine-tuned tasks such as identifying varying treatment effects and generalizing results from one population to another. However, should these more advanced methods change our fundamental views about how difficult it is to infer causality? In this talk, I will discuss some potential advantages and disadvantages of using machine learning for causal inference and emphasize ways that we can all be more transparent in our inferences and honest about their limitations.

Beyond Algorithmic Fairness in Education: Equitable and Inclusive Decision-Support Systems

René Kizilcec, Assistant Professor of Information Science at Cornell University, USA

Advancing equity and inclusion in schools and universities has long been a priority in education research. While data-driven predictive models could help improve social injustices in education, many studies from other domains suggest instead that these models tend to exacerbate existing inequities without added precautions. A growing body of research from the educational data mining and neighboring communities is beginning to map out where biases are likely to occur, what contributes to them, and how to mitigate them. These efforts to advance algorithmic fairness are an important research direction, but it is critical to also consider how AI systems are used in educational contexts to support decisions and judgements. In this talk, I will survey research on algorithmic fairness and explore the role of human factors in AI systems and their implications for advancing equity and inclusion in education.

No data about me without me: Including Learners and Teachers in Educational Data Mining

Judy Robertson, Professor of Digital Learning at the University of Edinburgh, Scotland

The conference theme this year emphasizes the broadening of participation and inclusion in educational data mining; in this talk, I will discuss methodologies for including learners and teachers throughout the research process. This involves not only preventing harm to young learners which might result from insufficient care when processing their data but also embracing their participation in the design and evaluation of educational data mining technologies. I will argue that even young learners can and should be included in the analysis and interpretation of data which affects them. I will give examples of a project in which children have the role of data activists, using

classroom sensor data to explore their readiness to learn.

Test of Time Award:

Compassionate, Data-Driven Tutors for Problem Solving and Persistence

Tiffany Barnes, Distinguished Professor of Computer Science at North Carolina State University, USA

Determining how, when, and whether to provide personalized support is a well-known challenge called the assistance dilemma. A core problem in solving the assistance dilemma is the need to discover when students are unproductive so that the tutor can intervene. This is particularly challenging for open-ended domains, even those that are well-structured with defined principles and goals. In this talk, I will present a set of data-driven methods to classify, predict, and prevent unproductive problem-solving steps in the well-structured open-ended domains of logic and programming. Our approaches leverage and extend my work on the Hint Factory, a set of methods that to build data-driven intelligent tutor supports using prior student solution attempts. In logic, we devised a HelpNeed classification model that uses prior student data to determine when students are likely to be unproductive and need help learning optimal problem-solving strategies. In a controlled study, we found that students receiving proactive assistance on logic when we predicted HelpNeed were less likely to avoid hints during training, and produced significantly shorter, more optimal posttest solutions in less time. In a similar vein, we have devised a new data-driven method that uses student trace logs to identify struggling moments during a programming assignment and determine the appropriate time for an intervention. We validated our algorithm's classification of struggling and progressing moments with experts rating whether they believe an intervention is needed for a sample of 20% of the dataset. The result shows that our automatic struggle detection method can accurately detect struggling students with less than 2 minutes of work with 77% accuracy. We further evaluated a sample of 86 struggling moments, finding 6 reasons that human tutors gave for intervention from missing key components to needing confirmation and next steps. This research provides insight into the when and why for programming interventions. Finally, we explore the potential of what supports data-driven tutors can provide, from progress tracking to worked examples and encouraging messages, and their importance for compassionately promoting persistence in problem solving.

Empirical Evaluation of Deep Learning Models for Knowledge Tracing: Of Hyperparameters and Metrics on Performance and Replicability

Sami Sarsa Aalto University, Finland

Juho Leinonen Aalto University, Finland

Arto Hellas Aalto University, Finland

New knowledge tracing models are continuously being proposed, even at a pace where state-of-the-art models cannot be compared with each other at the time of publication. This leads to a situation where ranking models is hard, and the underlying reasons of models' performance – be it architectural choices, hyperparameter tuning, performance metrics, or data – is often underexplored. In this work, we review and evaluate a body of deep learning knowledge tracing (DLKT) models with openly available and widely-used data sets, and with a novel data set of students learning to program. The evaluated knowledge tracing models include Vanilla-DKT, two Long Short-Term Memory Deep Knowledge Tracing (LSTM-DKT) variants, two Dynamic Key-Value Memory Network (DKVMN) variants, and Self-Attentive Knowledge Tracing (SAKT). As baselines, we evaluate simple non-learning models, logistic regression and Bayesian Knowledge Tracing (BKT). To evaluate how different aspects of DLKT models influence model performance, we test input and output layer variations found in the compared models that are independent of the main architectures. We study maximum attempt count options, including filtering out long attempt sequences, that have been implicitly and explicitly used in prior studies. We contrast the observed performance variations against variations from non-model properties such as randomness and hardware. Performance of models is assessed using multiple metrics, whereby we also contrast the impact of the choice of metric on model performance. The key contributions of this work are the following: Evidence that DLKT models generally outperform more traditional models, but not necessarily by much and not always; Evidence that even simple baselines with little to no predictive value may outperform DLKT models, especially in terms of accuracy – highlighting importance of selecting proper baselines for comparison; Disambiguation of properties that lead to better performance in DLKT models including metric choice, input and output layer variations, common hyperparameters, random seeding and hardware; Discussion of issues in replicability when evaluating DLKT models, including discrepancies in prior reported results and methodology. Model implementations, evaluation code, and data are published as a part of this work.

Latent Skill Mining and Labeling from Courseware Content

Noboru Matsuda North Carolina State University, USA
Jesse Wood North Carolina State University, USA
Raj Shrivastava North Carolina State University, USA
Machi Shimmei North Carolina State University, USA
Norman Bier Carnegie Mellon University, USA

A model that maps the requisite skills, or knowledge components, to the contents of an online course is necessary to implement many adaptive learning technologies. However, developing a skill model and tagging courseware contents with individual skills can be expensive and error prone. We propose a technology to automatically identify latent skills from instructional text on existing online courseware called SMART (Skill Model mining with Automated detection of Resemblance among Texts). SMART is capable of mining, labeling, and mapping skills without using an existing skill model or student learning (aka response) data. The goal of our proposed approach is to mine latent skills from assessment items included in existing courseware, provide discovered skills with human-friendly labels, and map didactic paragraph texts with skills. This way, mapping between assessment items and paragraph texts is formed. In doing so, automated skill models produced by SMART will reduce the workload of courseware developers while enabling adaptive online content at the launch of the course. In our evaluation study, we applied SMART to two existing authentic online courses. We then compared machine-generated skill models and human-crafted skill models in terms of the accuracy of predicting students' learning. We also evaluated the similarity between machine-generated and human-crafted skill models. The results show that student models based on SMART-generated skill models were equally predictive of students' learning as those based on human-crafted skill models – as validated on two OLI courses. Also, SMART can generate skill models that are highly similar to human-crafted models as evidenced by the normalized mutual information (NMI) values.

Insta-Reviewer: A Data-Driven Approach for Generating Instant Feedback on Students' Project Reports

Qinjin Jia, Mitchell Young, Yunkai Xiao, Jialin Cui, Chengyuan Liu, Parvez Rashid, Edward Gehringer

ABSTRACT

Providing timely feedback is crucial in promoting academic achievement and student success. However, for multifarious reasons (e.g., limited teaching resources), feedback often arrives too late for learners to act on the feedback and improve learning. Thus, automated feedback systems have emerged to tackle educational tasks in various domains, including novice programming, short-essay writing, and open-ended questions. However, to the best of our knowledge, no previous study has investigated automated feedback generation on students' project reports. In this paper, we present a novel data-driven system, named *Insta-Reviewer*, for automatically generating instant feedback on students' project reports, using state-of-the-art natural language processing (NLP) models. We also propose a framework for manually evaluating system-generated feedback. Experimental results show that feedback generated by Insta-Reviewer on real students' project reports can achieve near-human performance. Our work demonstrates the feasibility of automatic feedback generation for students' project reports while highlighting several prominent challenges for future research.

Feedback generation, automated review generation, instant feedback, learning at scale, mining educational data

1. INTRODUCTION

Feedback plays a vital role in the student learning process, as it can help students reinforce or correct their understanding of knowledge and content by giving them clear guidance on how to improve their learning [1, 19, 22, 39]. Furthermore, instant feedback is usually more effective than delayed feedback, presumably because timely feedback is more likely to motivate students to stay on task and encourage them to achieve learning goals [21, 51, 14]. However, owing to various constraints (e.g., staff availability), feedback often comes too late for students to enact the advice and benefit their learning [48, 38, 32, 22]. Students reported in a prior study

Q. Jia, M. Young, Y. Xiao, J. Cui, C. Liu, P. Rashid, and E. Gehringer. Insta-reviewer: A data-driven approach for generating instant feedback on students' project reports. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 5–16, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

<https://doi.org/10.5281/zenodo.6853099>

that delayed feedback is perceived as irrelevant because it has been so long that they have forgotten about the content, which discourages them from following the feedback [38]. Thus, tardy feedback can unintentionally position students as passive recipients of feedback information and limit their engagement with feedback and learning [8, 38].

One way of bringing about the much-needed immediacy is by way of automatic generation of instant feedback on students' work. Thanks to recent technological advancements, a variety of automatic feedback systems have emerged to tackle educational tasks in various domains, including novice programming [31, 56], short-essay writing [49, 5], and open-ended short answers [28, 3]. For instance, Malik and Wu proposed generative models for providing feedback on short answers and different types of programming assignments [28]. Marwan et al. designed a hybrid method to deliver instant feedback for block-based programming [31]. In addition to this, many other impressive studies focus on educational tasks that demand instant feedback to facilitate students' learning and show promising results across modalities and domains (e.g., [27, 36, 47, 2, 29]). It can be argued that automatic feedback systems will be integral parts of the future AI-powered educational ecosystem [41].

However, to the best of our knowledge, no attempt has been made to evaluate the feasibility of automatic feedback generation on students' project reports. It is well-known that course projects are an essential part of many university curricula, especially STEM courses [4, 17]. These projects can help students reinforce their theoretical knowledge and develop a host of skills that are increasingly important in the professional world [30, 17]. However, delivering immediate feedback on project reports is often infeasible for instructors. We summarize the reasons why such an automated feedback system for students' project reports is significant as follows:

1. Despite the fact that course projects have many positive educational impacts on students, the burden of providing timely feedback may prevent instructors from offering sufficient course projects. In this case, an automated feedback system can encourage instructors to provide more project work in classes.
2. Many instructors can merely provide summative feedback for a final project at the end of a semester, which does not give students an opportunity to implement the advice. However, if an automated feedback system is available to provide formative feedback, students will

have guidance on how to revise their work and reinforce their learning without adding workload to instructors.

3. An automated feedback system can help promote educational equity and diversity by giving students the benefit of quality feedback on projects in an institution that has high teaching loads and limited or nonexistent teaching assistant support, or even in a MOOC.

In this paper, we present a data-driven system, named *Insta-Reviewer*, for generating instant textual feedback on students’ project reports. Insta-Reviewer utilizes a select-then-generate paradigm consisting of two main steps: 1) the paradigm first uses an unsupervised method, called cross-entropy extraction, to summarize original reports to lengths acceptable for input into our text generation model used in the second step, and then 2) employs a supervised text-to-text generation model called BART to generate plausible and readable textual feedback for the corresponding report. In order to explore the quality of generated feedback, we employ a comprehensive set of evaluation metrics, including a content-overlap metric ROUGE, a model-based metric BERTScore, and a new human-centered evaluation metric.

To investigate the potential promise of our system, we design experiments to answer the following research questions:

RQ1: How effective is the proposed approach for generating feedback on students’ project reports?

RQ2: What are the problems of system-generated reviews? What are they not good at?

RQ3: How does the system perform compared with other potential methods?

RQ4: How does the automated feedback system perform in different small-data settings?

RQ5: Does the Insta-Reviewer automated feedback system raise any ethical concerns?

Our results show that feedback generated by Insta-Reviewer on real students’ project reports can achieve near-human performance, while it may include some non-factual or ambiguous statements in generated feedback. Our work demonstrates the feasibility of automated instant-feedback generation on students’ project reports. Experimental results also highlight several major challenges for future research.

Our main contributions are: 1) we present an effective data-driven approach for generating feedback on students’ project reports; 2) we collect a new dataset of students’ reports and expert reviews to facilitate future research endeavors; 3) we propose a new framework for manually evaluating generated feedback; 4) we evaluate the effectiveness of our approach in different small-data settings to help others who intend to apply the approach to their datasets; 5) we highlight several prominent challenges for future research.

The remainder of the paper is organized as follows: Section 2 presents related work. Section 3 describes the dataset used for this study. Section 4 elaborates our methodology for automatically generating feedback for students’ project reports and explains the new human-evaluation metric. Section 5 presents and discusses our experimental results. Section 6 concludes the paper, mentions the limitations of our work and provides some discussion about future research.

2. LITERATURE REVIEW

In the following, we first review prior studies on automated feedback systems. Then we survey potential metrics for evaluating system-generated feedback. Finally, we review previous work related to ethical concerns in feedback generation.

2.1 Automated Feedback Systems

In the field of education, feedback is defined as information provided by an agent (e.g., teacher, peer) about a learner’s performance or understanding, and it is one of the most significant influences on student learning and achievement [19]. Previous research has been devoted to designing a variety of automated feedback systems that provide feedback on various forms of student work, such as short-answer questions, essays, and programming problems. Although these efforts were not intended to provide feedback on student project reports, we reviewed these studies to gain some insight. The feedback-generation models (i.e., the feedback engines) used in previous studies on automated feedback systems for student work can be broadly categorized into two groups:

Expert-driven methods: Expert-driven methods (also called rule-based methods) use a set of expert-designed rules to provide feedback. For instance, Narciss et al. [34] presented an intelligent tutoring system for students learning mathematics. The system uses a set of pre-defined rules provided by domain experts to deliver feedback for students’ answers to numerical or multiple-choice questions. Nagata et al. [33] introduced an approach for leveraging the expert-driven method to diagnose preposition errors and produce feedback for learners’ English writing. While expert-driven methods are typically accurate and not data-hungry, they are not suitable for dealing with complex open-ended problems (e.g., generating feedback for students’ project reports) because creating and maintaining a vast set of expert-design rules for such open-ended problems is nearly impossible. Additionally, these methods usually produce feedback that is limited to fixed expressions without dynamic explanations.

Data-driven methods: Recent technological advances in artificial intelligence have enabled the development of various data-driven automated feedback systems to produce feedback for more complex open-ended tasks. Data-driven methods generate feedback by learning the mappings (i.e., patterns) from student work to expert feedback by means of machine-learning or deep-learning algorithms [10]. For example, Lu and Cutumisu [27] implemented several deep-learning models, including CNN, CNN+LSTM, and CNN+Bi-LSTM, for generating textual feedback on students’ essays. However, traditional deep-learning models usually fail to capture long-span dependencies in long documents and rely on large amounts of training data. More recent work has begun to use large-scale pre-trained language models, such as BERT [11], BART [23], and GPT-2 [40], for generating feedback on open-ended student work. These language models use the attention mechanism [45] to learn long-span dependencies and are pre-trained on large generic corpora in an unsupervised manner to reduce the need for labeled data. For instance, Olney [35] attempted to generate elaborated feedback for student responses using the ELI5 model and achieved promising results. In this paper, we also use such a pre-trained language model to exploit its ability to capture long-span dependencies in student reports.

2.2 Evaluation of Feedback Generation

Effective metrics for evaluating generated feedback are essential since we use them to compare different approaches and quantify the progress made on this research problem. However, unlike other tasks (e.g., text classification), accurately evaluating system-generated feedback (and many other natural language generation problems) is in itself a huge challenge, mainly because generating feedback is a highly open-ended task. For instance, an automated feedback system can generate multiple plausible reviews for the same student report, but all these reviews can be vastly different.

All existing evaluation methods for natural language generation tasks can be grouped into three categories: 1) content-overlap metrics, 2) model-based metrics, and 3) human-centered evaluation metrics. Content-overlap metrics and model-based metrics automatically evaluate a text-generation system by measuring the similarity between generated texts and reference texts provided by domain experts. Human-centered evaluation asks people to assess the quality of system-generated texts against set task-specific criteria [9].

It is worth noting that the ultimate goal of our Insta-Reviewer automated feedback system is to generate feedback that is valuable to students instead of generating the exact same feedback as provided by instructors. For this reason, human-authored evaluation should be viewed as the gold standard when evaluating generated feedback. However, human evaluations are inconsistent and subjective, which can lead to erroneous conclusions or prevent researchers from comparing results across systems [9]. Thus, we also employ a content-overlap metric and a model-based metric to validate our human-evaluation results. In the following paragraphs, we survey potential metrics that can be applied to our task.

Content-overlap metrics: Content-overlap metrics refer to a set of metrics that evaluate the quality of generation by comparing generated texts with reference texts (e.g., ground-truth feedback provided by instructors) based on the content overlap, such as n -gram match. Despite the fact that this set of metrics has many limitations (e.g., they do not take synonyms into account), text-generation research usually uses metrics from this set for benchmark analysis with models since they are objective and fast to calculate. Two of the most commonly used content-overlap metrics for evaluating generated text are BLEU [37] and ROUGE [25].

BLEU (the Bilingual Evaluation Understudy) is a precision-based content-overlap metric proposed by Papineni et al. [37] in 2002. The precision-based metric means that we compare the two texts by counting the number of words or n -grams in the generated text that occur in the human reference and dividing the count by the length of the reference text. Compared to ROUGE, BLEU focuses on precision and is suitable for tasks that favor high precision. However, recall is also essential for our task since we expect more words from the expert feedback to appear in the system-generated feedback. On the other hand, both recall and precision can be taken into account for the ROUGE metric [7].

ROUGE (Recall-Oriented Understudy for Gisting Evaluation) is the other most commonly used content-overlap metric introduced by Lin [25] in 2004. The original ROUGE

score is basically a recall-based version of BLEU. That is, for ROUGE, we check how many words or n -grams in the reference text appear in the generated text. Nevertheless, entirely removing precision can have substantial adverse effects (e.g., a system may generate extremely long text strings to capture all words in the reference text). In recent years, ROUGE has commonly referred to ROUGE-F₁ that combines both precision and recall ROUGE scores in the harmonic mean. We report ROUGE-F₁ scores in results since both recall and precision are vital for our system.

Model-based metrics: Model-based metrics use learned representations of words and sentences to compute semantic similarity between generated and reference texts. Model-based metrics are generally more correlated with human judgment than content-overlap metrics, but their behavior is not interpretable [9]. Given the excellent performance of BERT [11] across many tasks, recent work on model-based metrics commonly uses pre-trained contextual embeddings from BERT or similar pre-trained language models for evaluating the semantic equivalence between the texts [55, 53, 43]. One of the most widely used metrics is BERTScore [55].

BERTScore is a model-based metric proposed by Zhang et al. in 2020 and has been shown to correlate well with human judgments for many text-generation tasks. BERTScore leverages the pre-trained embedding from BERT and matches words in generated and reference sentences by cosine similarity. Moreover, BERTScore considers both precision and recall and combines them to compute an F₁ measure, which is appropriate for evaluating generated feedback in our task. Thus, we employ BERTScore to measure semantic similarity between expert feedback and generated feedback.

Human-centered evaluation: Human-centered evaluation asks human evaluators to judge the quality of generated text along some specific dimensions (e.g., readability). Caligiuri and Thomas [6] found that a positive tone and suggestions for improvement are key features of good reviews. Jia et al. [20] mentioned that providing suggestions, mentioning problems, and using a positive tone, are main characteristics of effective feedback. Celikeyilmaz et al. [9] pointed out that fluency and factuality are essential for evaluating system-generated text. In this paper, we manually evaluate generated feedback in five dimensions: Readability, Suggestions, Problems, Positive Tone, and Factuality. The details of these evaluation dimensions are described in Section 4.5.3.

2.3 Ethical Concerns in Feedback Generation

To date, ethical issues in feedback generation have received scant attention in the research literature. Celikeyilmaz et al. [9] pointed out that a potential ethical issue that may appear in text-generation tasks is the problem of generating improper or offensive language. Li et al. [24] also mentioned that using pre-trained language models for text-generation tasks may raise ethical issues, such as generating private content, because corpora used for pre-training are pulled from the web without carefully filtering. However, there is still a lack of systematic methods for evaluating how effectively a system can avoid generating inappropriate text. For these reasons and others, this work considers the ethical implications of an automated feedback system on student project reports by manually inspecting all generated feedback.

Table 1: Sample Human Reference Reviews

Very good writeup, as far as it goes. Good discussion of test cases and reasons for refactoring. It would have helped to see some code snippets. Good section on Future Refactoring Opportunities.
A very good description of changes, and appropriate code snippets are shown. Manual testing is shown with annotated screenshots, which are very useful. In a Rspec test, sending emails to an actual person’s address is not a good practice.
The wiki page covers all necessary items, but the “test plan” part can be more elaborated. And the last screenshot is useless. It will be better to show the DB records, instead of table structure.

Table 2: Statistics on the Dataset. We measure the percentage of reports that contain more than 1024 tokens since it is the maximum input length limit of the BART model, and we utilize BART to craft the generation function in our system.

# of data samples = 484		Average	Percentile					Maximum	Over 1024 tokens
			5th	25th	50th	75th	95th		
Reports	# of words	1193	405	734	1060	1499	2374	6512	
	# of subword tokens	1643	583	1040	1489	2025	3272	8422	76 %
Summarized Reports	# of words	704	395	649	742	803	865	908	
	# of subword tokens	951	580	1004	1021	1023	1024	1024	0 %
Reference Reviews	# of words	55	13	33	48	72	114	258	
	# of subword tokens	71	19	43	61	90	147	335	-

3. DATA

In this section, we introduce a new dataset collected for this study. Firstly, we describe the data source in Section 3.1. Then, we explain in Section 3.2 how participants’ privacy rights were respected during the data collection process. Finally, we present statistics on the dataset in Section 3.3.

3.1 Data Source

The data used in this study are collected from a graduate-level object-oriented development course at a public university in the United States. For a course assignment, two to four students form a group and work together on some course project, bid on topics from a list of potential projects provided by course instructors. The dataset includes group projects where students refactor code from an open-source project Expertiza, add new features to it, or write automated tests for a software module that needs them.

As a part of project deliverables, each team is required to submit a group report to document the work that has been completed, methodologies that they have utilized, and other project-related material (e.g., how they test their code). Such group reports are also called wiki pages since they are added to the wiki document maintained by the open-source project Expertiza. The instructor reviews each of these wiki pages (i.e., each group report) and provides textual feedback on each of them. To better understand our data, URLs to three anonymous and de-identified reports are provided in footnotes¹²³. Three randomly sampled⁴ instructor reviews from our dataset are displayed in Table 1.

¹Sample report 1: <https://anonymous.4open.science/r/EDM22-BF52/Student%20Report%201.pdf>

²Sample report 2: <https://anonymous.4open.science/r/EDM22-BF52/Student%20Report%202.pdf>

³Sample report 3: <https://anonymous.4open.science/r/EDM22-BF52/Student%20Report%203.pdf>

⁴According to our IRB protocol, in order to protect participants’ privacy rights, we do not display instructor reviews for the sample group reports.

3.2 Privacy protection

In this work, we take our responsibility to protect the privacy of students’ data very seriously. The use of the dataset has been approved by the IRB at our institution. Sensitive student data was de-identified and handled in a way that is FERPA compliant. More specifically, our data protection and de-identification procedure consist of four main steps: 1) we took our data from an anonymized database, which uses random identifiers for students and groups; 2) we utilized regular-expression techniques to automatically remove all names from reports; 3) we manually inspected and removed remaining sensitive data, such as links to documents that might identify individual authors; 4) we stored data securely on a cloud drive managed by the university.

3.3 Statistics on the Dataset

We collected de-identified students’ project reports and associated textual feedback provided by instructors from twelve semesters between Spring 2015 and Spring 2021. This gave us a set of 484 group projects. Table 2 summarizes statistics from the dataset. Note that since the pre-trained language model BART (detailed in Section 4) has a maximum input length limit of 1024 tokens⁵, we employ an unsupervised method to summarize original reports to lengths acceptable for input into the pre-trained BART. Statistics on these summarized reports are provided in the third row of the table.

We measured the average number of words and tokens for reports, summarized reports, and expert reviews in our dataset. The average number of words for each original report is 1193, which corresponds to 1643 subword tokens. We found that 75.8% of the reports comprise more than 1024 tokens. The average number of words in each summarized report is 704 (equivalent to 951 subword tokens). For expert reviews, the average number of words and the average number of tokens per instructor review are 55 and 71, respectively.

⁵A token is an instance of a sequence of characters that are grouped together as a useful semantic unit for processing. It is similar to, but not identical with, morpheme.

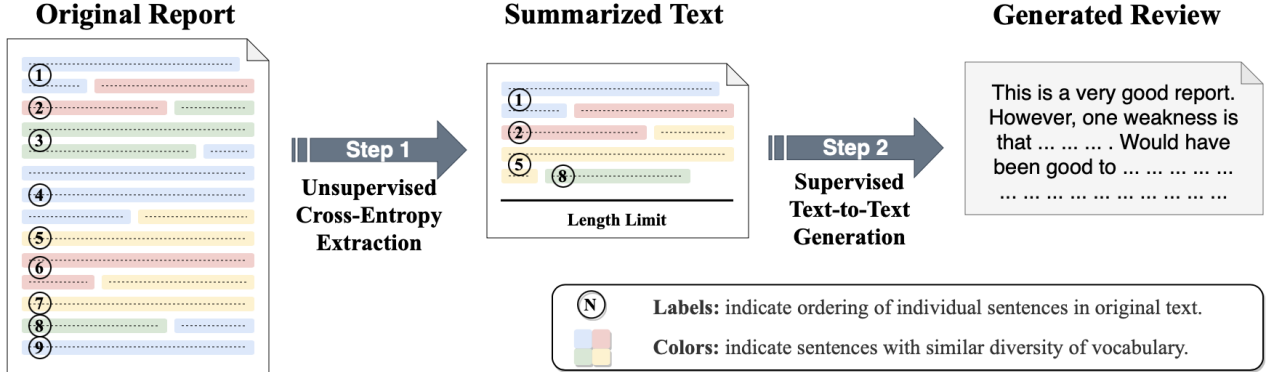

Figure 1: Operation of our *Insta-Reviewer* System. The system uses a select-then-generate paradigm [44, 18, 52]. The first step is to extract salient sentences (within the length limit) from students’ project reports. The second step is to utilize a supervised NLP model to generate feedback for students’ reports. Details of the system are described throughout Section 4.

4. METHODOLOGY

In this section, we detail our data-driven approach for automatically generating feedback on students’ project reports. We first formally define our task in Section 4.1. Then, we present the overall design of our feedback-generation system in Section 4.2. After that, Section 4.3-4.4 elaborates all components of the system. A set of metrics for evaluating generated textual feedback is given in Section 4.5. Finally, in Section 4.6, some ablation experiments are proposed to understand the contribution of each component.

4.1 Problem Formulation

We formulate the task of automatic feedback generation for students’ project reports as a *text-to-text generation* problem, where the source text is a long project report and the target text is a review. Our dataset can be represented as $D = (X^i, Y^i)_{i=1}^{N=484}$, where $X^i = \langle x_1^i, \dots, x_j^i, \dots, x_n^i \rangle$ denotes a sequence of input tokens representing an instance of report, and $Y^i = \langle y_1^i, \dots, y_k^i, \dots, y_m^i \rangle$ denotes a sequence of output tokens representing the corresponding textual feedback. Each token x_j^i or y_k^i is drawn from a token vocabulary \mathcal{V} .

Then, the problem can be formally described as:

$$Y = \mathcal{F}_{\mathcal{M}}(X, \mathbb{C}) \quad (1)$$

where the model, or generation function, $\mathcal{F}_{\mathcal{M}}$ takes a sequence of tokens X (i.e., a project report) as the input, and produces a sequence of tokens Y (i.e., generated feedback for the project report) as the output, while satisfying a set of constraints \mathbb{C} , which is a collection of desired properties (e.g., fluency, coherence, and length) for the output text.

The objective of the task is to effectively model the generation function $\mathcal{F}_{\mathcal{M}}$ in a data-driven manner using the dataset, so that it can generate plausible and readable feedback for unseen reports. In this work, the generation function $\mathcal{F}_{\mathcal{M}}$ is crafted based on a pre-trained language model (PLM) called BART (detailed in Section 4.4), which has been demonstrated to be the state-of-the-art method to model the generation function for various text-to-text generation tasks [23].

4.2 System Design

Despite the fact that the pre-trained language model BART is an effective method to model the generation function $\mathcal{F}_{\mathcal{M}}$, it has an input length limit of 1024 tokens⁶ [23]. Nevertheless, group reports are usually longer than that. In our dataset, 75.8% of the reports contain more than 1024 tokens, and the longest report is approximately eight times longer than that limit. One simple fix is to truncate the report by discarding all tokens beyond the length limit, but this can cause loss of critical information from the inputs (this hypothesis is verified in Section 4.6.1). Thus, we adopt a select-then-generate method [18, 44, 52] to generate feedback on student project reports, as illustrated in Figure 1.

Overall, the select-then-generate paradigm decomposes the problem into two sequential subproblems to resolve the issue of overlength input documents: 1) an unsupervised sentence-level extractive summarization task, and 2) a supervised PLM-based text-to-text generation task. More formally, the problem description becomes,

$$Y = \mathcal{F}_{\mathcal{M}}(\mathcal{S}_{\mathcal{E}}(X), \mathbb{C}) \quad (2)$$

where the input to the generation function $\mathcal{F}_{\mathcal{M}}$ becomes $\mathcal{S}_{\mathcal{E}}(X)$, which represents a summarized report. The new function $\mathcal{S}_{\mathcal{E}}$ represents an extractive summarizer, which can effectively extract salient sentences from an original report X and produce a summarized version of the report as the input to the feedback-generation function $\mathcal{F}_{\mathcal{M}}$.

Thus, our automated feedback-generation system comprises two stages. In the first stage, we use an unsupervised method, called cross-entropy extraction, to summarize original reports to lengths acceptable for input into the PLM BART (i.e., the implementation of the generation function $\mathcal{F}_{\mathcal{M}}$). In the second stage, we train the PLM BART on the summarized reports $\mathcal{S}_{\mathcal{E}}(X)$ and reference reviews Y . In the following sections (Section 4.3-4.4), we detail each stage of our feedback-generation system *Insta-Reviewer*.

⁶The length is limited to 1024 since the BART authors [23] chose this number and pre-trained the model with this limit.

4.3 Step 1: Cross-Entropy Extraction

The goal of the first step is to summarize original over-length reports to lengths acceptable for input into the pre-trained language model (PLM) BART that will be used in the second step, while retaining as diverse a subset of content as possible. We adopt an unsupervised extractive-summarization method, called cross-entropy extraction [15].

The cross-entropy method is an unsupervised technique that treats sentence-level extractive summarization as a combinatorial optimization problem [42]. More formally, we can let S_D denote the set of all sentences in the report we are trying to summarize. From this set we want to extract a subset of sentences $S \subset S_D$ that maximizes some quality target function $Q(S)$. This quality target function can be comprised of whatever features and measures deemed applicable to the task at hand. In our case, we used only a single feature in our quality function, namely the diversity of vocabulary in the summary. The reasoning behind this is that sentences with a more diverse vocabulary will also cover a more diverse set of information from the text. To measure this diversity explicitly, we calculate the unigram LM entropy of the summary S , as shown below,

$$Q(S) = - \sum_{w \in S} p_S(w) \log p_S(w) \quad (3)$$

$$p_S(w) = \frac{\text{COUNT}(w)}{\text{LEN}(S)} \quad (4)$$

Note that in the above equations w represents a single word in the summary S . Additionally, the function $\text{COUNT}(w)$ measures the frequency of the word w in summary S and $\text{LEN}(S)$ is the total number of words in the summary. Additionally, to encourage the method to prefer summaries as close to the length constraint as possible, we added an additional term to this quality function that is proportional to the number of tokens in S , denoted $\text{TOKENS}(S)$, the intuition behind this being that the BART model will perform better in most cases when it has more text to work with. The final quality function with this added length term is shown below, where β , our proportionality constant, is a hyper-parameter of the model.

$$Q(S) = \beta \cdot \text{TOKENS}(S) - \sum_{w \in S} p_S(w) \log p_S(w) \quad (5)$$

In order to enforce the length constraint on our summaries, we simply assign $Q(S) = -\infty$ whenever S has a length of greater than 1024 BART tokens. The actual output of the cross-entropy method is a vector $p = \langle p_1, p_2, \dots, p_n \rangle$ indicating the probability of selection in the summary for each of the n sentences in the original document. Initially, these probabilities start out the same for each sentence, but they quickly convert to either 0, for sentences that result in low Q values, or to 1, for sentences that result in high Q values. Below are the steps of the algorithm we used for carrying out this cross-entropy extraction procedure.

1. **Preprocessing Text:** For each student project report, we split it into its n sentences, enumerating each according to their order in the report. We then tokenize each sentence into word tokens, being sure to remove all stop words, punctuation, etc., when doing so.

2. **Initialize p :** Initially we want each sentence to be equally likely to be chosen, so set $p_0 = \langle 1/2, 1/2, \dots, 1/2 \rangle$. If $n > 60$ then we reduce this probability to ensure a sufficient sample of summaries that meet our length constraint. Then we set $t = 0$.

3. **Sample Summaries:** We sample N Bernoulli vectors, X_1, X_2, \dots, X_N according to the probability vector p_{t-1} . The sentences selected from each of these vectors define our N sample summaries S_1, S_2, \dots, S_N . Set $t = t+1$.

4. **Quality Scores:** For each of the summaries S_i , we calculate its quality performance score according to the above equations. We determine the cutoff value of the elite sample, γ_t , which is the Q value of the $(1 - \rho)$ sample quantile.

$$\gamma_t = Q(S)_{[(1-\rho)N]} \quad (6)$$

5. **Update p :** We use the sample values to update our probabilities, storing them as \hat{p}_t , according to the update rule below:

$$\hat{p}_{t,j} = \frac{\sum_{j=1}^N \delta_{[Q(S_j) \geq \gamma_t]} \delta_{[X_{i,j}=1]}}{\sum_{j=1}^N \delta_{[Q(S_j) \geq \gamma_t]}} \quad (7)$$

where $\delta_{[c]}$ is the Kronecker-delta function which evaluates to 1 if the condition c is satisfied, otherwise 0.

6. **Smooth p :** To balance exploration and exploitation of the summary samples, we smooth p_t like so:

$$p_t = \alpha \hat{p}_t + (1 - \alpha) p_{t-1} \quad (8)$$

7. **Termination:** If the value of γ_t has not changed in 3 iterations then the process terminates, returning the current p_t . Otherwise, it returns to step 3 and repeats.

In our implementation of the above algorithm, we found the following parameter settings to be optimal: $N = 1000$, $\rho = .05$, $\alpha = .7$. To get our final truncated summary text, we simply sample one more Bernoulli vector, X , using the final sentence extraction probabilities p . After doing so, we check that the resulting summary defined by the sentences in X meets our length constraint. If it does not, then we would sample a new Bernoulli vector X until we found a summary that did (though this was never necessary).

4.4 Step 2: PLM-based Generation Model

We now describe the second step of the approach. The objective of the second step is to effectively craft the feedback-generation function \mathcal{F}_M in Equation 2. We first introduce the BART model used for crafting \mathcal{F}_M , then we describe the beam-search method for improving the performance.

4.4.1 Modeling the Generation Function with BART

In this work, we employ a state-of-the-art PLM BART [23], which stands for bidirectional and auto-regressive transformers, to model the generation function \mathcal{F}_M . The BART model is suitable for text-to-text generation tasks since it utilizes an encoder-decoder architecture (as illustrated in Figure 2), which can effectively model complex mappings (i.e., the underlying patterns) from one sequence of text (e.g., summarized reports) to another (e.g., feedback).

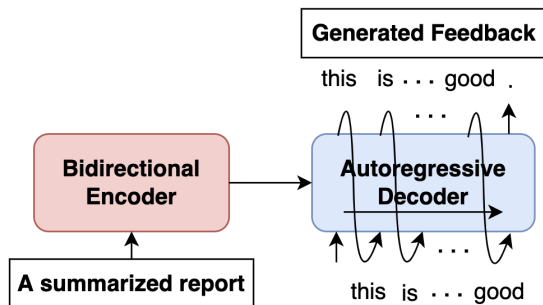

Figure 2: Illustration of an encoder-decoder architecture. The encoder can convert an input sequence of text (e.g., a summarized report) into a rich numerical representation, and then the decoder generates the output sequence (e.g., feedback) by iteratively predicting the most probable next word.

The BART framework consists of two steps: pre-training and fine-tuning. Instead of training the model from scratch on our dataset, the BART model is first pre-trained on a large generic corpus over different pre-training tasks, and then all parameters of the model are fine-tuned on our data. The model can acquire a sophisticated “understanding” of human grammar through the pre-training process, thus significantly reducing the need for annotated data when training the feedback-generation model while improving convergence rate and generalization [13]. In this work, we use the pre-trained checkpoint “facebook/bart-large-cnn⁷” to initialize all parameters of the model and then fine-tune the model on a training set drawn from our dataset D .

4.4.2 Diverse beam search for decoding

After fine-tuning the BART model on our data, we use the diverse beam search (DBS) [46] algorithm to decode the output sequences in inference time to generate better feedback. In the original BART model setting, feedback is generated by iteratively selecting the word with the highest probability at each position in the sequence, which is referred to as greedy decoding. Greedily choosing the word with the highest probability at each step might be optimal at the current spot in the sequence, but as we move through the rest of the full sentence, it might turn out to be a non-optimal choice (output can be ungrammatical, unnatural, and nonsensical) since the greedy decoding algorithm lacks backtracking.

On the other hand, the DBS algorithm keeps track of the top- n most probable next words, where n is the number of beams. The next set of beams is chosen by considering all possible next-word extensions of the existing set and selecting the n most likely extensions. Additionally, in order to improve the diversity in the outputs, all beams are divided into groups, and diversity between the groups is enforced by the DBS algorithm. In our experiments, we set beam size to 4 and the number of groups to 2 since this combination yields the best results. DBS is applied to all models in this work, including the BigBirdPegasus model (Section 4.6.2).

4.5 Evaluation Metrics

⁷<https://huggingface.co/facebook/bart-large-cnn>

We evaluate generated feedback with a comprehensive set of metrics, including a content-overlap metric ROUGE, a model-based metric BERTScore, and a new human-evaluation metric. As previously mentioned, the ultimate goal of Insta-Reviewer is to generate feedback that is helpful to students instead of generating the same feedback as provided by instructors. To this end, human-centered evaluation is considered the gold standard. ROUGE and BERTScore are employed to validate our human-evaluation results since human evaluations may be inconsistent and subjective, which can lead to erroneous conclusions [9]. The intuition is that while instructor feedback may only focus on certain aspects and be imperfect, it is valuable to know how similar the generated feedback is to the feedback provided by instructors. The implementations of the metrics are described below.

4.5.1 Content-overlap Metric: ROUGE

We use the standard ROUGE metric to measure content overlap between generated feedback and expert feedback. Specifically, we report the F_1 scores for ROUGE-1, ROUGE-2, and ROUGE-Lsum, respectively measuring the word-overlap, bigram-overlap, and longest common sequence between the texts. We obtain our ROUGE scores using the Google rouge package⁸ [25, 16]. Porter stemming is enabled to remove plurals and word suffixes (e.g., “ing”, “ion”, “ment”).

4.5.2 Model-based Metric: BERTScore

The BERTScore metric is leveraged to assess the semantic equivalence between generated feedback and expert feedback. We report the F1 measure of BERTScore that combines both precision and recall, which is proper for evaluating generated feedback in our task. We calculate the BERTScore utilizing the official BERTScore script⁹ [55].

4.5.3 Human Evaluation

After reviewing relevant papers (e.g., [6, 20, 50, 57]) and discussions among the authors of this paper, we selected the following five dimensions to evaluate the feedback manually: Readability, Suggestions, Problems, Positive Tone, and Factuality. Our scores for these five manual-evaluation dimensions are calculated as follows:

- (i) **Readability** (READ): In this work, readability is defined as the quality of feedback in grammar, word choice, and coherence. We judge it using a five-point rating scale: 0. Incomprehensible 1. Not fluent and incoherent 2. Somewhat fluent but incoherent 3. Fluent but somewhat incoherent 4. Fluent and coherent.
- (ii) **Suggestions** (SUGG): Providing suggestions is a key feature of quality feedback that is valuable to students. We give a score of 1 if the feedback contains at least one valid suggestion statement that can guide the reviewee in how to correct a problem or make improvements. Otherwise, we give a score of 0.
- (iii) **Problems** (PROB): Pointing out something that is going wrong in students’ work is also important for helping learners. We give a score of 1 if the feedback describes at least one issue that needs to be addressed in the student report. Otherwise, we give a score of 0.

⁸<https://github.com/google-research/google-research/tree/master/rouge>

⁹https://github.com/Tiiiger/bert_score

- (iv) **Positive Tone** (TONE): Feedback phrased in a positive tone can better stimulate students’ reflective competence. We give feedback a score of 1 if it has an overall positive semantic orientation, 0.5 if it is neutral, and 0 if it is negative.
- (v) **Factuality** (FACT): The statements in generated feedback should be factually correct. Otherwise, they may inadvertently mislead the reviewee and negatively impact learning. Factuality is calculated as:

$$\text{FACT} = \frac{\text{Count}(\text{factually correct statements})}{\text{Count}(\text{total statements})}$$

where the numerator is the total number of factually correct statements, and the denominator is the total number of statements in the feedback. If the denominator is 0, we directly give a score of 0.

This set of evaluation criteria is certainly not perfect, but it balances the accuracy and cost of the evaluation. For example, we could score the “Problems” dimension in a more sophisticated and accurate way, but it would be very time-consuming and expensive. We leave more accurate and efficient human-evaluation criteria for future work.

4.6 Ablation experiments

In order to understand the contribution of each step in our method, we designed two ablation experiments:

4.6.1 Ablation Exp. 1 - Naïve BART:

In the first ablation experiment, we intend to understand the contribution of the cross-entropy (CE) summarization. As we mentioned in Section 4.2, a straightforward way to solve the BART’s length-limit problem is to truncate all tokens beyond the length limit, which we hypothesize may lead to a loss of critical information from the inputs. Therefore, we measure the performance of a BART model that simply truncates all tokens exceeding the length limit of 1024 as input, and we call this setup - “Naïve BART.” If adequate information is contained in the truncated reports to generate feedback on students’ reports, then “CE + BART” should perform similarly to “Naïve BART.” Otherwise, it would demonstrate that using CE to summarize the original students’ project reports is better than simply truncating all tokens that exceed the length limit. In other words, it will suggest that the CE method can effectively summarize students’ reports while retaining critical information that helps the model generate feedback, and the CE step is necessary.

4.6.2 Ablation Exp. 2 - BigBirdPegasus:

In the second ablation experiment, we investigate whether the “CE + BART” method can be replaced using the recently proposed sparse-attention-based PLM BigbirdPegasus [54], which extends the input length limit to 4096 tokens. Briefly, BigBirdPegasus increases the input length limit at the cost of using a sparse attention mechanism, which may reduce the ability of the model to fit complex mappings between texts. Similar to BART, BigBirdPegasus also consists of the pre-training and fine-tuning steps. In this experiment, we use the pre-trained checkpoint “google/bigbird-pegasus-large-arxiv¹⁰” to initialize all parameters of BigbirdPegasus and then fine-tune the model on our data.

¹⁰<https://huggingface.co/google/bigbird-pegasus-large-arxiv>

5. EXPERIMENTS AND RESULTS

5.1 Experimental Setup

5.1.1 Training Details

For all experiments, we train our models with a batch size of 1/2, a learning rate of 2e-5/3e-5/5e-5, epochs of 2/3, and the AdamW optimizer [26] with a weight decay of 0.01 and a linear rate scheduler of 10% warm-up steps. For our dataset D , we use an 80-10-10 split for training, validation, and test data. After finding the optimal hyper-parameters, we merge the training and validation sets into the new training data.

5.1.2 Hardware Setup

The BART models are trained on an NVIDIA RTX6000 GPU (24GB). The BigBirdPegasus model (mentioned in Section 4.6.2) is trained on an NVIDIA A6000 GPU (48GB). We also employ the automatic mixed-precision training (use of both 16-bit and 32-bit floating-point types) to speed up the training processes.

5.2 Experimental Results

To investigate the potential promise of our system, we design experiments to answer the following research questions:

RQ1: How effective is the proposed approach for generating feedback on students’ project reports?

The goal of our first experiment is to find out if our automated feedback system Insta-Reviewer is effective in generating some readable and helpful feedback for students’ project reports. The evaluation results of Insta-Reviewer are shown in Table 3. Some generated feedback for actual student reports is shown in Table 5, and their evaluation scores are shown in Table 4. According to Table 3, the ROUGE1, ROUGE2, ROUGESum, and BERTScore for our “CE + BART” method are 28.54, 6.39, 18.21, and 59.18, respectively. These results imply that the generated and expert feedback are basically consistent in semantics, and there is some overlap in words (more precisely, n -grams).

We also evaluated the feedback provided by instructors, and the first row shows the human-evaluation scores for it. Compared to the expert feedback, we surprisingly find that in terms of “Problems” and “Positive Tone,” our method can outperform human experts by 6% and 2%. However, it is worth noting that the generated feedback tends to mention more generic problems (e.g., missing a test plan) rather than project-specific issues (e.g., “xxx files should be described”). Additionally, the expert feedback can outperform the generated feedback, with gaps of 6%, 16%, 15.2% for “Readability,” “Suggestions,” and “Factuality,” respectively. In summary, although our system is not as good as experts at providing suggestions and may produce some non-factual statements, it is good at generating fluent and positive feedback that mentions problems that need to be addressed.

RQ2: What are the problems of system-generated reviews? What are they not good at?

In the second experiment, we aim to explore the potential issues in system-generated feedback in more detail. Although the vast majority of the feedback is fluent, positive, and factually correct, we find two potential problems after manually inspecting all system-generated feedback in the test set.

Table 3: ROUGE F₁ (with porter stemming), BERTScore, and Human Evaluation scores (%) on the test set (n=50). All our ROUGE scores have a 95% confidence interval (CI) of at most ± 2.98 as reported by the official ROUGE script (bootstrap resampling). Our BERTScore has a 95% CI of at most ± 1.54 . The BERTScore script does not support BigBirdPegasus currently.

Method	ROUGE			BS	Human Evaluation						
	R1	R2	RLsum		READ	SUGG	PROB	TONE	FACT	Average	
1. Expert Feedback	-	-	-	-	100.0	82.0	90.0	93.0	100.0	93.00	
Insta-Reviewer	2. CE + BART	28.54	6.39	18.21	59.18	94.0	66.0	96.0	95.0	84.8	87.16
Ablation Exp 1	3. Naïve BART	25.88	4.98	17.23	58.03	82.0	58.0	94.0	93.0	76.8	80.76
Ablation Exp 2	4. BigBirdPegasus	15.92	4.04	13.45	-	56.0	2.0	12.0	58.0	23.4	30.28

Table 4: ROUGE F₁ (with porter stemming), BERTScore, and Human Evaluation scores (%) for the sample generated feedback shown in the Table 5. †“I would suggest that the reader read the ...” is not a valid suggestion for the reviewee.

	ROUGE			BERTScore	Human Evaluation					
	R1	R2	RLsum		READ	SUGG	PROB	TONE	FACT	Average
Generated Feedback 1	27.52	1.87	20.18	59.17	100.0	100.0	100.0	100.0	100.0	100.0
Generated Feedback 2	45.09	18.00	21.57	66.79	100.0	0.00†	100.0	100.0	83.33	76.67
Generated Feedback 3	22.22	0.00	13.89	52.92	80.00	0.00	100.0	100.0	80.00	72.00

Table 5: Sample expert and generated feedback. Scores for the generated feedback are shown in Table 4. The generated feedback may contain **non-factual or **ambiguous** statements.**

Expert Feedback 1: “The page is pretty well organized in what changes they made. Their pictures were not taken as a screenshot, instead were just taken with their phone camera. They didn’t provide a manual test plan, which is problematic as we have no good way of verifying their changes without significant work involved.”

Generated Feedback 1: “The writeup is quite readable, and the changes are described in good detail. However, the code changes are not described in prose, and there is no explanation of how they are implemented. The test plan is not described, and it would be much more useful to have a description of the tests that are to be added.”

Expert Feedback 2: “Your examples say that code was added, but don’t describe the code or what it is used for. The reader needs to figure that out by reading the code. For someone following on, it would be much more useful to have a description of how the code works.”

Generated Feedback 2: “The writeup is very readable, but it does not explain the changes made to the code. It is not clear how the code was changed. The test plan is not described. There is no description of the tests. **I would suggest that the reader read the code** to figure out what they test.”

Expert Feedback 3: “Well written, but does not mention design patterns or principles. ‘Gemfiles’ should be downgraded. Schema changes should be shown as migrations and not direct changes in schema file.”

Generated Feedback 3: “The wiki page is very short, but **the changes are described well**. It is not clear why the changes were made. The code changes are not described in prose. **They** (\leftarrow code snippets) are just shown. I would have liked to see more explanation of the changes”

Firstly, the automated feedback system may occasionally ($\approx 15.2\%$ of all statements) generate some non-factual or ambiguous statements in the feedback. For instance, the “generated feedback 2” shown in Table 5 contains a non-factual statement (italicized): “... there is no description of the tests. *I would suggest that the reader read the code to figure out what they test.*” However, this statement should probably be “... a description of the tests needs to be added. Otherwise, readers need to read the code to figure out what you test.”

Secondly, some pieces of text frequently appear in different generated feedback. For instance, we find that 66% of the system-generated feedback contains the sentence “the writeup is very/quite readable.” We speculate that this happens because 14% of the expert feedback that used for training contains the exact same sentence, which introduces some sort of “imbalance” problem. This repetition problem is not necessarily a drawback of the system, but it suggests that high-frequency text pieces can influence the generation.

RQ3: How does the system perform compared with other potential methods?

We now turn our attention to the experimental results of the two ablation experiments detailed in Section 4.6. The evaluation results are presented in Table 3. The second row, the third row, and the fourth row show the performance scores for our Insta-Reviewer system, naïve BART (the method utilized for the ablation experiment 1), and BigBirdPegasus (the model used for the ablation experiment 2), respectively.

The goal of the first ablation experiment is to verify our hypothesis that using the cross-entropy extraction (CE) to summarize the original students’ project reports is better than simply truncating all tokens beyond the length limit of BART. By looking at the ROUGE scores and BERTScore, we can find that the “CE + BART” method consistently outperforms the “naïve BART” method, with gaps of 2.66, 1.41, 0.98, and 1.15 for R1, R2, RLsum, and BERTScore

Table 6: ROUGE F₁ (with porter stemming) and BERTScore on the test set (n=50) in small-data settings (≤ 100 samples). For each score, we report a 95% confidence interval (CI).

data points	ROUGE			BERTScore
	R1	R2	RLsum	
434	28.54±2.98	6.39±1.56	18.21±1.83	59.18±1.54
50	24.29±2.47	4.99±0.94	17.42±1.70	56.12±1.42
100	25.75±2.65	5.56±1.15	17.86±1.61	57.36±1.43

respectively. Additionally, based on the human evaluation scores, “CE + BART” significantly ($\geq 8\%$) outperforms the “Naïve BART” method on “Readability,” “Suggestions,” and “Factuality.” The “CE + BART” method can also achieve higher ($\geq 2\%$) scores on dimensions “problems” and “positive tone.” The results demonstrate that the CE method can effectively summarize students’ reports while retaining critical information that helps the model generate feedback.

The second ablation experiment aims to know whether the sparse-attention-based PLM BigBirdPeagsus can effectively fit the complex mappings from student reports to textual feedback and replace our “CE + BART” approach. As shown in Table 3, the results clearly indicate that “CE + BART” substantially outperform the BigBirdPeagsus model on all metrics. The results suggest that although the BigBirdPeagsus model extends the input length limit to 4096 by using the sparse-attention mechanism, it may not be suitable for complicated tasks such as generating feedback.

RQ4: How does the automated feedback system perform in different small-data settings?

In order to help other researchers who intend to apply our approach on their datasets, we evaluated the effectiveness of the approach in different small-data settings. Table 6 shows the ROUGE scores and BERTScore when training with only 50 and 100 data samples, respectively. The scores (R1=25.75, R2=5.56, RLsum=17.86, BS=57.36) for our model when training with 100 samples are similar to the scores (R1=25.88, R2=4.98, RLsum=17.23, BS=58.03) for the “Naïve BART” when training with 434 samples. The results demonstrate that the performance of our approach is acceptable in small-data settings. Thus, our method can potentially be applied to other tasks that have limited data.

RQ5: Does the Insta-Reviewer automatic feedback system raise any ethical concerns?

The objective of the last experiment is to investigate whether the automated feedback system raises any ethical concerns. In this work, we consider two main potential ethical issues related to the system. The first major concern is whether the system will generate improper or offensive language. The second potential issue is whether the generated feedback will contain some private content. Although we have filtered out all inappropriate information from our dataset, these ethical concerns may still arise since the BART model is pre-trained on a large-scale corpus crawled from the Internet without fine-grained filtering. Therefore, we manually vetted all generated feedback, and failed to find any of the aforementioned ethical transgressions.

6. CONCLUSION

Timely feedback is critical to learning because it is more likely to motivate students to stay on task and achieve their learning goals. This suggests that future AI-powered educational applications will include automated feedback systems to generate real-time feedback. In this paper, we have presented a data-driven system, named *Insta-Reviewer*, for generating instant textual feedback on students’ project reports. The system leverages a select-then-generate paradigm consisting of two main steps: 1) cross-entropy extraction and 2) BART-based supervised text-to-text generation. The results demonstrate that the generated feedback could achieve near-human performance and even outperform human experts in the “Problems” and “Positive Tone” dimensions. However, the system may occasionally generate some non-factual or ambiguous statements in the feedback. The generated feedback seems to be free of any ethical complications. Our work demonstrates the feasibility of automatic feedback generation for students’ project reports while laying the groundwork for future research on this topic.

Limitations: There are three main limitations to this study. Firstly, we simply used textual information extracted from the student reports and ignored all images. As a result, our model could not produce feedback like “Their pictures were not taken as a screenshot, instead were just taken with their phone camera.” If we could design a multi-modality model that incorporates all text, images, and artifacts such as code into the input, we would be able to provide more comprehensive feedback to students. Secondly, we used a set of metrics, including ROUGE, BERTScore, and human-evaluation scores to evaluate the generated feedback. However, ROUGE and BERTScore cannot accurately reflect the quality of the generated feedback. Human evaluation can more accurately assess the quality, but it is inconsistent, subjective, and time-consuming. Thus, we believe it is worthwhile to explore more effective automatic metrics to evaluate the generation. Thirdly, we manually inspected all generated feedback, and found that it did not raise any ethical concerns. Nevertheless, this result does not guarantee that the model will never produce improper or offensive language. Systematic methods should be investigated to evaluate how the system can avoid generating inappropriate language. However, this problem is particularly challenging because the output of neural networks is not always predictable.

Future Work: An important direction for future work is to investigate how to avoid generating non-factual statements in feedback. This problem of factual correctness has two potential solutions. The first promising way is to automatically evaluate the correctness of each sentence in generated feedback and remove all non-factual statements before delivering the feedback to students. Dusek & Kasner [12] have proposed an entailment-based model to evaluate the correctness of the generated text. However, this approach does not capture which part of the generated text is non-factual. Future work can explore further along this direction. The other possible method to address the problem of non-factual statements is to design new architectures that can more effectively capture the complex mappings from student reports to feedback. The latter approach is significantly more challenging but may get to the root of the problem.

ABSTRACT

Item response theory (IRT) is a popular method to infer student abilities and item difficulties from observed test responses. However, IRT struggles with two challenges: How to map items to skills if multiple skills are present? And how to infer the ability of new students that have not been part of the training data? Inspired by recent advances in variational autoencoders for IRT, we propose a novel method to tackle both challenges: The Sparse Factor Autoencoder (SparFAE). SparFAE maps from test responses to abilities via a linear operator and from abilities to test responses via an IRT model. All parameters of the model offer an interpretation and can be learned in an efficient manner. In experiments on synthetic and real data, we show that SparFAE is similar in accuracy to other autoencoder approaches while being faster to learn and more accurate in recovering item-skill associations.

Keywords

item response theory, logistic models, variational autoencoder, sparse factor analysis

1. INTRODUCTION

A foundational problem in educational data mining is to automatically infer students' ability from their observed responses in a test. Item response theory (IRT) addresses this problem by fitting a logistic model that describes how student ability and item difficulty interact to generate an observed response [5]. However, IRT faces at least two challenges. First, whenever a test involves multiple skills, we need to model the relation between skills and items, which standard IRT does not do [10]. Second, an IRT model contains student-specific parameters which are fitted to a specific population. For any new student, we need to fit at least one new parameter.

The former challenge can be addressed via automatic methods for item-skill association learning, such as the Q -matrix method of Barnes et al. [2], the alternating least squares method [12], or sparse factor analysis [7]. The second challenge requires a student-independent parametrization of the model, which is offered by variants like performance factor analysis [11] or variational autoencoders [3]. In the present paper, we propose to address both challenges at once by combining sparse factor analysis with autoencoders, yielding a new method which we call sparse factor autoencoder (SparFAE).

In more detail, our contributions are: We introduce SparFAE, a sparse factor autoencoding method for IRT. We provide an interpretation for all parameters in the SparFAE model, as well as an efficient learning scheme. Further, we empirically compare SparFAE to sparse factor analysis [7] as well as variational autoencoders [16] on synthetic and real data and show that SparFAE is similar in accuracy to other encoders but is much faster to learn and more accurate in recovering item-skill associations. Finally, we use SparFAE to analyze an expert-designed math test and verify the identified Q -matrix against the expert-designed Q -matrix. The source code for all experiments can be found at <https://github.com/bpaassen/sparfae>.

2. BACKGROUND AND RELATED WORK

IRT models the responses of m students on a test with n items. In particular, let $y_{i,j}$ be a random variable, which is 1 if student i answered item j correctly and 0, otherwise. We assume that $y_{i,j}$ is Bernoulli-distributed, where the success probability is given as $p_{i,j} = \sigma(\theta_i - b_j)$, where $\sigma(x) = 1/(1 + \exp[-x])$ is the logistic link function, θ_i is an ability parameter for student i , and b_j is a difficulty parameter for item j [5]. The parameters θ_i and b_j need to be fitted to observed training data, for example, via likelihood maximization or Bayesian parameter estimation [1]. In particular, the negative log likelihood of the data (also known as crossentropy loss) is expressed by the formula

$$\ell = \sum_{i=1}^m \sum_{j=1}^n -y_{i,j} \cdot \log[p_{i,j}] - (1 - y_{i,j}) \cdot \log[1 - p_{i,j}]. \quad (1)$$

This loss is convex in the parameters θ_i and b_j , meaning that an optimal model can be found efficiently via nonlinear optimization algorithms.

Over the decades, numerous extensions of this basic scheme have been proposed, such as a discrimination parameter for each item (two-parameter model), a minimum probability of correct answers for each item (three-parameter model), partial credit, and hierarchical models [1, 4, 5]. In this paper, we care particularly about the extension to multiple underlying skills, sometimes called multidimensional IRT [10]. In such a model, we represent a student’s ability by a K -dimensional vector $\vec{\theta}_i$, where $\theta_{i,k}$ models the ability of student i for skill k . A consequence of including multiple skills is that we need to model the relationship between skills and items. In this paper, we assume a linear relationship that is captured by an $n \times K$ matrix \mathbf{Q} , where $q_{j,k}$ models how important skill k is to answer item j correctly. Overall, our model is described by the two equations:

$$p_{i,j} = \sigma(z_{i,j}) \quad \text{and} \quad \vec{z}_i = \mathbf{Q} \cdot \vec{\theta}_i - \vec{b}, \quad (2)$$

where \vec{z}_i is the vector of response logits for student i , and \vec{b} is the vector of all item difficulties.

Our setup begs the question: how to learn the matrix \mathbf{Q} ? Such coupling matrices between items and skills have been popularized by Tatsuoaka [13], who imposed $q_{j,k} = 1$ if skill k is required for item j and $q_{j,k} = 0$, otherwise. Traditionally, such \mathbf{Q} -matrices have been hand-designed by domain experts [9], but recently, automatic methods to learn \mathbf{Q} have emerged, such as the method of Barnes [2] or the alternating recursive method [12]. Crucially, finding an optimal binary \mathbf{Q} -matrix is challenging due to the discrete search space. To simplify the search, Lan et al. [7] have relaxed the problem by assuming continuous, non-negative entries of \mathbf{Q} and applying methods from sparse coding, resulting in a method called Sparse Factor Analysis (SPARFA).

SPARFA applies an alternating optimization scheme. First, we initialize student abilities $\vec{\theta}_i$ randomly, for example with Gaussian noise. Second, for each item j , we adapt the j th row of \mathbf{Q} and the difficulty b_j by solving the following optimization problem:

$$\begin{aligned} \min_{\vec{q}_j, b_j} \quad & \ell + \lambda_1 \cdot \|\vec{q}_j\|_1 + \lambda_2 \cdot (\|\vec{q}_j\|_2^2 + b_j^2) \\ \text{s.t.} \quad & q_{j,k} \geq 0 \quad \forall k \in \{1, \dots, K\}, \end{aligned} \quad (3)$$

where ℓ is the crossentropy loss (1), $\|\vec{q}_j\|_1 = \sum_{k=1}^K |q_{j,k}|$ is the 1-norm of \vec{q}_j , $\|\vec{q}_j\|_2^2 = \sum_{k=1}^K q_{j,k}^2$ is the squared Euclidean norm of \vec{q}_j , and λ_1 as well as λ_2 are hyperparameters of the method. The squared Euclidean norm is intended to regularize the model parameters with a Gaussian prior, as usual in IRT [1] (chapter 7). The 1-norm is motivated by sparse coding and encourages sparsity in \mathbf{Q} , meaning that the optimization process tends to find solutions where many of the entries in \mathbf{Q} are zero [17]. In other words, the model is encouraged to connect any item j only to a few skills instead of all skills. This is reminiscent of traditional \mathbf{Q} -matrices, where $q_{j,k}$ is only nonzero if skill k is required to answer item j correctly [13]. Finally, SPARFA enforces that no entry $q_{j,k}$ can become negative, because a negative $q_{j,k}$ would imply that a higher ability in skill k *reduces* my chance to answer item j correctly, which does not make sense [7]. Note that problem (3) is convex, such that it can be solved efficiently with nonlinear optimizers.

The third step of SPARFA is to optimize the ability parameters $\vec{\theta}_i$ for each student i . This is done by minimizing the crossentropy (1) plus a regularization term $\lambda_2 \cdot \sum_{k=1}^K \theta_{i,k}^2$. We now iterate steps two and three of the SPARFA algorithm until the parameters converge.

Just as in standard IRT, a challenge of SPARFA is that we can not immediately apply a learned model to new students. For every new student i , we need to fit new parameters $\vec{\theta}_i$. Many extensions of IRT have circumvented this problem by removing ability parameters altogether and only using item parameters. For example, performance factor analysis replaces the ability parameter by a weighted count of correct and wrong responses on past items for the same skill [11]. More recently, Converse et al. [3] proposed a variational autoencoder model to simplify the application of IRT models to new students.

A variational autoencoder (VAE) views the student abilities $\vec{\theta}_i$ as a compressed representation of the student’s response vector \vec{y}_i . More precisely, a VAE tries to learn an encoder function which compresses \vec{y}_i to abilities $\vec{\theta}_i$, and a decoder function which de-compresses $\vec{\theta}_i$ back into estimated responses \hat{y}_i , such that \vec{y}_i and \hat{y}_i are close and such that $\vec{\theta}_i$ is standard normal distributed [6]. As decoder, we use a multi-dimensional IRT model (2), whereas the encoder could be a multi-layer artificial neural network [3]. In contrast to traditional IRT models, a VAE model is typically non-convex and multi-layered, and thus needs to be optimized with deep learning methods [3, 6]. Wu et al. [16] have further extended the VAE version of IRT by analyzing the theory more closely and including the difficulty parameters \vec{b} as an additional input to the encoder. Fig. 1 illustrates the approach for a single-layer encoder. The encoder is given as $\vec{\theta}_i = \mathbf{A} \cdot \vec{y}_i + \mathbf{B} \cdot \vec{b} + \vec{\gamma}$ for some bias $\vec{\gamma}$ (Fig. 1, left, in orange), whereas the decoder is a multi-dimensional IRT model like in (2) (Fig. 1, right, in blue). Note that we obtain all models in this section as special cases of this diagram. If we set the connections \mathbf{B} to zero, we obtain the IRT-VAE of [3]. If we, further, remove the connections \mathbf{A} and treat $\vec{\theta}_i$ as parameters, we obtain SPARFA. Finally, if we set $K = 1$ and $q_{j,1} = 1$ for all j , we obtain a classic IRT model.

Interestingly, the state-of-the-art VAE approaches do not apply a sparsity penalty to facilitate interpretability of \mathbf{Q} . Further, deep learning can be quite slow. To address these limitations, we propose an autoencoder model based on the SPARFA loss, which we describe in the next section.

3. METHOD

Our proposed model is a single-layer autoencoder as illustrated in Fig. 1. More formally, our model can be concisely expressed in the following equations:

$$\begin{aligned} \vec{\theta}_i &= \mathbf{A} \cdot \vec{y}_i, \\ \vec{z}_i &= \mathbf{Q} \cdot \vec{\theta}_i - \vec{b}, \quad \text{and} \\ p_{i,j} &= 1 / (1 + \exp(-z_{i,j})), \end{aligned} \quad (4)$$

where the first equation expresses the encoder and the second and third equation the decoder.

Our interpretation of the parameters is as follows. \mathbf{A} maps

Figure 1: A sketch of a one-layer autoencoder for student responses, following Algorithm 1 of [16]. The Encoder is shown in orange (left), the decoder in blue (right). Encoder bias parameters are not shown for simplicity.

from responses to student ability, with $\alpha_{k,j}$ modeling the amount of ability in skill k that is expressed by answering item j correctly. Conversely, \mathbf{Q} maps from abilities to responses, with $q_{j,k}$ modeling how much skill k helps to answer item j correctly. b_j models the difficulty of item j , as before. Note that our model requires no student-specific parameters, such that it can be directly applied to new students.

Note that we do not include “backward” connections \mathbf{B} or encoder bias parameters $\vec{\gamma}$ in our model because they do not contribute to the model’s expressive power in the single-layer case. Consider a “full” model with $\vec{\theta}_i = \mathbf{A} \cdot \vec{y}_i + \mathbf{B} \cdot \vec{b} + \vec{\gamma}$. If we plug this expression into our equation for z_i , we obtain

$$\vec{z}_i = \mathbf{Q} \cdot (\mathbf{A} \cdot \vec{y}_i + \mathbf{B} \cdot \vec{b} + \vec{\gamma}) - \vec{b} = \mathbf{Q} \cdot \mathbf{A} \cdot \vec{y}_i + \mathbf{Q} \cdot \mathbf{B} \cdot \vec{b} + \mathbf{Q} \cdot \vec{\gamma} - \vec{b}.$$

We now absorb \mathbf{B} and $\vec{\gamma}$ into \vec{b} by re-defining \vec{b} as $\mathbf{Q} \cdot \mathbf{B} \cdot \vec{b} + \mathbf{Q} \cdot \vec{\gamma} - \vec{b}$, yielding Equations (4). Accordingly, our model requires only $2K + 1$ parameters per item.

We can train the parameters of our model by solving the following minimization problem, inspired by SPARFA.

$$\begin{aligned} \min_{\mathbf{A}, \mathbf{Q}, \vec{b}} \sum_{i=1}^m \sum_{j=1}^n -y_{i,j} \cdot \log[p_{i,j}] - (1 - y_{i,j}) \cdot \log[1 - p_{i,j}] \quad (5) \\ + \lambda_1 \cdot (\|\mathbf{A}\|_{1,1} + \|\mathbf{Q}\|_{1,1}) + \frac{\lambda_2}{2} \cdot (\|\mathbf{A}\|_F^2 + \|\mathbf{Q}\|_F^2 + \|\vec{b}\|^2) \\ \text{s.t. } \alpha_{k,j} \geq 0, q_{j,k} \geq 0 \quad \forall k \in \{1, \dots, K\}, j \in \{1, \dots, n\} \end{aligned}$$

where $\|\mathbf{A}\|_{1,1} = \sum_{j=1}^n \sum_{k=1}^K |\alpha_{k,j}|$ denotes the entry-wise 1-norm, and where $\|\mathbf{A}\|_F^2 = \sum_{j=1}^n \sum_{k=1}^K \alpha_{k,j}^2$ denotes the squared Frobenius norm. Since the resulting model is an autoencoder-variant of Sparse Factor Analysis, we call it Sparse Factor Autoencoder (SparFAE). We denote the objective function as ℓ_{SparFAE} . As in SPARFA, the Frobenius norm applies a Gaussian prior on the parameters, whereas the 1-norm encourages sparsity. We also apply the same non-negativity constraints as in SPARFA to ensure a meaningful interpretation of \mathbf{A} and \mathbf{Q} . Additionally, the non-negativity constraints are likely to further enhance sparsity, as indicated by non-negative matrix factorization [8].

In contrast to SPARFA, we can *not* decompose this problem into independent problems for each item because there are item-to-item-dependencies: Manipulating $\alpha_{k,j}$ also influences the abilities $\theta_{i,k}$, which in turn influence the probability $p_{i,j'}$ for any item j' with $q_{j',k} \neq 0$. Accordingly, we

need to perform a joint optimization of all parameters. However, we do not need to resort to deep learning. Instead, we propose a standard L-BFGS solver, as implemented in the minimize method of scipy [14]. This is facilitated by the surprisingly simple expression for the gradients:

$$\begin{aligned} \nabla_{\mathbf{A}} \ell_{\text{SparFAE}} &= \mathbf{Q}^T \cdot \Delta^T \cdot \mathbf{Y} + \lambda_1 \cdot \mathbf{1} + \lambda_2 \cdot \mathbf{A}, \\ \nabla_{\mathbf{Q}} \ell_{\text{SparFAE}} &= \Delta^T \cdot \mathbf{Y} \cdot \mathbf{A}^T + \lambda_1 \cdot \mathbf{1}^T + \lambda_2 \cdot \mathbf{Q}, \text{ and} \\ \nabla_{\vec{b}} \ell_{\text{SparFAE}} &= -\vec{1}^T \cdot \Delta + \lambda_2 \cdot \vec{b}, \end{aligned} \quad (6)$$

where \mathbf{Y} is the $m \times n$ matrix of all responses, where Δ is the $m \times n$ matrix with entries $\delta_{i,j} = p_{i,j} - y_{i,j}$, where $\mathbf{1}$ is the $K \times n$ matrix of only ones, and where $\vec{1}$ is an m -dimensional vector of ones. Regarding computational complexity, notice that the matrix products in (6) require $\min\{2 \cdot K \cdot m \cdot n, n^2 \cdot (m + K)\}$ operations, such that each optimization step is in $\mathcal{O}(m \cdot n)$ for constant K . We can simplify our optimization further by inspecting the relationship between \mathbf{A} and \mathbf{Q} .

3.1 Single Matrix Variant

Note that the matrices \mathbf{A} and \mathbf{Q} have related interpretations. Intuitively, if skill k helps more with item j (high $q_{j,k}$), we would also expect that answering item j correctly is an indicator for skill k (high $\alpha_{k,j}$). Accordingly, it stands to reason that $\mathbf{A} = \mathbf{Q}^T$.

We can also motivate this setting mathematically. In particular, $\mathbf{A} = \mathbf{Q}^T$ is optimal if \mathbf{Q} is orthogonal, meaning $\mathbf{Q}^T \cdot \mathbf{Q}$ equals the identity matrix \mathbf{I} . In that case, $\mathbf{Q} \cdot \mathbf{Q}^T \cdot \vec{y}_i$ is the orthogonal projection of \vec{y}_i onto the hyperplane spanned by \mathbf{Q} . In other words, $\mathbf{Q} \cdot \mathbf{Q}^T \cdot \vec{y}_i$ is the most similar point to \vec{y}_i we can achieve with the decoder \mathbf{Q} .

However, is it plausible that \mathbf{Q} is orthogonal? Indeed, $\mathbf{Q}^T \cdot \mathbf{Q}$ becomes a diagonal matrix (orthogonal up to scaling) if every item tests exactly one skill. Let J_k be the set of items which test skill k . Then, we obtain: $(\mathbf{Q}^T \cdot \mathbf{Q})_{k,l} = \sum_{j=1}^n q_{j,k} \cdot q_{j,l} = \sum_{j \in J_k} q_{j,k}^2$ along the diagonal and zero off the diagonal. In other words, the sparser \mathbf{Q} becomes, the closer $\mathbf{A} = \mathbf{Q}^T$ is to optimal.

When we plug $\mathbf{A} = \mathbf{Q}^T$ into problem (5), we obtain:

$$\begin{aligned} \min_{\mathbf{Q}, \vec{b}} \quad & \sum_{i=1}^m \sum_{j=1}^n -y_{i,j} \cdot \log[p_{i,j}] - (1 - y_{i,j}) \cdot \log[1 - p_{i,j}] \\ & + \lambda_1 \cdot \|\mathbf{Q}\|_{1,1} + \frac{\lambda_2}{2} \cdot (\|\mathbf{Q}\|_F^2 + \|\vec{b}\|^2) \\ \text{s.t.} \quad & q_{j,k} \geq 0 \quad \forall k \in \{1, \dots, K\}, j \in \{1, \dots, n\}, \end{aligned} \quad (7)$$

where $\vec{z}_i = \mathbf{Q} \cdot \mathbf{Q}^T \cdot \vec{y}_i - \vec{b}$. The gradient becomes:

$$\nabla_{\mathbf{Q}} \ell_{\text{SparFAE}} = (\mathbf{Y}^T \cdot \mathbf{\Delta} + \mathbf{\Delta}^T \cdot \mathbf{Y} + \lambda_2 \cdot \mathbf{I}) \cdot \mathbf{Q} + \lambda_1 \cdot \mathbf{1}^T.$$

This concludes our description of the proposed method.

4. EXPERIMENTS

In our experiments, we evaluate our proposed approach, Sparse Factor Autoencoder (SparFAE), on both synthetic and real-world data. We compare Sparse Factor Analysis (SPARFA) [7], Variational item response theory with a novel lower bound (VIBO) [16], the two-matrix version of SparFAE (SparFAE2), as well as the single-matrix version (SparFAE1). As optimizers, we used L-BFGS for SPARFA and both SparFAE versions, and an Adam optimizer with learning rate 0.005, 100 epochs, and minibatch size 16 for VIBO (these settings are as similar as possible to the original work of [16]). The experimental source code with all details is available at <https://github.com/bpaassen/sparfae>.

4.1 Synthetic Experiments

First, we consider synthetic data, which we sample from a multivariate IRT model with $K = 5$ skills, standard normally distributed abilities $\theta_{i,k}$, and standard normally distributed difficulties b_j . We introduce two different sampling conditions for \mathbf{Q} : A) We sample a unique skill k for each item j and set $q_{j,k} = 1$, whereas all other entries of \mathbf{Q} remain zero. B) We first sample a number of skills $K_j \in \{1, \dots, 5\}$ for each item j with probability $p(K_j) = \frac{6-K_j}{15}$. Then, we draw K_j skills k without replacement and uniform probability for item j and set $q_{j,k}$ to a uniform random number in the range $[0.5, 1]$.

As evaluation measures, we use the area under the receiver-operator-curve in predicting correct responses (AUC), the correlation between the learned difficulties b_j and the actual difficulties (r_b), the correlation between the learned abilities $\theta_{i,k}$ and the actual abilities (r_θ), fraction of agreeing nonzero entries between the learned \mathbf{Q} matrix and the true \mathbf{Q} -matrix (r_Q), the time needed for training, and the time needed for prediction on new students. Since the ordering of skills is undefined, we allow arbitrary permutations of the skills in the learned \mathbf{Q} -matrix before computing r_Q . In practice, we re-order the columns of \mathbf{Q} according to the `linear_sum_assignment` function of `scipy` with the ground-truth \mathbf{Q} matrix [14]. We evaluate all measures on a separate sample of $m' = 100$ new students. We repeat all experiments 10 times for each of the hyperparameter settings in Table 1.

First, we inspect the effect of hyperparameters for $m = 100$ students and $n = 20$ items. Fig. 2 shows, from left to right, how AUC, r_b , r_θ , and r_Q change for higher regularization in conditions A (top) and B (bottom). For AUC, we observe

Table 1: Hyperparameter settings considered in the experiments.

setting	λ_{VAE}	λ_1	λ_2
1	10^{-5}	10^{-3}	10^{-3}
2	10^{-4}	0.05	10^{-3}
3	10^{-3}	1	10^{-3}
4	0.01	0.05	0.05
5	0.1	1	0.05
6	1	1	1

a slight degradation of all methods for higher regularization, with a notable decline for VIBO at the last setting. r_b generally rises for higher regularization, with the exception of SparFAE1, which stays relatively stable around 0.5. r_θ appears stable across regularization and improves only for SPARFA. r_Q improves for all methods with higher regularization in condition A (top), and remains roughly stable in condition B (bottom). For the remaining synthetic experiments, we report the results using hyperparameter setting 6 for SparFAE2 and SparFAE1, and hyperparameter setting 5 for SPARFA and VIBO. These settings maximize r_b , r_θ , and r_Q while retaining high AUC.

Fig. 3 displays the performance measures for varying numbers of students. We observe that AUC, r_θ , and r_Q tend to slightly increase for more students across methods and conditions, with only slight deviances for small numbers of students. The most striking impact is on r_b , which increases for SparFAE1 and VIBO, but decreases for SPARFA and SparFAE2.

Fig. 4 displays the performance measures for varying numbers of items. Across methods, AUC decreases, whereas r_b and r_θ increase and r_Q remains roughly stable for higher number of items. The decrease in AUC is likely explained by the fact that the models need to compress the information of more items into the same number of skills, which is bound to decrease performance. Conversely, it becomes easier to tease apart the difficulty of each single item for a higher number of items per skill (hence the improvement in r_b). Further, the more items we have in a test, the more accurate we can estimate the underlying ability, which is reflected in better r_θ values.

Finally, Fig. 5 summarizes the effect of hyperparameter setting, number of students, and number of items on training time in logarithmic plots. We observe that stronger regularization reduces the training time for both SparFAE variants, whereas it stays roughly constant for VIBO and SPARFA. This is likely because training time for SPARFA and VIBO is driven by the repeated optimization steps over students, whereas the training time for SparFAE is dominated by a single optimization process. Hence, SparFAE profits more from the simpler loss surface offered by higher regularization. As one would expect, all methods scale roughly linearly with the number of students, SPARFA with roughly 18 ms per student, VIBO with roughly 6 ms per student, and both SparFAE variants with roughly 1.5 ms per student (refer to the gray dashed reference lines). For the num-

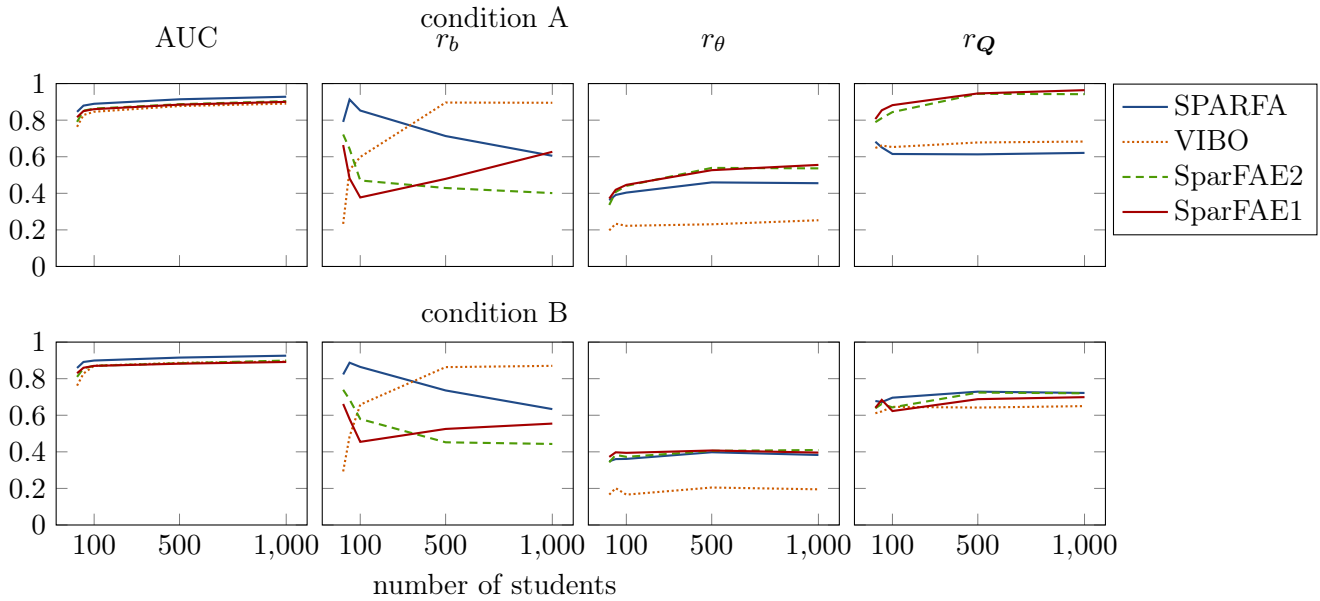

Figure 3: The effect of increasing the number of students on various performance measures (from left to right) on the synthetic data, either with one skill per item (A, top), or multiple skills per item (B, bottom).

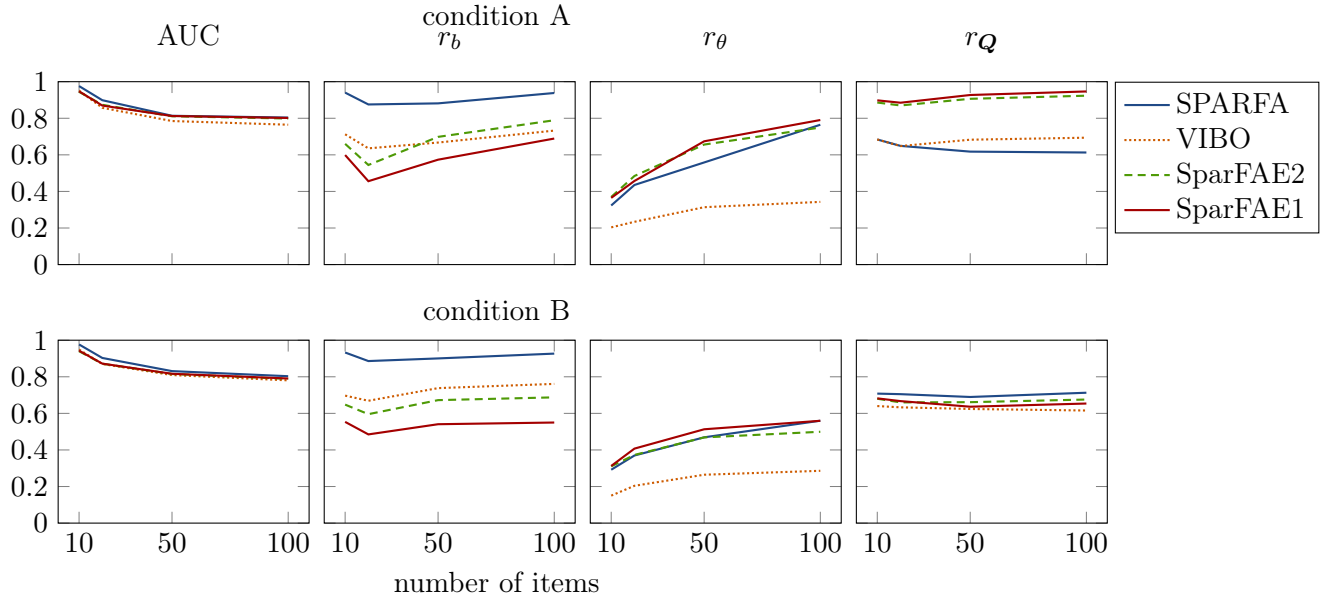

Figure 4: The effect of increasing the number of items on various performance measures (from left to right) on the synthetic data, either with one skill per item (A, top), or multiple skills per item (B, bottom).

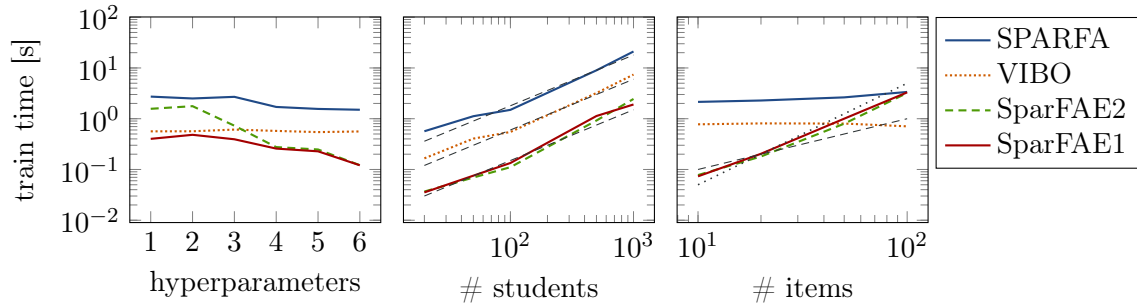

Figure 5: The effect of hyperparameter setting (left), number of students (center), and number of items (right) on training time for condition A. Gray dashed lines are linear references, the gray dotted line is a quadratic reference.

ber of items, the runtime for SPARFA and VIBO remains roughly constant, whereas it increases almost quadratically for both SparFAE variants. This is because the optimization for SPARFA and VIBO is dominated by iterations over students. By contrast, for SparFAE, every single gradient computation already depends linearly on n , and more items may also increase the number of required gradient computations until convergence, thus yielding the super-linear behavior.

4.2 NeurIPS 2020 education data

Next, we consider the NeurIPS 2020 education challenge data by Wang et al. [15]. The data set consists of multiple choice questions to assess mathematics knowledge. Items are grouped into different quizzes. We restricted the data set to the 948 items from task 3 of the challenge and quizzes with at least 50 students¹, which left 65 quizzes. On average, these quizzes contained 14.02 items and had 1675.06 students responding. To estimate the number of skills K , the first author analyzed all 948 items and assigned them to skills. This yielded 14 distinct skills, the most common ones being fractions (190 items), basic algebra (140 items), and algebra with variables (127 items). On average, quizzes involved 3.21 skills. For each quiz, we set K to the first-author estimate, but we upper-bounded K to be at most half the number of items in the quiz.

Based on the pre-defined \mathbf{Q} -matrix by the first author, we included two more baselines: A VIBO model, where we fixed the decoder matrix to the pre-defined \mathbf{Q} -matrix, and a SparFAE1 model, where we fixed the \mathbf{Q} -matrix and only trained the difficulty parameter for each item using logistic regression. We denote these methods as VIBO_f and SparFAE_f, respectively.

To perform hyperparameter optimization, we randomly set aside 10 quizzes and evaluated the AUC of all methods for all hyperparameter settings in Table 1 in a 10-fold cross-validation over students, that is, in each fold we used 90% of students as training data and 10% as test data. The hyperparameter settings which maximized AUC were 2 for SPARFA and SparFAE2, 3 for VIBO, and 4 for SparFAE1.

Next, we performed a 10-fold crossvalidation over students for the remaining 55 quizzes. Note that we can not evaluate r_b , r_θ , or $r_{\mathbf{Q}}$, because we have no access to a ground truth for b , θ , and \mathbf{Q} . However, we can evaluate the sparsity of \mathbf{Q} , that is, the fraction of zero entries. Sparsity is a rough proxy for the plausibility of a learned \mathbf{Q} -matrix because high sparsity indicates that \mathbf{Q} assigns items to distinct skills.

Table 2 reports the average performance measures across quizzes. Regarding AUC, Wilcoxon signed-rank tests revealed that SPARFA had the highest AUC, followed by SparFAE2, VIBO, SparFAE1, SparFAE_f, and finally VIBO_f ($p < 10^{-3}$ for all tests after Bonferroni correction). That being said, the AUC of all methods except SPARFA is very close (at most 2% difference between means). In terms of sparsity, SparFAE1 clearly outperforms SPARFA, VIBO, and SparFAE2 ($p < 10^{-3}$). Note that VIBO does not achieve any sparsity, as it does not encourage sparsity during train-

¹We also excluded one outlier quiz with more than 100 items and a lot of missing data.

ing. The sparsity of the pre-defined \mathbf{Q} -matrix was very high (94%) as it assigned each item to only one skill.

With respect to training time, SparFAE1 is considerably faster than SPARFA (ca. 15x), VIBO (ca. 4x), and SparFAE2 (ca. 8x). In terms of prediction time, SparFAE1, SparFAE2, and VIBO perform similarly as their prediction scheme is almost the same (although SparFAE1 is still significantly faster, $p < 10^{-3}$). Only SPARFA is much slower (ca. 300x) because it needs to fit new ability parameters to new students for each prediction.

Finally, we analyzed the relation of AUC to the numbers of students, items, and skills, as well as the amount of missing data in quizzes. Fig. 6 displays scatter plots, where each dot represents one quiz and lines show linear fits. Interestingly, the behavior is very similar for all methods. The linear correlation is $r \approx 0.3$ with number of students ($r = 0.4$ for VIBO; $p < 0.05$), $r \approx -0.4$ with number of items ($p < 0.01$), $r \approx 0.6$ with number of skills ($p < 10^{-3}$), and around zero with the amount of missing data (insignificant). This is in line with our results on synthetic data. The strong correlation with the number of skills is explained by the fact the methods have more parameters to fit the data when we increase K .

4.3 Math assessment data

In a final experiment, we evaluated the ability of SparFAE1 to identify a fitting \mathbf{Q} -matrix in comparison to an expert-designed \mathbf{Q} -matrix on real data. To that end, we used data from $m = 30$ students (ages 16-19) on a math assessment test for vocational education in chemistry². The test consisted of $n = 21$ questions, covering $K = 5$ topics, namely basic algebra, fractions, equation solving for a single variable, text tasks with two variables, and (linear) functions. Fig. 7 (top) shows the assignment of items (x-axis) to these five topics (y-axis) as provided by the test designers.

We applied a slightly adapted variant of SparFAE1 with the regularization $\sum_{k=1}^K \left(\sum_{j=1}^n q_{j,k} - 1 \right)^2$, that is, we punished deviations of the column sums from 1, thereby encouraging orthogonality in \mathbf{Q} . As regularization strength, we set 1. We performed 30 repeats of SparFAE1 and then selected the \mathbf{Q} -matrix which maximized accuracy in a leave-one-out crossvalidation over students (the resulting best accuracy was 89%).

The learned \mathbf{Q} -matrix is shown in Fig. 7 (bottom). We observe that the matrix assigns every item to only one skill, in line with the expert prediction. We further observe that—in line with the experts—the learned \mathbf{Q} tends to group items for the basic topics (basic algebra and fractions) together and tends to avoid grouping items for basic topics with items for advanced topics. However, there are also notable differences to the expert \mathbf{Q} -matrix. In particular, SparFAE1 merges basic algebra and fractions into one skill (except for item 8, which is in skill 4), and includes items 13 and 14. Overall, skill 1 accumulates relatively easy tasks without text- and function components. All other skills contains items which required text comprehension and/or un-

Figure 7: The expert-designed Q -matrix (top), and the learned Q -matrix via SparFAE1 (bottom) for the math assessment data.

Figure 8: The item-to-item correlations for the math assessment data.

understanding of functions, but the correspondence to expert-defined skills is less obvious.

To gain deeper insight into the learned Q -matrix, we inspected the item-to-item correlations $c_{j,j'} = \frac{\sum_{i=1}^m x_{i,j} \cdot x_{i,j'}}{\sqrt{\left(\sum_{i=1}^m x_{i,j}\right) \cdot \left(\sum_{i=1}^m x_{i,j'}\right)}}$, which are shown in Fig. 8. We observe that items 1-7, 9, and 13-14 exhibit relatively high pairwise correlation, explaining why SparFAE1 grouped them together in skill 1.

Skill 2 groups items 16 and 18, which are both text problems covering variable solution problems, but it also includes item 21, which is a question on functions. Inspecting the correlation matrix, we observe that item 21 generally exhibits low correlation, except for items 16 and 18, which explains the grouping.

Skill 3 groups items without obvious mathematical connection. Item 10 is a fraction problem, item 12 is a variable algebra problem, and item 20 is a function problem. Further, these items exhibit only moderate pairwise correlation. However, the only items with higher correlations are already contained in skill 1 and are, thus, unavailable for skill 3, thus indirectly explaining the grouping.

Skill 4 contains a variable algebra item (8), an equation solving problem (17), and a function problem (19). General variable algebra capacity (8) plausibly enhances equation solving (17) but the function question (19) seems less connected. The correlation matrix reveals that item 19 has generally low correlations, except for items 3, 7, 14, and 17, explaining its grouping with item 17.

Skill 5 contains two equation problems, one symbolic (11) and one text-based (15). Further, item 15 has very low

correlations with any other item, except for items 9 and 11, and 20, which explains the grouping with item 11.

Overall, we observe that the learned \mathbf{Q} -matrix tended to group more basic items together and more advanced items together, in line with expert opinion. Sometimes, the learned \mathbf{Q} matrix groups items which do not have an obvious connection, content-wise. In such cases, we could explain the grouping by inspecting the item-to-item correlation matrix.

5. DISCUSSION AND CONCLUSION

We proposed a novel method for factor analysis which extends Sparse Factor Analysis (SPARFA) [7] to an autoencoder approach. Hence, we call our proposed method Sparse Factor Autoencoder (SparFAE). More specifically, our approach encodes student responses to abilities via a linear map \mathbf{A} and decodes it again to predicted responses via a multi-dimensional item response theory model with a linear skill-to-item map \mathbf{Q} . Like SPARFA, our approach encourages sparsity in the \mathbf{Q} -matrix via non-negativity constraints and L1 regularization. In contrast to SPARFA, we do not need to fit new ability parameters for new students. Instead, we can simply apply \mathbf{A} , which automatically yields the desired ability parameters. We investigated two versions of SparFAE: One with separate matrices \mathbf{A} and \mathbf{Q} for encoding and decoding (SparFAE2), and one where we set $\mathbf{A} = \mathbf{Q}^T$, that is, we use the \mathbf{Q} -matrix for both encoding and decoding (SparFAE1).

In experiments on synthetic as well as real data, we showed that SparFAE1 is considerably faster than SPARFA, variational autoencoding [16], and SparFAE2. SparFAE1 also achieves higher sparsity, and higher correlation with ground truth \mathbf{Q} -matrices and student abilities. This comes at the price of slightly lower AUC and less accuracy in recovering ground truth difficulties. We also observed that AUC differences between autoencoder variants were quite small, whereas SPARFA achieved noticeably higher AUC, indicating that student-specific ability parameters allow for a better fit of the data than autoencoding. We also compared the learned \mathbf{Q} -matrix via SparFAE1 with an expert \mathbf{Q} matrix on a math assessment test, revealing some overlap but also meaningful differences which could be explained by item-to-item correlations.

Overall, our results indicate that SparFAE1 is a promising method for fast factor analysis, especially when each item in a test only refers to a single skill. As such, we believe that it can be an interesting tool for test designers who wish to analyze the factor structure of their test on a sample of students. While the learned \mathbf{Q} -matrix should still be interpreted with care, it can uncover latent item relationships (as we saw on the math assessment data). Our results also motivate the use of \mathbf{Q} -matrices for both decoding and encoding, which can serve as a starting point for future research.

Limitations of SparFAE1 lie in the slightly lower AUC compared to other autoencoders, the ability to recover ground truth difficulty parameters, and the superlinear scaling with respect to the number of items. Future work could address each of these shortcomings. Further, our experimental evaluation is limited to multiple choice math assessment questions. Future work should include further data sets from

other educational domains to ensure that SparFAE1 generalizes. Finally, just as any autoencoders, SparFAE1 makes the assumption that abilities do not change during a test. Future work may consider more dynamic settings, e.g. by incorporating concepts from performance factor analysis or knowledge tracing models.

ABSTRACT

As online learning platforms become more ubiquitous throughout various curricula, there is a growing need to evaluate the effectiveness of these platforms and the different methods used to structure online education and tutoring. Towards this endeavor, some platforms have performed randomized controlled experiments to compare different user experiences, curriculum structures, and tutoring strategies in order to ensure the effectiveness of their platform and personalize the education of the students using it. These experiments are typically analyzed on an individual basis in order to reveal insights on a specific aspect of students' online educational experience. In this work, the data from 50,752 instances of 30,408 students participating in 50 different experiments conducted at scale within the online learning platform ASSISTments were aggregated and analyzed for consistent trends across experiments. By combining common experimental conditions and normalizing the dependent measures between experiments, this work has identified multiple statistically significant insights on the impact of various skill mastery requirements, strategies for personalization, and methods for tutoring in an online setting. This work can help direct further experimentation and inform the design and improvement of new and existing online learning platforms. The anonymized data compiled for this work are hosted by the Open Science Foundation and can be found at <https://osf.io/59shv/>.

1. INTRODUCTION

The use of online learning platforms has increased rapidly in the past decade [37]. As online learning platforms grow to become a permanent fixture of educational systems, they have the potential to democratize education by providing high quality free or low-cost resources to compliment traditional classroom practices [1]. While in some cases online tutoring has been shown to be at least as effective as traditional in-person educational practices [33, 11, 16], there is still a need to validate the effectiveness of the various methods by which educational content is delivered to students. Placing an emphasis on objectively measuring the effectiveness of these emerging methods through randomized controlled experimentation is essential for ensuring that the quality of educational resources continues to increase.

This study works towards that endeavor by aggregating the results from 50,752 instances of 30,408 students participating in 50 different randomized controlled experiments conducted by various groups of researchers since February, 2019 within the online learning platform ASSISTments. In these experiments, K-12 students were randomized between different conditions as they completed online mathematics assignments. These conditions changed factors such as students' assignment completion requirements, the format of the tutoring students' received when struggling with the assigned problems, and the types of interactions students could have within their assignment. While these types of studies have been conducted in ASSISTments before [34, 40], this work goes beyond reporting the results of each individual study, and instead aggregates the results of these studies together, ultimately investigating 19 different research questions across 50 randomized controlled experiments. To achieve this, the following steps were taken.

1. Identify the independent measures of every condition in each experiment.
2. Normalize the dependent measures of all the experiments so they can be compared to one another.
3. Combine the data from different experiments when the research questions of the experiments match.

4. Determine the effects of the various experimental instructional interventions using these combined datasets.

The results of this aggregate analysis revealed actionable trends that can contribute to a broader understanding of the effectiveness of different educational interventions, help direct further experimentation, and inform the design and improvement of new and existing online learning platforms.

2. BACKGROUND

2.1 Educational Experiments

Experiments revolving around educational practices have been conducted since the late 19th century [49]. These early experiments, conducted by William James, Edward Thorndike, and Alfred Binet along with others, focused on determining individual differences between students, why they occur, and what methods teachers can employ to improve educational outcomes for them [49]. By the early 20th century, with the increased accessibility of formal education, educational experiments were more focused on improving teaching methods [49] and connecting cognitive psychology to classroom practices [24]. These studies investigated the differences in learning between students of varying socioeconomic levels [7], the effect of increasing student autonomy in the classroom [29], and the value of assessment in learning [21].

In the years following these studies, theories on educational development, classroom practice and structure, and how to approach individual differences between students were developed. In particular, research around effective feedback has proven to increase performance [23], interest in learning [9], as well as increasing students' abilities to self-regulate their learning [35]. These studies varied in the types of feedback students receive [9], level of specificity and frequency [48], level of praise present in the feedback [8], and what types of students benefit the most from certain types of feedback [14]. Data for these studies were collected from classroom observations of verbal feedback, collections of written feedback, and results on written assessments.

2.2 Experimentation within Online Learning Platforms

Computer-assisted instruction in education has been studied since the 1960s [47], results of these early studies show that providing specific, targeted feedback to student responses improves retention of information [19, 43]. In more recent years, educational data mining research has grown significantly, with large scale implementation of online A/B testing in web applications allowing thousands of users to be randomized into conditions simultaneously [3, 5]. With the rapid adoption of computers in the classroom in the past two decades, educational researchers now have access to an abundance of data on students. Online learning platforms track students' performance, demographics, interactions within the platform, statistics on content usage, feedback, and more [38]. Additionally, during the 2020-2021 school year many schools that had not previously used online learning platforms migrated to online learning platforms as a result of the COVID-19 pandemic [28]. This increase

in the size and scope of available data has made it possible to gain insights into educational practices that were not previously possible with traditional methods.

Recent studies have focused on predicting student outcomes, improving domain specific content, examining the effects of different kinds of pedagogical support, and advancing knowledge about how people learn [5]. Similar to early studies on computer-assisted learning, learning analytics research aims to determine what types of feedback and presentations work well for what types of students, in other words, discovering the potential for personalization in online learning platforms [31, 5]. Prior studies on personalization show the benefit of explanatory feedback over corrective feedback for novice students [31], differences in effect of feedback between male and female students [32], and the effects of immediate and delayed feedback for students with different prior knowledge levels [45, 10]. Additionally, by taking advantage of recent advances in data collection, research has been able to focus on determining methods for personalizing based on students characteristics, such as district locale and student interaction data [2] and what types of crowdsourced content is effective for students [39]. This work provides another data-intensive analysis on the effectiveness of different aspects of online learning platforms, but unlike the aforementioned analyses, this work compiled data from dozens of studies performed within an online learning platform instead of focusing on a single study. This revealed trends across experiments that provided deeper insight into the effectiveness of various instructional interventions and online tutor designs.

2.3 ASSISTments and E-TRIALS

The data in this work comes from ASSISTments, an online learning platform that focuses on providing teachers with mathematics content and resources to effectively manage their students. Within ASSISTments, teachers have the option to assign problem sets and skill builders to their students. Problem sets are a series of mathematics problems that must all be completed, in order, to finish the assignment. These problem sets come from various open educational resources for mathematics such as Engage New York, Illustrative Mathematics, and The Utah Middle School Math Project. Skill builders are assignments that focus on a specific mathematics skill. When students complete skill builders they are given a series of problems on the same mathematics skill until they get a specific number of problems correct in a row. Usually students must answer three problems correct in a row to finish the assignment, but this number is configurable by the teacher.

Regardless of whether the student is assigned a problem set or skill builder, they complete their assignment in the ASSISTments tutor [20]. In the tutor, students receive immediate feedback when they submit a response to a problem, which informs them if they are correct [27]. In addition to this immediate feedback, students are able to request tutoring, which is available to them at any point during their completion of a problem regardless of whether or not they have already attempted the problem. Tutoring comes in the form of hints, which are a series of messages the student can request, one at a time, that explain how to solve parts of the problem; explanations, which are full worked solutions to the problem; examples, which are full worked solutions

of a similar problem; common wrong answer feedback messages, which explain how to correct a specific error made by the student; and scaffolding, which breaks the problem down into a series of simpler problems that guide the student through how to solve the original problem [27]. These different types of tutoring strategies can come in the form of videos, images, or text. An example of a student receiving a text-based explanation within the ASSISTments tutor is shown in Figure 1. Once students have finished their assignment, teachers are provided with reports that aggregate information such as how each student progressed through the assignment and what the class’ most common mistakes were.

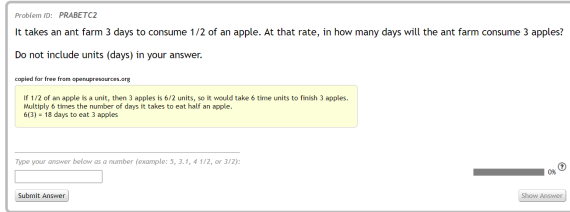

Figure 1: A student’s view of the ASSISTments tutor after requesting tutoring and receiving a text-based explanation.

The variety of assignments and tutoring strategies that can be delivered to students through ASSISTments provides opportunities to explore various research questions in learning science, educational psychology, and human-computer interaction. A research test-bed, E-TRIALS (an EdTech Research Infrastructure to Advance Learning Science), was built to deploy randomized controlled experiments in classwork and homework settings at scale within ASSISTments [25]. Since 2005, researchers have been able to create and modify problem sets, skill builders, and tutoring strategies. The modified content contains the original content within it, but adds experimental conditions. For example, a researcher could modify a skill builder for calculating the area of a triangle to randomly provide students with text-based or video-based hints. Teachers assign the modified content as if it were the original, and when teachers assign these modified assignments, students will be randomized (on an individual basis, not at the class level) to one of multiple conditions. This allows researchers to evaluate the impact of different pedagogical decisions on students’ learning [41]. The experiments run in ASSISTments cover a wide scope of research questions that range from whether offering students a choice in the difficulty of their instruction improves learning, to whether providing students with worked examples of similar problems is more effective than direct advice on the problem they are struggling with, to whether changing the number of problems students are required to complete affects their learning [44]. The following analysis of E-TRIALS experiments provides insight into the current state of experimentation within online learning platforms and can help inform the design of future experiments.

3. EXPERIMENT DATASET

The dataset used in this work comes from 50,752 instances of 30,408 unique students who participated in 50 E-TRIALS experiments since February, 2019. In addition to recording the purpose of the experiment, the experimental con-

dition each student was placed in, and the resulting dependent measure, the dataset also includes information on students’ performance within ASSISTments prior to participating in the experiment, the prior performance of the students’ classes, the experience of their teachers, and an indicator of their socioeconomic status. Socioeconomic status is indicated by a student’s school district’s Opportunity Zone status, which is a particular tax classification in the United States of America that indicates whether a region has opportunities for economic growth. The regions in opportunity zones are typically low-income regions with fewer educational resources [15]. The Opportunity Zone status for each student was determined using the domain name of their teacher’s school-provided email address. No demographic information was requested from students using ASSISTments to preserve their anonymity and prevent any bias associated with answering questions on how they identify themselves. The full set of features collected for each participant is shown in Table 1. In addition to containing features for each experiment participant, the dataset contains information on the independent and dependent measures used in the various experiments, which had to be aggregated in order to determine the common trends among the 50 experiments. The details of these independent and dependant measures and how they were aggregated are discussed in Sections 4.1 and 4.2.

4. METHODOLOGY

Due to the diversity in research questions, independent and dependent measures, and structure of the experiments, the first step to evaluate their overall trends was to identify similar conditions within multiple experiments. This process involved documenting each condition of each experiment and identifying when different experiments had an identical pair of conditions or the same research question. The second step was to normalize the various dependent measures such that they all represented similar metrics and used the same scale.

4.1 Pooling Experiment Data

To pool experimental data together, similar experiments had to be identified. To do this, every condition from every experiment was documented such that data from multiple experiments that each had an identical pair of conditions or research question could be aggregated. For example, if the following three experiments were run in ASSISTments, then Experiment 1 would have six documented conditions (one condition for each of the hint types for both choice and no choice), Experiment 2 would have two conditions (one for text-based hints and one for video-based hints), and Experiment 3 would have four conditions (one condition for each text color for both choice and no choice).

- **Experiment 1:** Randomize between A: giving students a choice of no hints, text-based hints, or video-based hints, or B: randomly selecting which type of hint to give them.
- **Experiment 2:** Randomize between A: text-based hints, or B: video-based hints.
- **Experiment 3:** Randomize between A: giving students a choice of black or red text color, or B: randomly selecting the text color.

Table 1: The Features Calculated for each Instance of a Student Participating in an Experiment

Feature Name	Description
Experiment Condition	An indication of which condition students are in.
Student Prior Started Skill Builder Count	Number of skill builders previously started by students.
Student Prior Skill Builder Percent Completed	Percent of skill builders completed by students.
Student Prior Started Problem Set Count	Number of problem sets previously started by students.
Student Prior Problem Set Percent Completed	Percent of problem sets completed by students.
Student Prior Completed Problem Count	Total number of problems completed by students.
Student Prior Median First Response Time	Students' median time to submit an answer to a problem.
Student Prior Median Time On Task	Students' median time to complete a problem.
Student Prior Average Attempt Count	Student's average attempts required to complete a problem.
Student Prior Average Correctness	The fraction of problems students answered correctly.
Class Age In Days	The number of days classes existed in ASSISTments.
Class Student Count	The number of students in the class.
Class Prior Started Skill Builder Count	Number of skill builders previously started by classes.
Class Prior Skill Builder Percent Completed	Percent of skill builders started by classes that were completed.
Class Prior Started Problem Set Count	Number of problem sets previously started by classes.
Class Prior Problem Set Percent Completed	Percent of problem sets started by classes that were completed.
Class Prior Completed Problem Count	Total number of problems completed by classes.
Class Prior Median First Response Time	Class' median time to to submit an answer to a problem.
Class Prior Median Time On Task	Class' median time to complete a problem.
Class Prior Average Attempt Count	Class' average attempts required to complete a problem.
Class Prior Average Correctness	The fraction of problems classes answered correctly.
Teacher Account Age In Days	The number of days teachers have had an ASSISTments account.
Experiment Id	The experiment students participated in.
Opportunity Zone	The school district's Opportunity Zone status [15].

In addition to documenting the conditions for the three experiments, Experiments 1 and 3 would be recorded as having the higher-level research question “Choice vs. No Choice” and Experiment 2 would be recorded as having no higher-level research question. To combine the results of these three experiments, students randomized to the text-based hint option of Condition B of Experiment 1 would be combined with students randomized to Condition A of Experiment 2 and students randomized to the video-based hint option of Condition B of Experiment 1 would be combined with students randomized to Condition B of Experiment 2. These groups would be used to evaluate the overall effect of giving video-based hints compared to text-based hints. Additionally, students randomized to Condition A of Experiments 1 and 3 would be grouped, and students randomized to Condition B of Experiments 1 and 3 would be grouped. These two groups would be used to evaluate the overall effect of offering students a choice.

When performing this aggregation on the real experiments, many experiments were too unique to have similar experimental conditions as other experiments. Additionally, some experiments were created incorrectly in ASSISTments or had broken links to videos, leading students to never be randomized to a condition. Even though 103 experiments have been deployed in ASSISTments since 2019, only 50 had at least one condition similar to a condition in another experiment and were complete enough to be included in the analyses. After parsing through the data and removing poorly structured and broken experiments, the most common research questions were selected for further analysis. Table 2 shows the selected research questions and statistics on the data aggregated to evaluate the research questions. Students were typically divided evenly between the different

conditions, but for the research question “Emotion vs. No Emotion”, there were six conditions that included positive emotional content and two conditions that did not include emotional content, which is why about three fourths of students are placed in the treatment condition.

The six research questions containing the phrase “Correct for Mastery” all investigated differences in the requirements to complete a skill builder assignment. In a skill builder, students must correctly answer a specific number of problems in a row to complete the assignment. The different values in these research questions represent the different number of problems students had to get correct in a row before finishing the assignment or completing a posttest. The six research questions that compare something to “Answer Only” investigated how six different tutoring strategies improved student learning compared to just giving struggling students the answer. Table 3 describes each tutoring strategy investigated by these research questions. The other seven research questions are not related to other research questions, but examined different aspects of the structure of assignments and tutoring in online learning platforms.

- **Video vs. Text** investigated the difference between providing two different types of tutoring which were almost identical, except in one condition the tutoring content was text-based, and in the other condition the same tutoring was provided in a video format.
- **Common Wrong Answer Feedback vs. No Feedback** investigated the effect of providing students with specific feedback messages when they submitted a common wrong answer to any of the the problems in their assignment.

Table 2: Research Questions Selected for Analysis

Research Question	Experiment #	Student #	% in Treatment
2 Correct for Mastery vs. 3 Correct for Mastery	4	1192	0.487
2 Correct for Mastery vs. 4 Correct for Mastery	4	1165	0.475
2 Correct for Mastery vs. 5 Correct for Mastery	3	846	0.483
3 Correct for Mastery vs. 4 Correct for Mastery	5	2030	0.492
3 Correct for Mastery vs. 5 Correct for Mastery	4	1683	0.494
4 Correct for Mastery vs. 5 Correct for Mastery	4	1681	0.495
Example vs. Answer Only	3	765	0.467
Explanation vs. Answer Only	1	85	0.471
Hint vs. Answer Only	5	1192	0.513
Scaffolding vs. Answer Only	7	2010	0.546
Video Example vs. Answer Only	1	366	0.484
Video Scaffolding vs. Answer Only	3	1033	0.509
Video vs. Text	5	2492	0.497
Common Wrong Answer Feedback vs. No Feedback	2	7046	0.497
Adaptive vs. Non-Adaptive	9	7754	0.498
Fill-In vs. Multiple Choice	2	4057	0.493
Choice vs. No Choice	9	12789	0.499
Emotion vs. No Emotion	2	1211	0.766
Motivational vs. Non-Motivational	14	12243	0.581

- **Adaptive vs. Non-Adaptive** investigated the impact of changing the difficulty of problems based on how well students performed at the beginning of their assignment. Students that got problems correct at the beginning were given more challenging problems than the students that got the beginning problems incorrect.
- **Fill-In vs. Multiple Choice** investigated the impact of requiring students to write the correct answer in themselves compared to selecting from multiple preset options when answering questions.
- **Choice vs. No Choice** investigated the impact of allowing students to choose which version of various configurations for their assignments they would complete.
- **Emotion vs. No Emotion** investigated the impact of including positive emotional phrases and images in the body of the problems in the assignment. For example, an emotional problem would say “Susan excitedly purchased three apples.” instead of “Susan purchased three apples.”.
- **Motivational vs. Non-Motivational** investigated the impact of interjecting motivational messages and videos into the assignment.

4.2 Normalizing Student Learning

In addition to identifying similar conditions and research questions, the different experiments dependent measures had to be normalized such that the results from one experiment could be compared to another experiment. Normally, it would be very difficult to combine dependent measures from different experiments, but conveniently, all of the experiment in ASSISTments are attempting to increase student learning, and therefore the various dependent measures are just different ways of measuring student learning and can thus be normalized and combined. In the various E-TRIALS experiments, there are five different dependent measures used, described in Table 4.

While all of these measures represent student learning, they do not all increase as student learning increases, nor do they all have the same range, nor do they all take into account when a student fails to complete the experimental assignment, which presumably means they learned the least. To rectify these concerns, Table 5 shows the function $f(x)$ applied to each of the dependent measures. After $f(x)$ is applied to the dependent measures, the values are z -scored within each experiment using the pooled standard deviation grouped by experimental condition. This ensured that all of the different measures of learning increased as student learning increased, had the same scale, and accounted for incomplete assignments. These transformations converted all the dependent measures into a measurement of how many standard deviations above or below average each student performed compared to other students that participated in the same experiment. $f(x)$ for problems to mastery is particularly complicated because unlike the other dependent measures, problems to mastery goes down the more a student learns, and problems to mastery is bounded in the range $[3, \infty)$. Therefore, to ensure that $f(x)$ for problems to mastery increases the more a student learns, problems to mastery was transformed by inverting it, then multiplying it by 3. However, this transformation alters problems to mastery non-linearly, so to correct some of the non-linearity, the square root is taken, which makes $f(x)$ appear linear in the range $[3, 10]$ where most of the results lie.

4.3 Evaluating Differences in Student Learning

To measure the effects of the various experimental treatment conditions, Cohen’s d [12] was used to calculate the effect size between the control and treatment conditions for each research question. To test for a difference between treatment and control, we ran ordinary least squares models and examined the associated p -values and 95% confidence intervals of the mean differences between conditions, and used Cohen’s d to capture the magnitude of any effect. This model was used to predict normalized student learning

Table 3: Descriptions of Different Tutoring Strategies

Tutoring Strategy	Description
Example	An explained solution to similar problem.
Explanation	An explained solution to the current problem.
Hint	Step-by-step advice on how to solve the current problem.
Scaffolding	A series of problems that break the current problem into smaller steps with explanations.
Video Example	An example recorded in a video instead of text.
Video Scaffolding	A scaffolding with explanations recorded in videos instead of text.

Table 4: Descriptions and Frequencies of the Dependent Measures used to Evaluate Student Learning

Dependent Measure	Frequency of Use	Description
Problems to Mastery	44%	# of problems the student completed to get n correct in a row.
Posttest Score	44%	% correct on posttest.
Learning Gains	7%	% correct on posttest - % correct on pretest.
Assignment Correctness	3%	# of problems correct / # of problems in condition.
Assignment Completion	1%	Binary indicator for if the student completed the assignment.

Table 5: Functions used to Scale the Dependent Measures Before z -Scoring

Dependent Measure	$f(x)$
Problems to Mastery	0 if incomplete else $\sqrt{\frac{3}{x}}$
Posttest Score	0 if incomplete else x
Learning Gains	0 if incomplete else $x + 1$
Assignment Correctness	x
Assignment Completion	x

based on the experiment condition the student was placed in, the experiment the student participated in, and features of the student, their class, their teacher, and their school district. Including fixed effects for which experiment the student participated in allowed the model to associate differences in normalized student learning between experiments with those coefficients, and not the experiment condition coefficient, helping to reduce noise from covariates. The inputs related to students, classes, teachers, and school districts also helped to remove noise from the experiment condition coefficient. For example, students with high prior knowledge performed better on the experimental assignments than students with low knowledge, and by including students’ prior knowledge in the model, the variability in students’ success based on their prior knowledge will be associated with the prior knowledge coefficient, and have a lesser effect on the treatment coefficient. Table 1 contains a full list of the features used to model the effects of the various experimental conditions. The “Experiment Condition” feature was used to determine the 95% confidence interval and p -value of the impact of the various experimental instructional interventions. When some features were not available, such as when students that had not previously used ASSISTments participated in the experiments, the missing values were filled using the average value across the data used to fit the model. This limited the extent to which the missing values biased the model’s coefficients.

5. RESULTS

5.1 Different Completion Requirements

Investigating the impact of different mastery requirements for skill builders found that requiring fewer problems led to higher student learning than requiring more problems, but that this effect is mostly due to students not completing the assignment when they were required to answer more problems correct in a row to proceed. Figure 2 shows the effect size and, in parentheses, the p -value of the effect of requiring students get different numbers of problems correct in a row. For example, the cell at row two, column three contains the effect size and p -value of requiring students get two problems correct in a row instead of three problems correct in a row. Figure 2 only shows significant positive effects when requiring students to complete two problems in a row correctly instead of three, four, or five.

The Effect of Changing Problem Completion Requirements on Normalized Student Learning (Column vs. Row)

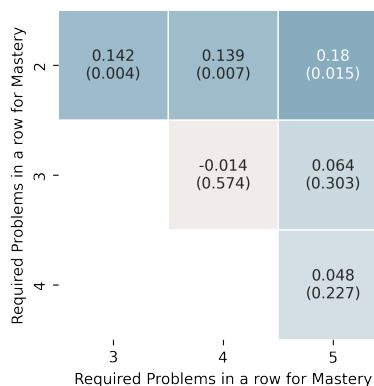

Figure 2: The effect of changing problem completion requirements on normalized student learning. Each cell contains the effect size, determined using Cohen’s d , and in parentheses, the p -value.

To investigate further, the effect of changing problem completion requirements on assignment completion and the effect of changing problem completion requirements on student learning for only students that completed the assignment were calculated. Figure 3 shows the results of these

analyses. Based on these results, there is no statistically significant effects on student learning for students that completed their assignment, regardless of how many problems they had to complete correctly in a row before finishing the assignment. The vast majority of the effects seen in Figure 2 come from more students failing to complete their assignment when having to complete more problems correct in a row. Essentially, when students have to complete more problems they are less likely to complete their assignment, but if students complete their assignment their learning will be unaffected by how many problems they had to complete.

The Effect of Changing Problem Completion Requirements on Assignment Completion (Column vs. Row)

The Effect of Changing Problem Completion Requirements on Normalized Student Learning for Students that Completed the Assignment (Column vs. Row)

Figure 3: The effect of changing problem completion requirements on assignment completion (top) and normalized student learning for only students that completed the assignment (bottom). Each cell contains the effect size, determined using Cohen’s d , and in parentheses, the p -value.

One would expect that if any of these mastery requirements were a meaningful metric for determining if students had learned the material, then there would be a statistically significant difference in students’ learning between students that had to complete above or below a certain number of problems correct in a row. However, this was not the case. These results imply that a more sophisticated method could be necessary to evaluate whether students have mastered

the mathematics concepts present in their assignments. It may therefore be advisable to integrate Knowledge Tracing [13] or Performance Factors Analysis [36], which are both effective methods for evaluating students’ mastery of individual skills, into ASSISTments and other online learning platforms.

5.2 Different Tutoring Strategies

Investigating the effects of different types of tutoring on student learning found that most tutoring is effective, and that giving students tutoring instead of showing them the answer is more effective for low knowledge students than high knowledge students. Figure 4 shows the confidence interval, effect size, number of students, and p -value for the effect of giving students each type of tutoring instead of just providing the answer. The only tutoring strategy that had no significant impact on student learning was explanations, which had a wide confidence interval and relatively few participants.

Prior studies done in ASSISTments reported that lower knowledge students benefited more from scaffolding while higher knowledge students benefited more from short explanations [42]. Therefore, in addition to evaluating the effect of each of the above tutoring strategies on all students that participated in the experiments, the data from the experiments were divided into below and above average prior knowledge groups based on whether students’ prior average correctness was above or below the average of all students’ prior average correctness. Figure 5 shows the difference in the effectiveness of four of the six tutoring strategies for each of these groups of students. Only four of the six tutoring strategies from Figure 4 are included in these plots because the other two tutoring strategies were used in experiments that did not have any participants that had used ASSISTments previously, and therefore no prior average correctness was available for those students. The below average prior knowledge students consistently had statistically significant positive effects from being provided with tutoring and greater effect sizes for three out of the four tutoring strategies. These results agree with previous studies on the effectiveness of different tutoring strategies on different groups of students [42]. Additionally, Figure 5 shows that examples had the largest difference in their effectiveness between below and above average prior knowledge students and were the only tutoring strategy that had a statistically significant positive effect for below average prior knowledge students, but not for above average prior knowledge students.

Disparities in education, particularly in math, are often due to unequal access to opportunities to learn from highly qualified educators, otherwise known as the “opportunity gap” [17]. Although online learning platforms cannot replace a highly qualified educator, these results indicate that some online tutoring strategies can support in closing this opportunity gap for the most vulnerable students instead of just helping the more knowledgeable students succeed.

5.3 Other Instructional Interventions

Sections 5.1 and 5.2 covered two groups of related research questions, but there were many other research questions that did not fall into a group. Figure 6 shows the confidence intervals, number of participants, p -values, and effect sizes of these research questions. Of the various experiments, the ef-

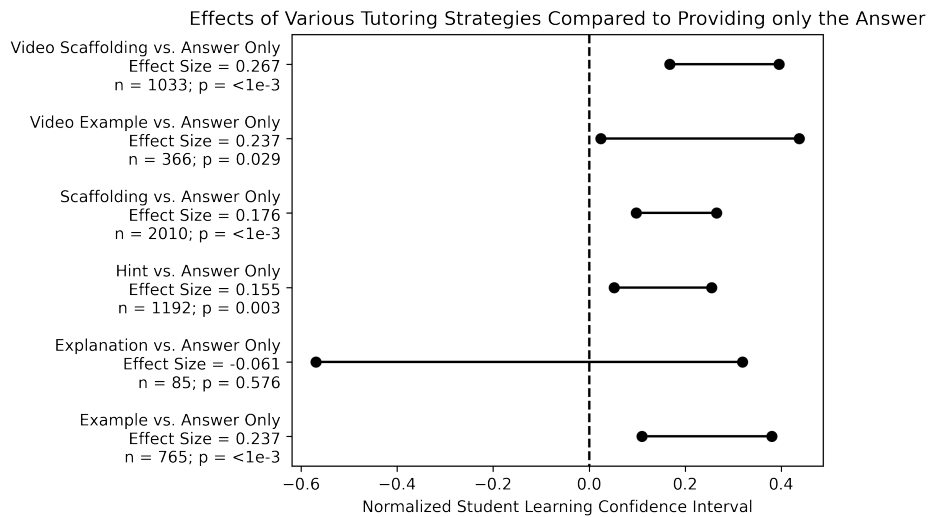

Figure 4: The effects of various tutoring strategies compared to providing only the answer. Effect size was determined using Cohen’s d , the confidence interval and p -value come from the experiment condition model coefficient.

Figure 5: The effects of various tutoring strategies for below average and above average students. Effect size was determined using Cohen’s d , the confidence interval and p -value come from the experiment condition model coefficient.

fect of giving video-based tutoring compared to text-based tutoring had the largest effect size, with students learning more from video-based tutoring than text-based tutoring. This could have been due to videos being more engaging and not requiring students to also be proficient readers. Additionally, giving students mathematics problems with open responses, where they are not given optional answers to choose from, resulted in more learning than when they were given problems with multiple choices. This could have been due to the added difficulty of attempting to answer a problem without knowing what the potential solutions are. Another significant finding was that adapting students’ assignments based on their prior knowledge by altering the material given to them had a statistically significant positive effect, lending support to the idea that learning platforms should personalize students’ learning based on their prior knowledge, which has been found to be true in various studies and meta-analyses [42, 26]. Lastly, it was found that motivational messages have a negative impact on stu-

dents’ learning. This could be a result of students finding the messages distracting. However, students’ perceptions of the messages were not recorded as part of these experiments, and follow-up experiments should be performed to investigate further.

5.3.1 Video vs. Text

Although providing students with video-based tutoring instead of text-based tutoring resulted in an overall positive effect for all types of tutoring, it is possible this was due to a particularly large impact of receiving video instead of text for one type of tutoring strategy. Figure 7 shows the effect of providing video-based tutoring instead of text-based tutoring for the three types of tutoring strategies that were used in experiments where a video-based and text-based version of the same content was provided to students. Video-based scaffolding had the only significant positive effect on learning compared to a text-based control. Hints and examples had no statistically significant difference in their effective-

ness when video-based or text-based. From these results, one can infer that students benefit differently from different types of tutoring being video-based. Scaffolding offers a series of simpler problems to help students understand the problem they are struggling with. It could be that students are more likely to engage with videos that give them necessary context. The scaffolding videos ask students questions that they must solve to move on, without watching the videos, they cannot know what the question is. Students may not be as willing to watch videos that provide relevant, but not entirely necessary information on a problem they must solve.

6. LIMITATIONS

The results in this work help to reinforce a foundation of knowledge on educational experimentation and can be used to influence the next generation of experimentation, but there are two notable limitations to the extent to which these results can be applied in the future. Firstly, the scope of the experiments analyzed in this work is limited to experiments conducted within ASSISTments. It could be that the user

interface of ASSISTments effects how beneficial certain instructional interventions are. For example, the way ASSISTments takes away partial credit for some tutoring strategies but full credit for others could impact the generalizability of these findings into a context where there is no scoring of student responses. All of the experiments also take place within skill builder assignments, in which students are given a series of similar problems on the same mathematics topic. The instructional interventions in the experiments analyzed in this work could have different effects on students completing assignments on topics outside of mathematics, or even a variety of mathematics topics within the same assignment. There could also be an issue generalizing these findings to contexts outside of online learning platforms. The differences between different tutoring strategies could be inconsequential if there is a teacher in the room to answer questions, and while the results of these experiments implied that motivational messages had a negative impact on learning, this was likely due to the distracting and impersonal nature of the motivational messages. Previous studies have shown the need for trust between teachers and their students and how this can lead to more motivated and academically successful students [4], but the trusting relationship needed for that impact is unlikely to exist between a student and a website.

Secondly, this work investigates many different research questions using data from a combination of experiments with similar, but not identical designs, which has increased the potential of discovering false positives in the analysis. This should influence the confidence that one has in the results of this work. While the results with effect sizes greater than 0.1 and p -values in range of 10^{-3} can likely be trusted, there are many weaker findings that some might consider significant while others may be more critical. By providing the sample sizes, effect sizes, confidence intervals, and p -values for every comparison carried out, for all the research questions investigated in this work, others can make an informed decision on the extent to which they should believe each of these findings, and which findings merit follow-up investigations and repeat experiments.

7. CONCLUSION

In this work, data from 50,752 instances of one of 30,408 students participating in one of 50 different experiments on a variety of instructional interventions conducted within ASSISTments were combined to investigate their impact on learning. Using this data, 19 different research questions regarding the effectiveness of these various instructional interventions were investigated, and this investigation revealed multiple actionable findings that can be used to design more effective online learning experiences.

The first insight discovered was that changing the number of problems students must get correct in a row to be considered as having mastered a skill had no impact on the learning gains of the students that were able to complete the assignment, but the more problems required, the more likely students were to stop doing the assignment before mastering the material, which overall decreased their learning gains. Based on this result, when creating mastery-based content, it might be better to use something like Knowledge Tracing [13] to evaluate mastery instead of forcing students to complete a fixed number of problems.

It was also discovered that across multiple experiments, the tutoring provided to students by ASSISTments had almost entirely a positive effect on students' learning compared to just giving students the answer when they were struggling. This falls in line with the larger findings from cognitive psychology that show students learn more when they productively struggle with solving problems, rather than being provided solutions [6]. Additionally, below average prior knowledge students benefited more from this tutoring overall than above average prior knowledge students, which can help to close opportunity gaps, and for all students, when scaffolding problems were video-based, they had a larger positive impact than when they were text-based. These results could help inform developing platforms on how to allocate limited resources when creating tutoring. For example, creating new tutoring could be prioritized for remedial courses, and the extra effort of making video-based tutoring could be saved for scaffolding.

Another insight from these analyses was that students showed greater learning patterns when they completed open-response questions rather than multiple choice questions. This corroborates some research that finds that memory and learning benefit most from free recall of information (e.g. answering an open-ended question) compared to cued-recall (e.g. multiple-choice items) during learning [22, 30]. Based on this, online learning platforms could move away from multiple choice questions when possible.

This study also found that adjusting students' assignments based on their prior knowledge level had a positive effect on their learning. This supports the idea that personalized learning can help students. Within ASSISTments, a previous study found that high-knowledge students learned more from explanations, while low-knowledge students learned more from scaffolding [42]. This is one example of how personalization based on prior knowledge within online learning platforms has been found to be effective in the past. Additionally, a meta-analysis of studies that measured the learning gains of students after grouping them by ability level found

that the instructional material was more than twice as effective when it was tailored to the students' ability levels than when it was held constant for all students [26]. The results of this study agree with prior work, and imply that personalizing students' education based on their prior knowledge increases their learning.

Another interesting result from these experiments was that motivational messages had a negative impact on learning. Past research has found positive effects of motivational interventions for some students, so why might these studies show a negative effect? One speculation is that the motivational videos may have unintentionally produced an effect similar to what is referred to as "seductive details" or highly engaging but unrelated information that is unnecessary for learning [46]. Including seductive details can lead to worse performance both in the classroom and in online learning environments [18], and is theorized to disrupt learning by redirecting attention away from the material and toward superfluous information, stopping students from appropriately allocating cognitive resources to the educational material. Providing motivational videos in the middle of the learning period may have produced a negative effect on learning because it disrupted cognitive processes necessary for learning, but more research is needed to fully investigate this and other possible mechanisms at play.

In addition to these results' capacity for improving online learning platforms, these results can help inform the next round of experimentation within online learning platforms. Future experiments could continue to investigate the inconclusive findings in this analysis, and expand upon the conclusive findings. For example, more types of problems besides multiple choice and open response problems could be compared to each other, and the effectiveness of different tutoring strategies could be investigated for differences based on subject matter or grade level. Through these analyses, learning platforms can continue to improve their design and increase their positive impact for all students that use them.

ABSTRACT

This paper studies the use of Reinforcement Learning (RL) policies for optimizing the sequencing of online learning materials to students. Our approach provides an end to end pipeline for automatically deriving and evaluating robust representations of students' interactions and policies for content sequencing in online educational settings. We conduct the training and evaluation offline based on a publicly available dataset of diverse student online activities used by tens of thousands of students. We study the influence of the state representations on the performance of the obtained policy and its robustness towards perturbations on the environment dynamics induced by stronger and weaker learners. We show that 'bigger may not be better', in that increasing the complexity of the state space does not necessarily lead to better performance, as measured by expected future reward. We describe two methods for offline evaluation of the policy based on importance sampling and Monte Carlo policy evaluation. This work is a first step towards optimizing representations when designing policies for sequencing educational content that can be used in the real world.

1. INTRODUCTION

E-learning platforms have seen a surge in popularity over the last decade [10], spurred on by the increased Internet penetration into developing communities [4]. The target demographic has expanded beyond casual users/students as more organizations adopt e-learning to train their workforce and actively engage them in life-long learning [34].

As online educational settings become ubiquitous, there is a growing need for a personalized sequencing of content/support that can adapt to the individual differences of the student as well as their evolving pedagogical requirement throughout the course progression [28]. Research in cognitive science has long demonstrated the strong correlation between adapted material sequencing and learning outcomes [26]. Static e-learning platforms lack the capacity to respond to a student's 'cognitive state' and therefore perform poorly relative

to a human tutor [34].

Reinforcement learning (RL) offer a potential approach for adapting a learning sequence to students [9]. A learning sequence can be optimized based on a numerical reward (for example test marks) by a pedagogical agent that prescribes actions (adaptive feedback or sequencing of content) based on different states (approximated users' cognitive states).

There are two main challenges to using RL 'out of the box' in educational settings. First, how to choose the best representation to model student behavior? On the one hand, increasing the granularity dimension of the state-space allows to capture intricate dynamics in the model such as students' cognitive states and skills. On the other hand, models with complex state spaces are inherently more difficult to learn and the resulting policy may lack support in the data for parts of the state space. Second, how to evaluate the resulting sequencing policy? Ideally, sequencing policies will be deployed online and evaluated with real learners. This is costly or not technically feasible to carry out in many cases and an imperfect policy may adversely affect students' learning.

This paper addresses both of these challenges in the context of a new publicly available dataset containing the online interactions of thousands of students [7]. Our approach provides an end to end pipeline for automatically deriving and evaluating robust representations of students' interactions and policies for content sequencing in online educational settings.

To address the first challenge, we present a new greedy procedure to augment the representation space, by incrementally adding new features and choosing the best performing representations on held out data. Each policy is evaluated using expected cumulative reward. We provide several key insights about the use of RL in Educational contexts. First, that 'bigger is not always better', in that more complex state spaces may not always lead to better policy performance. Second, that including a 'forgetting' element in the state space, which is known to affect students' learning, significantly improved performance. Third, that strongly penalizing rewards from unseen state-action pairs in the data, can increase the support of the resulting policy without reducing performance.

To address the second challenge, we use two existing offline

policy evaluation methods to reliably estimate the performance of the resulting policy using only the collected data. The first method uses importance sampling to correct for the difference in distributions between the learned policy and the policy that was used to gather the data. The second method simulates the learned policy using Monte Carlo methods. We also introduce a new approach that evaluates the policy with respect to perturbations induced by stronger and weaker learners. We find that perturbing the system dynamics have an adverse affect on performance of the learned policy, specifically in respect to weaker learners; and that increasing the granularity of the state-space makes the policy more robust to perturbations.

This work is a first step towards optimizing representations when designing policies for sequencing educational content that can be used in the real world. Our long term goal is to develop an adaptive RL based pedagogical agent that is able to optimize the sequence of learning materials (questions and lectures) to maximize student performance as measured by the expected ability to answer questions correctly at varying levels of difficulties. This agent will have the capacity to respond in real-time to a student’s current state as they progress through the learning material.

2. RELATED WORK

This paper relates to prior work in student modeling as well as automatically sequencing educational content to students [9]. A common approach in prior work is to integrate learning/cognitive theory into the construction of the student model. This imparts domain knowledge into the workflow and was shown to yield positive results by Doroudi et al. [9]. An example of such approach is the work by Bassen et al. [2]. Their objective was to optimize the sequencing of learning material from different knowledge components (KCs), to ‘maximize learning’. Their reward function is based on the difference between a post-test score (taken by users after completing the course) and a pre-test score (taken before the course). This metric is denoted as the Normalized Learning Gain (NLG). Training the agent with human participants is far too resource intensive. Instead their training is performed on a ‘simulated learner’ based on Bayesian Knowledge Tracing (BKT), a cognitive model that aims to estimate a learner’s mastery of different skills. The learner’s response to a particular question can be simulated based on the mastery of the related skill. The parameters of the BKT were set based on domain knowledge. Segal et al. [28] also utilised a similar cognitive based model, Item Response Theory (IRT) [14] to simulate student responses to questions of different level of difficulty. This is especially relevant since their objective was to sequentially deliver questions of differing levels of difficulty (rather than KCs) to maximize learning gains.

Other approaches forgo the framework of established learning models and instead manually design their simulators further integrating domain expertise. Dorcca et al. [8] employed a probabilistic model to simulate the learning process. Instead of sequencing activities by KCs or difficulties, they sequenced activities based on their associated learning style i.e. visual, verbal etc. Therefore, their simulator was manually designed based on research surrounding these principles. Iglesias et al. [15] utilised an expert derived artificial Markov Decision Process to act as the student model. This entails

manually describing the state space, transition probabilities and rewards. Similar to previous student models, this MDP can be used to simulate student responses to train the RL agent.

The works described so far do not utilise historical data (i.e., past interactions in the system and their results) to derive their student model. While integrating expert knowledge can be beneficial, a completely data-free proposition could impart strong biases. In our implementation, we take an alternative approach in using a purely data-driven model. There are existing literature which also do the same. For example, the authors of [30, 32, 5, 27] employed data-driven MDPs as their student model. Different than the hand-crafted MDP in Iglesias et al. [15], the transition probabilities and reward functions in these MDPs were obtained from the aggregated statistics observed in the dataset. Data-driven student models in literature were not only limited to data-driven MDPs. For instance, Beck et al. [3] utilised a linear regression model denoted as Population Student Model (PSM). PSM was trained on student trace data from a learning software and could simulate time taken and probability of a correct response.

Data-driven simulators require a quality training corpus that is sufficiently large and varied [30, 16]. In contrast to EdNet (a massive dataset collected over several years which we use in this work), the authors of previous papers were limited to much smaller scale datasets that were collected from a single cohort and could not evaluate their policy at scale. Our work is the first to provide an end to end pipeline from a large scale data source to a robust RL sequencing policy.

3. BACKGROUND

In this section we provide some necessary background in Reinforcement Learning & MDPs and briefly describe our dataset.

3.1 RL and MDPs

A Reinforcement Learning (RL) framework is governed by a Markov Decision Process [31, 17, 6] that is defined by the tuple of $(\mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R})$, where $\mathcal{S} = s_1, \dots, s_n$ is the state space, $\mathcal{A} = a_1, \dots, a_m$ represents all available actions, $\mathcal{P} : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow [0, 1]$ designates the transition probabilities between states conditioned on an action and $\mathcal{R} : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow \mathbb{R}$ denotes the reward function that is conditioned on the state, action and observed next state.

The goal of the agent is to maximize the **cumulative** reward it accumulates from each state. This cumulative reward is usually discounted by a factor γ raised to the power of t , to represent a lower perceived value for rewards received further in the future. The policy is a mapping of optimal actions to each state in \mathcal{S} . The discounted cumulative reward is denoted as the ‘return’, and the return from a particular state is associated with a policy π and the transition dynamics \mathcal{P} . The reward function ties the agent’s optimization goal with the modeller’s actual objective. Therefore its design must ensure those two criteria are aligned. The expected reward of a state (or the state value) under a deterministic policy

π can be defined as

$$V(s) = \mathbb{E}_{\pi, \mathcal{P}} \left[\sum_{t=0}^{\infty} \gamma^t r(s_t, \pi(t)) \mid s_0 = s \right] \quad (1)$$

where $\pi(t)$ is the action prescribed by the policy π at state t , $r(s_t, a_t)$ is the reward obtained in state s_t given action a , s_0 is the initial state and γ is a discount factor.

Model-based RL requires a model that holds information regarding the environment dynamics i.e. the transition probabilities \mathcal{P} and reward function \mathcal{R} . It is a common approach in domains where environment interactions are cost prohibitive [16][18]. The model mimics the behaviour of an environment and allows inferences about how the environment will respond to actions [31]. The real-world performance of the extracted policies are heavily influenced by the quality of the constructed model [16].

3.2 Data Description

EdNet [7] is a massive dataset of student logs from a MOOC learning platform in South Korea, *Santa*, collected by *Riiid! AI Research*¹. *Santa* covers a preparation course for the TOEIC (Test of English for International Communication) English proficiency exam. There are a total of 131,441,538 interactions collected from 784,309 students on the e-learning platform. These consist of user records of questions attempted, lectures watched and explanations reviewed, along with other meta information. EdNet logs are presented at 4 levels of hierarchy with higher levels providing higher fidelity logs, such as logs of lectures watched and the explanations reviewed. These are recorded in real time to provide an accurate chronological record of the students’ interaction with the platform. EdNet records detailed actions such as playing/pausing lectures and payment related information.

4. METHODOLOGY

Our approach, called GIFA (Greedy Iterative Feature Augmentation) maps a representation space of students’ activities to an optimal sequencing policy using RL. At each step, a representation-space for the education domain is defined using a set of features. An MDP model is defined over the representation space, and model-based RL is used to extract the optimal policy given the representation space. The policy is subsequently evaluated using the Expected Cumulative Reward metric. This process is iterated, greedily adding new features to the representation and computing the optimal policy given the representation (See top of Figure 1). The resulting representation and policy are verified using two offline policy evaluation processes (importance sampling and Monte Carlo) and the robustness of the policies is analyzed against perturbations corresponding to varying student types (See bottom of Figure 1). We proceed to describing our methodology in more detail.

4.1 State Space Representation

Several studies have shown the significant impact of the representation choice on RL performance, with some arguing it is just as influential as optimization algorithm itself [32, 29]. We design the representation candidates for our model to include features that are derived from the dataset. EdNet

¹<https://www.riid.co/>

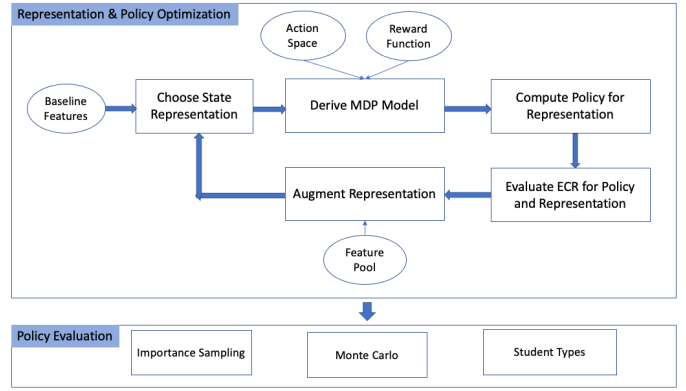

Figure 1: Pipeline of the GIFA approach

provides a total 13,169 questions and 1,021 lectures tagged with 293 types of skills [7]. Each question and lecture is segmented into one unique “part”, with 7 parts in total. Each part was grouped based on some meaningful domain criteria, such as a math topic [2]. EdNet offers a finer grouping of question/lectures according to the ‘skills’ (293 in total) they entail. Both ‘part’ and ‘skills’ grouping represent good candidates for the action space since they group the numerous questions/lectures in a domain meaningful manner. However the question bank is unevenly distributed with respect to the ‘skills’ grouping, which can lead to difficulties in getting equal support (or supporting observations) for each action type from the dataset. Therefore, ‘part’ was chosen on the basis that its 7 unique action space is both computationally feasible and better supported in the data.

A key aspect of modeling student learning is to represent the question difficulty in the state-space [28]. This enables to adapt the level of difficulty of a question to the student’s inferred skill level. Unfortunately EdNet does not directly classify questions/lectures into difficulty levels, meaning that they would need to be inferred from the student logs. A natural way to infer difficulty is to measure the percentage of correct answers submitted for a question and compare it with other questions in the question bank. A distribution over question difficulties can be created and quantiles can be derived to evenly split the questions into discrete levels of difficulty. Utilizing this process we created a difficulty level for each question, with the difficulty levels quantized into 4 levels ranging from 1 (easiest) to 4 (hardest).

To investigate the impact of the representation on performance, we create a feature pool, from which different representations are formed using the greedy iterative augmentation algorithm. The initial feature pool contains features that are widely seen in similar Reinforcement Learning driven Intelligent Tutoring implementations [2, 15, 32, 5]. The state features are longitudinal/temporal in nature so as to represent the users’ behaviour and performance over time. This sets a reasonable minimum requirement for the data gathering process, should this implementation be repeated with other datasets. The initial feature pool, their descriptions, and the associated granularity of their representations (bins), are shown in Table 1. Quantization of features to bins was performed so that a finite model can be formed.

Feature Pool	Bins	Description
"av time"	4	The cumulative average of the elapsed time measured at each activity.
"correct so far"	4	The ratio of correct responses to the number of activities attempted.
"prev correct"	3	A flag to indicate whether the user answered correctly in the previous question + fixed value for lecture.
"expl received"	4	Cumulative count of explanations reviewed by the user.
"steps-since-last"	8	A count of the number of steps since the current part was last encountered.
"lects consumed"	4	A cumulative count of the lectures consumed by a user.
"slow answer"	2	A flag to indicate whether the user's elapsed time for the preceding question was above the average elapsed time for that question.
"steps in part"	4	The cumulative count of how many steps a user has spent in the current part.
"avg fam"	4	The average part familiarity across all the 7 parts.
"topic fam"	4	Captures part familiarity of the previously chosen action (by amount of activities per topic).

Table 1: Initial Feature pool for state space

Relative to prior work that limited the feature size to be binary [2, 23, 32] our feature space is considerably larger. With each user covering on average 440 activities during their learning period within this dataset[7], a binary split would lose a lot of information on the evolution of a feature value throughout the course. Our features in contrast have up to 8 bins. This ultimately imposes a necessity for a quality training corpus that can provide sufficient support for each of the many unique combinations within the feature space. This is where the scale of the EdNet dataset provides a distinct advantage relative to previous implementations.

4.2 Deriving the student model

In this section we describe the derivation of an MDP-based student model using a selected set of features. We model the transition probabilities as multinomial distributions derived from state transition counts observed in the dataset as shown in Equation 2. This means that a particular outcome s_i , of enacting action a_k in state s_j has a probability given by the number of times that outcome was observed in the dataset, normalized by the sum of all possible outcomes observed under the same conditions.

$$\hat{p}(s_i | s_j, a_k) = \frac{c(s_i, s_j, a_k)}{\sum_{i=1}^n c(s_i, s_j, a_k)} \quad (2)$$

Where $c(s_i, s_j, a_k)$ is the count of observed transitions where enacting action a_k in state s_j leads to next state s_i . This provides the transition probabilities component of the MDP

student model for each (s, a, s') or the three argument dynamic [31].

In many standard MDP definitions [32, 30, 5], the reward function is also defined in terms of the three argument dynamic i.e. $\mathcal{R} : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow \mathbb{R}$. This assumes a deterministic environment reward with respect to a given (s, a, s') . The reward for a student's response depends on the question difficulty such that correct responses on harder levels indicate stronger performance and attain higher rewards. Inversely, incorrect responses on easier levels attain a larger punishment (negative reward). A symmetrical reward function was designed with rewards for questions ranging from 1 to 4 if answered correctly or -1 to -4 if answered incorrectly. We doubled the penalty of incorrect answers to achieve a normal distribution usually exhibited in student grades [13]. Thus rewards take values $r \in \{-8, -6, -4, -2, 0, 1, 2, 3, 4\}$. While the level of difficulty is captured by the action in the (s, a, s') tuple, the correctness is only captured in the states when 'prev_correct' (refer table 1) is included in the representation. Lectures do not have a correct/incorrect responses and so a default reward of '0' is assigned for lecture viewing actions.

The specific dynamic values are of course dependent on the actual state representations. As we continuously augment the representations (see next section), the support for each unique state will inevitably fall due to further division of the observations. Another factor in providing a balanced distribution of support within the transitions, is the variety of actions chosen in each state. This ultimately depends on the action space described earlier and the behaviour policy used to obtain the dataset. A higher fidelity action space will lead to an increase in the size transition space i.e. the unique combinations of (s, a, s') . Although unknown in most cases, it is important that the behaviour policy is sufficiently varied in terms of its action choices to ensure a balanced distribution of support. Because of this, a random behaviour policy fits the objective well [30]. Since users in EdNet are allowed to select the 'part' and the type of activity they work on [7], we make an assumption that this random criteria is partially fulfilled. The caveat here is that not all users have access to all parts i.e. free users are limited to parts 2 and 5 only.

4.3 Representation Selection

Key to designing a successful model of student behavior depends on deriving information on the student's cognitive state, which is a latent variable in the model. With more features in the representation, one should expect a better approximation of the students cognitive state and consequently a better equipped pedagogical agent to provide effective sequencing.

We utilise the GIFA approach in obtaining an optimal representation. This involves a search of the feature space and generation of several candidate feature subsets. Each of these subsets is evaluated based on its corresponding policy derived from a standard policy-iteration RL solution. The pseudocode for this process is shown in Algorithm 1. Note the limit on the number of features \mathcal{N} which can be based on a computational limit or a threshold of minimum support for every unique combination in the feature space.

Algorithm 1 Greedy Iterative Feature Augmentation algorithm

Input: Feature pool Ω , Dataset \mathcal{D} , Max. number of features \mathcal{N} (optional)
Set: Optimal feature representation \mathcal{S}^* .
while $size(\mathcal{S}^*) \leq \mathcal{N}$ **do**
 for $\omega_i \in \Omega$ **do**
 Set: $\mathcal{S}_i = \mathcal{S}^* + \omega_i$
 $MDP = Construct_MDP(\mathcal{S}_i, \mathcal{D})$
 $\pi^* = Policy_Iteration(MDP)$
 $ECR_i = Calculate_ECR(\pi^*)$
 end for
 Set $\mathcal{S}^* = \mathcal{S}_i$ with highest ECR_i .
 Remove feature from pool $\Omega = \Omega - \omega_i$
end while

Round	Rep.	ECR	ECR Diff. (%)	Rep. Size
Base	MDP_B	238.44	-	64
1	MDP_1	283.63	18.95	256
2	MDP_2	387.42	36.6	2048
3	MDP_3	392.05	1.19	4096
4	MDP_4	396.00	1.01	16384
5	MDP_5	396.00	0	65536

Table 2: ECR results showing best performing representation at each iteration

While our search procedure involves exhaustively looping through every remaining feature in the feature pool Ω to form the subsets, one can alternatively employ a different search algorithm such Monte Carlo Tree Search [12] or correlation based feature selection [29] to create more informed subsets that are likely to be better candidates. These techniques would be useful in limiting the number of iterations needed in larger feature pools and are left for future work.

As part of the greedy feature augmentation algorithm above, an evaluation metric for π^* , the computed policy, is required for each representation at every iteration. A common practice used to evaluate a given policy in RL is to use the Expected Cumulative Reward (ECR) metric which is the average of the expected cumulative reward under the policy π^* , across all initial states in the dataset ($V_{\pi^*}(s_0)$).

Note that in each state representation, the initial state of every user in the EdNet is the same. This is because we lack any prior information of the user before they begin to solve questions. When such information is available, the initial state can capture information from the students pre-test scores and so would vary across the students in the dataset.

5. RESULTS

A summary of the results from the greedy iterative augmentations is provided in Table 2. The feature description for the corresponding MDP representations are given in table 3. The base MDP is denoted as MDP_B. The ‘ECR Diff.’ column shows the percent improvement in ECR relative to the smaller representation preceding it. The ‘Rep. Size’ column illustrates the size of the state feature space. This is depen-

Representation	Features
MDP_B	topic_fam, correct_so_far, av_time
MDP_1	topic_fam, correct_so_far, av_time, expl_received
MDP_2	topic_fam, correct_so_far, av_time, expl_received, ssl
MDP_3	topic_fam, correct_so_far, av_time, expl_received, ssl, prev_correct
MDP_4	topic_fam, correct_so_far, av_time, expl_received, ssl, prev_correct, av_fam
MDP_5	topic_fam, correct_so_far, av_time, expl_received, ssl, prev_correct, av_fam, time_in_part

Table 3: Representation outputted by algorithm for each round (added features highlighted)

dent on each constituent feature’s bin size, i.e. the number of discrete bins allocated. Note that results presented here are only showing the best performing representation at each round of the feature augmentation.

5.1 ECR Analysis

The largest spike in ECR followed at the second round of augmentations with the addition of the ‘steps-since-last’ (ssl) feature with an increase of 36.6% over the preceding representation. This feature measures the number of steps or activities (questions/lectures) consumed since the current part was last encountered. This feature is inferring the ‘forgetting’ element during the learning process and was inspired by the ‘spacing effect’ described in [11].

Early research in instructional sequencing in language learning used models of forgetting to great success [1]. Our findings concur with this, in that by including ‘ssl’ into the feature space, we dramatically increased the policy performance. One could argue that this ECR increase was more influenced by the larger bin allocation to ‘ssl’ (8 relative to 4 for most other features) rather than the actual utility of the domain information it is measuring. However, if that were the case, then we would expect ‘ssl’ to be the first feature added to the base representation. This was not the case since the best performing feature in the first round of augmentations was ‘expl_received’, a 4-size bin feature. Nonetheless, further exploration is needed to further learn the influence of bin sizes on the results.

At the final round of iteration, the performance of representation MDP_5 only equals the performance of preceding representation MDP_4. Though we did not have a specified limit imposed on the number of features, \mathcal{N} , the performance plateau exhibited at this final round indicated a suitable termination point for the augmentation algorithm. And since MDP_4 produced equal performance to MDP_5 with a smaller representation size, it was chosen to be the optimum representation within this feature pool.

5.2 Correcting for OOD actions

This section describes our technique for handling the uncertainty induced by unseen or out of distribution (OOD) actions in the RL policy. Some of the extracted policies in the GIFA algorithm included state-actions pairs with 0 support from the training data. Such behaviour is deemed

unsafe for a computed policy [18, 20] as the resulting reward from such combinations of unsupported state-action pairs is unexpected. Specifically, this situation should not occur under policies derived from tabular methods as explained in section 3. Nonetheless we discovered that some of the larger representations yielded policies with unseen actions. The policy derived from MDP_4 prescribed unseen actions in 10 states. While this was a small fraction of the total state space (around 65,000), unseen actions are an important issue to address because, in the tabular case, any state-action value estimates must be derived only from related experiences [31].

By default, our algorithm prescribes state-action pairs a value of zero if it was never observed. We discovered that the problematic states themselves had very little support in the dataset and were only observed transitioning to themselves, before the episode ends. In the few times the state was visited, a negative or zero reward was produced. Since these states would only transition to themselves, the values of these valid actions were either negative or zero. Hence, from the algorithms perspective, an invalid (unseen) action with a default value of zero, was preferable (or equal) to the observed actions.

To combat this issue, we modified the MDP representations to strongly penalise the rewards from unseen state-action pairs, in the form of a -9999 reward. This discouraged the policy from choosing such actions even if the only valid actions yielded zero or negative returns (The worse case is bounded from below at $\sum_{k \rightarrow \infty} \gamma^k \times (-8)$ and is clearly higher than $\sum_{k \rightarrow \infty} \gamma^k \times (-9999)$). With these changes in place, we observe no unseen actions in any of the policies. The performance rank of representations remained constant with the ECR changes almost negligible. This is because the states involved were observed very infrequently and occupied a small probability mass in the transition probabilities. We note that the fix did not have a statistically significant effect on our results. In the analysis that follows we will utilise the penalised representations. We also note that research by Liu et al. [20] implemented a ‘pessimistic policy iteration’ approach that similarly penalises insufficiently supported state-action tuples (filtered by a threshold).

6. OFFLINE POLICY EVALUATION

Ideally, the outputted policy from the GIFA approach would be evaluated in real time with students who directly interact in the EdNet environment. However, mistakes in the policy can have adverse affects on students’ engagements and learning [21]. The offline policy evaluation (OPE) field has been developed specifically to address this issue, by providing reliable estimates of policy performance using only past collected data [21]. We undertake two different OPE approaches to evaluate the computed optimal policies from the previous sections. Furthermore, we add a 3rd offline evaluation approach which evaluates the robustness of the computed policies to different model perturbations representing several student types.

6.1 Rollouts: Monte Carlo Policy Evaluation

The first OPE approach relies on the family of ‘Direct Methods’ for policy evaluation. These methods focus on regression based techniques to directly estimate the value function

of a policy under a given target policy [33]. Most of these methods do not need an estimation of the behaviour policy which was used to collect the dataset. In this method we implement a model-based direct method, Monte Carlo (MC) Policy Evaluation. This involves performing ‘rollouts’ from the initial states using the target policy until episode termination. The observed returns from each state in the rollout are averaged across many rollouts to yield the value function of the state. To ‘rollout’ our policy we would need to interact with the environment. However, as the name ‘model-based’ suggests, a model (in our case, the data-derived MDPs) acting as simulator allows us to perform these rollouts offline.

A key requirement for MC policy evaluation is an **episodic environment**, one where the episode terminates at a finite step at a ‘terminating state’ [31]. Although the user episodes in EdNet are finite, our data-derived MDPs are continuing i.e. without a terminating state. While a default terminating state could have easily been created for this purpose, it is unclear as to which ‘action’ would transition the final observed state to this terminating state and what ‘reward’ it would receive in the process. The choice of reward, could inadvertently impact the decisions made by the policy at the earlier states. Hence our MDPs were designed to be continuing to avoid this ambiguity.

This poses a problem with MC policy evaluation since the returns are only calculated when the episode ends. A potential workaround was to manually terminate the episode at a fixed length of rollout and calculate the returns from there. We chose a rollout length of 1000 steps and show that because of the discounting, any reward, $r \in \mathcal{R}$, received past this step, will have a negligible influence on the return of the initial state i.e. $\max_r (\gamma^{1000} ||r \in \mathcal{R}||) \approx 3.5 \times 10^{-4}$. Hence this rollout length provides a good approximation of the long term return, since any future actions will have minimal influence on the value of the initial state, i.e. the only state value of concern in our analysis. However, this assumption will only work with the ‘first-visit’ variant of MC policy evaluation (equation 3), where only the returns of a state when it was first encountered in the episode are considered and averaged across the rollouts [31]. This is opposed to the ‘every-visit’ variant which considers all the returns from a state every time it is visited in the episode. A fixed rollout length will not be suitable in the latter variant, since the initial state could be encountered more than once during the rollout. For example, if s_0 was encountered again at the 500th time step, then its return estimate for the second visit is based only on the remaining 500 future steps. Implementing the first-visit variant ensures that all $V(s_0)$ estimates are derived from observations spanning 1000 time steps ahead.

$$V_{\pi_e}^{MC}(s_0) = \frac{1}{N_{rollouts}} \sum_1^{N_{rollouts}} \sum_{t=1}^{1000} \gamma^t r_t^t \quad (3)$$

We now evaluate the policies under the MC Policy Evaluation method. A curve is plotted for the returns (cumulative rewards) from the initial state as the rollout progresses until the 1000th step for a total of 100 rollouts. The 95% confidence intervals are plotted around the mean value of the

Figure 2: Monte Carlo Evaluation: Returns from s_0 across steps under the policies from the associated representations

rollouts. This analysis is shown in figure 2. As with the ECR, we can see that the improvements start to diminish significantly after the second round of augmentations. The performance of the estimated stochastic *behaviour policy* under this simulation (the policy that is directly induced from the data) is illustrated as a baseline. From this comparison, we see much better student performance under the RL policies than the baseline, signalling that the adaptive behaviour of the policy under RL framework is superior than the strategies used in the behaviour policy. We can also conclude that the larger representations exhibit better performance, potentially owing to a better approximation of the cognitive state as hypothesized.

6.2 Importance Sampling Policy Evaluation

The second OPE approach used relies on Importance Sampling. Importance sampling (IS) is a range of methods that in general estimate the expected values under one distributions given samples from another [31]. A wide range of RL literature have adopted this method as a way of evaluating a *target policy* (the policies derived from the RL algorithms) given samples derived from the *behaviour policy* (the policy used to gather the data) [16]. In this work we use the Weighted IS (WIS) metric presented in equation 4.

$$WIS = \frac{\sum_{i=1}^N [(\prod_{t=0}^{T_i} \frac{\pi_e(a_t^i | s_t^i)}{\pi_b(a_t^i | s_t^i)}) (\sum_{t=1}^{T_i} \gamma^t r_t^i)]}{\sum_{i=1}^N \prod_{t=0}^{T_i} \frac{\pi_e(a_t^i | s_t^i)}{\pi_b(a_t^i | s_t^i)}} \quad (4)$$

In this equation, N represents the number of users in the dataset and T_i is the trajectory length observed for user i .

A key feature in the formula is the **importance sampling ratio** $\prod_{t=0}^{T_i} \frac{\pi_e(a_t^i | s_t^i)}{\pi_b(a_t^i | s_t^i)}$, which considers the differences in ac-

Rep.	WIS
MDP_B	-4.146
MDP_1	-0.940
MDP_2	-4.382
MDP_3	4.319
MDP_4	4.910

Table 4: Importance sampling results - different representations

tion probabilities between the target policy π_e and the behaviour policy π_b . The product of the individual ratios across $t_i = 0 \rightarrow T$ quantifies whether a given sequence is more (or less) likely under π_e than π_b and therefore weights the returns accordingly. Averaging this across the entire dataset has the effect of adjusting the **expected return** sampled from the distribution generated by π_b to estimate the **expected return** sampled from π_e .

A well documented problem with IS estimators is the high variance induced by the importance sampling ratio due to: 1) a large difference between the two policies or 2) a long horizon length for the trajectories [33]. WIS reduces this variance by utilizing a weighted average instead of the simple average in standard Importance Sampling metric [31]. This method relies on the available knowledge of the behaviour policy. Since we do not have explicit information on this, π_b must be estimated from the dataset, \mathcal{D} as shown in equation 5.

$$\hat{\pi}_b(a|s) = \frac{\sum_{s,a \in \mathcal{D}} \mathbf{1}[s = s, a = a]}{\sum_{s \in \mathcal{D}} \mathbf{1}[s = s]} \quad (5)$$

The results of the WIS metric for the different representations are shown in table 4. We see that the 3 smaller representations yield negative values, indicating expected average failure in solving questions when utilizing these representations. For larger MDP representations, we can observe better performance, with MDP_4 demonstrating the best estimated performance.

6.3 Evaluating Model Robustness for Different Student Types

The optimal policy computed in the previous section relies on the average rewards and transition probabilities estimated from available data. In practice, these parameters are noisy and may change in different situations and during the execution of a policy [19]. As such, the performance of the computed policy may deteriorate significantly with changes in the environment dynamics [22]. In our case, with the MDP representing students acting in an educational system, this uncertainty represents the challenge of how to model parameters change for different student types and how do these changes influence the outcome of the computed policies. To model this uncertainty, we use a simplified robust MDP framework [25] where the uncertainty in model parameters is tied to specific student types. Specifically, we test the robustness of the computed policies under perturbations of the environment dynamics which are tied to two different student types. These perturbations are domain informed and are designed to correspond to ‘stronger’ and ‘weaker’ students types.

Algorithm 2 Domain informed perturbations

1: **Input:** Set of features to perturb $\bar{\Omega}$, MDP transition probabilities \mathcal{P}_{MDP} , set of domain filters for each feature ψ , positive perturbation constant $c = 0.05$
2: **for** $p_{s,a,s'} \in \mathcal{P}_{MDP}$ **do**
3: $\Delta_{s,a,s'} = \sum_{\omega \in \bar{\Omega}} \Delta_{\omega}$
 Where $\Delta_{\omega} = \begin{cases} c, & \text{if } \omega_s, \omega_{s'} \text{ satisfies } \psi_{\omega} \\ 0, & \text{else} \end{cases}$
4: **end for**
5: Adjust $\Delta_{s,a,s'}$ relative to others within the s, a pair:
 $\Delta_{s,a,s'} = \Delta_{s,a,s'} - \frac{1}{|\bar{\psi}|} \sum_{s'} \Delta_{s,a,s} \forall \Delta_{s,a,s'}$
6: Set perturbed transition probabilities $\bar{\mathcal{P}}_{MDP} = \mathcal{P}_{MDP}$
7: **for** $p_{s,a,s'} \in \bar{\mathcal{P}}_{MDP}$ **do**
8: $p_{s,a,s'} = \max(p_{s,a,s'} + \Delta_{s,a,s}, 0)$
9: **end for**
10: $p_{s,a,s'} = \frac{p_{s,a,s'}}{\sum_{s'} p_{s,a,s'}} \forall p_{s,a,s'}$
11: **Return:** $\bar{\mathcal{P}}_{MDP}$

Feature to Perturb	Strong	Weak
Topic_fam	$\omega_{s'} > \omega_s$	$\omega_{s'} = \omega_s$
Correct_so_far	$\omega_{s'} \geq \omega_s$	$\omega_{s'} < \omega_s$
Avg_time	$\omega_{s'} \leq \omega_s$	$\omega_{s'} > \omega_s$

Table 5: Domain perturbation filters, ψ for each feature in $\bar{\Omega}$ for the ‘Strong’ and ‘Weak’ perturbed MDPs, $\bar{\mathcal{P}}$ respectively

We now describe the perturbation process and analysis. We define a set of domain informed filters ψ for each perturbed feature. In our implementation we perturb three base features that were common in all representations i.e. ‘Topic_fam’, ‘Correct_so_far’ and ‘Avg_time’. The domain rules for the two separate perturbations ‘Strong’ and ‘Weak’ are defined in table 5. Specifically, in these perturbations we boost the topic familiarity and correctness and reduce the cumulative elapsed time for the ‘Strong’ student type and we reduce correctness and increase the cumulative elapsed time for the ‘Weak’ student type. For example, for the feature ‘Correct_so_far’ and the ‘Strong’ user case, we set the filter to capture transitions where the next state s' registers a greater or equal value relative to the current state s . When this filter is inputted in algorithm 2, the transitions that satisfy this filter will be boosted by the constant c . This ultimately has the effect of increasing the probability mass of this transition, perturbing the original MDP to make such transitions more likely.

Algorithm 2 introduces the perturbation process. In lines 2 to 4 we compute the transition probability deltas that are required for every transition which satisfies one or more perturbation filter. This is done for all state transitions in the MDP. In line 5 we create transition deltas for all transitions, accounting for the deltas introduced by the perturbed transitions. In lines 6 to 9 we apply the transition deltas to the transition probabilities, and finally in line 10 we normalize the transition probabilities following the changes made.

The results of two separate perturbations are measured by performing a policy evaluation algorithm with the original policy but under the perturbed MDPs (Strong & Weak) as the simulators.

Figure 3 shows the results of this analysis for the different representations. Notice that in all the representations, the original non-perturbed MDP always yielded the best performance (non-visible for MDP_4 as the student type lines overlap). This is expected, since the original policy was derived to perform optimally on the original MDP. However, as the representation size increases, the effects of the perturbations becomes less pronounced, almost becoming negligible past MDP_1. To determine if the larger representation would be affected with more features perturbed, we conducted another round of perturbations, this time only on MDP_4 and with **all** of its features (barring ‘ssl’) perturbed. The results show that the performance of the policy was not affected by the extended perturbations. This means that the MDP_4 is more robust towards deviations from the expected dynamics derived from the data. Hence, we have increased confidence that such policies would be robust in the real-world setting, maintaining their performance for students that exhibit different learning characteristics than those averaged over the observations in the EdNet dataset.

Taking the three offline evaluation results in combination we conclude that MDP_4 demonstrated the best performance across representations and perturbations.

7. DOMAIN RELATED INSIGHTS

By analyzing the state values and the policies derived from the RL algorithms, we can discover interesting insights in the way the policy behaves with respect to different learners. We demonstrate this approach on the simpler MDP_B which is based on the 3 features: topic familiarity, correct so far and average time. In figure 4, we plot the derived state values against the av_time and correct_so_far features in MDP_B. Based on our reward design, the state values indicates the future user performance. The expected future performance of the policy is much higher when the student has a high correct_so_far answer ratio. However, the relationship between the average time and state values is more complex. At higher values of ‘correct_so_far’, a higher ‘av_time’ entails a larger state value, but when ‘correct_so_far’ is low, the opposite is true and in such a case lower values of ‘av_time’ entails a larger state value. This means that for students with lower success so far, faster average time is indicative of higher future success. We hypothesize that this is due to the policy’s inability to significantly assist students which are consistently unsuccessful in solving questions and which are also taking relatively long time to dwell on each and every question. We note that even if the policies themselves are not used, findings like this can inform us of useful features and their relationships in predicting future user performance following informed interventions. Such findings can also inform us on the limits of automated approaches, and on the need for additional tailored support for struggling students, e.g. by supplying personalized human assistance where automated approaches are expected to demonstrate low effectiveness.

Analyzing the action choices in the policies, we discover that the RL algorithms tend to put preference on level 4 actions (harder questions). Indeed these do yield the highest reward and the lowest punishment in our reward design. One possible extension is to investigate how a change in the reward function design would impact the policy preferences.

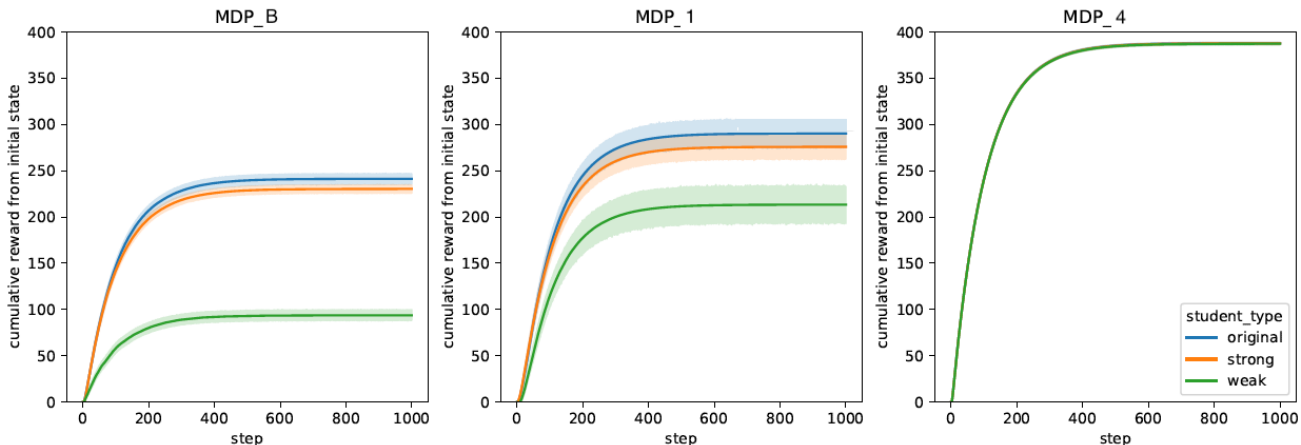

Figure 3: MC Policy Evaluation of the original policy under the perturbed MDPs

Figure 4: State values vs features

Again, even if the computed policies are not deployed in the field, such analysis can be useful as a technique in letting the data guide pedagogical strategies, for example by connecting pedagogically justified rewards to sequencing policies that maximize such a reward given the available data.

8. CONCLUSIONS AND FUTURE WORK

In this paper we approached the challenge of designing an adaptive RL based policy for optimizing the sequencing of learning materials to maximize learning. Human tutors usually outperform their computer counterparts, in that they are able to adapt to certain cues exhibited by the student during learning [34]. Training an RL policy with actual users is far too resource intensive. Therefore, we simultaneously tackle the problem of training and evaluating an RL algorithm offline based only on pre-collected data. A purely data-driven student model was created for this purpose. We hypothesized that a complex model is required to capture the intricacies of human learning. To investigate this theory, a large dataset, EdNet, was necessary to provide sufficient

support for the models.

Our student model was constructed in the form of a data-derived MDP, with the transition and reward dynamics estimated from the observations in the data. The raw logs were transformed into domain inspired features. By using the MDPs we then trained our agents with the model-based Policy Iteration algorithm. To determine whether a more complex model yields better tutoring, we employed a greedy iterative augmentation procedure. The ECR metric guided how we chose our features and demonstrated the positive relationship between representation complexity and policy performance. In our analyses we discovered issues with Out of Distribution actions in the policies and presented a solution in the form of penalising rewards. We further evaluated our policies using the Monte Carlo and Importance Sampling Policy Evaluation algorithms and tested the policies robustness against domain informed perturbations of the dynamics. We show that the larger representation are less impacted by the perturbations and therefore can provide a more equal learning experience for stronger or weaker students.

Several limitations are acknowledged which consequently open up further investigations. The influence of the bin-size on feature preference in the representations was discussed briefly but lacked conclusive evidence to rule out entirely. This work is necessary to ensure that the features are selected based only on the utility of the domain information they capture. From our model-based policy analyses we also discovered out-of-distribution actions in the policy space. Though we managed to remedy the problems for completely unseen actions through strong penalisation, the next course of action is to also penalise low supported actions/states **variably** according to their uncertainty as was explored by [20, 35]. We would also like to compare our approach to other feature selection and augmentation algorithms, such as genetic based metaheuristics [24]. Finally, the inferred policies should be evaluated in the real world in a controlled study.

ABSTRACT

Knowledge tracing (KT) models are a popular approach for predicting students' future performance at practice problems using their prior attempts. Though many innovations have been made in KT, most models including the state-of-the-art Deep KT (DKT) mainly leverage each student's response either as correct or incorrect, ignoring *its content*. In this work, we propose **Code-based Deep Knowledge Tracing (Code-DKT)**, a model that uses an attention mechanism to automatically extract and select domain-specific code features to extend DKT. We compared the effectiveness of Code-DKT against Bayesian and Deep Knowledge Tracing (BKT and DKT) on a dataset from a class of 50 students attempting to solve 5 introductory programming assignments. Our results show that Code-DKT consistently outperforms DKT by 3.07 – 4.00% AUC across the 5 assignments, a comparable improvement to other state-of-the-art domain-general KT models over DKT. Finally, we analyze problem-specific performance through a set of case studies for one assignment to demonstrate when and how code features improve Code-DKT's predictions.

1. INTRODUCTION

Modeling student knowledge to predict performance on future problems, called Knowledge Tracing (KT), is a fundamental feature of intelligent tutoring systems [50]. KT models enable tutoring systems to support mastery learning [14], select appropriate next problems [1], provide help [46], and provide analytics to instructors [34], all of which can improve learning. KT models have increased in complexity from the early 4-parameter Bayesian Knowledge Tracing (BKT) to modern models that train deep neural networks with tens of thousands of parameters using the latest deep learning innovations (e.g. attention [54] and transformers [51]). This has

led to improvement in KT model performance, especially for larger datasets, e.g. from ASSISTments [41, 17].

The *simplest version* of the KT problem uses only the sequence of: 1) which problems the student has attempted, and 2) whether or not each attempt was correct. While this makes KT models widely applicable across domains, this also omits a potential wealth of information about *how* the student attempted each problem. Increasingly, ITS being built to support complex problem solving tasks, like programming in Snap [35] and in games [22], logic proofs [30], science inquiry [25] and language learning [47]. In these domains, correctness may not provide enough information about student knowledge, varying significantly in the reasons both for incorrectness and correctness. In programming, for example, one incorrect attempt may have a minor syntax error while another includes a clear misconception. Similarly, two different *correct* answers could reveal dramatically different levels of concept mastery depending on their conciseness and the concepts used. Most KT models would treat all correct and all incorrect attempts identically. A domain-specific KT model, e.g. those for science by Rowe et al. [40], might greatly improve KT performance. Little work has investigated whether domain-general KT models can predict student success in programming, or how domain-specific features might improve performance.

In this paper, we explore when and how features extracted from students' submitted code can improve a KT model for programming. To do so, we introduce a novel code-based deep knowledge tracing (Code-DKT) model, which uses the code2vec model [4] to learn a meaningful representation of student code, and combines this with Deep Knowledge Tracing (DKT) [34] to track student progress. Specifically, student code submissions are represented with abstract syntax trees, and split into multiple code paths [4] (explained in Section 3). We assign the importance of different code paths by learning weights guided by the scores students received for the current and past submissions. We compared the performance of Code-DKT with baseline BKT and DKT models on a dataset of 50 introductory programming problems from 410 students, across 5 assignments. Our experiments show that the Code-DKT model is able to consistently improve DKT's performance by 3.08-4.00 percentage points in AUC. This improvement is comparable to that of other modern KT models over DKT (2-4%) [31, 44], suggesting that domain-specific features may be just as important as model structure. Finally, we investigate one assignment through 3

case studies to explore the mechanisms by which code features may improve the model, and when they are most useful. We also show that Code-DKT outperforms more naive code-feature models. Overall, this paper makes three contributions: 1) the Code-DKT model, which extends DKT for programming tasks; 2) evidence that Code-DKT outperforms both domain-general models and naive code-feature models; and 3) evidence of when and how Code-DKT’s code features improve model performance.

2. RELATED WORK

In this section, we present related work on knowledge tracing, student modeling in computer science education, and deep learning models for code/programs.

2.1 Knowledge Tracing

Knowledge tracing (KT) models student knowledge as they solve problems to predict future performance. In KT, problems are labeled with needed skills (i.e. knowledge components, KC) [49], the skill or q-matrix can be learned from data [9], or the problem ID can be used instead. In Bayesian Knowledge Tracing (BKT), the most popular KT method [14], a simple Bayesian model is built to model student knowledge using parameters for guess (getting a problem right when a skill is not known), slip (getting it wrong when known), and transition from unlearned to learned after practicing. These parameters are learned from prior students’ problem sequences, and then used to predict future performance. Researchers have improved BKT performance, for example, by calculating the bound or prior distribution of parameters [8], adding a priori estimates of student learning [32], or integrating speed factors [56].

A number of innovations have improved *domain general* KT, without using additional features from student’s work (only the correctness of each problem attempt). With the development of machine learning technologies and increasingly available large datasets, models based on deep learning have been proven more effective, especially with enough available data [17]. Piech et al. introduced deep knowledge tracing (DKT), using recurrent neural networks (RNN) to predict a student’s knowledge of each skill (or problem) after each problem attempt, and to learn the relationships among skills automatically [34]. As our work is based on this model, we will discuss the details of the model in Section 3. Some recent advances in deep learning for knowledge tracing focus on model structure, including SAKT and SAINT. Self-attentive knowledge tracing (SAKT) [31] added a self-attention mechanism [54] to DKT, while Separated Self-Attentive Neural Knowledge Tracing (SAINT) [12] later integrated a transformer (a type of deep neural network which has been successfully applied in text and image processing areas) into a knowledge tracing model [51]. Both of these models have outperformed DKT, especially on large datasets such as EdNet [13], e.g. by 2% AUC.

While these innovations have improved KT performance, often using complex networks and larger datasets, the datasets used generally only indicate whether a student’s attempt was *correct*, but not the *content* of a student’s answer or their *process* for achieving it, and the models therefore do not use this information. However, researchers have incorporated *other types* of information into deep models, such as course

prerequisites or the relationships among problems. For instance, Chen et al. attached prerequisite information in the DKT modeling process for a more accurate prediction [10]. The prerequisite concepts were modeled as graph matrices (as done by Wang et al. [53]), serving as an additional input to knowledge tracing models, similar to skill or q-matrices that can also be learned from student data [9]. On the other hand, Ghosh et al. introduced attentive knowledge tracing (AKT) [18]. They introduced a decay parameter to explicitly reduce the impact of distant problems, and at the same time used a Rasch model [37] to incorporate problem contexts, then embedding the differences among the problems. Student information can also be used for knowledge tracing models. Educational priors such as a learning or forgetting curves can be integrated into deep knowledge tracing models [11]. The closest such models come to incorporating students’ solution processes is including information about how *fast* students solved a problem. Yudelson et al. [56] added speed factors into BKT, and similar temporal information can also improve the performance of deep models (e.g. [44]).

None of the above work have used the student response information, besides submission correctness, in their models. This could be partially because of the simplicity of the problems. Most of them are true or false, multiple choice problems, or short answer problems. The availability of the exercise data is also limited, as some datasets only contains a sequence of binary correctness scores from students. Recent work (e.g. EKT, EERNN [45, 26]) used a joint embedding of *exercise* text and response correctness, combining the exercise text embedding together with student scores to represent student individualized submissions. This achieved better performance than the other models without using this information. However, these models only use *problem information*, but no information about the *students’ answer* beyond binary correctness information. This suggests an opportunity to create improved, *domain-specific* KT models in areas such as programming, math, science or writing, where students’ answers include complex written responses or structured problem-solving steps. Recent work has incorporated such problem-specific data in deep learning approaches used to adapt pedagogical policies for tutoring in logic [27], probability [58], or predict performance in programming [29] but generally have not been used to built KT models in these domains. In the domain of programming education, for example, students’ code submissions contain rich information on the state of their current knowledge. As proposed in this paper, more structural information could be extracted from student code submission to infer students’ learning status of certain concepts. We use these code features to make better knowledge tracing models.

2.2 Student Modeling in CS Education

Researchers in CS education have explored ways to model student source code for intelligent tutoring. In 2011, Jin et al. proposed that a linkage representation that reflected code structure could be used for programming hint generation [23]. In 2014, Yudelson et al. extracted code features from a MOOC on introductory Java programming to explore code recommendation methods [55]. Their work focused on using a combination of problem correctness and extracted code features to predict student success, and use this prediction to recommend an appropriate next problem to a stu-

dent. While they did not evaluate their model on a KT task per se, their approach of extracting atomic code features is somewhat similar to our TFIDF baseline (Section 4.3). Another work from Rivers et al. used code features for student learning curve analysis and attempted to directly extract meaningful knowledge components (and whether they were successfully applied) from student code [39]. In their work, student code submissions are represented as abstract syntax trees (ASTs), with the node types of ASTs (e.g. `for`, `if`) representing knowledge components (KCs). The error rate curves (referred to as “learning curves”) were plotted over time, visualizing the mastery of different KCs. They showed that while code-based KCs produced well-fitting curves, others did not. While this suggests the possible validity of AST-based KC extraction, the work did not directly evaluate the utility of these KCs for knowledge tracing. Like our current work, Wang et al. showed that incorporating structural code features can improve DKT for a single problem from a large “hour of code” (HoC) dataset [52]. However, this HoC exercise has a very simple solution, so their results may not generalize. Additionally, their features were learned in an unsupervised way from ASTs, while our approach learns an embedding from the data.

Code features have also been used in tasks other than KT as well, such as common bug identification in student code. Traditionally, experts manually examined student code to identify common bugs in different student levels and programming languages, such as Java [48] or block based programs [20]. However, manual examination is expensive for large-scale and quantitative studies. More advanced work takes advantage of the growing size of datasets, and used data-driven methods to find bugs in student code submissions. For example, Choi et al. used simple machine learning methods to detect malicious code in code by using simple feature extraction methods such as counting neighboring tokens in code text (n-gram). With the recent advance of computational power and even bigger datasets, more deep learning methods have emerged. These methods focused on developing deep neural network methods to extract structural information for automatic student bug detection. For example, Gupta et al. used a matrix to represent the ASTs of student code to localize student code submissions [19] in a large dataset (270K samples). For smaller sized dataset, Shi et al. evaluated the bug detection performance with the help of semi-supervised learning [42], and have also shown that unsupervised learning is possible with the help of experts [43]. All these methods reported better performance than traditional data-driven models on their tasks, showing the feasibility of similar usage on KT tasks.

While we focus on using student code submissions to extract features for student programming KT tasks, other less complicated approaches exist. Original programming tutors such as ACT [15] and Lisp tutor [6] decompose computational problems into small steps and let students make choices. This facilitates the KT tasks, as in these datasets, student submissions are simple multiple choices. However, with the development of newer Intelligent Tutoring Systems (ITSs), more systems provide intelligent support to students’ written code. This provides better practice for students, but also makes knowledge tracing in computer science a more challenging task. Our paper aims at extracting code fea-

tures for KT tasks in these new datasets.

2.3 Deep Code Learning

Besides code feature extraction in the CS education domain, programming code has also been analyzed with data-driven models in software engineering research. For example, Allamanis et al. used neighboring tokens in source code (n-grams) to represent programming code, borrowing methods from natural language processing studies to predict method names in big code datasets [3]. Later work further explored extracting features from code structure, such as Raychev et al. who used decision trees to model programming code, making probabilistic predictions on the types of nodes in AST [38]. However, these simple structural approaches are often outperformed by newly developed deep learning models, especially when applied to big datasets.

Deep neural networks have been applied in the software engineering domain, and achieved better performance than traditional data-driven methods. For example, Allamanis et al. used convolutional neural networks (CNNs) to classify code functions [2]; Mou et al. reworked the CNNs to an AST version, using the parent-children direction information in tree representations. Both methods greatly improved method classification tasks on classical machine learning models. Another recent model, code2vec, outperformed these models. Alon et al. designed this model, which leverages nodes and traversal paths in the ASTs to represent programs [5]. In their work, the leaf nodes of the ASTs are selected to represent the semantic information about the code. In addition, as there is a path through the AST from every leaf node to any other leaf node, this path is extracted to represent the code’s structural information. The traversal paths together with the corresponding leaf nodes serve as the basic units of a representation of code [4]. The code2vec model calculates the weight of each code path using an attention mechanism [54] to automatically classify function names. Code-DKT’s code extraction component is based on the code2vec model, but adds score to the attention mechanism to assign weights to code paths [4] for predictions.

We chose code2vec to represent student code in DKT due to its recent successes for modeling code, and its attention mechanism. The attention mechanism learns weights for different features, allowing the model to directly use score information to select the most predictive code paths. Future work could investigate other code representations such as ASTNN, which has also been applied to make predictions from student code [28], or more recent advances such as CodeBERT [16].

3. METHOD

Problem Definition: Knowledge tracing (KT) tasks model a prediction problem: Given the history of a student’s attempts at various KCs/problems, the model predicts if the student will succeed on their next attempt ¹. Specifically, we define each student attempt \mathbf{x}_t at time t as (q_t, a_t, c_t) , where q_t is the problem ID, a_t is the correctness, and c_t is the program code submitted for this attempt. Historically, KT algorithms have only utilized q_t and a_t , and in this work we extend the input sequence to include c_t . At each timestep T ,

¹We use problemIDs for KCs in this work

Figure 1: Recurrent neural network structure.

the model is given the T -length student attempt sequence $\mathcal{S}_T = \{(q_1, a_1, c_1), (q_2, a_2, c_2), \dots, (q_T, a_T, c_T)\}$, and it predicts whether the student’s next attempt ($T + 1$) on a given problem (q_{T+1}) will be correct (a_{T+1}). Note that students may attempt problems multiple times, and the model will make a prediction at each attempt.

Our proposed Deep Code Knowledge Tracing (Code-DKT) model integrates deep knowledge tracing (DKT) [34] with the code2vec classification algorithm [5]. In this section we introduce the DKT model and how we enhance it with code feature extraction and selection.

3.1 Deep Knowledge Tracing

Deep knowledge tracing uses a recurrent neural network (RNN) structure to learn the probability that a student will make a correct attempt on a subsequent problem. In the original implementation of DKT, the authors also implemented a version of DKT using a long short term memory (LSTM) model [21], which is widely perceived as an advancement over RNNs. For simplicity, we explain DKT using an RNN model; we performed DKT using both RNNs and LSTMs. In the experiments, the LSTM version yielded higher performance² (see performance comparison in Section 5.1.4). We chose DKT as our baseline model, to compare with and to extend, as it is a commonly used baseline in other more recent KT papers [31, 44]. Further, its LSTM structure makes it straightforward to extend with code features and to directly evaluate those features’ contributions. Some recent models have outperformed DKT, but only by about 2-4% AUC [31, 44], suggesting that DKT is still representative of modern deep KT models.

Model Input: For each student, DKT (RNN) takes as input a sequence $\mathcal{S} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_T\}$ of T attempt vectors \mathbf{x}_t . With M problems, each attempt consisting of problem-correctness pair $\{q_t, a_t\}$ at time t , is one-hot encoded into a binary vector \mathbf{x}_t of size $2M$, where $x_{q_t+M(1-a_t)}$ is set to 1, and the other bits are set to 0. For example, with $M = 3$, for student success on problem 1, $q_t = 1, a_t = 1$, so $x_{1+3(1-1)} = 1$, so $\mathbf{x} = \{1, 0, 0, 0, 0, 0\}$, and failure on problem 1 $q_t = 1, a_t = 0$, so $x_{1+3(1-0)} = 1$, so x_4 is set to one, and \mathbf{x} is $\{0, 0, 0, 1, 0, 0\}$.

Model Structure: The RNN version of DKT maps each input sequence \mathcal{S}_T into an output sequence of predictions $\mathcal{Y} = \{\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_T\}$ with a set of hidden states $\mathbf{h}_1, \mathbf{h}_2, \dots, \mathbf{h}_T$. More specifically, as illustrated in Figure 1, this process is

²See the appendix of [34] for the LSTM DKT equations.

defined as:

$$\mathbf{h}_t = \tanh(\mathbf{W}_{xh}\mathbf{x}_t + \mathbf{W}_{hh}\mathbf{h}_{t-1}),$$

$$\mathbf{y}_t = \sigma(\mathbf{W}_{hy}\mathbf{h}_t).$$

In the equations, element-wise operators $\tanh(\cdot)$ and $\sigma(\cdot)$ are activation functions of the network, introducing non-linearity to the network. The parameters learned in the network are \mathbf{W}_{xh} which transforms input \mathbf{x}_t into the hidden space, \mathbf{W}_{hh} which fuses the hidden state \mathbf{h}_{t-1} from the prior input with the current hidden state \mathbf{h}_t , and \mathbf{W}_{hy} which translates the hidden state h_t into an output. In both equations, the bias terms are omitted for simplicity, and the \mathbf{h}_0 is the initial hidden state, the zero-vector.

Model Output: The output sequence \mathcal{Y} contains prediction vectors \mathbf{y}_t , sized M . Every element of the vector represents the probability of the student making a correct submission on corresponding problems in their next attempt. Note that while the model makes predictions for each problem at each timestep t , only the value for the next attempted problem q_{t+1} is used during training and evaluation.

3.2 Deep Code Knowledge Tracing

We extend DKT into Deep *Code* Knowledge Tracing (Code-DKT), by using the code2vec [5] representation of student code attempts, c_t , along with problem and correctness information.

Code Representation: Abstract syntax trees (ASTs) are used to represent the hierarchical structure of code, for example with a node for a function (`method`) with children representing the function’s parameter (`input`) and body (`body`). AST leaf nodes often correspond to literal values or identifiers. Code-DKT extends the code2vec model for code classification, which encodes an AST using a set of *leaf-to-leaf paths* throughout the AST. For example, in Figure 2, a path from the leaf node `input` to the leaf node `"value"` (highlighted red in the example) consists of the nodes: `[input, method, body, String, "value"]`. Given an AST, code2vec extracts a set of leaf-to-leaf paths, as explained below.

Model Input: Since a deep learning model cannot operate directly on code paths, the Code-DKT must next convert this code-path representation of the AST into a binary vector. A student’s code submission c_t at time t is represented as $\{p_0, p_1, \dots, p_R\}$ where there are in total R randomly selected code paths in c_t . Every p_r has three components, namely the starting node of the code path \mathbf{s}_r , the textual representation of the full path \mathbf{o}_r , and the ending node \mathbf{q}_r , which are each one-hot encoded as binary vectors. For instance, for the example in Figure 2, \mathbf{s}_r is `input`, \mathbf{o}_r is a text string: `input|method|body|String|value`, and \mathbf{q}_r is `value`.

Model Structure: Rather than using a *static* vector representation of students’ code, Code-DKT *learns* an optimal embedding of student code. The detailed Code-DKT model structure is shown in Figure 3. This initial structure is drawn from code2vec. The nodes for each of R code paths in c_t (c_t has in total R paths), including starting and ending nodes ($\mathbf{s}_r, \mathbf{q}_r$) and paths \mathbf{o}_r for a single path r , are respectively embedded by the node embedding matrix \mathbf{W}_{encode}

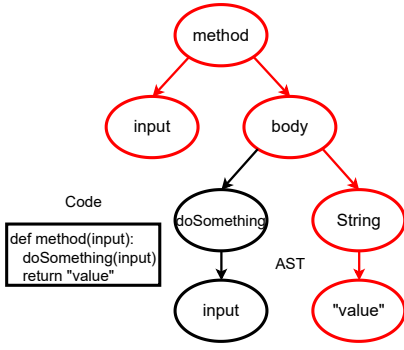

Figure 2: A simple AST where red nodes and edges represent a leaf-to-leaf path from input to "value".

and the path embedding matrix \mathbf{W}_{epath} . Both matrices are randomly initialized with a Gaussian distribution, but they are later updated during model training. The Code-DKT model structure then diverges somewhat from code2vec, to account for the specific needs of the KT problem. Specifically, the three embedded vectors representing c_t are concatenated with the problem-correctness vector \mathbf{x}_t from DKT (introduced in Section 3.1). This serves as a numerical representation of (q_t, a_t, c_t) . For a single code path p_r , this process is accomplished with embeddings for the start node ($\mathbf{e}_{s,r}$), path ($\mathbf{e}_{o,r}$), and end node ($\mathbf{e}_{q,r}$):

$$\mathbf{e}_{s,r} = \mathbf{W}_{enode} \mathbf{s}_r; \mathbf{e}_{o,r} = \mathbf{W}_{epath} \mathbf{o}_r; \mathbf{e}_{q,r} = \mathbf{W}_{enode} \mathbf{q}_r,$$

$$\mathbf{e}_r = [\mathbf{e}_{s,r}; \mathbf{e}_{o,r}; \mathbf{e}_{q,r}; \mathbf{x}_t].$$

Score-Attended Path Selection: Code-DKT now has an numerical representation of a single attempt: a set of R embedded vectors, \mathbf{e}_r , one for each code path in c_t . Note that the embedding, \mathbf{e}_r not only includes the code information, but also the current correctness score information \mathbf{x}_t at the submission t . However, not all parts of a student's code are relevant, and thus not all code paths \mathbf{e}_r are important for predicting a student's future success. Therefore, the model uses an attention mechanism to identify how much weight to give to each of these paths. The embedding vectors $\mathbf{E} = \{\mathbf{e}_0, \mathbf{e}_1, \dots, \mathbf{e}_R\}$ are multiplied by the attention matrix \mathbf{W}_a to get R scalars a_0, a_1, \dots, a_R , representing the importance (commonly known as the "attention") of each of the code paths. The importance a_r uses a SoftMax mechanism for normalization, having 1 as the sum. This process is formulated as:

$$\alpha = \text{SoftMax}(\mathbf{E}\mathbf{W}_a)$$

$$\text{SoftMax}(\mathbf{a}) = \frac{e^{a_i}}{\sum_{i=1}^R e^{a_i}}$$

where each elements α_r in $\alpha = \{\alpha_1, \alpha_2, \dots, \alpha_R\}$ are the calculated weights for the code path p_r . Finally, Code-DKT weights each code path \mathbf{e}_i by its attention α_i , and sums them together, giving a weighted average: a single vector representing the important parts of the code. The weighted average vector is then multiplied by a matrix \mathbf{W}_0 to get the code vector \mathbf{z} , representing features extracted from code

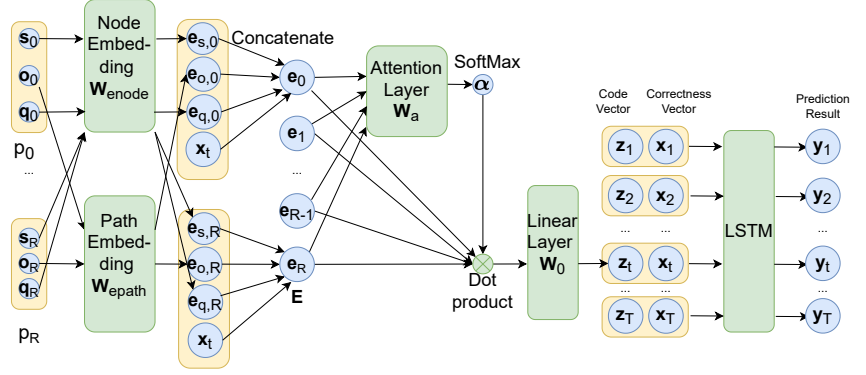

Figure 3: Code-DKT model structure.

submissions, as in equation:

$$\mathbf{z} = \mathbf{W}_0 \left(\sum_{i=1}^R \alpha_i \mathbf{e}_i \right).$$

In a sequence of T student attempts, Code-DKT produces T code vectors $\{\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_T\}$. The code vectors are concatenated with the correctness vectors $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_T\}$ as the input to the final LSTM (as in DKT), giving the predictions $\{\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_T\}$. Even though \mathbf{x}_t was already used to produce \mathbf{z}_t , this final concatenation ensures the Code-DKT model has direct access to the student correctness score information.

4. EXPERIMENTS

We designed an experiment to evaluate 3 research questions about student modeling in the domain of programming:

- RQ1** How effective are domain general KT approaches (DKT, BKT) on our programming dataset?
- RQ2** How can features derived from students' code be used to improve KT models?
- RQ3** When are these code features most useful, and how can they lead to improved predictions?

4.1 Dataset & Experiments Setup

Our study uses a dataset of an introductory Java programming class at a large, university in the US, collected in Spring 2019, stored in the ProgSnap2 format [36]. The dataset includes work from 410 students on 50 problems divided over 5 assignments. These were completed throughout the semester as homework, with each assignment focusing on a specific topic (e.g. conditionals, loops). For these problems, typical solutions ranged 10 to 20 lines of code. Students tended to make multiple submissions before succeeding finally, and 23.68% of the attempts were correct. Student code was automatically graded using test cases, and We treated a submission as correct (1) only when all test cases passed, and incorrect (0) otherwise.

For each assignment, students were then split into training and testing sets with a ratio of 4 : 1. One quarter of the training data were used for hyperparameter tuning and validation (see below). Then, we trained the model on the whole

Table 1: Performance Comparison on all assignments.

Model	A1	A2	A3	A4	A5
DKT	71.24%	73.09%	76.84%	69.16%	75.14%
Code-DKT	74.31%	76.56%	80.40%	72.75%	79.14%

Table 2: Overall and the first attempt performance of all models on assignment A1.

Models AUC (STD)	Overall	First Attempts
Code-DKT	74.31% (0.90%)	75.74% (0.69%)
DKT-TFIDF	69.94% (0.88%)	72.77% (0.79%)
DKT-Expert	69.52% (0.68%)	69.53% (0.72%)
DKT	71.24% (2.54%)	72.26% (3.69%)
BKT	63.78% (4.68%)	50.22% (2.86%)

training dataset, and tested on the holdout test dataset, repeating this process 10 times to account for model variation (e.g. due to random initialization). All deep learning models were implemented using the PyTorch[33] library, and our BKT implementation was pyBKT [7].

4.2 Hyperparameter Tuning & Optimization

For hyperparameter tuning, we split the training data into training and validation sets, and created a model with each possible set of hyperparameters (described below), and calculated AUC performance on the validation dataset. We repeated this process 100 times and chose the hyperparameter setting with the best average validation performance to use in testing/evaluation. Specifically, we selected the embedding size of code feature extraction as 300, from a range of (50, 100, 150, 300, and 350); learning rate was selected as 0.0005 from a range of (0.00005, 0.0005, 0.005, 0.01); the training epochs were set at 40 to save training time while keeping the best prediction results, selected from a range of (20, 40, 100). All other parameters were defaulted as the original settings of code2vec and DKT. We fixed the longest length of student attempts at 50 to filter extra long submission traces from students. In cases where more than 50 attempts were submitted, we used the last 50 submissions, assuming the latest submissions were more useful.

As the models were deep neural networks, we used binary cross entropy as a loss function to track the difference between the ground truth and predicted probabilities. The models used back propagation to update weight matrices (parameters), using the Adam optimizer [24], which is also a default for code2vec and DKT.³

4.3 Baselines

We compare the performance of Code-DKT to DKT, BKT, and two modified DKT methods: DKT-TFIDF adding data-driven features, and DKT-Expert adding expert features. Specifically, DKT-TFIDF uses TFIDF, a data-driven feature that counts the term frequency (TF) of tokens (variables, functions, and operations, etc.) in code text, and forms a frequency vector for every term. This frequency is multiplied by the inverse document frequency (IDF) to show how often terms show up in *unique* documents. As students use various

variable names, we limited the top 50 best features (selected from a range of (30, 50, 100, 300) in hyperparameter tuning) in TFIDF to remove redundant features. For the DKT-Expert model, two authors examined the problems in the dataset, and determined 9 rule-based code features. These features include code component existence checks such as the usage of `else if` statements, the usage of `&&` operations, etc. These statements and operations represent students’ usage of certain concepts such as writing alternative conditions, or using “and” logic to solve a problem.

To improve the TFIDF and Expert models to serve as more robust baseline models, we added one additional set of features (only to baseline models) to encode information about the skills practiced in each problem, as has been done in prior work [57]. Two authors examined the problem descriptions and solutions and agreed on 9 skills we expected students to learn. For example, one skill was solving problems with negative conditions in the instructions (using words such as “unless”, “otherwise”), requiring students to negate these conditions in their code. We represented each problem as a binary vector of practiced skills, and we used this skill vector to represent problems, instead of the one-hot encoded problem ID (see Section 3.1 for model input encoding). Testing on the validation dataset showed slightly improved performance using these skill vectors.

Metric: Our primary performance metric is AUC, a standard evaluation metric for KT models [34, 44, 31], as it uses the predicted *probability* of success, rather than a binary correctness prediction, and is more appropriate than accuracy for imbalanced datasets like ours (23% positive).

5. RESULTS

5.1 Performance Comparison

5.1.1 Code-DKT vs DKT

Table 1 shows a comparison of DKT and Code-DKT across all 5 assignments (the average of the 10 test runs). Note that for each assignment, a new model is trained and tested separately, without using data from prior assignments. This was because assignments were spaced out with weeks between them, including additional learning content, so students’ performance on prior assignments is less relevant. To address RQ1, we consider the overall performance of the baseline DKT model on our dataset, which has an AUC of 69-75% across assignments. This low score means it may be difficult to use model predictions to inform instruction or an automated intervention, as we discuss in Section 6. To address RQ2, we see that Code-DKT *consistently* outperforms DKT by 3-4% AUC on each assignment. This shows that our approach, which augments correctness features with additional information from student code, can improve DKT predictions. For perspective, this improvement is comparable to SAINT+’s improvement over DKT on EdNet (+2.76%) [13], or SAKT’s improvement on various datasets (+3.8%) .

5.1.2 Code-DKT vs Naive Code Features and BKT

We now investigate a single assignment, A1, to illustrate Code-DKT’s performance, and create a DKT-Expert baseline using assignment-specific, expert-authored code features. We selected assignment A1, as it came first (and was therefore not influenced by prior assignments) and its skills are

³Repository: <https://github.com/YangAzure/Code-DKT>

the least complex. Table 2 shows the performance of Code-DKT, DKT, as well as 3 new baselines: BKT, and 2 simple code-feature extensions of DKT: DKT-TFIDF and DKT-Expert (described in Section 4.3). Model performance is given for predicting all attempts (Overall) and for predicting only first attempts at each problem. The results show that neither the simple expert features nor the TFIDF data-driven features improve the overall performance of DKT. These simple features derived from student code instead negatively affect overall performance. This suggests that a more effective model structure is necessary for making use of code features, such as our Code-DKT model. We also see that BKT has an AUC score of only 63%, suggesting that deep models are more effective for our dataset.

5.1.3 When is Code-DKT Effective?

We used assignment A1 to investigate *when* Code-DKT was more effective than DKT, helping to answer RQ3.

Overall vs First Attempts: We investigated Code-DKT’s performance at predicting a student’s *first* attempt at each problem (Table 2, column 3). First attempts are important in a KT task because they represent points at which an ITS might make key interventions (e.g. offering a worked example if a student might fail at problem solving). Therefore, many KT evaluations differentiate a student’s first attempt on a task (where a model must make predictions using only performance on *other* problems) from subsequent attempts. This distinction also helps us understand when the Code-DKT model is most effective. One might ask, is Code-DKT using student code submissions to learn a better representation of student knowledge (which *would* help it predict first attempts), or is it simply estimating how close a student is to solving the *current* problem (which would only help to predict *subsequent* attempts). Our results shows that Code-DKT actually performs *best* when predicting first attempts, and it also shows a similar improvement over DKT for first attempts (+3.48%), compared to all attempts (+2.93%) . This suggests that the content of a student’s code is helpful for not only predicting how quickly they will solve the *current* problem, but also *future* problems.

Problem-specific Performance: Table 3 shows the decomposed AUC performance of Code-DKT and DKT on each problem. We observe that Code-DKT outperforms DKT overall on 6 of the 9 problems. The difference ranges from +15.54% AUC (problem 13) to -4.43% (problem 236), suggesting that the benefit of Code-DKT’s code features depends somewhat on the programming problem. It also shows that code features *can* reduce model performance, but the potential for Code-DKT’s improvement seems to be greater than the potential for harm.

To understand *when* Code-DKT’s code features were useful, we investigated differences between the problems where it outperformed DKT and those where it did not. We found that many of the problems where there was improvement shared similar learning concepts and solution structure. For example, problems 3, 232 and 234 all used the “independent choice” programming pattern, which is often solved with nested if-statements. Similarly, problems 1, 3, 5 and 13 all included a pattern where one condition changes a value used in another condition. These common patterns seem to have

Table 3: Decomposed performance of Code-DKT and DKT AUC performance on different problems in assignment A1.

Problems	Code-DKT		DKT	
	Overall	First	Overall	First
234	64.60%	71.38%	63.75%	73.48%
13	78.45%	86.55%	63.59%	68.81%
232	74.93%	78.99%	72.49%	73.09%
233	64.79%	74.57%	67.18%	76.33%
5	75.38%	81.34%	74.28%	81.79%
235	70.65%	71.96%	75.03%	70.80%
236	74.25%	74.30%	78.68%	77.06%
1	68.62%	70.32%	66.67%	73.20%
3	71.00%	71.00%	64.02%	64.02%

helped the model make better predictions on problems that used them. However, 2 of the 3 of the problems where Code-DKT performed poorly involved a unique learning concept that did not appear in any other problems. For example, problem 236 requires students to check if any 2 of the 3 given variables are equal (which has no analog among other problems) and 233 requires the `Math.abs` function (which many students failed to use correctly). Together, these results suggest a hypothesis that Code-DKT’s code features are most useful at predicting problems that share code structures with other problems, and less useful at predicting problems that emphasize novel code structures. This suggests Code-DKT may be successfully modeling students’ knowledge of common code patterns.

5.1.4 Ablation Study

Our Code-DKT model design choices include: where to incorporate correctness information, how to update the embedding, and what underlying network to use (LSTM or RNN). Table 4 shows the results of an ablation study on assignment A1 to determine which of these choices improved the performance of our final DKT model (first row). The final Code-DKT model concatenates the *correctness* of a students’ attempt with code features in two places (see Section 3.2): before the attention mechanism (the vector \mathbf{e}_r), and in the final trace fed into the LSTM (\mathbf{z}_i concatenated with \mathbf{x}_i). The model in row 2 only includes correctness information in the first case, and row 3 includes it only in the second case. Both models lose performance, but not by much (0.5%), suggesting that correctness information helps both in attending to relevant code paths, and final predictions, but this information is somewhat redundant. We also investigated using an RNN (row 4) instead of an LSTM, but this was, as predicted, moderately less effective. Finally, recall that Code-DKT uses `code2vec` to embed students’ code as a vector, and updates this embedding throughout model training. Row 5 shows a version where we pretrained this embedding on the training dataset, using `code2vec` to predict the correctness of students’ code, and then fixed the embedding when training the LSTM. This model does much worse, suggesting that the relevant features for predicting the *correctness* of code are different from those for predicting *future performance*.

5.2 Case Studies

Figure 4: Code-DKT generated correctness predictions heatmap for a student.

Figure 5: DKT generated correctness predictions heatmap for a student.

Table 4: Code-DKT ablation study on A1.

	Model	Overall AUC
1	Code-DKT (Final Model)	74.31%
2	Correctness: Attention Only	73.81%
3	Correctness: Trace Only	73.84%
4	Model: RNN	73.63%
5	Embedding: Static	68.74%

To further answer RQ3, we examined *how* code features may have improved Code-DKT through 3 case studies. We use prediction heatmaps from Code-DKT and DKT for one student, shown in Figures 4 and 5 for Code-DKT and DKT, respectively. The rectangular cells show which problem the student actually attempted (y-axis) at each time-step (x-axis), and the numbers in the cells represent the ground truth values of whether student’s attempt was successful (1) or unsuccessful (0). Black frames indicate correct (i.e. accurate) model predictions, while grey ones indicate incorrect predictions. The color of the heatmap in each cell specifies the predicted probability of students making a correct submission on a given problem (y-axis) at the given time-step (x-axis), and darker means a higher probability of success. For example, in Figure 4, the student makes 4 unsuccessful attempts at problem 13, followed by a successful attempt, then succeeds at problems 232 and 233 in one attempt each.

The heatmaps for the student (Figures 4 and 5) show that Code-DKT is able to make better predictions on the traces than DKT, making 11 out of 16 successful predictions, while DKT is able to make 8 of them correct. Another observation is that Code-DKT heatmaps have much stronger predictions with values close to 1 or 0 compared with DKT, showing that with code features, the model is more confident.

Case A: Successful Prediction: In Case A, Code-DKT uses code features to make better predictions than DKT on the predictions of the student’s final submission on Problem 235. As shown in Figures 4 and 5, while both Code-DKT and DKT can successfully predict the incorrect submission on the student’s second submission of Problem 235 and fail to predict the correct submission on the third, Code-DKT gives a higher prediction than DKT. In Figure 6, the student’s code submissions show the reason. The student’s second submission is almost correct, demonstrating a correct (if inefficient) nested if-else structure, but they have omitted the nested condition in their else branch. Code-DKT is able to

```

public int dateFashion(int you, int date)
{
    int value = 0;
    if (you >= 8 || date >= 8)
    {
        if (you <= 2 || date <= 2)
        {
            value = 0;
        }
        else
        {
            return 2;
        }
    }
    else
    {
        value = 1;
    }
    return value;
}

public int dateFashion(int you, int date)
{
    int value = 0;
    if (you >= 8 || date >= 8)
    {
        if (you <= 2 || date <= 2)
        {
            value = 0;
        }
        else
        {
            return 2;
        }
    }
    else
    {
        if (you <= 2 || date <= 2)
        {
            value = 0;
        }
        else
        {
            value = 1;
        }
    }
    return value;
}

```

Figure 6: Code at times t and $t + 1$ for Case A, where the code c_1, \dots, c_t is used to predict correctness at $t + 1$.

infer the quality of the student’s code, since its prediction of success probability increased from 44.2% to 49.1% after the student’s second (incorrect) attempt, while DKT’s prediction decreased from 47.7% to 46.7%. Code-DKT’s higher prediction may be because the if-else structure the student was missing was very similar to one they had already written, as shown in Figure 6. These code structures are easily captured by the path-based AST representation used by code2vec. Without code features, it is difficult for DKT to predict whether the student is going to succeed on $t + 1$, since it only knows the student has failed twice, not how close they are to succeeding. Even with code features, there is still a great deal of uncertainty. No matter how close a student is to a correct answer, there is no guarantee they will achieve it on their next attempt. This may help to explain why Code-DKT does not more dramatically outperform DKT overall.

Case B: Unsuccessful Prediction: Case B shows that even when a student’s code is nearly correct for a given problem, it doesn’t guarantee that they will be successful on their next attempt. Sometimes Code-DKT is overconfident in these situations, and incorrectly predicts success, as in Case B. Figure 7 shows the last three attempts the student made on Problem 13: two incorrect followed by a final correct attempt. The only differences between the final attempt and the earlier two is shown in the red frames. The student’s 4th attempt achieved the correct logic for Problem 13, the

```

  }
  return !isMorning;
}

```

Figure 8: Case C, using code from problems 232 and 233 to predict the same student’s performance on problem 5

5th attempt adds an empty `return` statement, and the 6th and final attempt adds the appropriate return value. After seeing the almost-correct code at their 4th attempt, Code-DKT predicted that the student would succeed on the next attempt since the modifications they needed were minimal (just write “`return value;`”), but it took one extra attempt to get it right. An expert might make a similar conclusion, that the student was close enough to realize their mistake and submit a correct answer, and would have similarly been wrong. This highlights the uncertainty present in any KT task and the challenges of applying KT to student code.

Case C: Successful Prediction (First Attempt): Case C illustrates that Code-DKT can also use code from *previous problems* to improve its predictions of *first attempts* of new problems (as shown quantitatively in Table 2). For example, when the student successfully completes problems 232 and 233 in a single attempt, Code-DKT’s prediction of the student’s success on problem 5 increases from 42.0% to 50.0% to 72.5% respectively, leading it to successfully predict success on the student’s first attempt at problem 5. However, DKT’s confidence only modestly increased from 41.8% to 47.3% to 47.0%, leading it to incorrectly predict failure. Both models know that these problems are related, and share some learning concepts (based on how other students’ successes on the problems are related), but Code-DKT’s analysis of the student code allowed it to infer more about the knowledge that

was demonstrated in past problems.

We use these three consecutive code submissions to explain why this may be the case in Figure 8. For example, in Problem 232, the student directly uses Boolean variable in the if-condition (`if (vacation)`) rather than a superfluous comparison (`if (vacation == true)`) that many students use, demonstrating a higher level of understanding. This same direct usage of Boolean variables is seen in the if condition and `return` statement of Problem 5. The code submission on Problem 233 further suggests the student is able to combine logical operators with Boolean variables to `return` a Boolean expression. This occurs again in the `return` statement of the students’ attempt at Problem 5, shown in the lower rectangular. While we cannot know for certain which code features Code-DKT used to make its success prediction for Problem 5, these repeated code structures are one possibility, given code2vec’s ability to recognize repeated patterns in ASTs.

6. DISCUSSION

RQ1: How well do domain-general models perform? We used domain-general KT models (DKT) as the baseline models for our programming dataset. These models performed relatively poorly, averaging 73.09% AUC across assignments. While this is considerably better than chance, the performance may not be high enough to use in some student modeling contexts. For example, for assignment A1, the recall of DKT was 31.4% and the precision was 46.5%, so the model fails to identify two thirds of unsuccessful attempts, and over half of the time when the model predicts a failed attempt, the student actually succeeded. This suggests that KT is a difficult challenge on this dataset. By contrast, DKT has historically been effective on other datasets, which are both larger and in other domains, such as EdNet [13], Assistments [41] and KhanAcademy [34]. One possibility is that the more complex nature of programming problems, with myriad possible correct and incorrect solutions, makes KT prediction more challenging on this dataset, compared to those in other domains. If this is the case, several aspects of programming may contribute to the challenge of modeling student success. Programming problems often require many attempts to get correct (6.1 on average in our dataset), leading to class imbalance. In our dataset, the problem descriptions were complex, and their solutions involved complex conditional logic, and students had to write perfect Java syntax for the program to compile. These factors mean there are many ways for students to make small “slips”, making the relationship between skill and success less direct.

Another possibility is that our dataset (410 students) was simply too small for complex deep models to find success, compared to the 1000s or even 100,000s of learners in other datasets where DKT has been evaluated. However, model complexity alone does not explain the difference, since the simpler BKT model did even worse than DKT, and our Code-DKT model, which had far more parameters, performed better. Additionally, DKT has historically performed well on some other small datasets (e.g. the “ASSIST-Chall” and “STATICS” datasets from [31] with 300-700 students). Regardless, many tutoring systems only have hundreds of students, and effective KT models must still be able to perform well on these small datasets. Thus, to the extent that

our datasets is representative of the domain, our results suggest the need for improved KT models for programming.

RQ2: How can code features improve KT models? Our results show that a simple extension of DKT with code features does not improve its performance. This result is somewhat surprising, given that relatively simple features (e.g. the presence of a `return` statement) should be at least somewhat related to how close a student is to a correct answer. It is possible such features may improve a model with different structure, but in our dataset, they were not helpful to DKT. This suggests the need for thoughtful approaches to incorporating domain-specific features into deep models. Our Code-DKT model was able to make reasonable improvements to DKT (+3.07% overall on A1). This is comparable to the improvement of SAINT over DKT on the EdNet dataset (they achieved +2.76% in AUC), or SAKT over DKT on various datasets (+3.8%) [31]. This suggests that domain-specific features can be just as important as model structure for effective KT. Code-DKT’s improvement is also robust. It has a +3% to +4% improvement overall on all five assignments. Importantly, however this is still a relatively poor performance overall, suggesting the need for more work on leveraging domain-specific features for improved KT.

RQ3: When and how do code features work? We also explored when and how the code features improved model performance. We found that code features are most useful on problems that share similar learning concepts with other problems in the dataset, and less useful on problems with unique and difficult concepts (e.g. `Math.abs()`). This makes sense – if we make an analogy to the original BKT where each problem was labeled with KCs, if you had a unique KC, the model would have no way of predicting on that problem. In our case, the KCs are inferred by the model, but the same limitation exists. However, most problems in our dataset did share primary learning concepts (e.g. loops, conditionals) and benefit from code features, and this repeated practice is a common feature of many CS1 courses. We also found that code features are useful for predicting both first attempts and subsequent attempts. Our case studies reveal potential mechanisms for both of these effects. For repeated attempts, the model seems to use the relative correctness of a student’s code to determine how close they are to a solution and therefore how likely they are to get it right on the next attempt. For first attempts, the model seems to identify code structures in prior attempts that indicate knowledge or competence with certain programming concepts, which it uses to make predictions on new problems. More work is needed to verify these hypotheses, and to understand how the model represents this knowledge.

Limitations: Our model and experiment have several limitations. 1) All models evaluated, including Code-DKT, have a relatively low performance, partially due to the difficulty of the problem and low data size (410 students), as discussed in Section 6. Still, they perform considerably better than chance, and such models could still be useful, e.g. in prioritizing help to struggling students. 2) Our dataset was from a single semester of a course. While our semester-long dataset of 50 problems is considerably more robust than some of the prior work on KT in programming (e.g. using 1-2 problems [52]), it is unclear how our results will gener-

alize to other semesters, classes or programming languages. 3) We used only DKT as a baseline model to extend and to compare against, and it is possible code features may have different effects on other models. However, as explained in Section 3.1, DKT has a comparable performance to more modern deep models, and made sense as a starting point to explore the effect of code features.

7. CONCLUSION

The contributions of the paper are 1) the Code-DKT model, which extends DKT with embedded code feature extraction; 2) results showing that CodeDKT consistently improves over DKT in a programming dataset; and 3) comparisons and case studies highlighting when and why Code-DKT code features help. This paper compared our new Code-DKT model to domain-general BKT and DKT baselines, and two DKT models extended with simple code features, demonstrating improved performance for Code-DKT over these baselines. However, the best baseline model performance was about 73%, and Code-DKT was 74.3%, demonstrating considerable room for improvement on modeling for knowledge tracing in programming. The case studies in this paper illustrate specific situations where knowledge tracing can be particularly difficult in programming, and where there is potential for improving code KT, e.g. when common code structures are used across problems.

ABSTRACT

Working collaboratively in groups can positively impact performance and student engagement. Intelligent social agents can provide a source of personalized support for students, and their benefits likely extend to collaborative settings, but it is difficult to determine how these agents should interact with students. Reinforcement learning (RL) offers an opportunity for adapting the interactions between the social agent and the students to better support collaboration and learning. However, using RL in education with social agents typically involves training using real students. In this work, we train an RL agent in a high-quality simulated environment to learn how to improve students' collaboration. Data was collected during a pilot study with dyads of students who worked together to tutor an intelligent teachable robot. We explore the process of building an environment from the data, training a policy, and the impact of the policy on different students, compared to various baselines.

Reinforcement learning, teachable robots, balance of participation, lexical entrainment

1. INTRODUCTION

Pedagogical agents have demonstrated the potential to positively impact student learning and motivation in an educational setting [38, 39]. They are commonly characterized as either physical robots or virtual agents and provide an extra opportunity for students to have a social, interactive, and personalized learning experience. Pedagogical agents can be scaled by deploying multiple instances for students to use. While robots are not as easily deployed as virtual agents, recent research suggests that robots can be more effective than virtual agents in engaging students [32]. There is increasing interest in understanding how robots might play a role in formal and informal learning environments [31, 40].

One potential advantage of a robotic agent over a virtual agent is its ability to physically interact with the students. Some work has explored the use of robots capable of facial expressions and found its behavior increased the learning efficiency of students [51]. It had been observed that the physical embodiment of a robotic agent resulted in a higher level of social influence [46]. Other work has explored using gestures from a humanoid robot to help provide feedback to students about multiplication table problems [30].

Robots can take on multiple roles in interactions with a learner, including a tutor, a peer learner, or a tutee [4]. When robots take on the role of tutee, they are often called teachable robots. There are examples of success with teachable robots and a single student [23, 59, 37]. However, there has been less exploration of the use of teachable robots in a collaborative learning setting [12], with a student dyad [58]. This is a limitation of prior work since student collaboration is a powerful tool for improving learning [8, 14, 41]. Collaboration among peers in a computer-supported group setting can be supported by specially designed tasks that encourage interaction. [13]. Computer-supported group settings can encourage collaboration by targeting specific areas and difficulties of group interaction [57].

There are many ways that pedagogical agents adapt and personalize to students. One standard method is a statistical approach, such as multi-armed-bandit [11, 53], but these approaches have some trade-offs [47]. These systems require task-specific expert-authored rules; this may not be a sustainable approach for multi-disciplinary use. In contrast, a data-driven and automated approach is an exciting new way of understanding how to implement personalization.

Reinforcement learning (RL) is a data-driven approach for learning a policy for interacting with the students [44]. While multi-armed bandit approaches identify one action as the best and only select that action, RL policies use context about their environment to choose the best action for a specific moment¹. Traditionally, reinforcement learning uses a

¹We note that *contextual* multi-armed bandits exist. However, they make the assumption that the actions picked have no effect on the environment (in this case, the students). We aim to model how the students' behaviors change over time in response to the actions selected, and thus a contextual multi-armed bandit does not fit this problem.

virtual environment, which is used to train an initial policy, that is then transferred to the real world.

The RL-controlled robotic tutor described in Park et al. [44] does not involve the use of a virtual environment to train, instead training directly on the students. The experiences collected are always using the latest iteration of the policy, which is continually changing. While real-world RL ensures that the students interact with the most up-to-date policy, it actively uses students to test potentially sub-optimal actions during training, which might lead to confusion and unnatural interactions. With this approach, the policy learns through extensively interacting with students, requiring many months of training and needs to build a profile about each student. Real-world RL is also well-known as being particularly challenging [16].

Learning an RL policy in a virtual environment has two main benefits over real-world reinforcement learning. A policy can be trained in just a few hours by simulating millions of different versions of the environment and their outcomes. Furthermore, by training solely in a simulation, there is no need to train a policy through extensive experimentation on students. However, building such a simulation of the real world is challenging. One solution is offline reinforcement learning, in which an algorithm learns from a set of previously collected data, which obviates the need for a simulated virtual environment. Unfortunately, offline reinforcement learning requires an extensive collection of saved experience data [17], which is infeasible to collect from students.

We, therefore, assume a hybrid approach, using the set of previously collected data to model and build a data-driven simulation, effectively allowing for online reinforcement learning in an offline reinforcement learning setting. We explore the process of building a high-quality data-driven virtual environment, the difficulties in modeling the students, and ensuring environmental continuity.

We aim to see how a pedagogical robot can assist students in a group setting. The humanoid robot interacts with two students concurrently, as a social learning companion. We attempt to use Reinforcement Learning to aid in the decisions made by the teachable robot, to improve student learning outcomes and motivation by supporting students in a personalized manner.

The robot, named Emma, interacts with students via natural language. As the students work out the multi-step problems, they explain their solutions to Emma. Emma responds to the students' solutions, clarifying the purpose of the most recent step or occasionally asking thought-provoking follow-up questions. These actions are combined with gestures to make interacting with the robot feel more natural.

Student interactions with Emma were collected using an expert-authored natural language dialogue script. We built a simulation describing the interactions between the students and modeled the different types of interactions those students had with Emma. The simulation uses collected data to represent various types of student groups.

Extensive testing of the policies trained and tested in the

simulation demonstrates that RL methods outperform the dialogue script baseline in terms of collaboration metrics. Furthermore, in our simulation, we find that the RL methods improve collaboration among all student groups, unlike our baseline method, which fails to improve collaboration for some groups. Our contributions include:

- A hybrid approach to perform offline RL in a robot-student setting using online RL trained in a virtual environment.
- A novel method for building a virtual environment from previously collected data, to simulate student collaboration.
- An early exploration of applying RL for a teachable robotic agent in a collaborative setting with students.

2. BACKGROUND

Reinforcement Learning (RL) has provided recent breakthroughs in solving complex machine learning tasks, highlighted by applications in self-driving vehicles [29], super-human performance in competitive board and video games [54, 55], and advanced autonomous robotic control [1, 42]. RL allows an agent or policy to sequentially select actions to achieve some (potentially non-differentiable) goal.

Reinforcement Learning differs from the more traditional supervised learning, where a classifier is exposed to a set of labeled examples, with the goal of correctly classifying an unseen example. There is often no label or ground truth for what actions are right or wrong for an RL agent to select in the settings where reinforcement learning is used. Additionally, each action may have cascading effects on the environment's future, and similar actions may have varying effects that depend on the current state of the environment.

The policy in RL is a function, typically modeled with a neural network, that selects actions to navigate some environment given information about the current state of the environment and a reward that grades the actions. In the described reinforcement learning scenarios above, such as self-driving, competitive gaming, and autonomous robots, an agent is typically trained from scratch in a simulated environment. This policy, trained in the simulation, is then transferred to the real world.

For example, consider the case of autonomous robots. A realistic virtual environment, like those created with video game engines, is used, with an accurate model of the robot and the various motors involved in its control [7]. The policy can then control the motors of the simulated robot to try and attain some reward or goal. Transferring a policy from a simulated space to the real world is easier when the simulation is similar to the real world, emphasizing the quality of the simulated environment to decrease the domain gap [64].

Constructing an environment requires a deep understanding of how actions cause the environment to respond. In some settings, such as competitive chess playing, this is trivial: strict rules define how the pieces move and there is no stochasticity that affects the outcome of each action. In the case of self-driving, the actions and how the environment responds have a measure of stochasticity. While turning the

wheel to the left typically turns the vehicle to the left, features of the environment, e.g. a patch of ice on the road, can affect the car’s trajectory in a unintended manner.

In our setting, the effects of a policy’s actions on the simulated environment are not easily defined. For example, similar actions performed by the policy may vary in their outcome due to differences between students. Even when asking two different students the exact same question, their responses will most likely differ. The environment, therefore, must use the collected data to model many potential outcomes for actions taken.

2.1 Education and Reinforcement Learning

Reinforcement learning in education has been a topic of exploration since the early 1960s [24], specifically for the sequencing of instructional activities. Various approaches have been built on this concept over the years [3, 33, 11]. A survey performed by Doroudi et al. found that 21 of 36 studies of RL-sequenced instructional policies determined that the RL policy outperformed baseline policies [15].

Singla et al. present a recent survey of the use of RL in education [56], which identifies five main research directions of RL in education. Singla found RL was used for: personalizing curriculums [15, 48], personalizing hints/scaffolding/quizzing [2, 62, 45], A/B testing educational methods [34, 63, 49], modeling human students [22, 60, 26], and content generation [28, 27, 20]. Our work combines personalizing constructive feedback and modeling human students. In our setting, where we attempt to maximize collaboration between students, we model the students’ interactions regarding the feedback and hints provided.

2.2 Emma: The Teachable Robot

Our study context involves Emma, a humanoid NAO robot who interacts with a pair of students tasked to solve multiple ratio word problems, using natural language and basic gesture. NAO robots are commonly used and have been effective in social robot student learning settings [25]. The students work together to solve the problem and teach the solution to Emma. This collaboration has two benefits. First, we can obtain more data regarding student thinking, as they must vocalize more between themselves, compared to when working alone. Second, there are known benefits for student collaboration for improving student learning [8, 14].

During a study session, each question is shown to the pair of students, who need to solve the problem and then describe to Emma how to calculate the solution. The problems require multiple steps to solve, and the students need to convey each step to Emma. If one of the steps is wrong, Emma is designed to either ask a question to guide the students in the right direction or make a statement regarding the students’ response. An example interaction between students and Emma is shown below:

1. **Emma:** So I know that I need 66 hours worth of batteries and I know how much time I need for one battery.
2. **Student B:** So we can tell her 66 hours divided by 3 and three quarter hours.
3. **Student A:** Yeah, that’s right

4. **Student B:** So you’re going to divide 66 hours by 3 and three quarter hours.
5. **Emma:** Since we need to figure out what times 3 and three quarters is 66. So then 66 divided by 3 and three quarters is 17.6 Is that it?
6. **Student B:** Yes, that is correct.
7. **Emma:** I need 18 batteries because I need more than 17. I will put the answer as 18.

Students use an in-house web interface to see the math problem that the robot was solving, which provides controls to advance to the next step, a button to “push to speak” with the robot, and to see what the robot most recently said (as a backup to hearing it over the video chat service). The video feeds from each session (group) were recorded, along with the audio from each participant. The audio feeds for each participant were transcribed using IBM Watson’s Speech-to-Text system, with word timings maintained.

Our work follows two theoretical frameworks for identifying productive collaboration. First, the interactive-constructive-active-passive (ICAP) framework of cognitive engagement [10] hypothesizes that students collaborate best when actively interacting, taking turns to contribute constructively to the task at hand. In our environment, this would involve the students both working to teach Emma, participating relatively equally and engaging in dialogue with each other rather than pursuing independent parallel work. Second, we draw on the Interactive Alignment Model (IAM), which postulates that in order for two collaborators to align their understanding, they must align their communication [19]. One indication of this alignment is lexical entrainment, which is indeed related to student success in group learning settings [18]. Lexical entrainment measures the similarity between the language used by speakers in a group over time [6], and might be a sign of students converging to a shared mental model [18], which can lead to successful group performance [61]. We are interested in exploring both balance of participation and lexical entrainment as rewards in an RL environment.

2.3 Data Corpus

Due to the COVID-19 pandemic, sessions were held using an online video-chat service to connect the students with Emma. For our pilot studies, we collected data from twenty-eight undergraduate students who interacted with the robot in groups of two (i.e., 14 dyadic sessions; 11% Male, 89% Female; 32% Asian, 14% Black, 46% White, 7% no response; Mean age = 19.4 years, SD = 1.19)². Each session lasted approximately 30 minutes.

In addition, students were individually tested and surveyed before and after collaboratively interacting with the robot. These assessments were used to determine pre-existing (i.e., pre-collaboration) factors that may impact mid-collaboration interactions and participation and post collaboration learning outcomes. The pre-collaboration measures included: motivation (i.e., interest, utility, efficacy, attainment, and cost), goal orientations (i.e., mastery approach, performance approach, performance-avoidance), attitudes towards robots

²This data is part of a more extensive study that includes another condition in which individuals taught Emma. For the purposes of the current work, we focus on the dyads.

and collaboration (i.e., work quality, peer support, interdependence), affinity for technology, and prior knowledge (i.e., pretest on ratios). The post-collaboration measures included ratings of rapport with their partner and Emma (i.e., general, positivity, or attentiveness), perceptions of Emma (i.e., anthropomorphism, likeability, animacy, and intelligence) [36, 35], and posttest scores (i.e., counterbalanced with pretest). Given the need to consider the group as the unit of analysis, we used the dyads’ average measures for our analyses, with higher averages representing a larger presence of each construct. In total, 27 metrics were collected from the surveys and assessments. This study was approved by the Institutional Review Board.

3. METHODOLOGY

We construct our simulated environment using real-world data collected from interactions with real students. The environment models the conversational interactions between all participants and uses probabilistic methods to capture the various sources of stochasticity. This allows us to model *potential* outcomes that could occur when Emma interacts with the students, even when such an interaction was not captured in the pilot study. We then train a set of three RL algorithms using the environment and compare the results of each algorithm with a series of baselines.

3.1 Data and Setup

Building an end-to-end RL environment is highly task-specific but can be generally simplified into two steps. We first extract the data gathered during the student interaction sessions. Next, we use the extracted data to model student interaction and observations in the environment in conjunction with various probabilistic sequence modeling techniques. This process involves identifying reward metrics and modeling how the environment responds to stimuli.

3.1.1 Student Participation Metrics

Our data-driven simulation uses various metrics captured during the data collection studies. Specifically, we capture the change in student participation metrics after Emma performs an action. We observe how these metrics change throughout the study as the students interact with each other and the robot. We use metrics that approximate the balance of interactive participation (following the ICAP framework) and lexical entrainment between the students. For our environment, we use Measure of Participation and Word Co-Occurrence metrics, respectively.

The text transcripts were tokenized at the sentence level using NLTK [5]. The Measure of Participation and Word Co-Occurrence were calculated as shown below, and associated with each sentence. This methodology allows us to estimate the balance of participation and lexical entrainment at intermediate points of the session.

Measure of Participation (MoP) MoP indicates the balance of group participation as proposed by Paletz and Schunn [43]. MoP computes the average level of involvement in the group, scaled between 0 (equal) and 1 (dominated) participation. MoP is defined in Equation 1, where \bar{n} is the average number of people during the session, N is the max number of people present (always 2 in our setting), M is the total

number of utterances said in the session, n_k is the number of people present on utterance K (always 2), i is the index representing a student, and m_i is the number of utterances where person i is present.

$$P_s = \bar{n}^2 * \frac{\sum_{i=1}^N |\sum_{K=1}^M f(n_k, i, K)|}{2(\bar{n} - 1) \sum_{i=1}^N m_i} \quad (1)$$

$$f(n_k, i, K) = \begin{cases} \frac{n_k - 1}{n_k} = \frac{1}{2} & \text{if } i \text{ is speaking during utt. } K \\ \frac{-1}{n_k} = -\frac{1}{2} & \text{if } i \text{ is silent during utt. } K \end{cases}$$

For example, given two utterances and one participant speaks during each, $MOP=4*(|1/2-1/2|+|-1/2+1/2|)/[2*(2+2)]=0$. If only the first participant speaks during each utterance, $MOP=4*(|1/2+1/2|+|-1/2-1/2|)/[2*(2+2)]=4*2/8=1$.

This metric is invariant to changes in group size and supports groups of different sizes. In our RL environment, since the agent’s goal is to maximize the reward, we use $1 - P_s$ for the feedback. This, in turn, rewards the agent for achieving equal participation.

Word Co-Occurrence (WCO) WCO provides a simple estimate of lexical entrainment. WCO is defined as the number of lemmas common between both participants. Lemmatization was performed using WordNet in NLTK. To get WCO in the same range as MoP, the value is normalized between 0 and 1 by dividing by the number of unique words said in the session. The size of the shared set of words increases only if both participants are contributing and talking about similar material.

3.2 Overview of the RL Environment

A reinforcement learning environment requires four essential components. The first is the set of potential actions A that the agent can take at each step. The second is the set of states that the environment can take S . The last is the set of rewards R that the agent will be attempting to maximize.

The first step to building an environment is defining each of the required components of the environment and at what level of abstraction these components will be represented. We define how the environment responds when the robot interacts with it, the information provided by the environment to the robot, and the options the robot can take at each step.

3.2.1 States

The environment state is used to describe to the RL policy what is happening at a specific point in time. In this case, we model the environment state as a representation of the sentence said directly to Emma by one of the students - this is what Emma observes and uses to select her next action. For example, a student may tell Emma, “If you use 3/4 of your battery in 1 hour, you multiply that by 3 to figure out how much you use in 3 hours”.

Figure 1: A high-level overview of the different parts of the environment. Emma’s actions each use a Markov chain, trained using collected data, to transition between states. The current state of the environment conditions the state transition. States are represented as sentence embeddings.

3.2.2 Actions

In the case of determining the action space of the environment, we look at what Emma was capable of during the data collection sessions. As a proof of concept for our reinforcement learning approach, we simplify the action space to include the two general responses – questions and statements. For example, one response from Emma is this question-based reply: “So if I have forty-five hot dogs and I now know how much it costs for one, can I figure out how much it costs for forty-five hot dogs by multiplying?”. For the statement-based reply for the same problem, she says, “With the unit rate, I know it costs two dollars and fifteen cents for each hot dog. I don’t remember what I am supposed to do with that, though.” As we can see, while the responses convey similar information about the problem, they could potentially invoke very different responses in the student participants.

3.2.3 State Transitions

In addition to defining the states and actions of the environment, we need to define how the actions cause the states to transition from one to another. Our state transitions describe how the students react to Emma’s responses. Between Emma’s actions, there are a series of interactions between the students, where they decide what to say to Emma or work on the problem solution. We model the progression of these inter-student interactions probabilistically to describe how the students’ conversations lead to different interactions with Emma.

3.2.4 Reward

The purpose of the reward is to coerce the policy towards performing the actions needed to achieve the required outcome. There are broadly two ways to reward the agent: at constant intervals throughout a session or once at the end, but the latter sparse option is more complex than frequent rewards [21]. Our student participation metrics (Sec. 3.1.1), derived from learning theory hypotheses, can be calculated at intermediate points during the session. To keep the environment simple, we give an intermediate reward after each of the robot’s actions. The value of the reward is the sum of the student participation metrics associated with the current state (MoP + WCO), as observed during data collection.

3.3 Simulation

Now that we have presented a high-level view of the environment that was designed, we will delve into the technical

Figure 2: An example of the interactions between the students and Emma. The black blocks signify a sentence said by a student to another student, the orange blocks a sentence said to Emma, and blue blocks a response to the students.

details about how it is implemented. In the sections below, we highlight three difficulties in implementing a data-driven environment from previously collected data. First, the conversations between the students can vary significantly but need to be accurately modeled. Second, with data collection limits, we must handle missing information when simulating the outcome of actions. Third, the simulation must provide a reward to provide feedback for the selected actions.

3.3.1 Simulation Design

An overview of the environment is shown in Figure 1. Emma is capable of two responses, to either reply with a question or a statement. Each action has a unique Markov chain, which generates a sequence of simulated interactions between students. The generation of the simulated interactions is dependent on the current state of the environment and is used to generate the subsequent state. This subsequent state is associated with a reward for Emma.

In Figure 2, we depict an example of the structure of the collected data, with time represented on the x-axis. Here, the black blocks signify a sentence said by a student to another student, the orange blocks represent a sentence said to Emma, and the blue blocks indicate Emma’s response to the students. The students say four sentences among themselves before one student says a sentence that is an input to Emma. The 6th block is the reply Emma chooses for the students. The students talk between themselves for three sentences before interacting with Emma again. Emma responds, the students continue talking, and the cycle repeats.

We can see that the interactions between the students have a structured turn-taking nature, which follows a repeated

pattern: 1. students converse between themselves, 2. students provide an input to Emma, 3. Emma replies to the student’s input. Using this general structure of interaction, we can define the necessary portions of the environment. The state of the environment, as observed by the RL policy, is the sentence that is said directly to Emma. The actions in the environment are the replies from Emma to the students. The rewards of the environment are the changes in the levels of the Measure of Participation and Word Co-Occurrence scores that occur as the students discuss. The rewards are provided at the end of each sentence. The state transitions occur due to Emma’s responses (actions) to the students - this invokes conversation between the students, resulting in a specific response from the student (state).

3.3.2 State Space (S)

The first step in building the environment is setting a level of abstraction to represent the states, S . This step is important for modeling the environment input to the RL agent and is necessary in describing how the environment transitions from one state to the next. The interactions between the students and Emma can be modeled using the input sentence tokens, which are the orange blocks in Figure 2.

The tokens are encoded using Google’s pre-trained Universal Sentence Encoder [9]. The Universal Sentence Encoder provides embedding vectors of each token, for the tokens said between the students and the tokens said as input to Emma. Embedding vectors are high-dimensional representations in a semantic space. The embeddings of semantically similar tokens will have a higher cosine similarity score than semantically different tokens.

Let $p \in P$ be a sentence in the set of sentence tokens said as input to Emma, collected during data collection, and $encode(x)$ converts a token to a 512-dimensional embedding with the Universal Sentence Encoder. A state in the environment is defined as $s \in S$, where $s = encode(p), \forall p \in P$.

3.3.3 Action Space (A)

In Figure 2, Emma’s “actions” are her natural language replies shown as the blue blocks. For simplicity, Emma has the same set of actions that can be taken at each step. The replies to the students are roughly split into two categories: question-based replies and statement-based replies. An action $a_{t,p} \in A$ at timestep t has an indicator, p , to describe the type of action taken. p can be one of (q, s) , i.e. Emma can reply with a question $a_{t,q}$ or a statement $a_{t,s}$.

3.3.4 State Transitions

One vital mechanism for an environment is the *state-action transition*. The state-action transition defines for some state s_t and action a_t at time step t , the next state s_{t+1} emitted by the environment, at time step $t + 1$. Referring again to Figure 2 (black-colored sentence tokens), we see that an action is followed by dialogue between students, which takes place when transitioning between states.

We model this state-action transition using the Markov chain, a probabilistic sequence model. We choose to use the Markov chain for this simulation due to its simplicity and ability to model time-series data. A Markov chain is a simple model

where the probability of the n^{th} event $e_{t,n}$ at time t , is conditioned and only dependent on the previous event $e_{t,n-1}$. Here, each event is a sentence uttered by a student, and the chain represents the transitions of the conversation had between the students before they converse with Emma.

To build the Markov chain, we must simplify the events from the continuous space (sentence embeddings) to a countable space. With semantically similar sentences existing close together in the embedding space, unsupervised clustering methods allow for an intelligent way to represent the sentence tokens in a countable space. The embeddings for the transitional sentences are assigned to clusters in an unsupervised manner via KMeans clustering. Each sentence is assigned and represented by a cluster c via this method. The set of clusters $C, c \in C$ is the countable space for the Markov chain. We denote here a function $c_{t,n} = k(e_{t,n})$ which for event embedding $e_{t,n}$, returns the cluster identifier of each embedding, $c_{t,n}$. For simplicity, we extend $k(x)$ to support operations on a sequence of events, which it converts to a sequence of cluster identifiers in the same order.

The state-action transition sequences collected from the pilot study are used to build the chains. For each state-action transition sequence, we store the action a_t , the starting state s_t , the transitional sequence of sentence embeddings $E_t = e_{t,1}, e_{t,2}, \dots, e_{t,n}$ and ensuing state s_{t+1} . The transitional sentences, and ensuing state are combined as a sequence of embeddings $\hat{E}_t = e_{t,1}, \dots, e_{t,n}, s_{t+1}$. This sequence of embeddings is then transformed to be represented in terms of each sentence’s cluster identifier, $H_t = k(\hat{E}_t)$. We also define another function, $j(c)$, which randomly samples and returns a sentence (its embedding) from cluster c . These sequences of cluster identifiers are used to build a Markov chain. A separate Markov chain is built for each action to separate the state transitions of the two types of actions. These action-specific Markov chains are m_q and m_s , respectively.

State transitions are modeled using a conditional generation of the Markov chains. Sequences generated by Markov chains are typically initialized randomly by selecting a random event as the starting point. Conditional generation involves selecting a specific event as a starting point, which affects the subsequent generation of events in a cascading manner. This conditioning ensures the actions selected by Emma in the virtual environment affect the following simulated interactions between the students. To describe conditional generation, we provide the example $m_q(e_{t,1})$, to represent the conditional generation of the next state using the *question* Markov chain. The output of $m_q(e_{t,1})$, is a sequence of cluster identifiers H_t , that starts with cluster identifier $k(e_{t,1})$.

Mappings, $r_{s,a} = [(s_t, a_t) \rightarrow e_{t,1}]$, are extracted from the recorded state-action transitions, to be used for the data-driven conditional generation. For an observed state s_t with action a_t , the Markov chain conditionally generates with starting point $k(e_{t,1})$, and ends with some cluster identifier $c_{t,n}$. For example, we generate the following sequence of events, $E_t = e_{t,1}, e_{t,2}, \dots, e_{t,n}$, and use the last event to obtain our sampled cluster identifier, $c_{t,n} = k(e_{t,n})$. This cluster is used to sample next state, $s_{t+1} = j(c_{t,n})$. We denote the set

Figure 3: A scenario where an action’s outcome is not contained in the collected data. To approximate the effect of the action, we substitute in a similar state-action transition from the collected data in a probabilistic manner.

of recorded state-action transition mappings R .

State-Action Map Substitution The data-driven mappings, $r_{s,a} \in R$, are a straightforward way to conditionally generate the next state, for some observed set of state and action, (s_t, a_t) . However, consider the example in Figure 3. During data collection, we observed and recorded the mapping $(s_t, a_{t,q}) \rightarrow e_{t,1}$, shown in the top row. However, we may, during the simulation, want to test what happens for the state-action set $(s_t, a_{t,s})$, for which no recorded mapping exists. With no existing mapping, we need to find a substitute - a recorded mapping with a state that is similar to s_t , that instead contains action $a_{t,s}$.

We propose to find a substitute mapping by filtering the set of all recorded state-action transition mappings R . Within R , we filter and keep recorded mappings that contain the desired action, $a_{t,s}$ in this example. For each mapping in the filtered set, we calculate the cosine similarity score $sim_{t,m} = \cos(s_t, s_m)$ between the current state s_t of the environment, and the state s_m stored in the mapping. This similarity score is used to assign a probability for being selected as the substitute mapping to each mapping in the filtered set. The probabilities are proportional to the similarity score so that the most similar states have the highest probability of being selected. The filtered set is then sampled using the probabilities to find a new mapping, with a similar state s_m , the selected action $a_{t,s}$, and a new substitute event for conditional generation $e'_{t,1}$.

3.3.5 Reward (R)

The formulation of the environment reward is simple since each entry in the Markov chain has an associated change in WCO and MoP that was observed during data collection. Therefore, during a state transition, we aggregate the WCO and MoP across the sequence generated by the Markov chain while generating the next step. The sum of the rewards over the chain is the reward provided for the action.

As a reminder, each entry in the chain is a specific cluster identifier in which various sentences reside. We use the cluster’s mean reward (using all the sentences in the cluster). As an example, if Emma selects a question as her action, we sample the Markov chain, $m_q(e_{t,1})$, to generate the next state s_{t+1} . This generates the chain: $E_t = e_{t,1}, \dots, e_{t,n}$ where $s_{t+1} = j(k(e_{t,n}))$. Each entry, $e_{t,m}$, in the chain has an associated reward (WCO + MoP). Let $r_{t,m}$ be the average reward for cluster $c_{t,m}$, where $c_{t,m} = k(e_{t,m})$. To get an action’s full reward, we compute the sum of the associated rewards along the sampled chain $R_t = \sum_{m=1}^n r_{t,m}$.

Time Constraints To ensure that the environment does not provide rewards that bias policies towards selecting actions that have longer Markov chains, we add a time limit to how long an environment can run. The sentences said during data collection are timestamped, which describes how much time was required to say each sentence. Throughout the simulation, a timer is kept, and if a sentence is sampled by the Markov chain, the timer increments by the amount of time required to say the sentence, using the word timings extracted from the automated Speech-to-Text system. The time limit is a 30-minute cutoff, which mirrors the cap to session length that was in place during data collection. Any reward obtained after the cutoff is excluded.

3.3.6 Additional Implementation Details

Random Student Initialization The environment is designed to create a policy that is capable of handling different types of learners, different styles of student participation, and different levels of student interaction with Emma. To emulate this, during the environment initialization, Emma is blindly assigned to a random student group (one of the 14 from the pilot study); the policy is not provided information about which group was selected. Emma interacts with a version of the environment that uses state, state transition, and reward parameters collected from only the selected student group during that session. For subsequent sessions in the simulation, the student group is blindly and randomly re-assigned, ensuring that the learned policy can generalize to multiple types of students. These parameters differ per group, meaning the environments respond quite differently, depending on the current student group being represented.

Environment Tuning The first step, before training the Reinforcement Learning policy, is to make sure that the environment works as intended given the assumptions we used to model the states, actions, rewards, and state transitions. To do so, we built a deterministic policy for each group, which selects actions exactly as were selected by Emma in the pilot study - we call this deterministic policy the *mirror policy*. To be specific, in the simulation, she *only* picks actions that have an **observed** state-action transition, so no action substitution is used. While there is some stochasticity in the environment that comes from sampling the Markov chains, the environment should respond, on average, similarly to the outcomes that were observed during the pilot study.

To calculate the environment similarity, we directly compare the mirror policy’s action distribution and the action distribution of the studies during data collection. This comparison is made by comparing the ratio of mirror policy’s action distribution and the study action distribution, using mean squared error (MSE). We call this metric the *action distribution difference*. A low action distribution difference indicates that the environment reacts as expected.

Policy Tuning We tested three standard methods for reinforcement learning, Deep Q-Network (DQN), Proximal Policy Optimization (PPO), and Advantage-Actor Critic (A2C). DQN is a Q-learning method where a neural network learns the value of actions for a particular state. PPO is a policy-gradient method, which estimates the policy gradients directly with respect to the reward. A2C is an actor-critic method, where the critic learns the value of a state, and

Figure 4: The *environment’s action distribution difference* varied with the k -value for the sentence KMeans clustering. After about $k = 400$, we see little change.

an actor to learn how to select actions. These policies are implemented using the Stable Baselines package [50].

4. RESULTS

Comparing RL Policy to Observed Decisions Once we identify the best RL policy, we compare the actions and rewards it achieves to those of the deterministic policy used during data collection, as a sanity check for our environment.

Comparing RL Policy to Random Baseline To see the performance of the learned policy against an unbiased policy, we compare the former against a random policy, which selects actions with equal probability. Consistently outperforming a random policy demonstrates that the learned policy learned to navigate the environment and correctly select actions.

Group Equality The amplitude of a policy’s reward in the environment is not the only goal for a successful policy. On top of maximizing the reward, we look to ensure *group equality*, i.e. positive reward across *all* groups - to verify that the learned policy helps different types of students.

Correlations of RL Policy Gains with Student Survey and Test Metrics The survey and assessment measures were not used in the environment design or parameters but could impact, or be impacted by, our RL metrics. Thus, we used the Pearson correlation coefficient to determine which dyadic factors (i.e., from the average survey and assessments metrics) were most highly associated with our RL Policy’s improvement in rewards. Doing so provides insight into how pre-existing factors connect to rewards during interactions with the robot and how these interactions connect to post-collaboration perceptions and assessments.

4.1 Evaluating the Environment

The mirror policy is used to tune the environment, and ensure that the environment works as expected. The number of clusters used for the sentence representation affects the level of stochasticity in the environment. This stochasticity is present in the language generated via the Markov Chains. An insufficient amount of clusters can result in a loss of the structure in the environment. With less clusters, the language generation becomes more random, and fails to capture the information from the pilot study. An excessive amount of clusters can cause the environment to respond *only* as was

Figure 5: The action distributions of the various policies. In the simulated environment, the mirror policy acts similarly to the actions observed in the pilot study. The RL policies all tend to prefer statements.

observed during the pilot study, generating nearly-identical language to what was observed.

To determine the correct number of clusters, the mirror policy’s action distribution was evaluated while varying the number of clusters compared to the real distribution, as shown in Figure 4. Under 100 clusters, we see a large difference in how the environment responds to the mirror policy’s actions compared to the observed distribution. However, as we increase k , we see a decrease in the difference, with little improvement when $k \geq 400$. For that reason, we set $k = 400$ for all further experiments to ensure that there is some variability in the environment without deviating from what was observed in data collection.

In Figure 5, we display the action distribution of the mirror policy in the simulated environment compared to the observed real-world data. We can see the mirror policy acts quite similarly to what was observed in the real world – differences in actions come from the various sources of stochasticity in the environment.

4.2 Evaluating the Policy

Questions are used more often than statements in both the pilot study and the mirror policy, but *all* RL policies flip the action distribution around - preferring statements over questions, indicating that there may be deficiencies in the deterministic policy used for the pilot study.

Tuning and validating the policy were done via two types of cross-validation. We tested the environment using traditional 5-fold cross-validation, where the 14 groups are separated into five subsets or folds, and each fold is used as a testing set. This methodology models the scenario where Emma is trained then evaluated with multiple unseen groups of students. This setting aims to demonstrate that learned policies provide benefit to *more than one group*.

To further validate policies learned in the environment, we also test leave-one-out cross-validation, where each student group is used as a testing set. In this scenario, we model the event where Emma is trained in a simulated environment, then evaluated with a single unseen group of students. This setting is to demonstrate that learned policies provide benefit to *all groups*.

Figure 6: The difference in the performance of the RL policies and the mirror policy, per fold in K-fold cross-validation.

We compared various learning rates in both scenarios and three RL policy optimization algorithms, PPO, DQN, and A2C. In total, 7087 different policies were trained and tested. Cross-validation takes 75W of power and runs for approximately 35 minutes. Training was performed on 2 Nvidia GTX 1080ti (\$699 MSRP each). Data collection was performed with one NAO Robot (\$12990 MSRP).

4.2.1 RL Method Performance Differences

We refer to the difference in reward between an RL method and the mirror policy baseline as the *Magnitude of Reward*. In 5-fold cross-validation (Figure 6), the mirror policy outperformed the median A2C and DQN policies, as demonstrated by the slightly negative magnitude of reward. A2C’s magnitude of reward distribution is roughly normal, while DQN’s is negatively skewed. The median PPO policy outperformed the mirror policy, with a positive magnitude of reward. Furthermore, the PPO magnitude of reward distribution is positively skewed. PPO has an average magnitude of reward of 0.20, while A2C and DQN both have an average magnitude of reward of -0.11 and -0.10 , respectively.

In leave-one-out cross-validation (Figure 7), we see that the median magnitude of rewards for all RL policies is slightly negative. However, while A2C is negatively skewed, DQN is positively skewed - the average DQN magnitude of reward is slightly positive. The mean rewards of A2C, DQN, and PPO are -0.03 , 0.06 , and 0.02 , respectively. In both settings a higher learning rate resulted in an increase in the policy’s reward on average.

A2C under-performed the mirror policy in both cross-validation settings, indicating that it does not work well in this environment. While DQN outperformed PPO in leave-one-out cross-validation, it under-performed the mirror policy in 5-fold cross-validation, indicating a lack of stability between settings. PPO outperformed the mirror policy in both settings, demonstrating positive and stable performance.

4.2.2 Gains for Individual Groups

The magnitude of reward of the policy is not the only goal of using an RL policy. We also aim to help improve groups that performed poorly during the diagnostic testing so that there is equal performance and improvement among all groups. Gains among low-performing groups mean that the policy may potentially aid students who learn in non-standard ways.

Figure 7: The difference in the performance of the RL policies and the mirror policy in leave-one-out cross-validation.

Figure 8: Average reward of the PPO RL policy in K-fold cross-validation, compared to the mirror policy and the random policy. The learned policies have a more consistent and positive average final reward.

Figure 8 shows that the learned PPO RL policies achieve a consistent and positive average final reward in cross-validation among all folds. Here, the mirror policy achieves very inconsistent results among folds and a negative reward for Fold 3. The random-action baseline outperforms the mirror policy here but achieves approximately 0 reward for Fold 3.

We see similar trends in leave-one-out cross-validation (Figure 9) but slightly more variation. Here, the PPO RL policies again achieve a positive reward, while the mirror policy and random-action baseline do not. The mirror policy and random baseline both achieved a negative reward for Fold 7, and the random baseline achieved a slightly negative reward for Fold 2. We note that Fold 2 generally did not respond significantly to any method, but the PPO RL policies achieved the highest average reward.

4.3 Correlations with Diagnostic Metrics

To determine the connections of our simulated environment to different dyadic factors, we calculated correlations between the Magnitude of Reward and metrics obtained by the questionnaire and assessments administered to students. These correlations may reveal which students are most positively affected by the boost in MoP and WCO that the learned policies can achieve in the simulated environment. We select the three diagnostic metrics with the highest Pearson correlation coefficients (in amplitude).

First, the large positive Pearson correlation ($+0.672$, $P =$

Figure 9: Average reward of the PPO RL policy in the leave-one-out cross-validation setting compared the random policy and mirror policy. The learned policies have a consistently positive average final reward.

.008) between the dyads’ average self-reported values for quality of work in groups and the Magnitude of Reward suggests that students who more highly value the quality of work in collaborative settings may have benefited more from the actions of the learned policies. We would expect to see this correlation, given the overlapping nature of the group-work quality construct and key components of Magnitude of Reward (i.e., balance of participation and entrainment).

Furthermore, the high negative correlation between the dyads’ average pretest scores ($-0.634, P = .015$) and the Magnitude of Reward of the policy may suggest that the groups with lower prior knowledge before the activity would likely have benefited more (i.e., better entrainment and balance of participation) from a policy that was trained in the reinforcement learning environment. Similarly, the high correlation between Magnitude of Reward and the dyadic-average understanding of ratios at posttest ($-0.781, P = .001$) implies that the groups who performed worse, on average, than their counterparts could have been benefited by the improved balance of participation and word co-occurrence from the reinforcement learning policies.

5. DISCUSSION AND CONCLUSION

Our tests show that our environment exhibits a similar behavior under the mirror policy as was observed during the pilot study, in terms of action distribution (Figure 5). Notably, the policies learned in the environment differ significantly from the pilot study and the mirror policy, heavily favoring statements over questions, opposite to the rule-based approach used for the mirror policy. One explanation is that a question occasionally resulted in a direct response from the student who originally spoke to Emma. We observed that statements more often resulted in the students reconvening and then discussing how to reply to Emma.

This assignment of actions may have its merits, based on its improvements in both the amplitude and consistency of environment reward. In both forms of cross-validation, the policies trained with PPO outperform the mirror policy. We note that other RL methods had inconsistent performance across different types of cross-validation. In the Proximal Policy Optimization algorithm paper [52], the author finds a improvement in performance *and sample efficiency* using

PPO over DQN and A2C. In our setting, we are limited in our number of data-driven samples, and therefore PPO’s strong performance may be from this data efficiency.

When looking at the results of the individual folds for both forms of cross-validation, we see that the PPO RL policies consistently achieve a net positive reward. In 5-fold cross-validation, RL’s rewards are consistent across folds, while the mirror policy and random baselines were inconsistent and even resulted in a significant decrease in one fold’s average reward. This trend extends to leave-one-out cross-validation, where the PPO RL policies again achieved a positive reward on all folds. From our testing, we believe that the PPO RL policies may benefit all students and demonstrate performance equity among groups.

These findings are further highlighted by the connections between the learned policies’ Magnitude of Reward and the metrics obtained by the questionnaire and students’ diagnostic tests. The Pearson correlations may reveal which students are most positively affected by the additional MoP and WCO that the learned policies can achieve in the simulated environment. The actions of the learned policies may help the most for students who care highly about their quality of work in a group setting and may provide the most benefit for underperforming students. Further empirical investigation into these links might reveal new understanding of how interventions under the ICAP and IAM frameworks interact with individual differences to improve collaboration.

However, the policies trained in this environment have not yet been validated in a real-world setting with students. Additionally, the pilot study was performed using a hand-crafted and deterministic script for interacting with the students. The data collected by the script’s actions may have biases, which could affect the accuracy of the environment. Furthermore, the pilot study data collection was performed with undergraduate school students, held virtually. We aim to test this system in-person and with middle-school students. We expect some of our findings in this study may not carry over to this new setting. In addition, our investigation only looked at one modality. In the future, we aim to extend this work, adding additional actions such as verbal references towards particular students and adding physical gestures and gaze to the robot.

The framework presented here provides a hybrid approach for using RL in a robot-student setting, by building an environment from collected student interaction data. This environment can be adapted to any number of actions and students without requiring extensive training in the real world.

ABSTRACT

Self-regulated learning (SRL) is a critical component of mathematics problem solving. Students skilled in SRL are more likely to effectively set goals, search for information, and direct their attention and cognitive process so that they align their efforts with their objectives. An influential framework for SRL, the SMART model, proposes that five cognitive operations (i.e., searching, monitoring, assembling, rehearsing, and translating) play a key role in SRL. However, these categories encompass a wide range of behaviors, making measurement challenging – often involving observing individual students and recording their think-aloud activities or asking students to complete labor-intensive tagging activities as they work. In the current study, we develop machine-learned indicators of SMART operations, in order to achieve better scalability than other measurement approaches. We analyzed student’s textual responses and interaction data collected from a mathematical learning platform where students are asked to thoroughly explain their solutions and are scaffolded in communicating their problem-solving process to their peers and teachers. We built detectors of four indicators of SMART operations (namely, assembling and translating operations). Our detectors are found to be reliable and generalizable, with AUC ROCs ranging from .76-.89. When applied to the full test set, the detectors are robust against algorithmic bias, performing well across different student populations.

Keywords

self-regulated learning, SMART model, automated detectors

1. INTRODUCTION

Work over the last two decades has developed automated detectors of a range of behaviors and constructs in students’ interaction with computer-based learning environments [12]. These detectors utilize log data collected from these learning environments to infer the presence or absence of a complex behavior or a construct in student learning. For example, detectors have been built to identify student affect (e.g., [7, 21, 31]), engagement (e.g., [6, 37]), and problem-solving strategies [43]. Such detectors can be split into two broad categories: detectors for post-hoc analysis and detectors for real-time adaptation. Post-hoc analysis allows researchers to detect

constructs retrospectively and subsequently understand their prevalence (e.g., [32]) and conduct further analysis (e.g., [17, 41]). Detectors designed to be run in real-time facilitate adaptive experiences and real-time feedback [48], as well as reports to teachers [1].

In particular, considerable work has been devoted to detecting and understanding behaviors and strategies involved in self-regulated learning (SRL). By examining student behavior patterns, automated detectors have been developed for a range of SRL related constructs, including help avoidance [3], gaming the system [7], setting goals [5, 14], and planning and tracking progress [14]. However, the specific constructs being modeled often have not been clearly linked to any of the growing number of theoretical models of SRL (although [29] is an exception to this) and have mostly been operationalized in terms of high-level strategies that combine several of behaviors treated as separate in SRL theories, rather than the finer-grained behaviors used in those theories [cf. 46, 48]. Capturing fine-grained indicators of key aspects of SRL in terms of these theoretical models may yield a better understanding of the process of SRL and help EDM research make more direct theoretical contributions.

Self-regulation is a critical component of learning, and has been positively associated with learning outcomes [20, 34, 57]. In mathematics problem-solving, students who are skilled in SRL are able to effectively set goals, search for information, and direct their attention and cognitive resources to align their efforts with their objectives [56]. As a result, SRL facilitates the successful problem-solving process [20, 34, 57] and enables students to acquire a deep and conceptual understanding of the embedded knowledge [31]. Given its benefits, theory-based interventions have been developed to promote SRL [21]. However, current SRL assessments, such as self-reports and think-aloud activities, are not sufficient to provide measurement at scale; at the same time, existing scalable SRL assessments based on automated detection in log data are typically not connected back to theory, making it difficult to use them in theory-driven interventions. SRL assessments based on automated detectors have therefore been used in more ad-hoc, system-specific interventions, often with unintended consequences or unexpected patterns of findings [2, 35]

In the current study, we develop automated detectors that identify fine-grained evidence of SRL constructs drawn from theory. This study does so in the context of CueThink, a digital learning application that focuses on enhancing middle school student mathematics problem-solving skills. Through the lens of the SMART model of SRL (described in greater detail below) [53], we identify and operationalize five SRL indicators: numerical representation, contextual representation, strategy orientation, outcome orientation, and data transformation. We then build automated

detectors for each indicator, evaluate their performance, and check them for algorithmic bias.

2. BACKGROUND

2.1 SRL and the SMART Model

Grounded in information processing theory, Winne and Hadwin [55] characterize the process of SRL as four interdependent and recursive stages, in which learners: 1) define the task, 2) set goals and form plans, 3) enact the plans, and 4) reflect and adapt strategies when goals are not met.

The SMART model of SRL [53] was later proposed to further elucidate the processes involved in these four tasks. Specifically, the model separates the “cognitive and behavioral actions applied to perform the task” into five categories: *searching*, *monitoring*, *assembling*, *rehearsing*, and *translating*. Each operation describes a way that learners cognitively engage and interact with information. For example, when working on a task, learners direct their attention to particular information (searching) and compare the information with a standard (monitoring), evaluating the relevance or the importance of the information. When relevant information is identified, students relate pieces of information to one another (assembling), in order to create a comprehensive understanding of the problem. When information does not fit into the current problem representation, learners manipulate the ways information is presented in order to find a solution (translating). Throughout the process, working memory is used to actively maintain and reinstate information (rehearsing).

These cognitive operations are an integral aspect of self-regulation: they help determine student success at completing each of the four SRL tasks, which, in turn, influences the progression of the problem-solving process [52]. However, despite the SMART categories' importance for SRL, they are often difficult to observe or measure, as most learning activities (whether online or offline) do not fully reify the cognitive process involved in their learning tasks. Further, these operations may occur non-linearly, and multiple operations can be employed when completing the same task—making the measurement of these constructs challenging.

2.2 Challenges in SRL Measurements

SRL has typically been measured using three common approaches: self-reports, think-aloud activities, and log data collected in computer-based learning environments [51]. With traditional self-report studies, students are asked about their SRL process either outside of a task (i.e., before or after completing a task) or while working on a task. In decontextualized self-report (outside of a task), students report on the SRL strategies they plan to use or recall on the strategies they used, using a pre- or post-task survey. Even though this approach is widely used, the nature of surveying cognitive processes outside of the task may lead to inaccuracies in the representation of cognition [51]. For example, when recalling a cognitive process retrospectively, students may aggregate the out-of-context, self-reported experience across numerous tasks, failing to demonstrate the relationship between the task and the corresponding SRL strategies. For this reason, several studies have adopted in-context self-report (e.g., [42, 47, 54]), in which students are asked to tag their SRL strategies as they occur.

Other research has leveraged think-aloud activities that ask students to verbalize their cognitive processes when solving a problem [28]. As with in-context self-reports, think-alouds give researchers an opportunity to identify processes that are contextualized in the problem-solving activity and are approximately concurrent with

their occurrences. However, this process can suffer from an observation effect. Students being prompted to discuss their thinking process in real-time may alter that process and not provide an accurate representation of the processes they would engage in naturally [16, 44]. This, in turn, calls into question the validity of findings obtained using this type of measurement and whether they are generalizable to new students and contexts.

2.3 Use Log Data to Measure SRL in Computer-Based Learning Environments

Both self-report and think-aloud approaches are labor-intensive and time-consuming, which make them difficult to scale. As such, a third approach, analyzing log data collected from computer-based learning environments, has emerged as a promising way to measure SRL.

Aleven and colleagues [3] designed an exhaustive set of production rules to represent help-seeking behaviors within a geometry learning system, and then compared these rules to student problem-solving steps to determine whether those steps were warranted by the current situation. Similarly, Biswas et al. [14] used sequences of student behaviors to model a range of SRL behaviors, such as monitoring through explanation, self-assessment, tracking progress, and setting learning goals. Additionally, Segedy et al. [45] utilized log data and coherence analysis to assess students' ability to seek out, interpret, and apply information in an open-ended learning environment, examining if a student's subsequent action is coherent based on the information presented.

Researchers have also used textual responses within dialogue-based learning systems to measure SRL. Graesser and colleagues [27] used latent semantic analysis to study student conversations with animated pedagogical agents to assess and support SRL. Students who frequently use questions in a conversation can be interpreted as showing initiative, and engagement in monitoring can be inferred when students demonstrate in their responses that they feel they know the answer [26].

However, often the log data collected does not straightforwardly reflect a SRL construct [4]. Researchers must decide what data to use, what constructs to measure, and how to operationalize the constructs with the existing data [30]. SRL, as a process, covers a range of behaviors and strategies, so the constructs can vary depending on how SRL is conceptualized and also based on the design of the activity the learner is participating in. To ensure the validity of the operationalization, it is recommended that the operationalization should be conceptualized in terms of a SRL model and contextualized in the learning environment where the data is generated [51].

2.4 Algorithmic Bias

In order to use detectors at scale, we must ensure that they will be valid for the entire populations they are scaled to rather than only subgroups of students. Recent evidence suggests that many published detectors are prone to algorithmic bias, functioning better for some populations of learners than others [11]. However, there has been limited attention to algorithmic bias within the field of educational data mining, where analyses of algorithmic bias are rare and even overall population demographics are only reported in 15% of publications [38]. Verifying detector fairness is particularly pertinent to our study given the diverse student population who use CueThink, making it important to evaluate detector effectiveness across demographic groups before deploying and using the detectors at scale.

2.5 Current Study

In the current study, we address the challenges noted above by building automated detectors of SRL constructs from a theory-driven lens. Using a dataset of 79 students as they interacted with the online math learning platform CueThink, we first examine the learning environment understanding how students interact with the platform and the context of where the log data is generated. Based on the context and the log data available, we identify relevant theoretical constructs grounded in the SMART model. In particular, five SRL indicators relating to cognitive operations in the SMART model (in this case, all either *assembling* or *translating*) are identified for investigation.

We use text replay to code student interactions for each defined indicator. These labels are then used as ground truth for machine learning. We distill a variety of features from the log data to represent multiple aspects of a student’s interaction, including the number of responses and the content in the responses. The ground truth and the features are then input into a machine learning process, training a model to emulate human coders’ judgement, making predictions on the presence or absence of a SRL indicator.

We demonstrate that trained detectors provide accurate detection, suitable for real-time use. Finally, we also evaluate, through slicing analysis, the performance of our models across different demographic groups.

3. METHODS

3.1 Learning Environment

CueThink is a digital learning application that focuses on enhancing middle school student math problem-solving skills, by encouraging students to engage in self-regulated learning and to develop math language to communicate problem-solving processes. CueThink asks students both to solve a math problem and to create a shareable screen-cast video that provides the student’s answer and also demonstrates their problem-solving process. As Figure 1 shows, CueThink structures a problem into a *Thinklet*, a process that includes four phases—*Understand*, *Plan*, *Solve*, and *Review*—that closely align with Winne & Hadwin’s model of SRL [55].

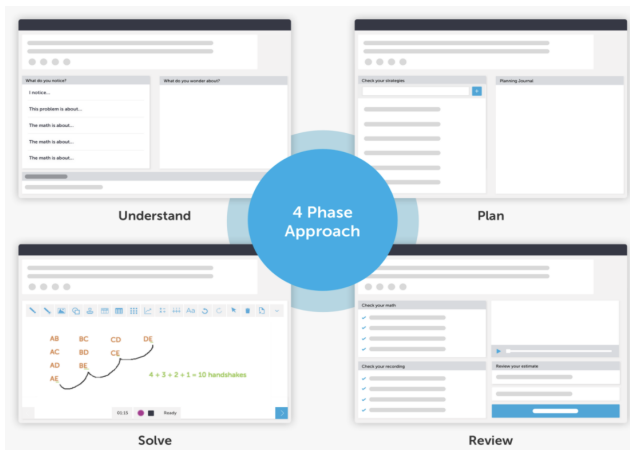

Figure 1. Screenshots of CueThink’s 4 Phase Approach

Each phase of the *Thinklet* (outlined in Table 1 and described in more detail below), asks students to focus on a different part of the problem-solving process. While working on a *Thinklet*, students can move freely across the four phases, including going back to a previous phase or skipping phases.

Starting with the *Understand* phase, students read a problem and provide text-based responses to three questions: (1) “What do you notice?” (2) “What do you wonder?” and (3) “What is your estimated answer to the problem?” This phase encourages students to actively look for information in the problem and create a representation of the problem space. Thus, students demonstrate their understanding of what they know and what they need to know at this phase.

In the *Plan* phase, students build on what they have established in the *Understand* phase by planning how they will solve the problem. Students are first prompted to select what strategies they will use to solve the problem. They may choose from a predefined strategy list (i.e., draw a picture, model with an equation, work backwards, etc.) or define their own strategies. Once the student has selected which strategies they will use, the student is prompted to write a plan on how they will use the strategies to solve the problem.

In the *Solve* phase, students explain and present their answer. Specifically, they create a screen cast video using an interface that provides them with a whiteboard and mathematical tools (i.e., number lines, ruler, etc.).

In the *Review* phase, students provide the final answer to the math problem, but also reflect on whether the answer makes sense and whether their communication is clear, using checklists to scaffold their reflection.

Once students have completed the problem, they share their screen-cast explanation for *Peer Review*. In this phase, teachers and peers annotate both the textual responses and video, often asking the student for their underlying reasoning or why the student picked specific methods. These annotations are then sent back to the video’s author for possible revision.

Table 1. Summary of Responses by *Thinklet* Phase

Phase	Tasks Description & Data Types
Understand	What I notice is (<i>textual response</i>)
	What I wonder is (<i>textual response</i>)
	Estimate your answer (<i>textual response</i>)
Plan	Choose your strategies (<i>select all that apply, textual response</i>)
	Planning journal (<i>textual response</i>)
Solve*	Video creation tools (<i>Whiteboard, math tools, and recording tools</i>)
Review	Check your math (<i>select all that apply</i>)
	Check your recoding (<i>select all that apply</i>)
	Review your estimate (<i>textual response</i>)
	Final answer (<i>textual response</i>)

* Student activity in the *Solve* phase is not used in this paper’s analyses

3.2 Student Demographics

In this study, 79 students in grade 6 and 7 at a suburban school in the southwestern U.S. used CueThink during the 2020-21 school year. The school contains a diverse student population with around 40% Hispanic or Latino, 40% White, 15% African American, and 5% Asian students. Students’ self-reported demographic information on gender and race/ethnicity was collected. For gender, students could choose to identify as male, female, non-binary, or leave the question blank. For race/ethnicity, options included African America, Hispanic/Latinx, White, Asian, Native American, two or more races, other, or prefer not to say. Students reporting

“other” for their race/ethnicity were provided the option to give detail.

3.3 Log Data

CueThink was used in six classrooms over multiple weeks, with teachers assigning problems for students to complete in the application. We collected log files that reflect how students use the application and their problem-solving process. On average, students spent 5.2 hours in CueThink and 1.8 hours working on each *Thinklet*. Specifically, for each problem, encapsulated in a *Thinklet*, data generated during the problem-solving process that includes the questions students answered and their textual responses at each phase were collected. In this study, we analyzed textual and click-stream data, but did not analyze data from the videos. In total, we collected 349 *Thinklets* from 79 students working on 24 different problems. Of those 349 *Thinklets*, not all were first attempts. Students have the opportunity to revise their work, which creates another *Thinklet*. In those cases, it is possible that students do not go through the entire problem-solving process. Of the total number of *Thinklets*, 146 were duplicate attempts.

4. BUILDING DETECTORS

Building automated detectors of self-regulated behaviors was a multi-step process (detailed in the following subsections). First, we distilled human-readable text replays from log data. Using these text replays, we identified and operationalized qualitative categories that corresponded with SRL constructs, grounding the operationalization in Winne’s SMART model. We then labeled the self-regulated behaviors, generating ground truth data. Feature engineering and feature distillation were conducted and used to train the predictive models. Lastly, we evaluated model performance and checked for algorithmic bias.

4.1 Text Replays of Interaction Logs

To facilitate inspection and exploration of the data, we used text replays. This method presents segments of interaction data (referred to as clips) in a human-readable presentation. This process facilitates both initial exploration of the data (such as in section 4.2) along with the final coding process (section 4.3). Clips are then viewed by human coders who label them accordingly [8]. Previous studies have used text replay coding to label student affect, disengagement, and learning strategies, such as gaming the system [10], confusion [32], player goals [22], and SRL strategies such as whether a student is using a table to plan their analyses [43]. This approach demonstrates a similar level of reliability as classroom observations and is 2-6 times faster compared to other methods of generating labels, such as classroom observations, screen replay, and retrospective think/emote-aloud protocols [8].

The length and the grain-size of text replay clips can vary depending on both the available data and the granularity of the predictions the researcher intends to make. Because this study seeks to detect cognitive SRL operations in the problem-solving process, which requires a comprehensive examination across questions and phases, the log files were delineated into clips on the level of entire *Thinklets*. Each clip contains a student’s actions and text-based responses that were submitted as that student worked through the four phases to produce a single *Thinklet*. (Note that because video data was not available in these replays, our coders did not see information from the *Solve* phase.) The clips were distilled from log files and presented using a Python window, shown in Figure 2. As video data could not be trivially converted into a common text format (due to wide variability in the videos), video data was not included in the text replays at this time. Creating videos is the primary action

in the *Solve* phase, thus the text replays did not contain any data from the *Solve* phase. Coding videos explicitly poses challenges to scalability of the work and is beyond the scope of this paper, but may be considered in future work.

4.2 Construct Operationalization

To identify constructs to detect, we first examined the clips containing student responses in *Thinklets* and coded student responses for indicators of SRL—qualitative categories that correspond with SRL constructs (we discuss the details of exactly how the data was coded in section 4.3). The definitions of the indicators we coded were developed through dialogue between the research team and system developers. This process followed the recursive, iterative process used in [49] that includes seven stages: conceptualization of codes, generation of codes, refinement of the first coding system, generation of the first codebook, continued revision and feedback, coding implementation, and continued revision of the codes [49]. The conceptualization of codes included a review of related literature, including several theoretical frameworks and perspectives [13, 15, 24], primarily focusing on the SMART model [53]. Using grounded theory [18], we identified common behaviors that were (1) indicative of SRL as characterized by Winne’s SMART model [53] and (2) salient in the log files. A draft lexicon and multiple criteria were generated for a coding system to help identify these constructs.

Given the learning environment’s design and the available data, our efforts focused on defining behaviors related to two categories of cognitive operations (the assembling and translating operations from the SMART model) as they are frequently employed in the initial stages of SRL as learners define tasks and set goals. Following the process used in [49], two coders (the first and second authors) coded a set of clips together, identified five SRL indicators (i.e., numerical representation, contextual representation, strategy orientation, outcome orientation, and data transformation), outlined the criteria for each indicator, and created a rubric.

The draft coding manual was discussed with all members of the research team and developers and designers at CueThink to build a common understanding of the criteria and constructs being examined as well as the features of the system to gain feedback for further refinement. This process was repeated until the entire team had reached a shared understanding of the criteria and constructs being examined by the codebook. The SRL indicators identified, the criteria, and alignment with the SMART model are included in Table 2.

Numerical and contextual representation consider a learner’s process of creating a problem representation, which often occurs in the initial stage in the problem-solving process (i.e., define the task), outlined in the four-phase model of SRL [55]. In problem representation, learners create a problem space by identifying information they know and information they need to know. The two SRL indicators encode how learners represent and process information in math problems, denoting if numerical components and/or contextual details are noted. We consider both of these processes to reflect assembling in the SMART model as students are creating their representation of the data from the information provided. There may also be overlap with translating in some cases, especially if the question provides a different representation to the one the students use. However, as this is not always the case, we primarily consider both indicators to reflect assembling actions and tag translating actions in a different code (see below).

Strategy and outcome orientation also reflect student assembling behaviors. Both indicators consider how students set their goals and form plans for the problem-solving process. These two indicators demonstrate a difference in focuses (process vs. output).

Lastly, data transformation reflects behaviors that are associated with the translating operation, in which the learner manipulates the ways information is represented to them in the problem to find a solution.

Table 2. SRL Indicators Coded through Text Replays

SMART Category	SRL Indicator	Working Definition
Assembling	Numerical Representation (NR)	The learner’s representation of the problems includes numerical components and demonstrates a level of understanding of how the numerical values are used in the math problem.
Assembling	Contextual Representation (CR)	The learner’s representation of the problem includes contextual details relating to the setting/characters/situations within the given math problem.
Assembling	Strategy Orientation (SO)	Learners explicitly state a plan for how they will find the answer for the given math problem, decomposing information into a step-by-step process.
Assembling	Outcome Orientation (OO)	The learner provides only a numerical estimate of the final answer for the given math problem, suggesting that learners are focused on the output instead of the process itself.
Translating	Data Transformation (DT)	The learner manipulates the ways information is represented to them in the problem to find a solution. This suggests active problem solving.

4.3 Coding the Data

After constructs were operationalized and defined, we proceeded to code the remainder of the data. Two coders, (the same as in the previous section), completed the text replay coding in three phases: preliminary coding (discussed above), separate coding (two coders per clip; for establishing inter-rater reliability), and individual coding (one coder per clip; for completeness).

The two coders each used the codebook/rubric to code the same set of clips separately. They then compared the labels and computed the inter-rater reliability (IRR) kappa. For constructs with low kappa, the two coders discussed their differences in labeling and conducted another round of coding. This step of separate coding and comparing is repeated until an acceptable reliability is established. After two rounds of coding, as shown in Table 3, the two coders reached an acceptable IRR above 0.60 for all five SRL indicators (M=0.75).

Table 3. Inter-Rater Reliability in Separate Coding

SRL Indicator	IRR Kappa
Numerical Representation (NR)	0.83
Contextual Representation (CR)	0.63
Strategy Orientation (SO)	0.74
Outcome Orientation (OO)	0.78
Data Transformation (DT)	0.74

Once the reliability was established, the coders moved on to the individual coding where they split the rest of the clips and coded them individually.

Each construct was considered over the entire *thinklet*. Thus, in total, the two coders coded 349 clips. However, in order to consistently examine the entire problem-solving process, 167 clips that were marked incomplete because students stopped before completing the entire problem were excluded. Of the remaining 182 clips, coding resulted in the following distribution of labels: 64% numerical representation, 77% contextual representation, 8% strategy orientation, 72% outcome orientation, and 73% data transformation. These were produced by 72 students, who, on average, each contributed 3 clips (max=4, min=1, median=3).

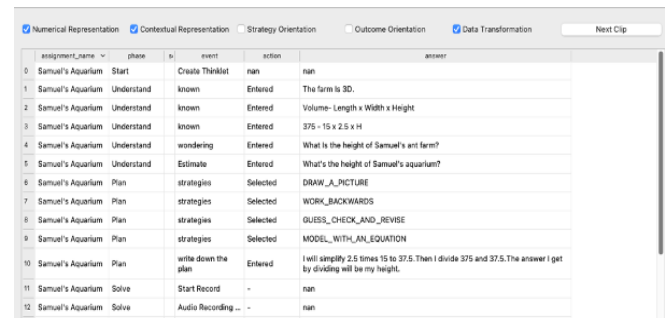

Figure 2. Screenshot of Text Replay Coding Window

4.4 Feature Distillation

Two sets of features were distilled to build the detectors. Both sets of features consist solely of features that can be extracted and used in real-time. The first set of features were designed to provide an overview of a *Thinklet* by examining the number of responses in a *Thinklet*. These features (N = 10) were distilled at the *Thinklet* level. For example, we distilled the number of questions students answered in a *Thinklet* and the number of responses in each phase. To understand the strategies that students select in the *Plan* phase, we also created a feature that counts the number of strategies a student selects among the top two strategies used by peers for the same problem.

The second set of features were designed to examine the content and the linguistic features of students’ text-based responses. These features (N = 90) were first extracted at the response level and then aggregated to the phase level. These aggregations were calculated for the *Understand*, *Plan*, and *Review* phases. (No textual data was extracted from the *Solve* phase as there was no textual input in this phase.)

Specifically, we distilled whether each response: 1) contains a numerical value, 2) consists of only numerical values, 3) has mathematical operation signs, 4) contains a question (if it contains a question mark or uses keywords such as “wonder”, “why”, etc.), 5) uses language that indicates the formation of a plan (e.g., the use of keywords like “plan”, “I will”, “going to”, etc.) , and 6) is the exact repetition of a previous answer. These criteria generate a set

of binary variables for each response. We averaged these binary variables across the responses within a phase, creating 18 features for each *Thinklet*.

Additionally, in each response, we counted the number of 7) characters, 8) words, 9) numerical values, 10) verbs, 11) nouns, and 12) pronouns. Features 10-12 were counted using Udpipes, a natural language processing toolkit [50]. We also 13) counted the number of keywords used from a predefined list that provides the context of each problem; and 14) computed how similar each response is to the problem item using the Smith-Waterman algorithm [46]. For these continuous variables, we computed the mean, standard deviation, and max of the values for each phase, creating 72 features.

Features distilled from the two sets were combined. In total, 100 features were extracted from each *Thinklet* process and were then used to construct the automated detectors. Note that we did not extract any features from the video that students make in the current work. Similarly, we did not use any of the audio from the video (or transcription thereof) for any features.

4.5 Machine Learning Algorithms

We used the scikit-learn library [40] to implement commonly-used models, including Logistic Regression, Lasso, Decision Tree, Random Forest as well as Extreme Gradient Boosting (XGBoost) as implemented in the XGBoost library [19]. XGBoost outperformed other algorithms in all cases; we therefore only discuss the XGBoost results below.

XGBoost uses an ensemble technique that trains an initial, weak decision tree and calculates its prediction errors. It then iteratively trains subsequent decision trees to predict the error of the previous decision tree, with the final prediction representing the sum of the predictions of all the trees in the set. We tested the detectors with 10-fold student-level cross-validation. For this approach, the dataset was split into 10 student-level folds, meaning that in cases where students had multiple *Thinklets*, all of their data would be contained within the same fold and at no time could data from a student be included in both the training and testing set. Nine folds were used to train the model, and the trained model was used to make predictions for the 10th fold. Each fold acted as the test set once. Student-level cross-validation was conducted to verify generalizability to new students.

Models were evaluated using the area under the Receiver Operating Characteristic curve (AUC ROC), which indicates the probability that the model can correctly distinguish between an example of each class. An AUC ROC of 0.5 represents chance classification, while an AUC ROC of 1 represents perfect classification. Results were calculated for each fold and averaged to yield one AUC ROC score per detector.

5. RESULTS

5.1 Model Performance

Due to the rarity of strategy orientation (only 14 clips were labeled with this construct), a detector could not be built for this construct. Automated detectors were built for the other four constructs. As shown in Table 4, the average AUC ROC derived from 10-fold student-level cross-validation is 0.894 for numerical representation (NR), 0.813 for contextual representation (CR), 0.761 for outcome orientation (OO), and 0.815 for data transformation (DT). These findings suggest that the detectors were generally successful at capturing these four SRL constructs. We also calculated the standard deviations (SD) of the AUC ROCs across the 10 folds for each detector to investigate the variability across folds.

Table 4. Detector Performance Measured by AUC ROC

SRL Indicator	AUC ROC (SD)
Numerical Representation	0.894 (.078)
Contextual Representation	0.813 (.132)
Outcome Orientation	0.761 (.076)
Data Transformation	0.815 (.163)

5.2 Feature Importance

To better understand the detectors as well as to inform our understanding of how these features relate to the constructs, the SHapley Additive exPlanations (SHAP) [33] value, which reflects feature importance, was calculated for each feature within each test set.

These values were then averaged across the 10 testing sets and ranked based on their absolute values. Of the 100 features used, Table 5 reports the top five features with the highest absolute SHAP values for each detector. To understand the directionality, we examined the average SHAP values of the features listed. A positive average SHAP value was found for all the features listed (except for one, as indicated in the Contextual Representation section of Table 5). The positive values indicate that the features are positive predictors of the SRL indicators, suggesting that the higher the values in each feature, the more likely the model is to infer the presence of a SRL indicator.

Table 5. The Top Five Features from each Detector

Feature Phase	Feature
Numerical Representation	
Understand	Mean N of responses that give numerical values
Understand	Max value of the similarity feature which indicates how parallel a student's response is to the original problem
Understand	SD of the similarity feature
Understand	Total N of responses
Plan	Avg value of the similarity feature
Contextual Representation	
Understand	Is there a response to the "what do you notice" question?
Understand	Avg N of keywords used
Understand	SD of the N of characters used (Contextual Representation less likely)
Thinklet	Total N of responses
Plan	Max value of the N of characters used
Outcome Orientation	
Review	Avg N of keywords used
Review	Avg N of words used
Understand	SD of the N of numerical values used
Understand	Is there a response to the "what is your estimated answer" question?
Review	Avg N of nouns used
Data Transformation	
Plan	N of strategies selected that were among the most common strategies used by peers
Understand	SD of the similarity feature
Plan	SD of the N of characters used
Understand	SD of the N of nouns used
Plan	Max value of N of words used

We note that of the 20 features listed in Table 5, 11 are from the *Understand* phase, 5 are from the *Plan* Phase and 3 are from the *Review* phase. In other words, behaviors in the early phases

Table 6. Detector Performance by Gender and Racial/Ethnic Groups

	All Students (k-fold)	All Students (Pooled)	Gender			Race/Ethnicity					
			Male	Female	Left Blank	African American	Hispanic/Latinx	White	Prefer Not to Say	Other	Two or more races
N. students	72	72	33	28	9	6	18	8	19	14	5
N. clips	182	182	81	73	24	20	38	19	50	37	12
NR	0.89	0.89	0.82	0.93	0.97	0.92	0.88	0.96	0.86	0.85	0.86
CR	0.81	0.80	0.74	0.75	0.94	0.75	0.72	0.80	0.90	0.65	0.78
OO	0.78	0.75	0.78	0.74	0.72	0.71	0.81	0.80	0.74	0.78	0.46
DT	0.82	0.86	0.88	0.87	0.78	0.92	0.91	0.83	0.84	0.82	0.86

contributed more heavily to the predictions. This finding aligns with how the *Thinklets* were initially coded. Specifically, the coders primarily examined student responses in the *Understand* phase for numerical and contextual representation as this phase contains information demonstrating how student assemble information and create a problem representation; the coders examined the *Thinklet* more broadly when coding for other SRL indicators, as they encompass behaviors that span across phases.

5.3 Algorithmic Bias

Algorithmic bias occurs when model performance is substantially better or worse across mutually exclusive groups separated by generally non-malleable factors [11]. To validate our detectors, we tested the model performance in different student populations, based on gender and race/ethnicity using slicing analysis [25]. Specifically, utilizing the predictions made in the testing sets, AUC was computed for each subgroup of students in the data for which we received data on group membership. However, due to sample size, comparisons were not possible for gender non-binary students (N=2), Asian students (N=2), or Native American students (N=0).

As Table 6 shows, the difference in model performance measured by AUC between male and female students is small, ranging from 0.01-0.11 for the four detectors. The detectors for numerical representation and contextual representation performed somewhat better for female students ($AUC_{NR} = .93$, $AUC_{CR} = .75$) than for male students ($AUC_{NR} = .82$, $AUC_{CR} = .74$), while detectors for outcome orientation and data transformation performed somewhat better for male students ($AUC_{OO} = .78$, $AUC_{DT} = .88$) than for female students ($AUC_{OO} = .74$, $AUC_{DT} = .87$).

Table 6 also shows the analysis of algorithmic bias in terms of race/ethnicity, comparing the AUC between student racial/ethnic subgroups that had more than 5 students in our sample: African American, Hispanic/Latinx, and White. Small to moderate differences were observed across the three groups, though the differences were not consistent (i.e., no racial/ethnic group consistently had the best-performing detectors). However, performance remained acceptable for all four detectors across all groups. When detecting numerical representation and contextual representations, the detectors performed somewhat better for White students ($AUC_{NR} = 0.96$, $AUC_{CR} = 0.80$), than for African American ($AUC_{NR} = 0.92$, $AUC_{CR} = 0.75$) and Hispanic/Latinx ($AUC_{NR} = 0.88$, $AUC_{CR} = 0.72$) students. However, the outcome orientation detector had somewhat higher performance for Hispanic/Latinx students ($AUC_{OO} = 0.81$), than for White ($AUC_{OO} = 0.80$) and African American ($AUC_{OO} = 0.71$) students. The data transformation detector performed better for African American students ($AUC_{DT} = 0.92$) than for Hispanic/Latinx ($AUC_{DT} = 0.91$) and White ($AUC_{DT} = 0.83$) students.

Performance was substantially lower for two constructs/group combinations: detecting contextual representation for students who identify race as other ($AUC_{CR} = 0.65$) and detecting outcome orientation for students who identify as belonging to two or more races ($AUC_{OO} = 0.46$). These more substantial differences may be due to the small sample size of these constructs within these subgroups; in future work, larger samples will be collected in order to validate performance in these groups.

Given the data collected, we noticed a considerable number of students who declined to report gender (N = 9) and race (N = 19). Both groups performed close to the average model performance, across groups and contexts.

6. CONCLUSION AND DISCUSSION

6.1 Main Findings

Given the importance of self-regulation in learning, specifically in the problem-solving process, an increasing number of studies have looked into ways to promote self-regulated learning. This first requires the ability to accurately measure SRL, so that interventions can be introduced to encourage and guide students to self-regulate effectively. However, the most common ways of measuring SRL in a fine-grained fashion – either through self-report and think-aloud protocols – are difficult to automate and scale, and they can also interrupt or interfere with the learning task. Log data collected from computer-based learning environments offers an unobtrusive and potentially scalable solution to help understand when and how students self-regulate within the problem-solving process, in order to inform decisions on intervention (e.g., [3]). However, previous automated detection of SRL constructs using log data has mostly not been explicitly connected to SRL theory. In the current work, we explored the possibility of detecting SRL constructs at a fine-grained level, focusing on detecting cognitive operations (i.e., assembling and translating), outlined in the SMART model [53]. Specifically, we detected the presence of four self-regulation indicators related to two categories of operations: numerical representation, contextual representation, outcome orientation, and data transformation. Evaluated using 10-fold student-level cross-validation, our detectors were found to be accurate and valid across demographic groups, with AUC ROC ranging from .76-.89.

To understand the detectors, feature importance was examined using SHAP values. The top five features with the highest absolute SHAP values were identified for each detector. With the features identified, we find that except for outcome orientation, the detectors primarily rely on features extracted from the *Understand* and *Plan* phases of the learning activity, the two phases where students assemble information and make plans. In particular, the numerical representation detector mainly relies on features that examine the

numerical values used in the *Understand* phase as well as features that compare the similarity between student responses and the problem item. The numerical value feature makes sense, as the detector is operationalized to identify if numerical components are processed and represented when students assemble information.

However, the maximum similarity feature, a feature that takes both numerical values and text into account, also contributes to the NR indicator. This finding suggests that the NR detector not only examines if numbers are used in responses, but also how they are used in relation to the problem. As such, this finding validates the operationalization of this indicator, showing that the learner demonstrates a level of understanding of how numerical values are used in math problems, creating a representation of the problem space utilizing numbers.

The contextual representation detector looks at the keywords used in student responses in the *Understand* phase and the length of the responses in the *Plan* phase, which indicates the relationship that the longer the responses are when a student is forming a plan, the more likely it is for the student to contextually representing the problem. When predicting the presence of outcome orientation, the model utilizes features extracted in the *Understand* and the *Review* phases, understanding students' use of keywords, nouns, and numerical values in these two phases. At last, the data transformation detector checks the number of top strategies students select as well as the length and the variation in the length of the responses in the *Understand* and *Plan* phase.

Additionally, we examined model performance on different demographic subgroups of students, both in terms of gender and racial/ethnic groups, to verify their fairness and lack of algorithmic biases. Relatively small differences were observed in each comparison, and no student group (either gender or racial/ethnic group) consistently had the best-performing detectors.

6.2 Applications

The detectors built in the current study provide two advantages over previous SRL detectors. First, previous SRL detectors generally identify higher-level strategies and are not typically linked to theory; in contrast, we specifically based our detectors on a SRL model in order to identify theoretically-grounded SRL constructs at a finer-grain size. Having developed these fine-grained models of behavior associated with the assembling and translating operations of SMART, we can conduct analyses to further our understanding of the role that cognitive operations play in the broader process of SRL. For example, we can investigate questions about how often students use these cognitive operations in each of the four tasks outlined in the Winne and Hadwin's four-stage model, and how the engagement and the frequency of the engagement in these cognitive operations contributes to the success of completing the tasks. Results from future analyses will help expand the current theoretical understanding on SRL, adding specificity to the still high-level processes represented in contemporary SRL theory.

Second, given that most previous detectors are not connected back to SRL theory, it has been difficult to use them with theory-driven interventions. The detectors proposed in the current study are developed based on a theoretical model of SRL [46, 48] and are operationalized to capture key aspects of the cognitive operations in the model. These detectors can therefore be used to facilitate the development of adaptive learning environments that respond to student SRL, in a fashion connected to theory. For instance, a student demonstrating an outcome orientation could be encouraged to reflect further on their strategy.

Similarly, these detectors could also provide theory-grounded information to teachers (e.g., through a dashboard), providing insight on how students are approaching problems. This data can inform teachers as they create and refine their problems, as well as informing how they support their students. As with any application of this nature, careful attention will be needed in design to ensure that data is presented in the most useful form for teachers and appropriately represents the uncertainty in the model (i.e., false positives or false negatives).

6.3 Limitations and Future Work

This work has five principal limitations that should be addressed in future work. First, when validating the fairness of the models, the sample size is small (less than five students) for several student groups. Reliable comparison of the model performance for these groups of students is therefore not possible. In future work, larger and more representative samples should be collected in order to validate model performance for a broader range of student groups.

Second, although our detectors are based on a theoretical model of SRL, the operationalization of our constructs is contextualized in the current learning environment, so our detectors may be platform-specific. Future work should study the transferability of the current detectors by examining their applicability and predictive performance, and explore how they can be adapted for use in other learning environments. To the extent that some of our detectors (such as the data transformation detector) apply across learning environments, we can investigate their performance within those contexts to evaluate their transferability (see, for instance, [39]).

Third, since the detectors are currently trained on complete *Thinklets*, they will have some limitations in the ways they can be used when being implemented in a learning platform. Specifically, the detectors will only be able to make predictions after a student has solved a problem, providing an indicator at that point on the student's use or lack of use of assembling and translating in the problem-solving process. As such, these detectors will not provide immediate detection of these strategies when students are working through a problem. However, they can still be used to inform teachers and direct their feedback after a problem has concluded, in between problems or for the next problem. To enable other uses, it may be relevant to examine ways of also making early predictions based on incomplete *Thinklets* in order to provide detection during the problem-solving process, enabling real-time interventions.

Future work should also consider additional methods for ground truth labelling. In this work we used a post-hoc tagging approach (through text replays), to identify indicators of SRL-related strategies. This approach has the potential to miss crucial "in-the-moment" events that are not evident from the log data alone. Future studies could examine how post-hoc tagging used in the current study align with in-the-moment tagging, reported by either student themselves or external observers/interviewers (e.g. [7]) to examine additional aspects of SRL.

Finally, future work should consider expanding the scope of this work. In the current study, five constructs were identified and four modeled. SRL as a process covers a much broader range of behaviors and strategies that elicit the use of various cognitive operations. Future studies should model and detect a broader range of cognitive operations throughout the four stages of self-regulated learning in the context of problem-solving.

6.4 Conclusions

To better understand and facilitate the use of self-regulation in problem-solving, the current study tested the possibility of scaling up SRL measurement by leveraging machine learning to automatically detect individual SRL indicators through the lens of the SMART model. We built automated detectors that identify four commonly used strategies in math problem solving, indicating assembling and translating operations. Our detectors were found to be reliable and generalizable. Additionally, the detectors were also tested on different student populations to verify their fairness and lack of algorithmic bias, addressing a previously overlooked issue in the field of educational data mining. Given these properties, we anticipate implementing the detectors in the learning environment to collect more fine-grained data and to leverage the detection to inform interventions, creating more positive experiences in mathematical problem-solving.

ABSTRACT

In an Intelligent Tutoring System (ITS), problem (or question) difficulty is one of the most critical parameters, directly impacting problem design, test paper organization, result analysis, and even the fairness guarantee. However, it is very difficult to evaluate the problem difficulty by organized pre-tests or by expertise, because these solutions are labor-intensive, time-consuming, leakage-prone, or subjective in some way. Thus, it is of importance to automatically evaluate problem difficulty via information technology. To this end, we propose a novel difficulty prediction framework, named SQL-DP, for Structured Query Language (SQL) programming problems, mastering which plays a vital role in learning the database technology. In SQL-DP, semantic features of problem stems and structure features of problem answers in the form of SQL codes are both computed at first, using the NLP and the neural network techniques. Then, these features are used as the input to train a difficulty prediction model with the statistic error rates in tests as the training labels, where the whole modeling does not introduce any experts, some as knowledge labeling. Finally, with the trained model, we can automatically predict the difficulty of each SQL programming problem. Moreover, SQL programming problem answering log data of hundreds of undergraduates from Guangxi University of China are collected, and the experiments conducted on the collected log data demonstrate the proposed SQL-DP framework outperforms the state-of-the-art solutions apparently. In particular, SQL-DP decreases the RMSE of difficulty prediction by at most 7.23%, compared with the best-related framework.

Answer:	SELECT Sname FROM Student WHERE Sno IN (SELECT Sno FROM SC WHERE Cno = 'C1');
Difficulty:	0.4

Figure 1: An example of SQL programming problem.

With the progress of information technology, Intelligent Tutoring System (ITS) services are broadly applied, where problem (or question) difficulty has become one of the most critical parameters. The problem difficulty refers to the percentage of students who wrongly answer the problem [14]. Given the information of problem difficulty, an ITS can recommend exercises of suitable difficulty to students with varied knowledge proficiency [31], can automatically organize a test paper by choosing questions with different difficulty levels [12], and can better achieve a fairness guarantee for various other types of education tasks [29]. However, the difficulty of a problem is not directly observable before the test is conducted. To predict the problem difficulty in advance, traditional methods often resort to expertise (e.g., experienced teachers) who are asked to manually label the question difficulty according to their experience, or artificial tests organization [15]. Unfortunately, these human-based solutions are limited in that they are labor-intensive, time-consuming, leakage-prone, or subjective in some way [16]. Therefore, there is an urgent need to design problem difficulty prediction methods without manual intervention.

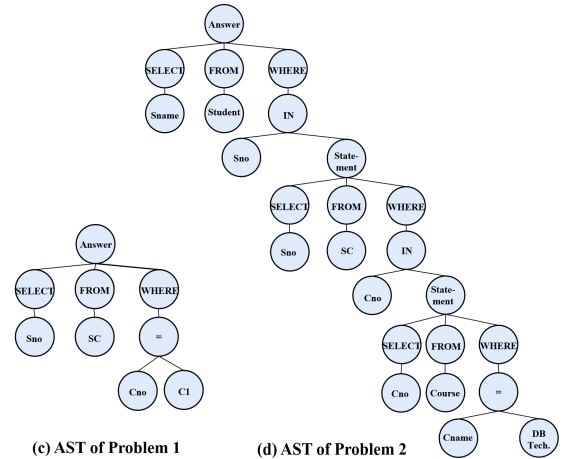

Recently, several non-human-based solutions that rely on machine learning techniques have been proposed [16, 23, 29, 18, 21, 8, 11]. For example, in [16], Huang et al. present TACNN, a test-aware attention-based convolutional neural network to automatically solve the difficulty prediction task for reading comprehension problems in standard English tests. In specific, TACNN utilizes the information of reading passage, question, option, and answer together to predict the difficulty. As another example, Qiu et al. in [23] propose a document enhanced attention-based neural Network (DAN) to predict the difficulty of multiple-choice problems in medical exams. Besides considering stem, option, and answer, DAN fetches relevant medical documents to enrich the information of each question. Moreover, in [29], Tong et al. design a group of salable data-driven models, i.e., C-MIDP and R-MIDP, based on CNN and RNN neural network architectures to predict the difficulty of mathematical

questions, which are leveraged by the historical test logs and the corresponding item materials (e.g., stem, option). However, no work is still proposed to estimate the difficulty of Structured Query Language (SQL) programming problems. Structured Query Language (SQL) is the de-facto database query language widely used in industry and taught in almost all computer-related majors in universities [19, 28], we thus focus on solving the difficulty prediction for SQL programming problems in this paper. Figure 1 shows a SQL programming problem containing a stem, an answer, and a difficulty label.

Being different from the existing non-human based solutions which only emphasizes the analysis of stem and option of problems, the difficulty of a SQL programming problem is not only influenced by the stem, options, or answer of the problem, but also depends to a great extent upon the structure of the SQL code answer to the problem. Taking the two SQL programming problems defined over the ‘Student-Course Database’ in Figure 2 as an example. Note that the ‘Student-Course Database’ has three tables, namely Student, Course, and SC, which records student-course selection relationships. Though the two examples of SQL programming problems in the figure have very similar stems, their standard answers in the form of SQL codes exhibit significantly different code structures depicted by Abstract Syntax Trees (ASTs) [17], which makes their difficulty values apparently different from each other.

To this end, we propose SQL-DP, a novel difficulty prediction framework for SQL programming problems and name it as SQL-DP. SQL-DP consists of two major modules. First, the feature extraction module is responsible for computing representations of SQL programming problems by not only considering the semantic information in their stems, but also taking the structure information of their answers in the form of SQL code into account. Using the computed representations of SQL programming problems as the input, then the difficulty prediction module in SQL-DP trains a difficulty prediction model with the statistic error rates in tests as the training labels. The trained difficulty prediction model can be applied to estimate the difficulty of a SQL program-

ming problem in an automatic manner. Note that the whole modeling in SQL-DP does not introduce any human intervention or knowledge labeling, ensuring the usability of the solution in a wide range of application scenarios. The Main contributions of this paper include:

- We propose SQL-DP, a novel difficulty prediction framework for SQL programming problems, which not only considers the semantics of problem stems, but also leverages the information of code structures of problem answers to quantify the difficulty of the problem. As far as we know, this is the first systematic solution to predict the difficulty of SQL programming problems.
- We collect the stems, answers, and answering results of hundreds of SQL programming problems by organizing undergraduates to complete tests of SQL programming problems using our self-developed SQL online judge (OJ) system.
- We conduct a group of experiments using the collected physical-world dataset, and the experimental results show the superiority of the proposed SQL-DP framework in predicting the difficulty values of SQL programming problems.

The rest of our paper is organized as follows. Section 2 discusses the related works; Section 3 states the preliminaries of this work; Section 4 describes details of the proposed SQL-DP framework for the prediction of SQL programming problems; then Section 5 evaluates the effectiveness of the proposed SQL-DP framework using physical-world dataset; finally Section 6 concludes the paper and points out future research directions.

2. RELATED WORKS

Problem (or question) difficulty prediction is an important problem having been widely studied in educational domain.

Traditionally, the difficulty of a question is predicted and labeled by expertise (e.g., experienced teachers) according

to their experience[1], which is labor-intensive and subjective, and not applicable when there are too many questions. An alternative solution is to organize an artificial test (also called as pretest) [1, 15], where a small group of students are required to take part in the artificial test and their error rates are then used to estimate the question difficulty. To improve the estimation precision, a group of educational measurement theories are applied, including *Classical Test Theory* (CTT) [6], *Item Response Theory* (IRT) [9], and *Cognitive Diagnosis Theory* [30]. Many well-known tests, such as Test of English as Foreign Language (TOEFL) and Scholastic Assessment Test (SAT) predict question difficulty following such solution. Unfortunately, the artificial tests based difficulty prediction solution is limited in that it is not only labour-intensive, time-consuming, but also has the risk of question leakage [16].

To overcome the shortcomings of traditional methods, with the development of machine learning technologies, many non-human based solutions of problem difficulty prediction emerge, which can be divided into two categories, i.e., simple regression analysis based and artificial neural network based.

Simple regression analysis based methods establish a simple regression model (e.g., linear regression, multiple regression, and SVM) to construct a mapping function between question difficulty and its influence factors, and the difficulty of new questions can be predicted based on the regression model. As an early example, Chon and Shin [3] built a difficulty prediction model for multiple-choice reading test items by using the multiple regression technique and maximum likelihood estimation. Several features of items, such as response time of testees and paragraph length, are set as the influence factors of item difficulty. A difficulty estimation model based on correlation and regression analysis for English vocabulary questions was then discussed in [27]. As another example, in [25], Makoto Sano proposed to extract a series of language features from multiple-choice questions of reading comprehension, and analyze the extracted features using multiple regression models to obtain the features most related to the question difficulty. Moreover, in [8], Masri et al. proposed to analyze influence factors (e.g., topic and depth of knowledge) of difficulty questions in the sixth grade science test of British primary schools, and establishes a stepwise regression model to predict the difficulty of questions. A difficulty prediction model was also presented towards suggestive blank filling questions for English Tenses [21], which employs the ridge regression model to analyze many factors (e.g., questions text and blank filling words) affecting the question difficulty. These regression analysis based methods, however, have limitations, since they require some domain knowledge and artificially define the factors affecting the question difficulty.

In view of the limitations of simple regression analysis, many researchers proposed to learn the complex relations between influencing factors and question difficulty via artificial neural networks, and as a result achieved the goal of automatic question difficulty prediction. For example, in [16], Huang et al. proposed a model, named TACNN, to predict the difficulty of reading comprehension questions in English test via Convolutional Neural Network (CNN), by using the in-

formation of reading passage, question, options, and answer of each question. Similarly, Tong et al. in [29] proposed a prediction method for the difficulty of mathematical questions based on both of CNN and Recurrent Neural Network (RNN), by analyzing stem, options, and answers of every question. Besides, in [11], Hsu et al. introduced a novel method for automated estimation of multiple-choice items which consist of the following item elements: a question and alternative options. The proposed method utilizes neural network to learn embeddings of question materials in semantic space. Then, it computes the semantic similarities among the stem, answer, and distractors, which are then together fed to a SVM for training the question difficulty prediction model. Then, in [18], Lin et al. proposed a question difficulty prediction model for Chinese reading comprehension problems based on long-term and short-term memory artificial neural network, while in [23] proposed a difficulty prediction method, named as DAN, for multiple-choice questions in medical examination based on neural network model. In specific, besides considering stem, options, and answer, DAN fetches relevant medical documents to enrich the information of each question.

Although recent years have witnessed many works that predict problem difficulty automatically without manual intervention. However, none of these works focus on solving the difficulty prediction of SQL programming problems whose answers in the form of SQL codes are significantly different from their answers. Considering the structure information of SQL codes has great impact on the difficulty of SQL programming problems, all existing works hence can not well handle the difficulty prediction problem for SQL programming items which is discussed in this paper.

3. PRELIMINARY

In this section, we first introduce the method of capturing code structure information. Then we formally define the problem of difficulty prediction for SQL programming problems.

3.1 Code Structure Extraction

In [13], Hindle et al. demonstrate that programming languages, similar to natural languages, also contain abundant statistical properties. However, there are also obvious differences that the code of programming language contains rich and clear structural information between programming language and natural language[20]. By extracting the structure information in the code, we can better analyze the source program. Therefore, some works have studied how to capture the code structure information[2, 20, 22].

In [20], Mou et al. parse code into AST and design a novel Tree-Based Convolutional Neural Network (named as TBCNN) to capture code structural information. In TBCNN model, an AST node is first represented as a distributed, real-valued vector so that the (anonymous) features of the symbols are captured. The vector representations are learned by a coding criterion in [22]. Then Mou et al. design a set of subtree feature detectors, called the tree-based convolution kernel, sliding over the entire AST to extract structural information of a program. Thereafter they apply dynamic pooling [26] to obtain information over different parts of the tree. Finally, a hidden layer and an output layer are added.

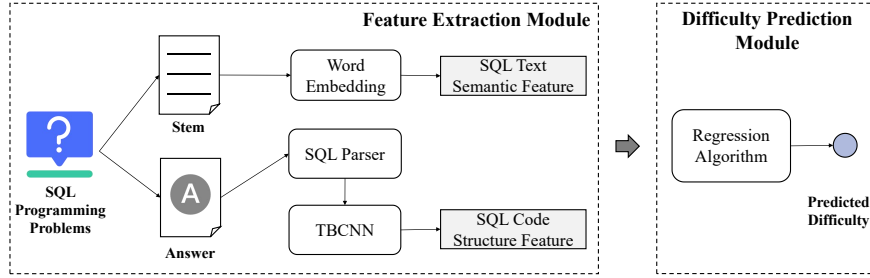

Figure 3: SQL-DP: A difficulty prediction framework for SQL programming problems.

Because the TBCNN model can capture code semantics efficiently, it has become one of the most classical models of code structure feature extraction.

As a programming language, SQL can generate AST through SQL syntax parsers, and then we can use the TBCNN model to extract the structure information of AST, that is, the structure information of SQL code. In short, to obtain more problem information to predict the problem difficulty, except the stem of SQL programming problems, we use the TBCNN model to capture the code structure information from the answers to SQL programming problems.

3.2 Problem Definition

This paper focuses on the difficulty prediction of SQL programming problems. The example of SQL programming problem is shown in Figure 2. The goal of this paper is to train problem difficulty prediction model by using problem stems, answers and real difficulty of SQL programming problems, and then predict the difficulty of new SQL programming problems.

Formally, given the SQL programming problem set $P = \{p_1, p_2, \dots, p_m\}$ and the corresponding real problem difficulty set $D = \{d_1, d_2, \dots, d_m\}$, the goal is to use the above data P and D to train a model \mathcal{M} , and the trained model \mathcal{M} can estimate the difficulty of new SQL programming problems without test logs. Where P includes the problem stem text set $T = \{t_1, t_2, \dots, t_m\}$ and the problem answer set $A = \{a_1, a_2, \dots, a_m\}$. In addition, $p_i = \{t_i, a_i, d_i\}$, $i \in \{1, 2, \dots, m\}$, p_i represents the SQL programming problem i , t_i represents the problem stem text of p_i , a_i represents the answer to SQL programming problem i , d_i represents the real difficulty of p_i , and m represents the total number of SQL programming problems.

In addition, We obtain the real difficulty of each SQL programming problem from the test logs, followed the previous works[23, 16, 29]. Specifically, we calculate the proportion of incorrect answers by dividing the number of students who have answered the problem incorrectly by the number of students who have responded to the problem[23]. The calculation equation of the difficulty of the problem p_i is as follows:

$$d_i = \frac{s_i}{S_i} \quad (1)$$

where d_i is real difficulty of p_i , s_i represents the number of students who have answered p_i incorrectly, and S_i represents

the total number of students who have responded to the problem p_i .

4. SQL-DP FRAMEWORK

This section will describe the difficulty prediction framework of SQL programming problems in detail. As shown in Figure 3, the difficulty prediction framework of SQL programming problems can be divided into two modules: 1) Feature extraction module, which mainly extracts features from the stem and answer of SQL programming problems. The extracted features include stem text semantic features and code structure features; 2) The difficulty prediction module, which uses machine learning to predict the difficulty value of SQL programming problems. Briefly, given the SQL programming problem include stem, answer, and difficulty, we use the feature extraction model to obtain the text semantic features and code structure features from the stems and answers. Then we take the above features and real difficulty as the input of the difficulty prediction module, where the real difficulty is the trained label. Finally, we can use the trained model, the stem and answer of new SQL programming problems to predict the difficulty of new problems, that is, the new SQL programming question without test logs.

4.1 Feature Extraction Module

The feature extraction module consists of SQL text semantic feature extraction module and SQL code structure feature extraction module. The former module uses word embedding techniques to obtain the text semantic features from the stem of SQL programming problems, and the last module extracts SQL code structure features from the answer to problems. The two modules mentioned above will be described in detail below.

4.1.1 SQL Text Semantic Feature Extraction Module

In the task of question difficulty prediction, word embedding technique is often used to obtain the text features of the question, including word2vec, Term Frequency–Inverse Document Frequency (TF-IDF), etc[16, 18, 29]. To extract textual semantic features in SQL programming problems effectively, we adopt various word embedding techniques used in [16] and [29] to extract textual information, including Bag-of-Words (BoW), TF-IDF, and word2vec. Finally, we select the optimal word embedding technique for follow-up experiments.

BoW does not consider the order of words in the sentence.

Figure 4: The structure of TBCNN model.

Figure 5: Tree-based convolution.

Still, it only counts the number of occurrences of words, so the value of each position of the text vector calculated by the model is the number of occurrences of the corresponding word. Because the model only records the first occurrence of each word and the number of occurrences of each word, the text features calculated by the model do not contain important information such as the grammar and semantics of the text.

TF-IDF is a word embedding technique used to calculate the importance of each word. The importance of the evaluation word is based on the term frequency and the inverse document frequency of the word appearing in the text. The term frequency counts the number of times each word appears in the text. And the inverse document frequency is used To measure the commonness of each word. The more common words have smaller IDF values.

word2vec is a technique that can efficiently learn the vector representation of text, which can accurately capture the syntactic and semantic word relationships in the text. When using word2vec to extract semantic information in the stem of SQL programming problems, we firstly take all the stem texts of SQL programming problems to train the word2vec model and obtain the word embedding vector of each word or character. Then, we segment the stem, remove the stop word, and replace the remaining words or characters with the corresponding word embedding vector in order to obtain the representation vector of the stem. Next, the input of the difficulty prediction module is a fixed length feature, but the length of words in the different stems is not the same. According to the method of [29], we set the text semantic feature of the stem to a fixed length J . If the length of stem vector is less than J , it is filled with zero. Otherwise, the

word behind J is deleted. Finally, we get the text semantic feature vector of SQL programming problem, which can retain certain semantic features.

4.1.2 SQL Code Structure Feature Extraction Module

Inspired by [20] and [32], in order to capture the tree structure information of the code as much as possible and enrich the input of the difficulty prediction of SQL programming problems, we apply TBCNN model to capture SQL code structural information. The TBCNN model structure is shown in Figure 4.

TBCNN model includes embedding layer, tree-based convolution layer, dynamic pooling layer, and output layer. TBCNN first converts the abstract syntax tree of SQL code into a vector representation suitable for later calculation. Then, local features are extracted by tree-based convolution, and a new set of feature vectors with the same structure as the input tree are obtained. However, the tree structure of different SQL codes will be different. Therefore, in order to input it into the final full connection layer, the tree structure obtained from the convolution layer is simplified into a fixed vector shape through the dynamic pooling layer. Finally, classification or regression is carried out through the full connection layer. This paper applies TBCNN model to the regression problem, and the training label of the model is the real difficulty of the problem.

Specifically, the input of TBCNN model is the serialized abstract syntax tree (AST). Therefore, the model first uses the pre-training method in [22] to obtain the representation vector of nodes in ASTs. The more specific representation method of node vector can be found in [22].

Then, in the tree-based convolution layer, a set of fixed-depth feature detectors that can slide on the whole AST is designed to extract the structure information of the program. The subtree feature detectors can be viewed as convolution with a set of finite support kernels, so the subtree feature detector is called tree-based convolution. The output of the feature detector is calculated by Equation 2.

$$y = \tanh\left(\sum_{i=1}^n W_{conv,i} \cdot x_i + b_{conv}\right) \quad (2)$$

where $y \in R^{N_c}$, x_1, x_2, \dots, x_n is the vector representation

of nodes in the sliding window, and $W_{conv,i} \in R^{N_c \times N_f}$ is the parameter, $b_{conv} \in R^{N_c}$ is the bias, N_c is the number of feature detectors.

In addition, continuous binary tree (as shown in Figure 5) is proposed to handle the different number of child nodes. The convolution layer uses three weight matrices as parameters, including W_{conv}^t , W_{conv}^l , and W_{conv}^r , in which superscript t , l , and r refer to “top”, “left”, and “right” respectively. The weight matrix of node x_i in the sliding window is a linear combination of W_{conv}^t , W_{conv}^l , and W_{conv}^r (as shown in Equation 3). η_i^t , η_i^l , and η_i^r are the coefficients. In this paper, we use the method in [32] to calculate the coefficient η_i^t , η_i^l , and η_i^r , as shown below:

$$W_{conv,i} = \eta_i^t W_{conv}^t + \eta_i^l W_{conv}^l + \eta_i^r W_{conv}^r \quad (3)$$

$$\eta_i^t = \frac{d_{max} - d_i}{d_{max}} \quad (4)$$

$$\eta_i^l = \begin{cases} \frac{i-1}{n-1}(1 - \eta_i^t) & \text{non-leaf} \\ 0.5(1 - \eta_i^t) & \text{leaf} \end{cases} \quad (5)$$

$$\eta_i^r = (1 - \eta_i^t)(1 - \eta_i^l) \quad (6)$$

where d_{max} represents the depth of the sliding window and d_i represents the depth of node i in the sliding window.

After convolution, structural features in an AST are extracted, but the features are still a tree structured set of vectors, which can not be directly fed into the fully connected layer. Therefore, dynamic pooling [26] is applied to reduce the tree into a fixed shape vector.

Finally, a full connection layer and an output layer are added to predict the difficulty of SQL programming problems. The difficulty prediction task of SQL programming problems in this paper belongs to regression problem, inspired by [29], we construct the loss function of the TBCNN model as the Equation 7.

$$L = \frac{1}{n} \sum_{i=1}^n (\tilde{p}_i - d_i)^2 \quad (7)$$

where \tilde{p}_i and d_i represent the predicted difficulty value and the real difficulty value of the problem p_i respectively.

4.2 Difficulty Prediction Module

The difficulty of SQL programming problems can be predicted using various regression models. Therefore, the difficulty prediction module of SQL programming problems uses a variety of regression models to predict the difficulty of SQL programming problems to obtain the optimal regression model. Regression models used include linear regression (LR) [4], support vector machine (SVM) [7], gradient boosting decision tree (GBDT) [10], random forest (RF) [5] and back propagation (BP) [24] neural networks. The linear regression model is one of the basic regression models commonly used in linear regression problems, but it cannot solve nonlinear distribution problems. The SVM model is common in both linear and nonlinear problems. The RF model is a kind of integrated algorithm with the advantages of difficult overfitting, strong anti-noise ability, and strong interpretability. The GBDT model is an iterative decision

Table 1: The statistics of the dataset.

Statistics	Value
# of answer logs	10952
# of students	283
# of SQL programming problems	318
Average answer logs per question	34.4
Average answer logs per student	38.7

tree algorithm that can be used for regression tasks. The BP neural network refers to the multilayer feedforward neural network trained by the BP algorithm. It has strong representation ability and nonlinear mapping ability, but its strong learning representation ability makes it easy to overfit.

The following describes the specific process of the difficulty prediction module:

- Firstly, the text semantic features and code structure features of the extracted SQL programming problems are concatenated together and used as the input of the above regression model. The regression models are trained using the actual difficulty of the SQL programming problems as the training labels.
- Secondly, the model with the best results among the regression models mentioned above is selected as the regression model of the difficulty prediction module of SQL programming problems.
- Thirdly, input the text features and code structure features of the SQL programming problems that need to predict difficulty into the trained regression model. The difficulty of the SQL programming problems can be obtained.

5. EXPERIMENTS

In this section, we first introduce the source of the dataset. Then we raise the evaluation metrics and experimental comparison methods used in the experiment. Next, we present the experimental settings in detail. Finally, we summarize and analyze the experimental results.

Figure 7: Results of text semantic features obtained by different word embedding technologies on different algorithms.

5.1 Dataset Description

The dataset in this paper comes from our self-developed SQL OJ system (as shown in Figure 6). The data collection lasted for two years, involving 306 students from Guangxi University of China. In addition, if only a small count of students have tried to solve a problem, the obtained difficulty of this problem will have severe randomness[23]. Therefore we use the processing method in [23] to process our data. Specifically, we eliminate the problems having no more than ten test logs, and the detail of dataset after processing is shown in Table 1.

5.2 Evaluation Metrics

Followed the previous works[23, 29, 16], we use the evaluation metrics commonly used in question difficulty prediction: *Root Mean Square Error* (RMSE) and *Mean Absolute Error* (MAE). The above two evaluation metrics are widely used in question difficulty prediction to measure the distance between the predicted difficulty value and the actual difficulty value. The smaller the evaluation metric value is, the better performance the results have. The two evaluation metrics are shown in Equation 8 and Equation 9 respectively:

$$\text{RMSE} = \sqrt{\frac{1}{M} \sum_{i=1}^M (\tilde{p}_i - d_i)^2} \quad (8)$$

$$\text{MAE} = \frac{1}{M} \sum_{i=1}^M |\tilde{p}_i - d_i| \quad (9)$$

where M represents the number of SQL programming problems, and \tilde{p}_i and d_i represent the predicted difficulty and real difficulty of programming problem i respectively.

5.3 Comparison methods

The difficulty prediction of questions mentioned in the previous related work is not for SQL programming problems. Therefore, we modify C-MIDP model, R-MIDP model, and H-MIDP model of the mathematical questions proposed in [29] to adapt to the SQL programming problems. The above three models first use the word2vec to vectorize the texts of mathematical questions and use the scoring rate of the students in the mathematical questions as the actual difficulty value of the mathematical questions. Then take the

real difficulty value of the mathematical questions as the training labels. Finally, input the text representation vector of the mathematical problem into different neural networks for learning. The main processes of the C-MIDP, R-MIDP and H-MIDP models (The structure diagram of C-MIDP, R-MIDP, and H-MIDP is presented in the appendix Table 10) are given below .

- First, use the word2vec model to train all the texts of the mathematical questions, and then the text representation vector of the math questions can be obtained.
- Secondly, the text representation vector of the mathematical question is used as the models' input. The actual difficulty of the question is the scoring rate of each question, and it is used as the training label of the model. During the training process, different models extract different mathematical question information.
- Thirdly, considering that the data in the dataset comes from many different schools. And the student groups in other schools have differences in the knowledge level status, which will cause the scoring rate of the question (i.e., the actual difficulty value) to be affected by the difference in the level of the student group. To eliminate this effect, a context-related training method is proposed. That is, a new loss function is constructed for training the model.
- Finally, for new math questions for which there is no student answer data or insufficient student answer data, the text vector of the new question can be input into the trained model to predict the difficulty of the question.

The C-MIDP, R-MIDP, and H-MIDP models have the same process, and the differences between the three models are: The C-MIDP model uses a multi-layer Convolutional Neural Network to mine different levels of text semantic information from the text of mathematical questions. The R-MIDP model uses the recurrent neural network (RNN) suitable for mining long-range logical relations to mine the sequential logical information of mathematical problems from the text. The H-MIDP model combines the advantages of the

Table 2: TBCNN’s hyperparameters.

Hyperparameter	Value
Initial learning rate	0.001
Learning rate decay	0.001
Node embedding dimension	100
Convolutional layers’ dimension	50

C-MIDP and the R-MIDP and can simultaneously extract crucial semantic information and sequential logic information of mathematical problem text.

5.4 Experimental Setup

Word Embedding: In [16] and [29], Huang et al. and Tong et al. use BoW, TF-IDF, and word2vec technologies to obtain the text semantic features of questions. Following their works, we use the aforementioned methods to process the text semantic features. The Bow and TF-IDF methods are relatively simple, so we only introduce the setting of the word2vec in detail. Specifically, the corpus used for word2vec training is all the stem texts in the dataset. The maximum number of words after word segmentation in the problem stem is 17, so we set the number of words in each problem to 17, and the word vector dimension of each word is 50. Therefore, the stem text vector of each problem has a dimension of 850.

TBCNN Setting: The input of TBCNN model is the AST of programming code. So we first use SQL parser `pglast`¹ to parse the SQL codes, and then we obtain the AST of the codes. After that, we serialize the ASTs and take the serialized ASTs as the input of the TBCNN model. Besides, TBCNN’s hyperparameters are shown in Table 2.

Other Setting: All models in the experiment use ten-fold cross-validation to verify the performance of the model. In experiment, the programming language we used is python, and the experiment is configured with 2-core CPU, 8GB memory, 1TB hard disk, and 64-bit Ubuntu operating system.

5.5 Experimental Results

In this section, we run an ablation study to highlight the individual contribution of each module in SQL-DP and compare the SQL-DP proposed in this paper with the C-MIDP, R-MIDP, and H-MIDP model proposed in [29].

5.5.1 Text Semantic Feature Extraction

A variety of word embedding techniques can be used in the SQL-DP framework proposed in this paper, so we need to experiment with different word embedding techniques to obtain the optimal problem text semantic features for subsequent experiments.

Figure 7 shows the results of text semantic features obtained using different word embedding techniques on various machine learning algorithms. But the RMSE of the LR algorithm exceeds 0.5, and the result on the MAE is also poor, so we do not show the results of LR algorithm in Figure 7 in

¹<https://pglast.readthedocs.io/en/v3/index.html>

Table 3: Experimental results of regression model selection

Models	RMSE	MAE
SVM	0.2176	0.1744
GBDT	0.2128	0.1721
RF	0.1977	0.1570
BPNN	0.2022	0.1702

order to a more intuitive display. And the poor experimental results of LR also prove that LR is not competent for difficulty prediction problem. Therefore, we will no longer use the LR algorithm to predict the difficulty of SQL programming problems in the subsequent experiments.

In addition, as shown in Figure 7, the text semantic features extracted by BoW perform the worst in predicting the difficulty of SQL programming problems, while the overall performance of word2vec is the best. This shows that the word2vec is more suitable for extracting text semantic features of problem stems than BoW and TF-IDF for SQL programming problems. Therefore, we will use word2vec to obtain the text semantic features of SQL programming problems in the subsequent experiments.

5.5.2 Regression Model Selection Experiment

SQL-DP can use a variety of regression models to predict the difficulty of SQL programming problems. Therefore, we experiment with multiple regression models to select the best model for subsequent experiments. In the regression model selection experiment, text semantic features and code structure features are used as the input of the regression model at the same time. Table 3 shows the results of using the two features mentioned above as the input of multiple regression models simultaneously. As can be seen from Table 3, when both text semantic features and code structure features are used as the input of the regression model, the results of SQL-DP using the SVM model are the worst, while the effects of the RF model are the best. Therefore, in the subsequent comparative experiment, the SQL-DP framework will use the RF model to predict the difficulty of SQL programming problems.

5.5.3 Comparative Experiment

In this section, we compare SQL-DP with C-MIDP, R-MIDP, and H-MIDP to prove the effectiveness of the difficulty prediction framework of SQL programming problems proposed in this paper. Given the above text semantic feature extraction experiment and ablation experiment results, we choose the SQL-DP framework using word2vec, TBCNN, and RF algorithm to compare with the C-MIDP, R-MIDP, and H-MIDP.

Table 4 shows the experimental results of SQL-DP, C-MIDP, R-MIDP, and H-MIDP. We can see from Table 4 that results of SQL-DP with respect to the two evaluation metrics, i.e., RMSE and MAE, are consistently better than those of C-MIDP, R-MIDP, and H-MIDP models, which verifies the superiority of the proposed SQL-DP in predicting the difficulty of SQL programming problems. Moreover, we are delighted to see from the table that SQL-DP increases the RMSE by 7.23%, compared with the best comparison model H-MIDP,

Figure 8: Comparison between the difficulty predicted by four models and the ground truth on ten SQL programming problems.

which is a great progress made under the context of difficulty prediction for SQL programming problems. Because the C-MIDP, R-MIDP, and H-MIDP models only extract information from the text of SQL programming problems and do not extract the code structure information of the answers. Unlike those three comparison models, in SQL-DP, in addition to the text semantic feature extraction module, we can obtain rich semantic information from the stem of SQL programming problems. The code structure extraction module can also obtain rich code structure information from the answers to SQL programming problems. It is the consideration of code structure information in SQL-DP that further enhances the difficulty prediction ability of it towards SQL programming problems, compared with state-of-the-art models.

In addition, we can observe from Table 4 that the H-MIDP model performs best among all state-of-the-art models, while the R-MIDP model performs worst among the three models C-MIDP, R-MIDP, and H-MIDP. The reason may be that the RNN in the R-MIDP model is better at capturing the logical relationship in long sentences. But in the SQL programming problem dataset collected in this paper, the descriptions of the stem of the SQL programming problems are generally short, so the performance of the R-MIDP model on the SQL programming problems is the worst.

To more intuitively see the advantages of our proposed SQL-DP in predicting the difficulty of SQL programming problems, we randomly select 10 problems in the test set. And we test them with the trained C-MIDP model, R-MIDP model, H-MIDP model, and our proposed SQL-DP. After that, we use a broken line diagram (as shown in Figure 8) to show the distance between the predicted problem difficulty of the above models and the real problem difficulty. As shown in

Table 4: Comparative experimental results.

Models	RMSE	MAE
C-MIDP	0.2167	0.1603
R-MIDP	0.2228	0.1785
H-MIDP	0.2131	0.1578
SQL-DP	0.1977	0.1570

Table 5: Ablation experimental results of SQL-DP.

Feature	RMSE	MAE
Text semantic feature	0.2106	0.1711
Code structure feature	0.2124	0.1721
Text semantic + Code structure	0.1977	0.1570

Figure 8, we can see that the prediction difficulty of SQL-DP for the selected SQL programming problems is closer to the real problem difficulty than the C-MIDP, R-MIDP, and H-MIDP models.

5.5.4 Ablation Experimental

To get deep insights into the contributions of various modules in the SQL-DP framework proposed in this paper, we also conduct some ablation prediction outcomes.

As shown in Table 5, we can observe a performance decrease by removing the SQL text semantic feature extraction module or the SQL code structure feature extraction module. Besides, we can also see that the overall performance of the SQL text semantic feature extraction module is similar to that of the SQL code structure feature extraction module. This observation shows that both SQL code structure fea-

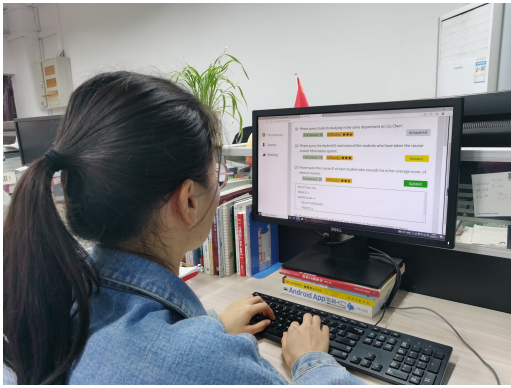

Figure 9: Scenario of a student using self-developed SQL OJ system.

tures and SQL text semantic features play an essential role in the difficulty prediction of SQL programming problems.

5.5.5 Application

Given the effectiveness of the SQL-DP framework proposed in this paper, we use the trained SQL-DP to predict the difficulty of new SQL programming problems. That is, the problem without student test logs. And apply it to our self-developed SQL OJ system, as shown in Figure 6. Specifically, we map the problem difficulty value from 0 to 1 to 5 stars. Among them, the problem difficulty value from 0 to 0.1 is half a star, value from 0.1 to 0.2 is one star, and so on. Figure 9 shows a student practicing SQL programming problems using our self-developed SQL OJ system. The student can choose to do simple SQL programming problems first according to the problem difficulty labels or challenge herself to choose more difficult SQL programming problems in our system.

6. CONCLUSIONS

Conclusions. In this paper, we propose SQL-DP, a novel framework that automatically predicts difficulty of SQL programming problems. SQL-DP makes full use of the information in problem stems and problem answers in the form of SQL codes, based on which the difficulty values of SQL programming problems can be effectively estimated using machine learning techniques. Besides, we organized many tests of SQL programming problems in real teaching practice, which last for two years and involve seven different undergraduate classes in Guangxi University of China, and collected a SQL dataset containing materials and student answering logs of hundreds of SQL programming problems. Experimental results over our collected physical-world SQL dataset show that the proposed SQL-DP gains apparently better prediction performance towards SQL programming problems, compared with state-of-the-art solutions.

Generalization. Though SQL-DP is discussed for the difficulty prediction of SQL programming problems, it can be easily generalized to address the difficulty prediction of programming problems using other languages (such as C and Java), since the consideration of structure information of problem answers is also very important for these programming problems.

Future Works. Two important directions for future works can be considered. First, we will consider more features of SQL programming problems, such as equivalent answers, SQL concepts (e.g., nested queries, multiple tables), etc. Second, to support the difficulty prediction task of programming problems corresponding to more types of programming languages, we will modify and adapt the proposed SQL-DP framework, including the design or use of neural network layers.

Related Resources. To better promote related study of SQL programming problems, the source code of the proposed SQL-DP framework and partial of our collected SQL dataset used in the experiment are all released and can be assessed though the link below: <https://github.com/SQL-DP/SQL-DP>

ABSTRACT

Neural networks are ubiquitous in applied machine learning for education. Their pervasive success in predictive performance comes alongside a severe weakness, the lack of explainability of their decisions, especially relevant in human-centric fields. We implement five state-of-the-art methodologies for explaining black-box machine learning models (LIME, PermutationSHAP, KernelSHAP, DiCE, CEM) and examine the strengths of each approach on the downstream task of student performance prediction for five massive open online courses. Our experiments demonstrate that the families of explainers **do not agree** with each other on feature importance for the same Bidirectional LSTM models with the same representative set of students. We use Principal Component Analysis, Jensen-Shannon distance, and Spearman’s rank-order correlation to quantitatively cross-examine explanations across methods and courses. Furthermore, we validate explainer performance across curriculum-based prerequisite relationships. Our results come to the concerning conclusion that the choice of explainer is an important decision and is in fact paramount to the interpretation of the predictive results, even more so than the course the model is trained on. Source code and models are released at <http://github.com/epfl-ml4ed/evaluating-explainers>.

1. INTRODUCTION

The steep rise in popularity of neural networks has been closely mirrored by the adoption of deep learning for education. For the majority of educational data modeling tasks such as student success prediction (e.g., [1]), estimating early dropout (e.g., [2]), and knowledge tracing (e.g., [3, 4]), the recent literature relies on neural networks to reduce human involvement in the pipeline and boost overall prediction ac-

curacy. Unfortunately, these advances come at a significant cost: traditional machine learning techniques (e.g., linear regression, SVMs, decision trees) are simple, but interpretable, where deep learning techniques trade transparency for the ability to capture complex data representations [5].

There is a compelling need for interpretability in models dealing with human data, especially in education. [6] emphasizes that explainability and accountability should be incorporated in machine learning system design to meet social, ethical and legislative requirements. Other work [7] strongly argues for the necessity of interpretable models in education, specifically in settings where students can see the effect of a decision but not the reasoning behind it (e.g., Open Learner Models). Predictions of student performance are often used to determine underachieving students for targeted downstream interventions. Identifying important features motivating failure or dropout predictions is crucial in designing effective, personalized interventions.

However, there exists only a handful of papers focusing on explainability in the field of machine learning for education. For example, [8] examined the inner workings of deep learning models for knowledge tracing through layer-relevance propagation. Other researchers [9] experimented with traditional machine learning models for student success prediction and implemented local explanations with LIME for transparency in the best performing model. Additionally, [10] used SHAP feature importances to interpret student dropout prediction models. [11] suggested interventions for wheel-spinning students based on Shapley values. Finally, [12] explored LIME on ensemble machine learning methods for student performance prediction, [13] integrated LIME explanations in student advising dashboards, and [14] used LIME for interpreting models identifying at-risk students.

While field of neural network explainability is also nascent in the broader machine learning community, the last five years have shown a sharp increase in research and industry interest in this topic. Local, instance-based explainability methods like LIME [15] and SHAP [16] have become immensely popular. These methods have been successfully applied on models predicting ICU mortality [17], non-invasive ventilation for ALS patients [18], and credit risk [19]. Recent work in counterfactual explanations [20, 21, 22] searches for a minimal subset of features that leads to the prediction alongside a minimal feature subset that needs to be changed for the

prediction to change. Counterfactuals have been used in tasks like image classification [23], loan repayment [24], and grouping websites into topics for safe-advertising [25].

Although the explainability corpora is growing, there is a clear gap in explainability literature for education, with an even more pressing need for work (quantitatively) comparing different explainability methods. To the best of our knowledge, current research on explainability in education is exclusively applied: the majority of previous research implements only one specific explainability method to interpret the predictions of their proposed approach.

To address this research gap, we examine and compare five popular instance-based explainability methods on student success prediction models for five different massive open online courses (MOOCs). We formulate comparable feature importance scores for each explainer, scaled between $[0, 1]$ on a uniformly sampled, stratified representative set of students. To quantitatively compare the feature importance distributions, we propose the use of different measures: rank-based metrics (Spearman’s rank-order correlation), distance metrics (Jensen Shannon Distance), and dimensionality analysis (Principal Component Analysis). We validate the explanations through an analysis of feature importance on a MOOC with known prerequisite relationships in the underlying curriculum. With our experiments, we address three research questions: 1) How similar are the explanations of different explainability methods for a specific course (**RQ1**)? 2) How do explanations (quantitatively) compare across courses (**RQ2**)? 3) Do explanations align with prerequisite relations in a course curriculum (**RQ3**)?

Our results demonstrate that the feature importance distributions extracted by different explainability methods for the same model and course differ significantly from each other. When comparing the feature importances across courses, we see that LIME is far apart from all other methods due to selecting a sparse feature set. Furthermore, our findings show that the choice of explainability method influences the feature importance distribution much more than the course the model is predicting on. Our examination on prerequisite relationships between features further indicates that the three families of methods are only partially able to uncover prerequisite dependencies between course weeks. Source code and models are released on Github¹.

2. METHODOLOGY

The goal of this paper is to compare explanations from deep learning models tasked with identifying student success prediction in MOOCs. In this section, we formalize the student success prediction task addressed in this paper including the data collection and preprocessing, feature extraction, and model preparation. We then introduce the considered explainability methods and describe the process to extract explanations for student success predictions from a trained model, showcased as feature importance weights.

2.1 Formal Preliminaries

We consider a set of students S enrolled in a course c part of an online educational offering \mathcal{C} . Course c has a prede-

defined weekly schedule consisting of $N = |\mathcal{O}|$ learning objects from a catalog \mathcal{O} . Students enrolled in a course interact with the learning objects included in the course schedule, generating a time-wise clickstream (e.g., a sequence of video plays and pauses, quiz submissions). We denote a clickstream in a course c for a student $s \in S$ as a time series $I_s = \{i_1, \dots, i_{K_s}\}$ with K_s being the total number of interactions of student s in course c . Each interaction $i \in I_s$ is represented by a tuple (t, a, o) , including a timestamp t , an action a (videos: load, play, pause, stop, seek, speed; quiz: submit), and a learning object $o \in \mathcal{O}$ (video, quiz). Given the weekly course schedule, we assume that t_w identifies the time t where the course week $w \in \{0, \dots, W\}$ ends, and that the clickstream of student s generated until the end of the w week can be denoted as $I_s^{t_w}$. We also assume that the course schedule includes one or more assignments per week and that the grade record of student s across course assignments is denoted as $G_s = [g_1, \dots, g_W]$, where $g_w \in G_s$ is the grade student s received on the assignment in week w . In the case of multiple graded assignments for a certain week, we considered the average score of graded assignments for that week and scored non-attempted assignments with 0. We denote as $y_s \in \{0, 1\}$ the success label for student s .

2.2 Data Preprocessing

A significant portion of MOOC students enroll just to watch a few videos or find that the curriculum material is not what they expected and drop out of the course in the first weeks [26, 27]. It follows that it is easy to predict the success labels y_s for this selection of students by simply looking at their initial few weekly assignment grades in G_s . Therefore, optimizing complex deep learning models for predicting student success on early-dropout students is inefficient. Using these complex deep models also leads to less interpretable predictions in comparison with traditional models. For this subset of early-dropout students, traditional models can both achieve a comparable accuracy and still remain interpretable. To identify early-dropout students, we fit a *Logistic Regression* model on the assignment grades of the first two course weeks. The input data is the vector G_s^W , where W is the number of course weeks ($W = 2$ in our experiments) whereas the ground truth is the student success label y_s . Once the model is fitted, we filter out the students that had a predicted probability of course failure $\hat{p}_s > 0.99$. We determine the optimal threshold via a grid search over $\{0.96, 0.97, \dots, 0.999\}$, maximizing the model balanced accuracy. Henceforth, we consider S to be the student population obtained after the early-dropout student filtering.

2.3 Feature Extraction

As an input for our student success prediction models, we consider a set of behavioral features extracted for each student $s \in S$ based on their interactions I_s . We include four feature sets proved to have high predictive power for success prediction in MOOCs [28]. Given the size and variety of the course data considered in our study, we included all features of the four features sets, instead of considering only the specific features identified as important by at least one course [28]. Formally, given interactions I_s generated by students S until a course week w , we create a matrix $H \subset \mathbb{R}^{|S| \times w \times f}$ (i.e, each feature in the feature set is computed per student per week), where $f \in \mathbb{N}$ is the dimensionality of the feature set. We focus on the following behavioral aspects:

¹<http://github.com/epfl-m14ed/evaluating-explainers>

Figure 1: Our experimental pipeline, from data processing to post-hoc explainability methods.

- **Regularity** features (H_1 , shape: $|S| \times w \times 3$) monitor the extent to which a student follows regular study habits [29].
- **Engagement** features (H_2 , shape: $|S| \times w \times 13$) monitor the extent to which a student is engaged in the course [30].
- **Control** features (H_3 , shape: $|S| \times w \times 22$) measure the fine-grained video consumption per student [31].
- **Participation** features (H_4 , shape: $|S| \times w \times 4$) monitor attendance on videos/quizzes based on the schedule [28].

We extract the above features for each student s and concatenate features across sets to obtain the final combined behavioral features h_s per student. The overall matrix of features is defined as $H \in \mathbb{R}^{|S| \times w \times 42}$, with $H = [H_1 \cdot H_2 \cdot H_3 \cdot H_4]$ (\cdot denotes a concatenation). Due to the different scales, we perform a min-max normalization per feature in H (i.e., we scale the feature between 0 and 1 considering all students and weeks for that feature). We elaborate on the most important features later on in the paper as highlighted by the analyses in subsequent experiments (e.g., Table 1).

2.4 Model Building

Given a course c , we are interested in creating a success prediction model that can accurately predict the success label y_s for student s , given the extracted behavioral features h_s . To this end, we rely on a neural architecture based on *Bidirectional LSTMs*, which can provide a good trade-off between effectiveness and efficiency². The model input is represented by H , i.e., the extracted behavior features, having a shape of $|S| \times W \times 42$. NaN values were replaced with the minimum score the student can receive for each respective feature. These features are then fed into a neural architecture composed by two simple yet effective *BiLSTM* layers of size 32 and 64 (loopback of 3) and a *Dense* layer (with Sigmoid activation) having a hidden size of 1. The model outputs the probability the student will pass the course.

2.5 Explanation

Input behavioral features contribute with varying levels of importance to the prediction provided by a success prediction model. We unfortunately cannot examine the importance of these features directly, since deep neural networks act as **black boxes**. Explainability methods can therefore be adopted to approximate the contributions of each feature in H towards the prediction associated with a specific student s . To explore this aspect, we consider five instance-based explainability methods that are popular in the literature and cover different method families [32, 5]. We then compute the feature importance vector for each student s , based on

²Experimental details can be found in Appendices A and B.

each explainability method. Formally, given an explainability method, we denote $e_s \in \mathbb{R}^{w \times 42}$ as the feature importance weights returned by the explainability method for student s . The feature importance weight $e_s[i]$ is a score, comparable across explainability methods, that represents the importance of feature $h_s[i]$ to the model’s individual prediction for student s . The considered explainability methods are described below.

LIME [15] trains a local linear model to explain each individual student instance h_s . To this end, it first generates perturbed instances $h_s^1, h_s^2 \dots h_s^n$ by shifting the feature values of h_s a small amount. These new instances are then passed to the original model to get their associated predictions. Finally, a local interpretable model (e.g., a Support Vector Machine) is trained on the perturbed instances (input) and the corresponding predictions obtained from the original model (labels), weighting perturbed instances by proximity to the original instance. Mathematically, the local model can be expressed with the following equation:

$$\text{LIME}(h_s) = \operatorname{argmin}_{g' \in G'} L(g, g', \pi_{h_s}) + \Omega(g') \quad (1)$$

where h_s is the instance being explained, G' is the family of all possible explanations, L the loss that measures how close the predictions of the explainer g' are to the predictions of the original model g , π_{h_s} is the feature proximity measure, and $\Omega(g')$ represents the complexity of the local model. As LIME returns feature weights $\pi_1 \dots \pi_{|h_s|}$ representing the feature influence on the final decision, we consider these absolute values to be the importance scores e_s , and scale them to the interval $[0, 1]$, where 1 indicates high importance.

KernelSHAP [16] draws inspiration from game-theory based Shapley values (computing feature contributions to the resulting prediction) and LIME (creating locally interpretable models). This SHAP variant uses a specially-weighted local linear regression to estimate SHAP values for any model. Let $x = h_s$ be the student instance being explained. A point x' in the neighborhood of x is generated by first sampling a coalition vector $z \in \mathbb{R}^{|h_s|}$. The coalition vector uses a binary mask to determine which features from x will be kept the same in the new instance x' , and which will be replaced by a random value from the data distribution of that feature in H . Feature importance weights for each new instance x' are calculated using a predefined kernel, after which the local model can be trained. A SHAP explanation is mathematically defined as:

$$g'(z') = \pi_0 + \sum_{h_s=1}^{|h_s|} \pi_{h_s} z'_{h_s} \quad (2)$$

Set	Feature	Description
<i>Regularity</i>	DelayLecture	The average delay in viewing video lectures after they are released to students.
	RegPeakTimeDayHour	Regularity peak based on entropy of the histogram of user’s activity over time.
	RegPeriodicityM1	The extent to which the hourly pattern of user’s activities repeats over days.
<i>Engagement</i>	AvgTimeSessions	The average of users’ time between subsequent sessions.
	NumberOfSessions	The number of unique online sessions the student has participated in.
	RatioClicksWeekendDay	The ratio between the number of clicks in the weekend and the weekdays
	StdTimeSessions	The standard deviation of users’ time between subsequent sessions.
	TotalClicksProblem	The number of clicks that a student has made on problems this week.
	TotalClicksWeekend	The number of clicks that a student has made on the weekends.
	TotalTimeProblem	The total (cumulative) time that a student has spent on problem events.
	TotalTimeVideo	The total (cumulative) time that a student has spent on video events.
StdTimeBetweenSessions	The standard deviation of the time between sessions of each user.	
<i>Control</i>	AvgReplayedWeeklyProp	The ratio of videos replayed over the number of videos available.
	AvgWatchedWeeklyProp	The ratio of videos watched over the number of videos available.
	FrequencyEventLoad	The frequency between every Video.Load action and the following action.
<i>Participation</i>	CompetencyAnticipation	The extent to which the student approaches a quiz provided in subsequent weeks.
	ContentAlignment	The number of videos for that week that have been watched by the student.
	ContentAnticipation	The number of videos covered by the student from those that are in subsequent weeks.
	StudentSpeed	The average time passed between two consecutive attempts for the same quiz.

Table 1: Features used in model explainability analysis. For brevity, we only list the 19 features that have been identified as important by at least one explainability method in our analysis in Section 3.

where g' is the local explainer, $\pi_{h_s} \in \mathbb{R}$ is the SHAP value (feature attribution) of feature h_s , and $z' \in \{0, 1\}^{|h_s|}$ is the coalition binary value. To achieve Shapley compliant weighting, Lundberg et al. [16] propose the SHAP kernel:

$$\pi_{h_s}(z') = \frac{(|h_s| - 1)}{\binom{|h_s|}{|z'|} |z'| (|h_s| - |z'|)} \quad (3)$$

where $|h_s|$ is the maximum coalition size and $|z'|$ is the number of features present in coalition instance z' [5].

SHAP methods directly provide values π_{h_s} representing the feature contribution to the prediction y_s of instance s . To obtain the importance scores e_s , we apply the same transformation as LIME, by taking the absolute values of the SHAP feature attributions and scaling them to the interval $[0, 1]$.

PermutationSHAP (PermSHAP) [16] is very similar to the KernelSHAP formulation, but does not require the tuning of a regularization parameter or a kernel function. We made the decision to include both KernelSHAP and PermSHAP as a form of validation of our comparative evaluation analysis; the distance between two very similar SHAP methods is expected to be smaller than the distance between these SHAP methods and other families of explainability methods. PermSHAP approximates the Shapley values of features by iterating completely through an entire permutation of the features in both forward and reverse directions (antithetic sampling). To extract the feature importance vector e_s , we again consider the absolute values of the SHAP feature attributions and scale to the interval $[0, 1]$.

Contrastive Explanation Method (CEM) [22] identifies which features need to be present (pertinent positives) or which features must be absent (pertinent negatives) in order to

maintain the model prediction y_s for a student s with behavioral features h_s [22]. For our setting, we consider pertinent negatives as they are intuitively more similar, and therefore comparable, to other counterfactual-based explainability methods. For each generated pertinent negative, we calculate the importance score for each feature by multiplying the absolute change from the value in the original instance to the value in the pertinent negative, modeled as the standard deviation (SD) of that feature $\tilde{X}(h_s)$ across all instances used for the experiment $X(h_s)$, as shown in the following formula:

$$\text{CEM}(h_s) = [X(h_s) - \tilde{X}(h_s)] \times SD(h_s) \quad (4)$$

The importance score therefore takes into consideration both the necessary perturbation of the feature as well as the significance of the change relative to the feature range. We normalize the scores in the range $[0, 1]$, such that the resulting feature importance weights e_s can be directly comparable.

Diverse Counterfactual Explanations (DiCE) [20] generates example instances to explain the model prediction as well. However, while CEM describes conditions necessary to keep the prediction unchanged, DiCE describes the smallest possible change to the initial instance that results in a different prediction. In other words, DiCE generates nearest neighbor counterfactual examples by optimizing the loss:

$$\begin{aligned} \text{DiCE}(h_s) = \arg \min_{\mathbf{c}_1, \dots, \mathbf{c}_k} \frac{1}{k} \sum_{i=1}^k y_{\text{loss}}(g(\mathbf{c}_i), y) \\ + \frac{\lambda_1}{k} \sum_{i=1}^k \text{dist}(\mathbf{c}_i, h_s) \\ - \lambda_2 \text{diversity}(\mathbf{c}_1, \dots, \mathbf{c}_k) \end{aligned} \quad (5)$$

where \mathbf{c}_i is a counterfactual example, k is the total number

of examples to be generated, g is the black box ML model, y_{loss} is a metric that minimizes the distance between the prediction g' makes for c_i and the desired outcome y , h_s is the original input with $|h_s|$ input features, and diversity is the Determinantal Point Process (DPP) diversity metric. λ_1 and λ_2 are hyperparameters that balance the three parts of the loss function. The stopping condition is convergence or 5000 time steps per counterfactual. Microsoft’s DiCE library [20] has a built-in function to compute local feature importance scores from the counterfactual instances, scaled in $[0, 1]$. We use them as feature importance weights e_s .

3. EXPERIMENTAL ANALYSIS

We evaluated the explainability methods on five MOOCs. We first explored how feature importance varies across different explainers for one specific course c (RQ1). We then investigated the similarity of the explainability methods across the five courses using distance metrics (RQ2). Finally, we assessed the validity of the explainers using simulated data from a course c with a known underlying prerequisite skill structure (RQ3). In the following sections, we describe the dataset and optimization protocol used for the experiments before explaining each experiment in detail.

3.1 Dataset

Our experiments are based on log data collected from five MOOCs of École Polytechnique Fédérale de Lausanne between 2013 to 2015. We chose the five courses to cover a diverse range of topic, level, and language. Table 2 describes the five courses in detail. We include two subsequent iterations of the same computer science course (*DSP*) with different student populations (French Bachelor students vs. English MSc students). Besides computer science, we also cover courses in the areas of mathematics (*Geomatique*), social sciences (*Villes Africaines*) and engineering (*Micro*). In total, the raw data set contained log data from 75,992 students. After removing the early-dropout students (see Sec. 2.2), 19,805 students remain in the data set. The smallest course contains 452 students, while the largest course contains 5,643 students. Students’ log data consists of fine-grained video (e.g., play, pause, forward, seek) and quiz events (e.g., submit). Interaction data is fully anonymized with regards to student information, respecting participants’ privacy rights.

3.2 Experimental Protocol

For each course $c \in C$, we trained a *BiLSTM* model M_c on features H_c extracted from c . For the optimization, we used batches of size 32, an Adam optimizer with an initial learning rate of 0.001, and a binary crossentropy loss. After an initial grid search³, we selected the same architecture for all models: two *BiLSTM* layers consisting of 64, 32 units and one Dense layer consisting of 1 unit with a Sigmoid activation. As this work is not focused on improving model performance, we did not tune hyperparameters further. Formally, we split the data of each course c into a training data set $S_{train,c}$ (80% of the students) and a test data set $S_{test,c}$ (20% of the students). For each course, we performed a stratified train-test split over students’ pass/fail label. We then trained each model M_c on the training data set $S_{train,c}$ and then predicted student success on the respective test data set $S_{test,c}$. We chose the balanced accuracy

³Grid search is discussed further in Appendix A.

(BAC) as our primary evaluation metric because of the high class imbalance of most of the selected courses.

For the first two experiments (RQ1 and RQ2) we used the student log data collected for the full duration of the course for training and prediction of our models. In the third experiment, we optimized models for different sequence lengths, i.e. using only the log data up to a specific week w of the course (i.e. from week 1 to week w) to predict performance in the assignment of course week w . Additional replication details for model training can be found in Appendix B.

For all experiments, we applied the explainability methods to the predictions of the optimized models M_c . All five methods are instance-based; they compute the feature importance based on the model predictions for a specific instance. Training explainers on the scale of thousands of students across five courses is not feasible due to the computation time required to generate the explanation for one instance (e.g., the counterfactual explainability methods take a computation time of 30 minutes per instance s). Therefore, we determined a representative sampling strategy to pick 100 students from each course c , resulting in explanations for 500 students in total⁴. For the first two experiments (RQ1 and RQ2), we used a uniform sampling strategy to select the representative students $s_{i,c}^r$ for a course c and ensured balance between classes (pass/fail). We first extracted all failing students and ordered them according to the predicted probability of the model $\hat{p}(l_{S_i} = 0)$. We then uniformly sampled 50 failing students from this ordered interval. We repeated this exact same procedure to sample the 50 passing students. This sampling procedure ensures that we include instances where the model is confident and wrong, instances for which the model is unsure, and instances where the model is confident and correct. For the last experiment (RQ3), we used performance in the assignment of a given week w as the binary outcome variable. We then followed exactly the same uniform sampling procedure as for RQ1 and RQ2, ensuring class balance on assignment performance.

3.3 RQ1: Explanations for one course

In a first experiment, we compared the explanations of the instance-based methods for one specific course (*DSP 1*). The *BiLSTM* model M_{DSP1} trained on this course achieved a BAC of 93.9%. We then ran the explainability methods on M_{DSP1} and extracted normalized feature importance scores for 100 representative students of each course.

Figure 2 illustrates the features identified as most important by each explainability method. The heatmaps were computed by averaging importance scores for each feature and week across 100 representative students for *DSP 1* (see Sec. 3.2). To ensure interpretability of Figure 2, we only included the top five features for each method, resulting in 13 distinct features. The description of all the features can be found in Table 1. We used a log scale within the heatmaps, with darker colors indicating higher feature importance.

We observe that the top features cover all the different behavioral aspects included in the feature set: Regularity, Engagement, Control, and Participation. However, some aspects seem to contain more important features. For exam-

⁴Sampling strategy is discussed further in Appendix C.

Title	Identifier	Topic ¹	Level	Language	No. Weeks	No. Students ²	Passing Rate (%)	No. Quizzes

¹**Topic abbrev.** *Eng*: Engineering; *Math*: Mathematics; *CS*: Computer Science; *SS*: Social Science

²**No. Students** is calculated after filtering out the early-dropout students, as detailed in Sec. 2.2.

Table 2: Detailed information on the five MOOCs included in our experiments.

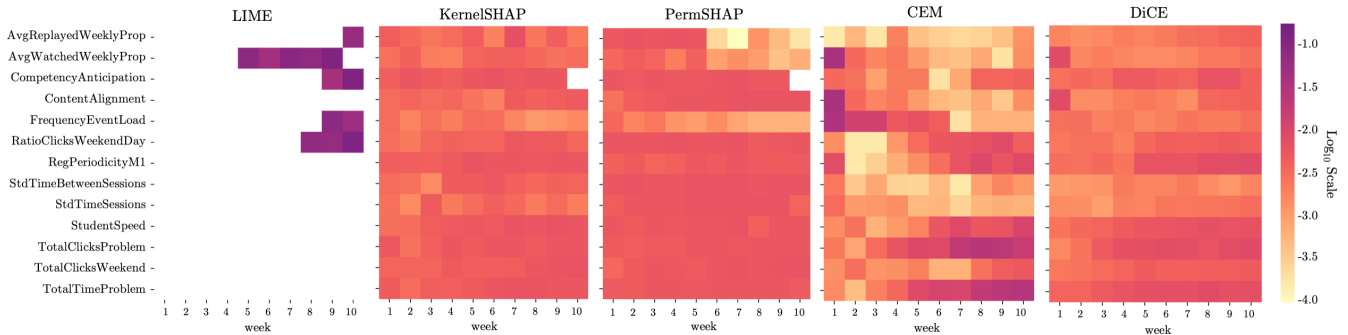

Figure 2: Heatmap of normalized feature importance scores (log scale) across explainability methods for *DSP 1*.

ple, 43% of the Participation features (3 out of 7 features) are in the top five features of at least one method, while this is the case for only 23% (5 out of 22 features) of the Control features. For Regularity and Engagement, 33% and 31% of the features get selected into the top feature set.

We also immediately recognize that the heatmap of LIME looks very different from the heatmaps of all the other methods. LIME assigned high importance scores to a small subset of features and weeks, while all the other explainability methods tend to identify more features and weeks as important, resulting in generally lower importance scores. We also observe that LIME does not consider student behavior in the first weeks of the course important; all importance is placed onto the second half of the course. Moreover, LIME seems to put more emphasis on Control than on the other three aspects: the features related to Control (*AvgReplayedWeeklyProp*, *AvgWatchedWeeklyProp*, *FrequencyEventLoad*) are important from week 5 through week 10, while the features related to Participation (*CompetencyAnticipation*) and Engagement (*RatioClicksWeekendDay*) are important only during the last 2 to 3 weeks of the course.

Interestingly, while CEM and DiCE are both counterfactual methods, their heatmaps look quite different: the feature importance scores of DiCE tend to be more similar to KernelSHAP and PermSHAP than CEM. We note that CEM shows a higher diversity in feature importance scores than the other three methods (KernelSHAP, PermSHAP, and DiCE), for which the importance values seem to be quite equally distributed across the top features. Furthermore, in contrast to all the other explainability methods, CEM seems to also identify features in the first weeks of the course as important (e.g., *AvgWatchedWeeklyProp*, *ContentAlign-*

ment, and *FrequencyEventLoad* in week 1). In contrast to all the other methods, CEM identifies features related to being engaged in quizzes as relevant (*TotalClicksProblem* and *TotalClicksWeekend*). Finally, as expected, the heatmaps of KernelSHAP and PermSHAP look very similar, with only small differences in importance scores.

In summary, while there is some agreement on the top features across explainability methods (the union of the top five features of each method only contains 13 distinct features), we observe differences across methods when it comes to exact importance scores.

3.4 RQ2: Comparing methods across courses

Our second analysis had the goal to *quantitatively* compare the explanations of the different methods across all five courses. Explainability method evaluation is an emerging field; most existing research focused on assessing the quality of explanations [33, 34] with only few works suggesting a quantitative ‘goodness’ score for each explainability method (e.g., [35, 36]). In contrast, we examined the distance between the feature importance scores per explainability method in comparison to each other, instead of individually. We first visualized the similarity of importances across courses using a Principal Component Analysis and then computed Spearman’s Rank-Order Correlation as well as Jensen-Shannon Distance to assess similarity regarding the feature importance ranking as well as their exact values.

Principal Component Analysis (PCA) We performed a PCA on the importance scores for each feature and week (length: $w_c \times h$) separately for each explainability method and course c . Figure 3 shows the results for all explainability methods and courses. Each marker in Figure 3 represents a specific

course, while each color denotes an explainability method.

We observe that the two SHAP methods (KernelSHAP and PermSHAP) cluster together very strongly. This result is expected, as the methodologies of KernelSHAP and PermSHAP are very similar. DiCE feature importances are quite close to the SHAP methods, showing that the three methods have similar notions of feature importance. LIME is quite different from all other methods, with high values on both PCA components. Based on differences in methodology, we would have expected that the difference between the counterfactual methods (DiCE and CEM) and the SHAP methods would be larger than the difference between LIME and the SHAP methods. The most notable takeaway from Figure 3 is that there are clearly identifiable clusters based on explainability method and not on course. It therefore seems that the resulting feature importance scores are mainly influenced by the explainability rather than by the model or data (i.e. the characteristics of the course and students’ data).

Spearman’s Rank-Order Correlation. Often referred to as Spearman’s ρ [37], this metric identifies the rank correlation (statistical dependence between the rankings) between two variables and is defined as the Pearson correlation coefficient between the rankings of two variables. We chose this metric for evaluating explainability methods to highlight the importance of feature ranking order in explanations. To compute Spearman’s Rank-Order Correlation $r_{m_1, m_2, c}$ between two explainability methods m_1 and m_2 on a course c , we first converted the vectors $e_{m_1, s}$ and $e_{m_2, s}$ of feature importance scores (length $w_c \times h$) for each student s into rankings $R(e_{m_1, s})$ and $R(e_{m_2, s})$. We then computed $r_{m_1, m_2, c}^s$ separately for each relevant student s and then averaged over all relevant students to obtain $r_{m_1, m_2, c}$.

Figure 4 illustrates the pairwise similarities between explainability methods using Spearman’s Rank-Order Correlation. Higher values imply stronger correlation between methods. We see similarities between KernelSHAP and PermSHAP

Figure 3: PCA of feature importance scores for five explainability methods across five courses.

prevalent once again as a center square for each course, affirming our intuition that two similar methodologies would result in similar rank-order scores. It can be observed that LIME consistently shows rank-order correlation scores with all other explainability methods. Additionally, for *DSP 1* and to some degree also *Villes Africaines*, DiCE is much closer to KernelSHAP and PermSHAP than to CEM. For *DSP 2* and *Geomatique*, DiCE and CEM are both equally correlated to the SHAP methods, but less correlated among themselves. Finally, the model trained on *Micro* has strong correlations across all explainability methods except LIME.

Jensen-Shannon Distance. We used the Jensen-Shannon distance [38] to compute pairwise distances between exact feature importance score distributions obtained with different explainability methods. The Jensen-Shannon distance is the square root of the Jensen-Shannon divergence, originally based on the Kullback-Leibler divergence with smoothed values. It is also known as the Information Radius (IRad) [39]. To compute the Jensen-Shannon distance $jsd_{m_1, m_2, c}$ between two explainability methods m_1 and m_2 on a course c , we first calculated the distance $jsd_{m_1, m_2, c}^s$ between the feature importance scores (length $w_c \times h$) $e_{m_1, s}$ and $e_{m_2, s}$ separately for each representative student s and then averaged across all representative students to obtain $jsd_{m_1, m_2, c}$.

Figure 5 shows the pairwise distance between explainability methods for all courses using Jensen-Shannon Distance. Larger numbers represent higher dissimilarity. The Jensen-Shannon Distance heatmaps confirm the observations made using Spearman’s Rank-Order Correlation (see Figure 4). Again, LIME consistently has a high distance to all other explainability methods across all courses. As expected, KernelSHAP and PermSHAP have low pairwise distances for all courses. However, when comparing feature importance scores directly instead of using rankings, we observe even less differences between courses. DiCE is closer across all courses to the SHAP methods than CEM. While LIME exhibits the highest distances to all other explainability methods, the explanations of CEM are also far away from all methods.

In summary, the two SHAP methods and DiCE seem to deliver the most similar explanations, while the feature importance scores obtained with CEM and LIME are different from the other explainability methods. More importantly, all our analyses (PCA, Spearman’s Rank-Order Correlation, Jensen Shannon Distance) demonstrate that the choice of explainability method has a much larger influence on the obtained feature importance score than the underlying model and data.

3.5 RQ3: Validation of explanations

The previous experiments delved into mapping the similarities and differences between explainability methods. While our analyses demonstrated that there are clear disparities across method choice, they do not give an indication regarding the ‘goodness’ of the obtained explanations. Recent work discusses traits of ideal explanations [40] and targets metrics to measure explanation quality [36, 41]. However, these metrics tend to be over-specialized to one explainability method over others due to the similarities in their methodologies. The community does not yet have a set of standard metrics for evaluating explainability methods. In our last experiment, we hence use information inherent to

Figure 4: Comparison of feature importance scores across courses using Spearman’s Rank-Order Correlation.

Figure 5: Comparison of feature importance scores across courses using Jensen-Shannon Distance.

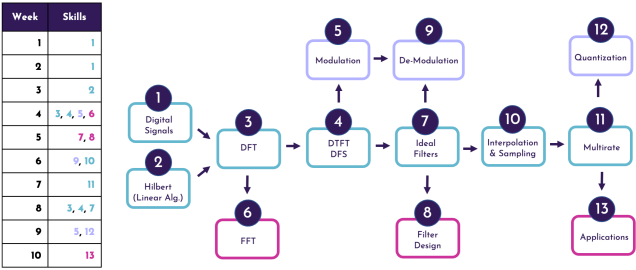

Figure 6: Prerequisite skill structure for DSP 1.

our model’s setting to perform an initial validation of the explanations provided by the different methods.

Specifically, we evaluated the explainability methods on a course with a known underlying skill map and used the prerequisite relationships between weeks of the course as a ground truth for the explanations. Based on the results obtained for the first two research questions (Sections 3.3 and 3.4), we selected one representative method from each methodological group for the analysis, while keeping the observed explanation diversity: PermSHAP (the most widely used SHAP method), CEM (chosen as a representative of counterfactuals for its further disparity from the SHAP methods), and LIME. In terms of courses, we used DSP 1 as a basis for the analysis as the instructor of this course provided us with the skill map derived from the curriculum.

Figure 6 illustrates the underlying skills, their relationships, as well as their mapping to the weeks of the course. The arrows denote the prerequisite relationships, while the numbers denote the unique skills in the order they are introduced in the course. The skills colored in pink (6, 8, and 13) refer to applied skills learned in the course. The middle track refers to core skills learned in the course (colored in blue) and the purple skills at the top (5, 9, and 11) are theory-

based extensions of core material. The skill prerequisite map allows us to analyze the dependencies between the different weeks of the course. For example, in order to understand *Modulation* taught in week 5, students need to already have learned the skills taught in weeks 3 and 4 (*DFT*, *DTFT*, and *DFS*). Intuitively, a model predicting performances in assignments in week 5 would have highly correlated features based on week 4. We assume that these dependencies would logically be uncovered by the explainability method.

We, therefore, adjusted our predictive task: using the optimization protocol and experimental design described in Section 3.2, we aimed at predicting the performance (binary label: below average or above average) of a student s in the assignment of week w based on features extracted from student interactions for weeks 1 to w . Given the prerequisite structure for the course, we ran experiments for $w \in \{5, 9\}$. For each predictive model $M_{DSP1,w}$, we then picked the 100 representative students using uniform sampling and taking into account class balance (see Section 3.2 for a detailed description of the sampling procedure) and applied the selected explainability methods to these representative instances.

Figure 7 shows the features for LIME, PermSHAP, and CEM for the prediction model of week 5. In the heatmap, darker values indicate a higher score. The scores for the heatmap have been computed based on a ranking of features and weeks: for each student s_i^r , we first ranked the features in order of feature importance as determined by the respective explainability method. We then scored each of the top 10 features according to its rank: 10 points for the top feature, 9 points for the second most important feature, and so on. Finally, we averaged the scores for each feature across the 100 representative students s_1^r through s_{100}^r and normalized them. This rank-based scoring allows us to compare explainability methods without having the relative feature importance scores bias the analysis. We only selected features with a score of at least 0.33 in any course week, showing only the top two-thirds of features per method.

Figure 7: Importance scores for LIME, PermSHAP, and CEM for week 5.

For LIME, we observe that four features have been identified as important for predicting assignment performance in week 5. Two of these features directly relate to student behavior on the week 5 assignment: *TotalTimeProblem* (the total time the student spent solving the assignment) and *StudentSpeed* (the time between consecutive trials of assignments). The high scores of these features for week 5 are thus expected. LIME also assigns high scores to these two assignments based features for week 4. This result is encouraging as week 4 teaches the prerequisite skills of week 5 and therefore, LIME seems to (at least partially) uncover the prerequisite structure of the course.

In PermSHAP results, we see again that the scores are more uniformly distributed across features and weeks. However, we observe again that the assignment-based features (*TotalTimeProblem* and *StudentSpeed*) have comparably high scores for week 4 and therefore PermSHAP also seems to (partially) uncover the prerequisite relationships. Curiously, watching videos and solving quizzes scheduled for subsequent weeks (*CompetencyAnticipation* and *ContentAnticipation*) is also considered important, hinting that being proactive when learning increases learning success.

CEM seems to be able to partially uncover the prerequisite relationship between weeks as well. For week 4, one feature related to assignment behavior (*StudentSpeed*) exhibits a high score. Additionally, watching content of the subsequent week (in this case, week 4’s *ContentAnticipation* for week 5 material) is important for assignment performance. Otherwise, CEM mainly explains performance in the assignment of week 5 with student behavior in week 5: besides the assignment-related features, the students’ actions in the inference week are considered important.

Figure 8 shows the importance scores for LIME, PermSHAP, and CEM for the prediction model of week 9. Again, darker colors in the heatmaps indicate higher scores. The scores in the heatmaps were computed using the same ranking-based procedure as for Figure 7. In week 9, Figure 6 indicates that weeks 5 and 6 cover the prerequisite skills. From Figure 8, we observe that LIME does not seem to be able to capture this prerequisite relationship. The top scores for LIME appear in week 9 itself for an assignment-based feature (*StudentSpeed*) as well as for video control behavior (*AvgReplayedWeeklyProp*, which computes the relative number of video replays). Furthermore, *StudentSpeed* seems to be generally important also in the weeks just before the predicted week (weeks 7 and 8). For PermSHAP, we again obtain

a more equal distribution, with only the two assignment-related features (*TotalTimeProblem* and *StudentSpeed*) in weeks 8 and 9 showing relatively higher scores. Furthermore, PermSHAP also assigns relatively higher importance to these features for week 6, which is a prerequisite for week 9. For CEM, we again observe that mainly student behavior in the actual week, i.e. week 9, seems to explain assignment performance. Only one feature (*TotalTimeVideo*) shows medium importance for weeks 5 and 6.

In summary, all the evaluated methods were able to (partially) detect the prerequisite relationship between week 4 and week 5. For week 9, detecting the prerequisite structure proved to be difficult; results differed between methods. However, we should take into account that none of the features of the feature set directly measure student performance and therefore, the generated explanations rely on behavioral features only. It appears that recent and actual behavior is a much stronger indicator for performance than past behavior.

4. DISCUSSION AND CONCLUSION

Explainability methods allow us to interpret a deep model in a way that is understandable not only to machine learning experts, but also end-users of educational environments, including instructors tailoring course designs and students the model is predicting on [6, 7]. In this paper, we aimed to understand explainers’ behaviour and the ways in which they differ for the task of student success prediction.

Our results demonstrate that all explainability methods can derive interpretable motivations behind student success predictions, confirming the similar yet coherent observations made by [8] for the knowledge tracing field. However, while there was some agreement regarding the top features across the five explainability methods, key differences across methods emerged when we considered the exact importance scores (RQ1). We observed substantial similarities between KernelSHAP, PermSHAP, CEM and DiCE with regards to the top ranked feature-weeks. Conversely, LIME only ranked very few features as important, and these less important feature similarities made the other explainability methods appear closer to each other. Overall, looking beyond top ranked features, we noted considerable differences in feature importances across explainability methods. Interestingly, LIME-detected features are more in line with the features marked as important by Random Forests in [28], still in a MOOC context. This observation further demonstrates the generalizability of the features’ predictive power even among very different experimental settings.

In a subsequent experiment, we compared the different explainability methods across five MOOCs. Our findings indicate that the choice of explainability method has a much larger influence on the obtained feature importance score than the underlying model and data (RQ2). With distance (Jensen-Shannon distance) and ranking-based metrics (Spearman’s Rank-Order Correlation), we uncovered that LIME is farthest from the other explainability methods. The sparsity of LIME-detected important features was also observed by [13], where the conciseness of LIME explanations supported integration in visual dashboards for student advising. We also detected a close relationship between KernelSHAP and PermSHAP, which strongly validates our evaluation strat-

Figure 8: Importance scores for LIME, PermSHAP, and CEM for week 9.

egy. Using PCA, we identified clear clusters of explanations by explainability method and not by the course the model was trained upon, suggesting that an explainability method might be prone to mark specific features as important regardless of the model (and the course).

Our analyses also confirmed that all the evaluated methods were able to (partially) detect the prerequisite relationship between weeks, while relying on behavioral features only (RQ3). Our experimental design was inspired by [11]’s work on predicting effectiveness of interventions for wheel-spinning students by simulating prerequisite relationships. While we have no way to examine the true underlying feature importances of our week n assignment performance prediction model, we intuit that a student’s prerequisite week performance should be important to predicting their performance in week n . We observed that the three families of methods (LIME, SHAP, and counterfactual) were able to partially capture the prerequisite relationship in week 5, but struggled to capture the prerequisite relationships in week 9. While there were few similarities in the top ranked features, each method found different groups of feature-weeks as most important for the same models. Our results indicate that recent and current behavior is more important than past behavior, implying that proximity of behavioural features correlates strongly with their perceived importance. A limitation is that the prerequisite relationships we deem important might not actually be used as the true features of the model since our feature set included only features that examined student behavior and not direct performance.

Our results indicate that there are noteworthy differences in generated explanations for student performance prediction models. However, our analyses also show that these explanations often recognize prerequisite-based relationships between features. That being said, our study still has several limitations that warrant future research, including our focus on a singular downstream task (student success prediction), specific modality of dataset (MOOCs), choice of model architecture (*BiLSTM*), and lack of assessment of the obtained explanations’ impact in the real world. First, extending our experiments beyond success prediction to a multi-task analysis (e.g., dropout prediction) across multiple modalities (e.g., flipped classrooms, intelligent tutoring systems) would allow us to build stronger intuitions about explain-

ability method differences. Second, extending our black-box *BiLSTM* model architecture to multiple traditional and deep machine learning architectures could examine whether certain explainability methods have stronger explanation affinity to different predictors. Choosing transparent shallow architectures instead of black-boxes could also allow us to validate our results against ground truth feature importances. Third, further research should be conducted to check which explanations (and explainability methods) lead to interventions that better improve learning outcomes. It follows that an assessment of the obtained explanations should be carried out involving educators. Finally, the disagreement of our selected explainability methods motivate an extension in an ensemble expert-weighting scheme, which might have merit in closely estimating the true feature importances.

Explainability in educational deep learning models can lead to better-informed personalized interventions [2, 42], curriculum personalization, and informed course design. If we were considering global interventions (as it might be too resource intensive to perform interventions on each student individually), we could take the mean feature importance vector over all students and try interventions in the order of the scores of this mean vector. If we were only able to intervene on k features due to resource constraints, Spearman’s rank-order metric could also be modified to include the size of the intersection between the features with the top k scores. However, it is important to note that when the model explanations are biased by explainability method and do not accurately reflect the inner workings of the model, the impact of incorrect predictions are further exacerbated by teachers and students’ misplaced confidence in the model’s justification. **We implore data scientists to not take the choice of explainability method lightly as it does have a significant impact on model interpretation, and instead urge the community to (1) carefully select an appropriate explainability method based on a downstream task and (2) keep potential biases of the explainer in mind when analyzing interpretability results.** Overall, our work contributes to ongoing research in explainable analytics and to the generalization of theories and patterns in success prediction.

APPENDIX

A. MODEL ARCHITECTURE

We experimented with traditional machine learning models (e.g., Support Vector Machines, Logistic Regression, Random Forest) and deep-learning models (e.g., Fully-Connected Networks, RNNs, LSTMs, CNNs, and BiLSTMs), and found that BiLSTM models perform best against the other baselines for our use case. To determine the optimal model architecture, we evaluate validation set performance on the course *DSP 1* as it is used in all three RQs. BiLSTMs have a 26.8% average increase in balanced accuracy over traditional machine learning methods. For the BiLSTM architecture grid search, we examined the following layer settings {32, 64, 128, 256, 32-32, 64-32, 128-32, 128-64, 128-128, 256-128, 64-64-32, 128-64-32, 64-64-64-32-32} before determining 64-32 performed best in balanced accuracy for *DSP 1*. We used the Tensorflow library to train our models [43].

B. MODEL TRAINING

Model training took approximately 35 minutes per model on an Intel Xeon E5-2680 CPU with 12 cores, 24 threads, and 256 GB RAM. Each model was trained for 15 epochs, and the best performing model checkpoint was saved. The five models’ performance metrics are showcased in Table 3.

C. SAMPLING STRATEGY

We experimented with several strategies to extract an appropriate representative sample including the greedy algorithm SP-LIME [15], random sampling, two sets of extreme students (those which the model predicts very well on and very badly on), and uniform sampling. We determined that our uniform sampling approach was the most fair with respect to the variable class imbalance between courses.

Identifier	Accuracy	Balanced Accuracy	F-1 Score
<i>DSP 1</i>	99.3	97.4	99.6
<i>DSP 2</i>	99.1	93.5	99.5
<i>Geomatique</i>	97.7	96.2	98.7
<i>Villes Africaines</i>	98.4	95.5	99.1
<i>Micro</i>	89.5	90.9	90

ABSTRACT

A strategy for allocating merit-based awards and need-based aid is critical to a university. Such a strategy, however, must address multiple, sometimes competing objectives. We introduce an approach that couples a gradient boosting classifier for predicting outcomes from an allocation strategy with a local search optimization algorithm, which optimizes strategies based on their expected outcomes. Unlike most existing approaches that focus strictly on allocating merit-based awards, ours optimizes simultaneously the allocation of both merit-based awards and need-based aid. Further, the multi-objective optimization lets users experiment with different combinations of institution-centric and student-centric objectives to deliver outcomes that suit desired goals. With this approach, we identify multiple allocation strategies that would yield higher enrollment, revenue, or students' affordability and access to higher education than the University's existing strategy. In particular, one strategy suggests that with moderate changes to the current funding structure the University can increase students' access to higher education by more than 100%, while still maintaining a similar level of enrollment and revenue.

institutional data analytics, financial aid optimization, scholarship distribution, enrollment management

1. INTRODUCTION

Public universities in the United States (US) create recruitment policies amidst decreased state funding and increased costs of attendance. Decreased funding was predicted as a result of state deficits [17]. This is now evident in data showing falling state appropriations as a percent of total revenue for public 4-year institutions from academic year 2008-09

(23.8%) to academic year 2018-19 (16.5%) [12]. Decreased state funding necessitates a greater reliance on tuition and fee revenue from enrolled students.

From academic year 2011-12 through 2016-17 tuition and fees increased by 9% at public 4-year institutions, making college too costly for an increasing proportion of students (especially those from low- and lower-middle-income families) [3, 9, 26]. Students are being priced out of college or choosing to take out loans and/or work while pursuing a course of study [25]. This rising cost has resulted in a national college debt crisis in which 57% of debtors with federal student loan debt owe up to \$20,000 [3].

The combination of decreased funding and increased costs of attendance have implications for enrollment management activities. An increased reliance on tuition and fee revenue means that setting policies surrounding student recruitment efforts and accurately forecasting their outcomes is increasingly important to universities' income and budget projections [2, 38]. However, these recruitment efforts are hindered by the increased prices charged to students. Higher prices reduce enrollment rates particularly for low-income students in public institutions [22]. The use of financial aid as an enrollment management tool to counteract these increased prices is well-established [15]. Further, the positive impact of both federal and state need-based financial aid programs on students from low-income families has also been explored [3, 8, 9]. With increasing costs of attendance leading to crises of affordability and access, universities should explore the role of need-based aid in their enrollment management strategies.

The call to optimize enrollment management activities with the consideration of access and affordability is one that appears difficult to achieve. However, the student and financial data needed for such predictions and optimizations are stored in universities' existing data systems [31]. Despite having access to this data, universities are not quick to leverage it themselves perhaps due to untrained personnel or poor data infrastructure [31, 32]. Instead, the data and these analyses are outsourced to external consulting firms who organize and process the data to be used in proprietary models [16]. With this type of industry environment there is limited published work to demonstrate how machine learning prediction and optimization can be used in tandem to inform university recruitment policies.

Existing work on financial aid optimization has been limited in two regards: (1) the optimization only takes enrollment as the sole objective and (2) the resulting strategy is for merit-based aid only [4, 28]. The limiting of the optimization to enrollment is short-sighted in that universities are targeting multiple objectives that may not move with enrollment. Additionally, when only considering merit-based awards, student-centric outcomes like access and affordability are neglected despite their increasing importance in the dialogue surrounding higher education. Our work seeks to address these shortcomings.

Our approach consists of an interactive feedback loop between two core components: a gradient-boosting classifier and *auto-start* local search optimizer. First, given a current strategy for award and aid allocation (together with many other features), the classifier is used to predict enrollment, revenue, the affordability and accessibility of higher education, and other outcomes. These predicted outcomes are then used by an optimizer to revise the current strategy and suggest a possibly better one. The interaction between the classifier and optimizer forms a feedback loop that is the basis of the optimization. This loop aims to identify optimal strategies for allocating awards and aid with expected outcomes specified by the University. The novelty of this work includes (1) the allocation both merit-based awards and need-based aid in the optimization process; (2) the inclusion of the affordability and accessibility of higher education in the optimization of allocation strategies; and (3) an *auto-start* local search optimization that allows users to target institution-centric and student-centric objectives in a flexible way to produce desirable outcomes.

2. RELATED WORK

The following describes research on enrollment prediction, scholarship allocation, and financial aid optimization. There is significant work on predicting enrollment, but far less with regard to optimization and allocation of scholarships. Most authors looked at only one of these issues and most work has been primarily concerned with merit-based aid alone.

Predicting Enrollment. Universities' increased reliance on tuition and fee revenue has increased pressure on their limited resources to accurately predict and increase enrollment (i.e. yield). Recruitment counselors need to allocate their limited time to contact students "on-the-fence" about their enrollment decisions [10]. This business need led to the literature on enrollment prediction at the individual applicant level using data mining and machine learning techniques.

There is a host of research that relies on logistic regression techniques to create these individual enrollment probabilities. A 2002 paper by DesJardins used a logistic regression to reveal the enrollment probabilities of applicants before any financial aid offers had been made. The resulting model, which relied heavily on demographic features, had a correct classification rate of approximately 67% [10]. In 2006, Goenner and Pauls used a logistic regression to predict the enrollment of students who had inquired about the university. The resulting model was 89% accurate at out-of-sample predictions [14]. Similarly, a 2014 paper by Sugrue generated a logistic regression to predict enrollment yield [34].

In another vein of literature, other prediction techniques are explored. Two related works explore the effectiveness of neural network models in predicting individual enrollment probabilities for applicants. A 1998 paper by Walczak revealed that a backpropagation neural network model could result in a 56% decrease in recruitment counselor caseloads due to its accuracy [39]. In a follow-up study, Walczak and Sincich explicitly compare the performance of neural network models to that of logistic regression and find that neural networks produce better results [40]. Chang similarly explores the efficacy of various prediction techniques, specifying models for logistic regression, neural networks, and classification and regression tree (CR&T). The work showed that both neural networks and CR&T outperformed logistic regression when judged based on prediction accuracy [6].

Scholarship Disbursement/Allocation. Not all scholarship policies employed by universities are rule-based. In these cases, the business process of selecting the applicants to receive an award may be ineffective and inefficient. Literature has shown that data mining techniques can be effective in creating rule-based scholarship allocation policies to help reduce business process inefficiencies. In 2019, Rohman et al. illustrated how an ID3 decision tree algorithm could generate rules to select the scholarship applicants most likely to be awarded a scholarship. This general rule allowed for the efficient identification of applicants so that offers could be made [27]. Alhassan and Lawal similarly used a tree-based data mining classification technique to determine a generic rule for scholarship disbursement. They found the technique to be effective and efficient [1].

Optimization of financial aid policies. Mathematical programming models are effective tools for generating and evaluating financial aid strategies. Spaulding and Olswang use discriminant analysis to test the efficacy of various aid strategies [33]. Linear programming was used by Sugrue et al in 2006 as an aid decision tool where the goal was to maximize net revenue with budget, average Scholastic Assessment Test (SAT) scores, recruitment pools, and enrollment targets as constraints [37]. In later work, Sugrue again employed a linear programming approach to optimize the quality of the incoming class with estimates of yield rates being derived from previous years' yield rates [35].

More recent research has incorporated enrollment prediction models with optimization techniques to recommend financial aid strategies. In 2015 Sarafraz et al used a neural network model to predict enrollment and then employed a genetic algorithm to find a scholarship strategy that maximized total enrollment [28]. In 2019 Sugrue used data from the University of Miami to develop a merit-based aid allocation model that predicted enrollment via logistic regression and maximized the quality of the incoming class via a linear programming model [36]. In 2020 Aulck et al tested a group of machine learning tools to predict the enrollment decisions of admitted, domestic nonresident first-time students and then used those results in a genetic algorithm to recommend an optimal disbursement strategy for a domestic non-resident merit scholarship that would maximize enrollment [4].

None of these previous works have considered merit-based award and need-based aid strategies simultaneously as our

paper proposes to do. Further, this joint consideration demands the consideration of a what an appropriate optimization objective should be given that the recruitment goals of merit-based awards and need-based aid differ in some regards. Though the joint consideration of merit and need strategies in one optimization problem does complicate the process, a multi-objective approach needs to be researched since these aid strategies compete for the same limited budget resources.

Local-search optimization. Local search is a heuristic method for solving computationally hard problems. A local search algorithm starts with an initial candidate solution and iteratively moves to a neighbor solution in hopes of finding better and better candidate solutions. The algorithm stops when it cannot find a neighbor solution that is better than the current candidate solution. For local search to work, a *neighbor relation* must be defined so that from an arbitrary candidate solution, a neighbor solution can be generated.

Stochastic hill climbing [20] is a fast local search method because it greedily moves from one candidate solution to a better one. It is similar to a popular method, stochastic gradient descent [19], but it is faster because it does not need to estimate the gradient of the objective function. The main disadvantage of stochastic hill climbing is that it is often stuck in locally optimal solutions.

Two popular methods that can find globally optimal solutions are simulated annealing [21] and genetic algorithms [41]. In a number of applications, genetic algorithms produced slightly better solutions than simulated annealing [30]. Nevertheless, simulated annealing and its variant, simulated quenching [18], seem to suit our technical approach better than genetic algorithm because it is not obvious to us how we can meaningfully apply the genetic algorithm’s crossover operator to allocation strategies.

3. METHODS

3.1 Overview of the problem and challenges

Merit-based awards and need-based aid. At the University, a certain amount of financial award or aid is offered to each applicant based on his or her profile on merit (academic performance) and need. Merit-based award eligibility is calculated based on a combination of standardized test scores (i.e. American College Testing (ACT) and Scholastic Assessment Test (SAT)) and high school GPA. Need-based aid eligibility is determined by expected family contribution from the Free Application for Federal Student Aid (FAFSA) and then adjusted in an ad hoc manner based on items such as cost of attendance and how much federal aid and other merit-based awards are promised to students. A student may receive both merit awards and financial aid. The allocation strategy of merit awards and aid strives to be fair in that two students with the same residency and academic performance profile will receive the same merit offer and two students with the same residency and need profile will receive the same aid offer. These offers are made in a guaranteed fashion in that each admitted applicant will be offered a merit-based award and/or need-based aid so long as requirements are met.

Allocation strategy of awards and aid. In the context of this work, an allocation strategy consists of a merit-based allo-

Figure 1: Overview of the technical approach

cation strategy and a need-based allocation strategy. Each allocation strategy consists of (1) a list of buckets into which students are placed, and (2) how much financial award or aid students in each bucket will receive.

An allocation strategy has an important impact on the budget of the University because it affects enrollment in complex ways. Enrollment affects revenue. Revenue affects the number and amounts of awards and aid the University can give to its students. And awards and aid directly affect the applicants’ decision to enroll at the University. Increasing awards and aid can increase enrollment, but may reduce revenue, which in turn limits the University’s ability to increase awards and aid.

Our mission. Our team was tasked with revising the University’s current way of offering merit-based awards and need-based aid. Although the current system is fair, as it should be, the Financial Aid Office has thought that due to multiple reasons the current strategy might not be optimal. We were asked to generate a revised strategy that uniformly impacts the domestic student body in a way that improves multiple, possibly conflicting objectives such as increasing enrollment, increasing revenue, increasing student performance profiles, and making higher education more accessible and affordable.

Technical approach. An overview of our approach is depicted in Figure 1. The approach utilizes a feedback loop that continually revises a feature set from which a classifier learns to predict various outcomes. In contrast to the traditional setting where features stay fixed, the features in our model are continually revised in this feedback loop. This is possible due to the fact that the University can change award and aid offer amounts, which is part of the feature set used to predict enrollment, revenue and other outcomes. The feedback loop is an iterative interaction between the classifier, which predicts expected outcomes, and an optimizer, which evaluates the outcomes and suggests a revised strategy with

possibly better outcomes. In each iteration of this interaction, depicted in Figure 1, the current allocation strategy dictates offer amounts for awards and aid. This changes the features, which leads the classifier to relearn and re-predict multiple outcomes (e.g. enrollment, revenue, student affordability and accessibility, etc.). This allows the *auto-start* local-search optimizer to revise and possibly improve the current strategy; and so on and so forth.

3.2 Data Collection and Cleaning

Data for this research is all first-time freshmen (FTF) domestic admitted applicants to the University in the Fall 2020. The data on students is compiled from the University’s admission application, the FAFSA, and the student information system. Only the students who filed a FAFSA (making them eligible for need-based aid) are included resulting 7,564 observations which is approximately 67% of the total number of domestic FTF students for that term. Data from the admission application includes admission test scores, high school GPA, location/residency, and intended major. Data from the FAFSA includes expected family contribution and family income. Data from the student information system includes whether or not the student had previously enrolled at the institution as a dual enrollment student, aid offer amounts for various categories of aid, and an enrollment indicator. Of the 7,564 students 2,340 chose to enroll (approximately 31%). No demographic variables are used in the study so as to avoid bias in recommending aid strategies to the University.

Financial data points are expected full time tuition, merit-based award offers, need-based aid offers, actual and estimated Pell grant offers, and all other aid offers before loans. Estimated Pell grant offers are included as the University will make offers prior to actual Pell amounts being known. These are estimated based on cost of attendance and expected family contribution using the Pell schedules released each year with the assumption that students will enroll full time. Each of the aid offer features enters the predictive model independently and in a total financial aid variable. These offer amounts are not manipulated when generating the predictive model, but are updated during the optimization process.

3.3 Feature Engineering

Prior to building prediction models and optimizations, feature engineering is done using Pandas [23]. Categorical variables are either converted to binary indicators or converted to binary dummies. Continuous distance variables that measure distance from the University and its key market competitors are converted to binary daily and weekly commute variables. We compute an historic 5-year average yield by high school to serve as a proxy of familiarity and/or social network at the University. We convert the major declared on the application into five major group binary indicators: STEM, Fine Arts, Health, Business, and Humanities. The feature engineering results in 95 features from our data sources on which to build our predictions.

Two important features that affect applicants’ decisions to enroll are the promised amounts of merit-based awards and need-based aid. These features are determined by a specific strategy for allocating awards and aid. As indicated in Fig-

ure 1, these two features are updated during an optimization process that traverses through the solution space to find an optimal one. As the features are updated, the classification model relearns to update its estimate of enrollment probabilities.

3.4 Modeling enrollment

The data is stored in a matrix D where each row represents an applicant’s profile. The first column of D is the binary enrollment variable, y , where y_i being equal to 1 means applicant i enrolled at the University and y_i being equal to 0 means the applicant did not enroll at the University. All other columns of D are features that a classifier uses to learn y . The goal in modeling enrollment is to assess the viability of using popular classification methods to predict enrollment, and to identify and adopt the best method to assist in the optimization of strategies for allocating merit-based awards and need-based aid.

Classifiers. We investigate the performance of several popular classifiers that can predict enrollment probabilities. These include classification methods based on diverse approaches such as support vector, logistic regression, and k-nearest neighbors. We also consider the ensemble methods of random forest, AdaBoost [29], gradient boosting [13], and a more regularized version of gradient boosting known as extreme gradient boosting [7]. Many of these methods do not strictly predict probabilities of a target variable. Rather, they can provide quantities that can loosely be interpreted as probabilities. For example, in case of ensemble methods, which output quantities based on binary decisions of the base learners, we interpret these quantities as probabilities. We used available implementations of these methods in the scikit-learn [24] and xgboost [7] libraries.

Data scaling. Classification methods such as support vector, logistic regression, and k-nearest neighbors operate on distances between data points. Since distances between different features are not of the same scales, the features need to be standardized first. We employ a popular method of data standardization. For each data point, we subtract from it the mean of the training samples, and then divide that by the standard deviation of the training samples.

Performance metrics. We employ multiple metrics to measure the performance of the classifiers from multiple perspectives. Since the data is imbalanced, a single metric, e.g. accuracy, does not meaningfully reflect different aspects of the performance of a classifier. We consider 3 compound metrics: F-score, balanced accuracy, and AUC (area under the ROC curve), which show different aspects of performance. F-score is a useful metric when we are interested in the ability to predict class-1 samples (applicants who ultimately enroll at the university). It combines two individual measures and is defined as $\frac{2 \cdot \text{precision} \cdot \text{sensitivity}}{(\text{precision} + \text{sensitivity})}$, where precision is the probability that a positive prediction is correctly predicted, and sensitivity is the true positive rate or the probability that class-1 samples are correctly predicted. Balanced accuracy is used when we are equally interested in the ability to predict both class-1 and class-0 samples. It gives equal weights to true positive rates (sensitivity) and true negative rates (specificity). AUC is useful when we are interested in the trade-offs between sensitivity and specificity at various

thresholds as it sums up the area under the curve defined by sensitivity (true positive rate) and 1-specificity (false positive rate).

Comparison to baseline. To gauge the performance of each classification method, we compare its performance to that of two baseline methods. The first baseline is a popular method, ZeroR [11], which always predicts the most frequent label in the training set. The second baseline, Stratified, makes predictions based on the distribution of the labels in the training set.

Cross-validation. To determine the performance of each classifier under a metric, we train the classifier using 90% of the data and test it using the other 10% of the data. We experiment with two popular cross-validation methods of partitioning the data randomly into training and testing sets: (1) repeated random subsampling (up to 50 random splits) and (2) k-fold with k=5 and 10. Although the data partitions are randomly generated, in each iteration, we compare the classifiers using the same random partition.

3.5 Optimization of allocation strategies

Algorithm 1 AutoStart-Optimizer(s_0, C, D, δ, S_T)

```

1:  $s \leftarrow s_0$ ;  $best\_strategy \leftarrow s_0$ 
2: Run Stochastic Hill Climb to find  $\Delta_{max}$ 
3:  $T \leftarrow \frac{\Delta_{max}}{\ln 0.5}$ 
4: while progress is still being made do
5:    $T \leftarrow T \cdot \delta$ 
6:   for  $i$  from 1 to  $S_T$  do
7:      $s\_value \leftarrow C.compute\_value(s)$ 
8:      $t \leftarrow RandomNeighbor(s)$ 
9:      $D.update\_strategy(t)$ 
10:     $C.fit(X_D, y_D)$ 
11:     $\Delta = C.compute\_value(t) - s\_value$ 
12:    if  $\Delta > 0$  or with probability  $e^{\frac{\Delta}{T}}$  then
13:       $s \leftarrow t$ 
14:      if  $s$  is better than  $best\_strategy$  then
15:         $best\_strategy \leftarrow s$ 
16:      end if

Local search optimization. Simulated annealing [21] is inspired from a physical annealing process, in which an initially hot temperature lets the local search explore the solution space more freely, allowing the adoption of neighbor solutions that are not as good as the candidate solution. As the search goes on, the temperature cools down and the search is more aggressive in finding better solutions. When the temperature is low enough the search essentially becomes a stochastic hill climb. Starting at a high initial temperature, the annealing is known to be able to escape locally optimal solutions and reach a globally optimal solution eventually.

We adopt a modified version of simulated quenching [18], which is a variant of simulated annealing. It is faster than

simulated annealing because it cools temperatures faster. It is shown that in practice simulated quenching was as good as simulated annealing [18].

While Figure 1 provides a high-level description of each iteration of the optimization, Algorithm 1 provides a more detailed description of how the optimization utilizes simulated quenching to find optimal strategies for allocating merit-based awards and need-based aid. The algorithm takes as input an initial allocation strategy (s_0), which is an estimate from the university's current strategy; a classifier C , which learns from historical or updated features to predict enrollment probabilities; an interface D to dataset, which can update features based on a new strategy or rollbacks previous features based on a previous strategy; δ and S_T , which dictate how fast the temperature schedule is decreased and how long the temperature is kept constant, in each quenching step.

The simulated quenching process aims to improve upon the initial strategy, s_0 , by moving from one neighboring strategy to the next. A better neighboring strategy replaces the current one. Additionally, a worse neighboring strategy can also replace the current one with a certain probability (lines 12-13, Algorithm 1), which is determined by the current temperature T and how much worse the neighbor is. At a higher temperature T , a worse neighboring strategy can replace the current one in hopes of getting to an eventual better optimum.

Auto-start simulated quenching To explore the search space liberally at the start of the search, the initial temperature needs to be sufficiently high. This initial temperature is, however, problem dependent. As such, users generally have to experiment with different values to find an appropriate one. We employ a stochastic hill climber to derive an initial temperature to start the simulated quenching process without requiring users to initiate the search by specifying an initial temperature (lines 2-3 in Algorithm 1). We set the initial temperature T to $\frac{\Delta_{max}}{\ln(0.5)}$, where Δ_{max} is the difference between the worst strategy and the best strategy (local optimum) that the stochastic hill climber finds. At this initial temperature, the largest backward move is accepted with probability 0.5. As T decreases, this probability decreases and a backward move is less likely allowed. When T is small enough, the search effectively turns into a stochastic hill climber.

Solution representation. The local search algorithm navigates through the search space of allocation strategies to find an optimal solution (strategy). An allocation strategy consists of a merit-based award allocation strategy and a need-based aid allocation strategy. Each consists of (1) a list of buckets into which students are placed and (2) how much money students in each bucket will receive. Buckets and amounts must be increasing. This means a higher achievement results in higher merit-based amounts, and higher need results in higher need-based amounts. As an example, consider this allocation strategy:

- Achievement buckets: [0, 0.25, 0.50, 0.75, 1]
- Merit amounts: [\$0, \$2000, \$6000, \$10000]

- Need buckets: [\$0, \$500, \$5000, \$10000, \$20000, \$40000]
- Need amounts: [\$0, \$1000, \$1500, \$2500, \$3000]

If an applicant’s achievement index (or need index) falls between bucket $[j]$ and bucket $[j+1]$, then the applicant receives amounts $[j]$. For example, if applicant i has a merit index of 0.4 and a need index of \$15000, then the applicant will receive a merit-based amount of $M_i = \$2000$ and a need-based amount of $N_i = \$2500$. Collectively, the offered amounts of merit-based awards and need-based aid are captured in the features M and N of D .

Generating neighboring strategies. Local search requires the ability to generate a neighboring strategy from a current candidate strategy. The two main steps of how the function RandomNeighbor (line 8, Algorithm 1) generates a neighboring strategy for a given strategy s are as follows:

- 1: First, select with probability 0.5 either the *merit amounts* list or the *need amounts* list of s . Call this list $A = [a_1, \dots, a_k]$.
- 2: Second, with probability 0.5, either add a small amount to a random amount a_r ($1 \leq r \leq k$) in A , or remove a small amount from a random amount a_r in A .

RandomNeighbor keeps repeating these steps of adding or removing small amounts from A until it finds a neighboring strategy that satisfies the following constraints: (1) A remains in an increasing order ; (2) the resulting amount, a_r , must be sufficiently different from its adjacent entries (a_{r-1} and a_{r+1}); and (3) the minimum amount in A cannot be too small (in case of a remove) or the maximum amount in A cannot be too big (in case of an add).

Updating allocation strategies and relearning. To determine if a neighboring strategy t is better or worse than the current one two steps must be taken. First, we have to use this strategy t to update the merit-based awards (feature M of the dataset D) and need-based aid (feature N of the dataset D) for all applicants (rows of D). Second, we have to refit the classifier C to this updated dataset. These two steps are shown in lines 9-10 of Algorithm 1.

If t ends up replacing s , the search moves on to the next iteration. If t does not replace s , we have to roll back to strategy s and refit the classifier C to the previous dataset with strategy s (lines 18-19, Algorithm 1).

Expected outcomes as a result of an allocation strategy. An allocation of funds to awards and aid affects enrollment, which affects multiple outcomes that the University is interested in. We utilized a classification method, e.g. gradient boosting, to predict enrollment probabilities of applicants. This enables us to compute the expected outcomes that we are interested in. Let $y = (y_1, \dots, y_n)$ be the binary target variable enrollment, and let $p = (p_1, \dots, p_n)$, where p_i is the probability that applicant i enrolls at the University.

The expected outcomes we are interested in include:

- Expected enrollment = $\sum_i p_i$. Denote the expected enrollment as E .

- Expected net revenue = $\sum_i p_i \cdot R_i$, where R_i is net revenue obtained from applicant i . $R_i = t_i - (m_i + n_i)$, where t_i is the tuition that the applicant pays, and m_i and n_i are the merit-based and need-based amounts offered to this applicant.

- Expected unmet need = $\frac{1}{E} \cdot \sum_i p_i \cdot (COA_i - EFC_i - Pell_i - M_i - N_i)$, where COA, EFC, and Pell are cost of attendance, expected family contribution, federal Pell grant; and M and N are the University’s merit-based award and need-based aid. A positive unmet need amount is what the applicant is expected to borrow to pay for attending the University. This definition is widely used as a measure affordability.

- Expected accessibility = $\sum_i p_i \cdot I_i$, where $I_i = 1$ iff applicant i is offered some financial aid (i.e. $M_i + N_i > 0$) and has unmet need that exceeds a certain threshold. Note that M_i and N_i are the amounts of merit-based award and need-based aid that applicant i is promised. This threshold is set by the University and is believed to represent a level of need that is not surmountable through existing State and Federal programs.

- Expected return on investment = $\frac{\sum_i p_i \cdot R_i}{\sum_i p_i \cdot (M_i + N_i)}$. It is the expected revenue divided by the expected total promised amounts of awards and aid.

- Expected achievement = $\frac{1}{E} \cdot \sum_i p_i \cdot A_i$, where A_i is the achievement index of applicant i and is calculated from a combination of the applicant’s standardized test scores (e.g. SAT or ACT) and high school GPA. Applicant i is offered a merit-based award in an amount of M_i based on A_i .

Multi-objective optimization. Algorithm 1 aims to find a strategy s^* that maximizes the weighted sum of expected enrollment (enr), net revenue (rev), unmet need (un), accessibility (acc), return of investment (roi), and achievement (ach) as follows:

$$f(s, D, C) = \alpha_1 \cdot E[\text{enr}] + \alpha_2 \cdot E[\text{rev}] - \alpha_3 \cdot E[\text{un}] + \alpha_4 \cdot E[\text{acc}] + \alpha_5 \cdot E[\text{roi}] + \alpha_6 \cdot E[\text{ach}] \quad (1)$$

where α_i ’s are the weights of the expected outcomes. Implicitly, the allocation strategy s is applied to the data D , from which the classifier C learns to predict enrollment the probability p , which is used to compute the expected values on the right hand side of the equation.

Although we do not expect the algorithm to find a strategy that is optimal in each individual objective, an overall optimal value of the function should benefit both the University and the applicants. While higher expected values of enrollment, revenue, and achievement benefit the University, less unmet need and high accessibility benefit applicants. On the one hand, it seems that reducing unmet need for applicants may reduce revenue. On the other hand, making attendance more affordable may actually increase both the expected enrollment, which in turn may increase the expected revenue. In other words, increasing merit-based and need-based amounts may reduce the revenue from each enrolled applicant, but may increase the number of enrolled applicants and, ultimately, the overall revenue.

Table 1: Performance of predicting enrollment

	balanced accuracy	F-score	AUC
Gradient Boosting	0.91	0.88	0.96
XGB	0.91	0.88	0.96
AdaBoost	0.88	0.84	0.95
Random Forest	0.77	0.69	0.92
Linear SVC	0.72	0.61	0.83
KNN	0.61	0.44	0.69
Stratified baseline	0.50	0.30	0.50
ZeroR baseline	0.50	-	0.50

Users can experiment with α 's to give different weights to different objectives to obtain realistically acceptable trade-offs and improvements among the individual objectives.

Constraints. In constructing this research, certain constraints were determined by the University’s administration. These constraints reflect the administration’s perspective on the competitive environment and internal business processes that will support any proposed strategy. These constraints depend on the award structure under consideration. For merit-based awards, there could be no more than 6 awards with award amounts restricted to a specific range. The need-based aid strategy specification was limited to 4 awards with their own maximum and minimum constraints on aid amounts. It is worth noting that the maximum value for a merit-based award was four times higher than the maximum need-based aid amount. Need-based aid eligibility also had a minimum need index cutoff ($COA_i - EFC_i - M_i - Pell_i$). For both allocation strategies there needed to be a minimum difference of \$100 between award buckets.

4. RESULTS

Predicting enrollment. We found gradient boosting [29] was the highest performing classifier and had very high performance in predicting enrollment. This result was obtained by comparing optimized versions of 6 different popular classification approaches, which could make probabilistic predictions. Figure 2 shows the ROC curve of the classifiers in one random partition the data into 90% training and 10% testing sets. The figure shows an excellent trade-off between true positive rate and false positive rate for the two top performers (gradient boosting and extreme gradient boosting).

Table 1 shows the performance of the classifiers averaged across 10 folds of cross validation. In validating the classifiers, we experimented with k-fold cross validation and repeated subsampling at various parameters. We ultimately decided that a 10-fold cross validation was a slightly better choice for our study than the others. All classifiers performed significantly better than the two baselines. Note that given the imbalance of the data, ZeroR did not predict any positive label, resulting in undefined precision and F-score. Gradient Boosting [29] and Extreme Gradient Boosting [7] had the same highest performance across all 3 metrics (balanced accuracy, F-score, and AUC). Gradient Boosting, AdaBoost, and Random Forest were optimized after consid-

**Figure 2: ROC curve of enrollment prediction**

ering various values of maximum depth and minimum leaf size of the decision-tree base learners.

Given an allocation strategy for awards and aid, we employed a gradient boosting classifier to predict expected outcomes if we were to apply the strategy. To assess this strategy, we compare the expected outcomes to the actual outcomes that were obtained from the original data based on the University’s existing strategy for allocating awards and aid.

Defining strategies for allocating funds. A *strategy* for simulated quenching consists of 3 parameters: (1) the number of steps in decreasing an initial temperature, (2) the number of times to keep the current temperature constant, and (3) the weights (α_i 's) of the expected outcomes in Equation 1. For example, we denote **SQ-enr-100,3** as the strategy that optimizes enrollment where temperatures are decreased 100 steps, and each temperature is kept constant for 3 steps. As another example, we denote **SQ-enr-un-2,0.6,100,3** as the strategy that optimizes enrollment and unmet need with weights 2 and 0.6, respectively, where temperatures are decreased 100 steps, and each temperature is kept constant for 3 steps.

Table 2 shows the expected outcomes (averaged across 10 random runs) relative to the baseline (actual outcomes) of a few distinguishing strategies. These expected outcomes are from (1) a strategy for optimizing enrollment; (2) two strategies for optimizing enrollment and unmet need; and (3) seven strategies for optimizing enrollment, unmet need, and revenue.

For clarity, expected outcomes are grouped into two categories: institution-centric outcomes and student-centric outcomes. In general, it is difficult to find a strategy that can improve all of the outcomes simultaneously.

Table 2: Expected outcomes of different strategies versus actual outcomes

Strategy	Institution-Centric				Student-Centric		Budget Change
	Enrollment (%)	Revenue (%)	ROI (%)	Achievement (%)	Accessibility (%)	Unmet need (\$)	Total Funding (%)
SQ-enr-100,3	32.0	29.0	-1.0	-2.0	189.0	3320.0	48.0
SQ-enr-un-2,0.6,100,3	17.0	-26.0	-3.0	-1.0	132.0	-403.0	191.0
SQ-enr-un-2,0.6,100,5	22.0	-25.0	-3.0	-2.0	142.0	-51.0	216.0
SQ-enr-un-rev-1,0.5,2,100,1	5.8	14.6	2.7	-0.4	119.8	1247.0	-28.1
SQ-enr-un-rev-1,0.5,2,100,5	8.1	16.6	2.9	-0.4	125.7	1429.7	-24.5
SQ-enr-un-rev-1,0.6,2,100,1	11.8	6.5	-0.8	-0.7	132.4	948.7	34.9
SQ-enr-un-rev-1,0.6,2,100,2	8.3	6.9	-0.2	-0.5	124.0	825.0	15.5
SQ-enr-un-rev-1,0.6,2,100,3	5.7	1.7	-0.6	-0.4	115.8	345.7	23.2
SQ-enr-un-rev-1,0.6,2,100,4	3.5	-0.2	-0.5	-0.3	109.8	135.2	19.5
SQ-enr-un-rev-1,0.6,2,100,5	2.0	-4.8	-0.4	-0.2	104.3	-288.6	29.9

Table 3: A comparison between the actual outcomes and expected outcomes resulting from a conservative solution for distributing awards and aid

Institution-Centric Outcomes				Student-Centric Outcomes		Budget Changes		
Enrollment	Revenue	ROI	Merit	Accessibility	Unmet need	Total Funding	Awards	Aid
1.3%	0.1%	-0.2%	-0.1%	104.7%	-\$2.7	6.5%	-2.2%	93.4%

Low impact on expected ROI and achievement in optimization strategies. In our evaluation of different strategies, it seems that the impact on expected ROI and merit profiles is relatively small. Percent changes to ROI are reported in column 5 of Table 2. ROI deviates 3% from the baseline in either direction at most, with the majority of deviations being a decrease of 1% or less. Similarly, expected achievement decreases from the baseline by 2% at most, which is equivalent to less than a one point drop in average ACT scores. As such these particular outcomes are not discussed at length in results discussed subsequently.

Optimizing for enrollment alone is good for the University but bad for students. Previous literature focused on optimizing for enrollment alone [4, 28]. In Table 2 this strategy is represented by **SQ-enr-100,3**. Enrollment and net revenue increase 32% and 29% over actual figures, respectively. These results appear attractive if considered in isolation. However, this return comes at the expense of a 48% increase in the total financial aid budget as well as a \$3320 increase in the average amount of unmet need carried by matriculates, indicating attending the University has been made less affordable on average. This increase in expected average unmet need is particularly interesting when compared with the 189% increase in accessibility. Together affordability and accessibility are student-centric outcomes often paired in institutional mission statements. However, there appears to be a trade-off between the two. The extension of more strategic awards and aid to those students with fewer means, may increase their likelihood of attending but it will also raise the average amount of unmet need as the awards and aid are not enough to offset the total cost.

Optimizing for both enrollment and unmet need is good for students but bad for the University. Since optimizing for enrollment alone increases unmet need, we next examine the impact of optimizing for both simultaneously. **SQ-enr-un-2,0.6,100,3** and **SQ-enr-un-2,0.6,100,5** in Table 2 are two such strategies for this dual optimization specification. In both strategies the University sees improvements in terms of enrollment (17 - 22% increase), accessibility (increase 132-142%), and unmet need (decrease \$51 - \$403). However, these improvements are costly the University. To achieve this, total financial aid funding is anticipated to rise 191-216%, causing a reduction in net tuition revenue of 25%. This trade-off between affordability and net revenue necessitates a more nuanced optimization specification.

Optimizing for enrollment, unmet need and revenue results in reasonable trade-offs. If the University wishes to strike a balance between institution- and student-centric outcomes, enrollment, unmet need, and revenue must be simultaneously optimized. Seven different strategies for such a specification are seen in the last two sections of Table 2. From the University’s perspective, each of these strategies results in modest increases in enrollment (2% - 11.8%) and has a negligible to modest impact on expected net revenue (-4.8% - 16.6%). Further, each requires significantly less investment in total funding as compared to optimizing for enrollment or enrollment/affordability and, in some cases, could result in cost savings. From the student perspective there is still a marked gain in accessibility of over 100% in all of the strategies. Unmet need, as a measure of affordability, on average still experiences an increase over the actual amount under all but one strategy, but the amount of the increase in unmet need is always below \$3000, which is a great improvement

Table 4: Effects of allocation strategies on the distribution of merit-based awards and need-based aid

Strategy	Awards (%)	Aid (%)	Total Funding (%)
SQ-enr-un-2,0.6,100,5	160.0	779.0	216.0
SQ-enr-un-2,0.6,100,3	147.0	624.0	191.0
SQ-enr-100,3	54.0	1079.0	48.0
SQ-enr-un-rev-1,0.6,2,100,5	19.6	133.2	29.9
SQ-enr-un-rev-1,0.5,2,100,5	-5.6	441.8	34.9
SQ-enr-un-rev-1,0.6,2,100,3	-0.1	256.4	23.2
SQ-enr-un-rev-1,0.6,2,100,4	-1.2	226.9	19.5
SQ-enr-un-rev-1,0.6,2,100,2	-15.8	328.8	15.5
SQ-enr-un-rev-1,0.6,2,100,1	-57.4	304.9	-24.5
SQ-enr-un-rev-1,0.5,2,100,1	-56.2	253.8	-28.1

over optimizing for enrollment alone.

Few moderate strategic changes can increase accessibility significantly. After we identify a viable strategy, we can narrow it down to a specific solution that maybe adoptable by the University. Adopting a bold strategy that is recommended by an algorithm can be risky. A few reasons that threaten the validity of such a strategy include (1) flawed assumptions made by the model, (2) insufficient amounts of data, and (3) external forces that influence enrollment decisions that are not captured by the data, particularly in a pandemic year. These and other reasons make it hard for administrators to adopt bold strategies even if they might predict large increases in expected outcomes. At times, risk-averse administrators may prefer solutions that make moderate changes, but can move the needle in some significant way.

In addressing this, we identified a viable solution, which came from a random run of the **SQ-enr-un-rev-1,0.6,2,100,4** strategy, which optimized for enrollment, affordability and revenue. Table 3 shows the expected outcomes as a result of adopting this solution.

If this solution is adopted, we expect that accessibility can increase more than 100% from baseline, while keeping enrollment, revenue, and most other relevant outcomes nearly identical as the status quo. For this big expected increase in accessibility to happen, the solution calls for an increase of 6.5% in financial aid funding, and a redistribution of merit-based awards (decreasing 2.2%) to need-based aid (increasing 93.4%).

How allocation strategies affect the redistribution of institution funds. As we assess strategies, we find that different levels of aggressiveness in financial aid spending are demanded. Table 4 illustrates this point by taking each strategy from Table 2 and presenting the percent change in expected spend on merit-based awards, need-based aid, and the total financial aid. As we move down through the table, the level of the impact on total financial aid generally decreases.

Table 5: Performance and runtime from optimizing enrollment of stochastic hill climbing (SHC) and simulated quenching (SQ)

Strategy	Runtime (sec)	Enrollment (%)
SHC-enr-100	8.6	31.4
SQ-enr-100,1	16.9	31.9
SQ-enr-100,2	24.4	32.1
SQ-enr-100,3	34.1	32.2
SQ-enr-100,4	43.8	32.0
SQ-enr-100,5	50.0	32.3

We find that optimizing for both enrollment and unmet need (**SQ-enr-un-2,0.6,100,5** and **SQ-enr-un-2,0.6,100,3**) is a very aggressive approach as the optimization seeks to enroll as many students as possible with the smallest amount of unmet need. This leads to increases in both the expected merit and need spend with an overall budget increase of approximately 200%. A less aggressive strategy is the optimization of enrollment alone (**SQ-enr-100,3**). This strategy seeks enrollment by focusing on expanding need-based aid by 1079% and merit-based awards by only 54%. Since the amount of need-based aid was lower to start with this only results in a 48% increase in the total budget.

It is only when revenue is added to the optimization’s objective with enrollment and unmet need that we reach more moderate budget increases and, eventually, cost savings. These strategies recommend a reduction in merit-based awards and a redistribution of funds to need-based aid.

Comparing simulated quenching and stochastic hill climbing. To contrast the runtime and performance of the two methods, we set both to have 100 iterations. For simulated quenching, temperature is decreased in each iteration, and in each iteration, the temperature is kept constant for another m steps. Thus, in addition to an overhead for estimating the initial temperature, the runtime of simulated quenching should be approximately m times slower than hill climbing. This can be observed in Table 5 for $m = 1, 2, 3, 4, 5$. Similarly, in terms of runtime, simulated quenching is slower than hill climbing by a constant that is directly proportional to m , when both methods were used to optimize for enrollment and affordability (Table 6) and, respectively, for enrollment, affordability, and revenue (Table 7). These tables show the average performance and runtime of the two methods over 10 random runs.

When optimized for enrollment (Table 5), simulated quenching has a higher increase (from 31.9% to 32.3%) than stochastic hill climbing (31.4%). Further, this increase grows with higher values of m (from 1 to 11). When optimized for enrollment and affordability (Table 6), performance also increases with higher values of m (from 1 to 11). However, the increase in performance seems to be on affordability than on enrollment. When optimized for enrollment, affordability, and revenue (Table 7), affordability increases, while enrollment and revenue decrease with higher values of m .

Table 6: Performance and runtime from optimizing enrollment and affordability of stochastic hill climbing (SHC) and simulated quenching (SQ)

Strategy	Runtime (sec)	Enrollment (%)	Unmet Need (\$)
SHC-enr-aff-100	10.2	16.9	-1031.9
SQ-enr-aff-2,0.5,100,1	19.6	26.3	-1193.0
SQ-enr-aff-2,0.5,100,3	39.5	16.7	403.2
SQ-enr-aff-2,0.5,100,5	53.1	21.9	51.4
SQ-enr-aff-2,0.5,100,7	66.4	21.1	205.6
SQ-enr-aff-2,0.5,100,9	84.6	16.1	602.2
SQ-enr-aff-2,0.5,100,11	98.5	18.0	489.6

Table 7: Performance and runtime from optimizing enrollment, affordability and revenue of stochastic hill climbing (SHC) and simulated quenching (SQ)

Strategy	Runtime (sec)	Enrollment (%)	Revenue (%)	Unmet Need (\$)
SHC-enr-aff-rev-100	36.5	11.0	6.4	-1091.8
SQ-enr-aff-rev-1,0.6,2,100,1	19.3	11.8	6.5	-948.7
SQ-enr-aff-rev-1,0.6,2,100,2	121.5	8.3	6.9	-825.0
SQ-enr-aff-rev-1,0.6,2,100,3	160.5	5.7	1.7	-345.7
SQ-enr-aff-rev-1,0.6,2,100,4	197.6	3.5	-0.2	-135.2
SQ-enr-aff-rev-1,0.6,2,100,5	227.5	1.8	-4.5	283.2

In our application, keeping the same temperature longer for simulated quenching (i.e. with large values of m) increases objective scores, but does not seem to produce solutions with more meaningful impacts on expected outcomes.

5. DISCUSSIONS AND CONCLUSIONS

We addressed multiple outcomes for each selected strategy. Two of those outcomes, achievement and ROI, did not see meaningful changes for the strategies selected. In the case of achievement, we could not improve it significantly over the actual outcomes. Perhaps this was due to the fact that as strategies drive the need-based aid budget upward we are successfully recruiting students from lower-income backgrounds who have traditionally scored lower in standardized tests [5]. Or there could be a limit to our ability to recruit high achieving students due to the University-constrained maximum merit-based award amount. For ROI, we could identify strategies that yielded small amounts of increase. However, those strategies were not as compelling as those we chose to include.

In our application, globally optimal solutions may be impractical. For example, a strategy that yields a 200% increase in enrollment might be mathematically optimal, but may not be accommodated easily. One could impose constraints. In our experimentation with the local search approach, however, having constraints on multiple objectives did not lead to great solutions. It can be very hard for a local search to navigate the search space from an initial random solution to get to an optimal solution that satisfies

multiple constraints. Our approach, instead, is to optimize a relatively constraint-free multi-objective function and be optimistic that locally optimal solutions are also practical. Experimenting with different combinations of objectives and ways to control the optimization, we could find strategies that accommodate different levels of risk tolerance.

Thus, this approach provides a path for administrators to weigh risks versus rewards in terms of increasing merit-based awards and need-based aid to support students while maintaining an acceptable level of revenue and enrollment. Table 2 shows the trade-offs in how spending on financial aid funding can affect expected enrollment and revenue. In particular, we were able to identify and recommend a viable solution that requires moderate changes in the budget and yet increases accessibility by more than 100% in Table 3.

Our approach can be adapted to solve other problems that share the same types of interactions between a classifier and an optimizer. In such problems, the classifier expects a set of features that keep evolving based on an external strategy, and the optimizer evaluates expected outcomes predicted by the classifier to recommend a better strategy. For optimization, we employ local search, which is flexible and easily adaptable to different types of problems. For classification, although we employ gradient boosting, any method that is readily available from popular tool kits such as scikit-learn [24] can be used as long as it can make dependable predictions for the problem of interest.

ABSTRACT

Automatic short answer grading is an important research direction in the exploration of how to use artificial intelligence (AI)-based tools to improve education. Current state-of-the-art approaches use neural language models to create vectorized representations of students responses, followed by classifiers to predict the score. However, these approaches have several key limitations, including i) they use pre-trained language models that are not well-adapted to educational subject domains and/or student-generated text and ii) they almost always train one model per question, ignoring the linkage across question and result in a significant model storage problem due to the size of advanced language models. In this paper, we study the problem of automatic short answer grading for students' responses to math questions and propose a novel framework for this task. First, we use MathBERT, a variant of the popular language model BERT adapted to mathematical content, as our base model and fine-tune it on the downstream task of student response grading. Second, we use an in-context learning approach that provides scoring examples as input to the language model to provide additional context information and promote generalization to previously unseen questions. We evaluate our framework on a real-world dataset of student responses to open-ended math questions and show that our framework (often significantly) outperform existing approaches, especially for new questions that are not seen during training.

Keywords

Automated scoring, Short-answer scoring, Math grading

1. INTRODUCTION

Automated scoring (AS) refers to the problem of automatically scoring student (textual) responses to open-ended questions with multiple correct answers, often utilizing various machine learning algorithms. AS approaches can potentially scale up human grading effort: by training on a

small number of example scores provided by human experts, they can automatically score a large number of responses. With the advancement in online learning platforms in recent years, there has been a growing body of research around the development of AS methods. AS has been studied in many different contexts, including automated essay scoring (AES) [1, 30] and automatic short answer grading (ASAG) [39, 51], which has been studied in various different subject domains [5, 12, 14, 37, 17, 3, 29, 49]. The majority of AS approaches follow two steps: First, obtaining a *representation* of student responses, often using methods in natural language processing, and second, applying a *classifier* on top of this representation to predict the score [4, 27]. Over the years, AS approaches have gradually shifted from classic text representations such as bag-of-words or human-crafted features [8, 16, 19, 30, 32, 41] that are human-interpretable to more abstract representations based on pre-trained neural language models [24, 26, 38, 40, 45].

In this paper, we focus on ASAG in one particular subject domain: Mathematics. Math questions, or questions that involve mathematical reasoning, are ubiquitous in many science, technology, engineering, and mathematics (STEM) subject domains. Recently, several works [5, 14] have studied ASAG for the responses students provide to math-based open-ended questions that (are often concise) include their reasoning or thinking process about a particular concept. As noted in prior work, a key technical challenge in this domain is that student responses to math-based open-ended questions often are a combination of text (natural language) and mathematical language (symbols, expressions, and equations). However, most existing pre-trained language models such as BERT [13] and GPT [7] are not specifically designed for mathematical language. Therefore, existing approaches for math ASAG that do not address the mathematical language present in student responses [5, 14] may not be able to accurately represent student reasoning processes in their responses. On the other hand, existing methods that focus entirely on mathematical language [22, 42, 50] cannot process natural language contained in open-ended responses.

Another significant limitation of existing AS approaches is that, in most cases, we need to train a separate AS model for each question. In contexts such as AES where questions (essay prompts) may not have high similarities, this approach can often be effective. However, in other contexts where reading comprehension or reasoning is involved,

multiple questions may be linked to each other through the background information provided. In the context of math questions, many questions share similar skills or are different parts of a multi-step question. Therefore, training a separate AS model for each question would result in models that can only identify typical patterns in student responses to each individual question but cannot really understand how to differentiate good responses from bad ones. It is likely that these models would not be able to generalize well to previously unseen questions, as noted in [12]. More importantly, training a separate AS model for each question may create a significant problem for model storage and management. This problem is especially significant for state-of-the-art AS approaches that fine-tune pre-trained language models that have millions of parameters.

1.1 Contributions

In this paper, we develop an ASAG framework for students’ open-ended responses to math questions. Building on a grand prize winning solution [15] to the National Assessment of Educational Progress (NAEP) Automated Scoring Challenge¹, our framework is based on fine-tuning a pre-trained BERT language model on actual student responses, with several main innovations:

- First, we use MathBERT [35], a version of the popular BERT language model adapted to mathematical content, as our base model. This model is capable of understanding math symbols and expressions to some extent and help us obtain a better representation of open-ended student responses.
- Second, we leverage in-context learning ideas in NLP research [11, 28] and develop an ASAG approach using on multi-task and meta-learning tools (that are popular machine learning tools to promote model generalizability). Specifically, we fine-tune MathBERT with a carefully designed input format that uses *example responses and scores* as additional input (together with question and response texts) to provide additional context of each question. This input format helps us train a shared AS model across all questions and outperforms the current state-of-arts approach [5].
- Third, we show that meta in-context learning leads to highly generalizable AS models. Our intuition on why our approach is highly effective is that, by explicitly using example responses and scores as input, we reduce the AS task to a *similar response finding* task, which is easier for the model to learn.

We evaluate our ASAG framework on a real-world dataset which contains students’ solution processes to open-ended math questions and grades provided by teachers. Through a series of quantitative experiments, we show that our framework (sometimes significantly) outperforms existing approaches in terms of score prediction performance. More importantly, we show that our framework significantly outperforms existing approaches [5, 12] (by up to 50% on some metrics under some settings) when applied to questions that are previously unseen during training, using only a few

¹<https://github.com/NAEP-AS-Challenge/info>

scored examples for these new questions. Perhaps surprisingly, we found that MathBERT does not provide additional benefit on top of the original BERT model while the in-context fine-tuning setup is key to the excellent generalization performance. We also summarize observations from qualitative evaluations of scoring errors, discuss the limitations of our framework, and outline several avenues for future work. Our implementation is publicly available.²

2. RELATED WORK

In recent years, there have been many developments in ASAG methods across various domains. Most of the prior works have focused on non-mathematical domains [6, 10] where student responses are purely textual. However, more AS works have started to focus on more specific domains that contain non-textual symbols, e.g., Math, Physics, Chemistry, Biology and Computer Science [19, 30, 41]. In these domains, a combination of natural language processing methods for the representation of responses and machine learning methods for score classification has shown promising results [5, 14, 23, 36, 38].

Here, we discuss two recent AS works in the mathematical domain, [5] and [12], that are the most relevant to our research. The authors of [5] proposed a scoring approach for short-answer math questions using sentence-BERT (SBERT)-based representation of student responses. Compared to this approach, our approach differs in many aspects and we highlight the following: First, we use MathBERT, a model pre-trained on mathematical content to represent student responses, while the approach in [5] ignores mathematical language in student responses. Second, we use an in-context meta-training approach to train one AS model for all questions while the approach in [5] trains one AS model for each question, which likely limits its generalizability to previously unseen questions.

The authors of [12] proposed a similar scoring approach for short-answer critical reasoning questions that combines various pre-trained representations, including SBERT, with classifiers for AS. Instead of using only student responses as input to the classifiers, they also use a series of question context information such as question text, rubric text, and question cluster identifier. As a result, they showed that their AS approach can generalize to previously unseen questions. Compared to this approach, our approach mostly differs in two aspects: First, we fine-tune MathBERT on actual student responses while the approach in [12] leaves the pre-trained representations fixed, which likely limits the accuracy of their student response representations. Second, we use scoring examples as input to MathBERT in addition to question text to further provide the AS model context of the question, which further enhances the generalizability of our model to previously unseen questions in a *few-shot* learning setting.

3. METHODOLOGY

In this section, we detail both the ASAG setup for math questions and our in-context meta-learning framework.

3.1 Problem Statement

²https://github.com/kikumaru818/meta_math_scoring

We treat math ASAG as a classification problem where our goal is to train a scoring model that is capable of generalizing to new, previously unseen questions using a few examples. This setting is well studied in machine learning, commonly referred to as few-shot learning [7, 11, 28], where the goal is to train robust models that excel at multiple tasks. Formally, we have a set of questions $T = \{Q_1, Q_2, Q_3, \dots, Q_n\}$, where each question $Q_i \in T$ can be seen as a classification task. Each question Q_i comes with numerous graded, training examples: $\{e_i^1, e_i^2, \dots\}$. Each example consists of multiple fields of information: $e_j^i = \langle q_{text}, q_{id}, x, y \rangle$, where q_{text} is the textual statement of the question, q_{id} is a unique question id, x is the text of student’s response and y is the grade from the teacher. We study on two problem settings in this work: i) generalization to new responses and ii) generalization to new questions.

3.1.1 Generalization to new responses

This problem setting follows from that used in prior work [5]: we train a scoring method on scored responses for all questions and test it on held-out responses. We treat this problem setting as supervised learning classification and learn a scoring model $f : x \mapsto \hat{y}$ that predicts an estimated score \hat{y} for a student response x with true score y by minimizing a loss function $L(y, \hat{y})$. For each question Q_i , we split the corresponding scored responses into two subsets, Q_i^{train} and Q_i^{test} , such that $Q_i^{train} \cup Q_i^{test} = Q_i$ and $Q_i^{train} \cap Q_i^{test} = \emptyset$. Instead of treating each question separately and train a model for each, we train one unified model on the union of training datasets for all questions, i.e., $\bigcup_{i=1}^{|T|} Q_i^{train}$. We detail the scoring model and our in-context learning setup in Section 3.3.

Let θ represent the model parameters, the optimization objective \mathcal{L}_i for question i is simply the cross entropy, i.e., the negative log-likelihood loss

$$\mathcal{L}_i(\theta) = \sum_{j:(x_j^i, y_j^i) \in Q_i^{train}} [-\log p_\theta(y_j^i | x_j^i, \dots)].$$

We minimize the total objective that spans all questions

$$\mathcal{L}(\theta) = \sum_{i=1}^{|T|} \mathcal{L}_i(\theta)$$

to learn the model parameters θ .

3.1.2 Generalization to new questions

This problem setting can be formulated as a few-shot (or zero-shot) classification problem: we train a scoring model on scored responses for some questions and test its generalization capability to student responses to held-out questions. We first split the set of questions T into T_{train} and T_{test} such that $T_{train} \cup T_{test} = T$ and $T_{train} \cap T_{test} = \emptyset$. We train the scoring model on all scored responses for the training questions $\bigcup_{i=1}^{|T_{train}|} Q_i$. Let γ represent the model parameters for this problem setting, the optimization objectives for each question and across all training questions change to

$$\mathcal{L}_i(\gamma) = \sum_{j:(x_j^i, y_j^i) \in Q_i} [-\log p_\gamma(y_j^i | x_j^i, \dots)]$$

and

$$\mathcal{L}(\gamma) = \sum_{i=1}^{|T_{train}|} \mathcal{L}_i(\gamma),$$

respectively.

At test time, we applied the trained model to new questions $Q_i \in T_{test}$ to see how it can adapt using few (or zero) scored examples for these new questions. We study two cases: i) we do not update the original model with gradient updates, i.e., γ remains unchanged, which we call the **Meta** setting, and ii) we update γ by backpropagating gradients calculated on a few scored responses for new questions, which we call the **Meta-finetune** setting.

3.2 BERT-based classification

We now detail our scoring method based on fine-tuning a pre-trained language model. BERT [13] is a pre-trained language model that produces contextualized representations of text and is also capable of encoding text. We use MathBERT [35], a variant of BERT pre-trained on a large mathematical corpus containing mathematical learning content ranging from pre-kindergarten (pre-k), high school, to college graduate levels. We use MathBERT as our base language model and fine-tune it on our data for downstream ASAG classification.

Figure 1 visualizes our method. The input to BERT is a sequence of tokens, starting with the [CLS] token, a special symbol added in front of every input during training process for BERT based model. Since [CLS] doesn’t have meaning itself and BERT-based models learn contextualized representations of text, we can use the [CLS] embedding as a representation that encodes the entire input. We then feed the [CLS] embedding to a classification layer followed by softmax [18], obtaining the predictive score class probabilities. A key difference between our work and prior works [5, 12] that use BERT is that we also fine-tune the BERT model, i.e., update its parameters and adapt it to ASAG. Prior works only use BERT-based models to extract the representation of student responses; these methods are not likely going to be effective since they cannot adapt to student-generated content. During training, we backpropagate the gradient on the prediction objective to both i) the classification layer, which is learned from scratch, and ii) BERT, which is updated from its pre-trained parameter values.

3.3 In-context Meta-learning

Our key technical insight is that we need to use a well-crafted input format to provide context to the model and help it adapt to the scoring task for each question. Therefore, instead of only inputting the target student response we want to grade, we also include several other features as the input. These features are important to ground the model in the context of each question. For each possible feature, we also add additional textual instructions as input to the model about the semantic meaning of the feature.

Table 1 shows all possible features we include as model input and the corresponding template. Student response denotes the target responses to be scored. Thus, the corresponding textual instruction is “score this answer.” Since student

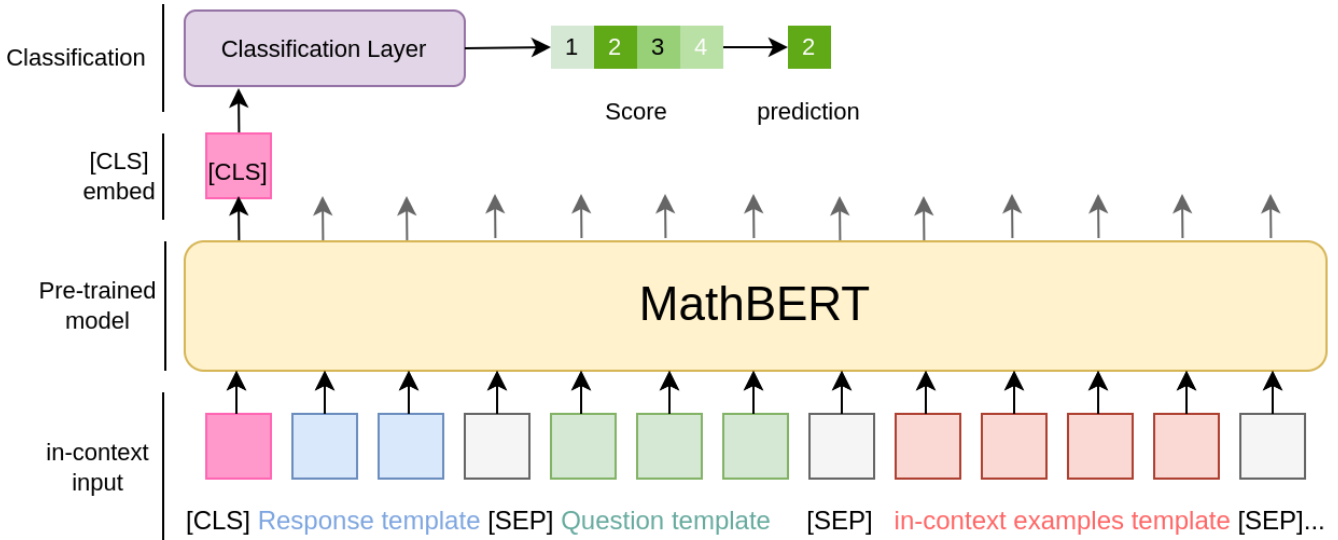

Figure 1: Overview of our in-context meta-learning-based ASAG method for math questions.

Table 1: Templates for different components we use as input into our scoring method.

Input Feature	Template	Sample Text
Student Response	<i>score this answer: x_j^i</i>	<i>score this answer: expand the equation we get $2x + 2 = 1$ then $x = -0.5$</i>
Question	<i>question text: $q_{text_j}^i$</i>	<i>question text: Solve the equation $2(x + 1) = 1$</i>
Question ID	<i>question id: $q_{id_j}^i$</i>	<i>question id: 21314</i>
Scale	<i>scale: possible grade for question i</i>	<i>scale: poor, fair, good, excellent</i>
Example	<i>example: x_{-j}^i, score: y_{-j}^i</i>	<i>example: move 2 to the right $x = 1/2$, score: fair</i>

responses are essential to the grading task, we place it directly after the [CLS] token. After the student response, we add either the question text or the question ID as input to the BERT model. Question text can help the model understand the question context and generalize across questions by leveraging their semantic relations. Question IDs enable the model to identify which question the target response belongs to, which can be helpful when the question text is not semantically meaningful; see Section 4.3 for an example. We can also add textual descriptions of the grading scales to the input. Since we use language models that are better at understanding text than numbers, we use “bad, poor, fair, good, excellent” to represent scores of 0, 1, 2, 3, and 4, respectively.

Another key innovation is that, following recent approaches [11, 28] for meta-training based in-context learning, we also input examples of scored responses, i.e., responses and corresponding scores, (x_{-j}^i, y_{-j}^i) from training dataset that belong to same question of the target response x_j^i . These examples provide further context to the model that the model can use to relate the target response to. Intuitively, when these examples are presented in the input, the AS model only needs to find example responses that are similar to the current response and use their scores to help score the current response. This task is easier for the AS model to learn than the real AS task when examples are not in the input.

4. EXPERIMENTS

This section details the experiments we conducted to validate our in-context meta-training approach for ASAG. Section 4.1 discusses details on the real-world dataset student response dataset we use and how our pre-processing steps. Section 4.2 details evaluation metrics and baselines. We design three groups of experiments to test our approach’s performance. In section 4.3, we examine how the approach performs on generalizing new student responses while having an assumption that the questions have already been seen during the training process. In section 4.4, we examine the performance of our approach generalizing to scoring student response to new questions; in section 4.3.3, we run experiments to test which part of the in-context has the most significant impact on the performance of our approach.

4.1 Dataset

In this study, we use data collected from an online learning platform that has been used in prior work [5, 14]. The dataset contains student responses to open-ended questions paired with scores provided by human graders. The dataset used in [5, 14] consists of 141,612 total student responses from 25,069 students to 2,042 questions, scored by 891 different graders. The numeric score given to each response is in a 5-point scale from 0-4 with 4 as full credit and 0 as no credit. We refer to this dataset as D_{orig} .

D_{orig} contains some noisy data points that increase the difficulty of learning. First, some student responses are the same, but the teacher grades are different. Second, all cor-

responding student responses get full credit for some questions. For example, even the student’s response is “I do not know”, the response’s grade is still full credit. Third, some students’ responses are answered by image, making the text content empty. Fourth, similar issues on question body; some questions do not have semantic meaning (such as questions that refer to a question in a book that we cannot access) or are represented as tables or images. For this work, we mainly focus on questions with corresponding students’ responses and scoring the responses no matter which student is and who is grading. Thus we hope to reduce the effect of these noisy data points and further clean up the dataset. We found that some student responses are the same but the teacher grades are different; therefore, we re-label 2,130 inconsistent responses with the highest grade that the corresponding response text can get. We remove 8,835 student responses that contain only images or broken characters (non-English words, non-math terms). Since our in-context meta-learning approach needs to learn coherent information between questions using question text, we need high quality question text. We remove responses (9,930 number of responses) with a question body (231 number of questions) that does not have semantic meaning. We also remove questions (478) that contain less than 25 number of students’ responses. We called the new dataset D_{clean} , it contains 131,046 responses in total and 1,333 questions. Table 2 shows some examples data points of this dataset. For each data point, it contains the student response, problem text, problem id and teacher grade.

4.2 Metrics

For the evaluation of math ASAG methods, we utilize three evaluation metrics for categorical, integer-valued scores, following prior work [5, 14]. The first metric is area under the receiver operating characteristic curve (AUC), which is designed for binary classification problems. Instead, we calculate the AUC in a way similar to [21] by averaging the AUC numbers over each possible score category, treating them as separate binary classification problems. The second metric is the root mean squared error (RMSE) which simply treats the score categories as numerical values. The third and most important metric is the multi-class Cohen’s Kappa that is often used for ordered categories, which fits the setting of our ASAG data.

4.3 Scoring new responses

4.3.1 Experimental Setting

For this experiment, we focus on comparing the performance of our approach to baselines on generalizing to new responses. We randomly divide all example responses in D_{orig} (we use this dataset for a fair comparison to [5, 14]) into 10 equally-sized folds for cross validation. For each run, we use 8 folds for training, 1 fold for validation to select a training epoch with the best performance on this fold and 1 fold for the final testing of all methods. Under this setting, we ensure every question is contained in the training set so for every response in the test set, our models have seen scored response examples from the exact same question in the training set.

For our approach we use MathBERT [35] as the pre-trained

model with 110M parameters as the base scoring model³. We use the Adam optimizer, a batch size of 16, a learning rate of 1e-5 for 5 epochs on an NVIDIA RTX 8000 GPU. We do not perform any hyper-parameter tuning and simply use the default setting. For each training response, we randomly sample one in-context example per score class and fill up with the rest of training examples up to 25 in total from the training dataset for the corresponding question. Due to the restriction on input length for language models (512 for MathBERT), we truncate an example to a maximum of 70 tokens if necessary to ensure that the question, the target response to score, and all examples all fit in. For testing, we repeat the process of randomly sampling examples eight times for each target student response to be scored and average the predicted score class probabilities.

We use an evaluation setting that follows from the one used in [14], for a fair comparison to compare it with SBERT-Canberra (SBERT-C) [5], the current state-of-the-art method. The evaluation utilizes a 2-parameter Rasch model [44]; We include three groups of terms as covariates in the Rasch model: i) the student ability and question difficulty parameters, ii) the score category predictive probabilities according to the trained scoring method, and iii) the number of words in the response. After training the scoring model, we use the predicted scoring probabilities to learn regression coefficients and the ability/difficulty parameters. Intuitively, this evaluation setup studies how textual information in open-ended responses help *in addition to* student ability and question difficulty during scoring; its purpose is not to evaluate how accurately response scoring models are themselves.

For this evaluation, we use Problem ID as input for each training response to help the model adapt to the task. We do not use question text as input since D_{orig} contains many (709 out of 2,042) question texts that have no semantic meaning (e.g., “For Page 100 question b, answer the question”). This noisy question text cannot help the model recognize different questions and may confuse the model.

4.3.2 Results and Analysis

Table 3 shows the average value for all metrics across the 10 folds for our method (Meta In-context), the SBERT-C baseline, and other baselines studied in [5]. We see that our method is able to achieve a 0.02 (or 4.2%) improvement over the best performing baseline, SBERT-C, on the most important metric, Kappa, while also outperforming on the other two metrics with smaller margins. This improvement validates the effectiveness of our overall method and further pushes the boundary on math ASAG. This improvement is more significant on the cleaned dataset D_{clean} , which we use for further evaluation next. We further note that there is a discrepancy between metric values (high AUC, low Kappa) on this experiment compared to other experiments due to the Rasch model-based setup.

4.3.3 Ablation Study

We conduct an ablation study to verify the effectiveness of each component of our scoring method: using question text as input vs. using only question ID as input, adding textual

32149	Ryan will divide the \$800 into 10 equal amounts of \$80. If he completely spends \$80 during each month of his school year, how much of his earnings will remain at the end of the third month of his school year? Explain how you got your answer.	he will have \$560 left. 800-240=560	4

Table 3: Evaluation results using the same dataset and under the same evaluation setting as [14, 5] show that our scoring method outperforms existing methods.

Model	AUC	RMSE	Kappa
Rasch* + Meta In-context (ours)	0.861	0.541	0.496
Rasch* + SBERT-Canberra	0.856	0.577	0.476
Baseline Rasch	0.827	0.709	0.370
Rasch + Number of Words	0.825	0.696	0.382
Rasch* + Random Forest	0.850	0.615	0.430
Rasch* + XGBoost	0.832	0.679	0.390
Rasch* + LSTM	0.841	0.637	0.415

instructions to provide information on the scoring scale, using scored examples to provide additional context, and using MathBERT as the base language model to fine-tune vs. using BERT. For this evaluation, we use the cleaned dataset D_{clean} and a different experimental setting to directly evaluate the scoring accuracy of ASAG methods without using the Rasch model. The rest of the experimental settings, from cross-validation to model training, remain the same. Table 4 shows the results for all variants of our approach on all three metrics. We see that removing question text, textual instructions on scoring scale, and scored examples as input all result in significant degradation in scoring accuracy on some (or all) metrics. Specifically, removing scored examples results in the most significant drop in scoring accuracy, by around 0.02 in Kappa; this result validates the effectiveness that providing in-context examples can significantly benefit language models by helping them adapt to the current task (question). This result clearly validates our intuition that in-context examples reduce the difficulty of the AS task by changing the nature of the task from scoring to finding similar responses, which is easier. Removing question text also results in a (less significant) accuracy drop off: this result directly contradicts our observations in the previous experiment using the original dataset in [5, 14] where we found that inputting the question text results in worse performance than inputting only the question ID. The likely reason for this result is that the cleaned dataset D_{clean} contains much more questions that are semantically meaningful, which are helpful to include in the scoring method to provide important information on the scoring task.

A surprising but important result of this experiment is that using MathBERT results in a small drop off in performance (0.015 on Kappa, 0.007 on RMSE, and a 0.002 improvement on AUC) compared to using BERT. This observation is counter-intuitive since MathBERT is specifically designed to handle math expressions and trained on mathematical content, while BERT is not. To further examine why MathBERT underwhelms on the scoring task, we further investigate its performance on subsets of responses divided according to how much math information is contained in them. Specifically, we divided responses in the test set into two groups according to the amount of mathematical expressions involved: D_{math} that contains responses where more than half of the tokens in the response are mathematical tokens and D_{text} that contains the rest of the responses. Table 5 shows scoring accuracy for our approach using MathBERT and BERT as the base language model on these different response subsets. We see that on responses that are primarily textual, BERT outperforms MathBERT, which suggests that MathBERT loses some ability to encode textual information. On responses that are primarily mathematical, MathBERT performs similarly to BERT on RMSE and Kappa while outperforming BERT on AUC. This result suggests that MathBERT may have some benefit in handling mathematical tokens but the advantage may be minimal. Therefore, an important avenue for future work is to develop language models that are capable of representing and understanding mathematical content.

4.4 Scoring new questions

4.4.1 Experimental Setting

For this experiment, we focus on testing the performance of our approach on generalizing to new questions (tasks) without seeing scored examples and how quickly our approach can adapt to them using few examples. Therefore, we randomly divide all questions in D_{clean} into 5 equally-sized folds in terms of the number of questions instead of the number of responses. As a result, the number of responses in each fold may vary ($26, 229 \pm 689$) since the number of student responses to each question is different. For each run, we use 4 folds for training and 1 fold for testing.

On the test set, we make $n \in \{0, 1, 3, 5, 7, 10, 25, 50, 80\}$

Table 4: Ablation results for different design components of our method on D_{clean} . Most components contribute significantly.

Method Component					Metric		
Question Text	Question ID	Scale	Example	MathBERT	AUC	RMSE	Kappa
✓		✓	✓	✓	0.733 ± 0.006	1.077 ± 0.002	0.589 ± 0.004

Figure 2: Results on generalizing to previously unseen questions using a few scored examples on all three metrics. Our approach, Meta-finetune, consistently outperforms SBERT-C and SBERT-P. Even without adjusting the model and using the scored examples as input (Meta), we outperform SBERT-C when the number of examples is small.

Table 5: Scoring accuracy on responses that contain more mathematical tokens vs. more text tokens.

Data	approach	AUC	RMSE	Kappa
D_math	MathBERT	0.755 ± 0.008	0.587 ± 0.003	0.690 ± 0.008
	BERT	0.741 ± 0.010	0.610 ± 0.009	0.691 ± 0.020
D_text	MathBERT	0.713 ± 0.006	1.022 ± 0.004	0.523 ± 0.006
	BERT	0.716 ± 0.006	1.001 ± 0.003	0.542 ± 0.008

scored responses per question available to methods trained on the training dataset and evaluate their ability to score other responses. We emphasize that there is no overlap between training responses and test responses for these previously unseen questions. We use two settings for our method. For the first setting, **Meta**, we do not further adjust the trained scoring model; instead, we only feed these responses and their scores, i.e., in-context examples, to the trained scoring model. For cases where $n < 25$, we only feed in n examples even though the method was trained with 25 examples. For cases where $n > 25$, we follow randomly sample 25 examples from the n total examples as input, following the same setting above. This experimental setting can be seen as “*zero-shot*” learning where we directly test how a scoring method trained on other questions works on new questions without observing any scored responses.

For the second setting, **Meta-finetune**, we further fine-tune our trained method on the n new scored responses per question. During this process, for each response as the scoring target, we use the other $n - 1$ responses as in-context examples. This experimental setting can be seen as “*few-shot*” learning where we test how quickly a scoring method trained on other questions can adapt to new questions.

Since **SBERT-C** is the current state-of-the-art math ASAG method on this dataset, we use it as our baseline. According to [5], it calculates similarities between the target response and other responses to the same question. Then it picks the score of the response with the highest similarity to the target response as its prediction, which means that it is not capable of zero-shot generalization to new questions. Therefore, we use n scored examples on these new questions to train the scoring method and evaluate on the other responses. We emphasize again that in both the zero-shot and few-shot settings, the scored examples are excluded from performance valuations.

We also use an additional baseline [12], which we refer to as **SBERT-P**. This method uses SBERT to encode responses and questions and feed the resulting representations to a classifier for predictions. This method also trains a single unified model across and is thus capable of zero-shot generalization to previously unseen questions. We use n scored examples on these new questions for SBERT-P to train on to evaluate it in the few-shot learning setting.

4.4.2 Result and Analysis

Table 6 shows the experimental results averaged over all folds. We see that Meta-finetune outperforms the other three approaches on all values of n for all metrics, achieving satisfactory results of AUC = 0.689, RMSE = 1.329 and Kappa = 0.456 in the one-shot learning setting ($n = 1$), significantly outperforming Meta, SBERT-P and SBERT-C (by up to 50% on Kappa). The performance of Meta-finetune stabilizes as n increases and still outperforms SBERT-C (0.03 on AUC, 0.154 on RMSE and 0.055 on Kappa) and SBERT-P (0.11 on AUC, 0.161 on RMSE and 0.113 on Kappa) at $n = 80$. These results clearly demonstrate that, compared to SBERT-C and SBERT-P, our method is highly

Table 6: Scoring accuracy for different methods on generalization to new questions not seen during training, using a small number of scored examples.

num-of new-data points / question	Method	AUC	RMSE	KAPPA
0	Meta	0.533 ± 0.017	1.650 ± 0.020	0.100 ± 0.052
	SBERT-P	0.558 ± 0.006	1.931 ± 0.001	0.170 ± 0.013

	SBERT-C	0.569 ± 0.061	1.543 ± 0.080	0.211 ± 0.016
10	Meta	0.611 ± 0.011	1.548 ± 0.011	0.341 ± 0.040
	Meta-finetune	0.701 ± 0.010	1.220 ± 0.008	0.489 ± 0.022
	SBERT-P	0.630 ± 0.037	1.662 ± 0.012	0.340 ± 0.064
80	SBERT-C	0.569 ± 0.006	1.485 ± 0.011	0.282 ± 0.019
	Meta	0.614 ± 0.010	1.543 ± 0.013	0.342 ± 0.043
	Meta-finetune	0.716 ± 0.008	1.235 ± 0.009	0.496 ± 0.021
80	SBERT-P	0.638 ± 0.031	1.453 ± 0.018	0.359 ± 0.080
	SBERT-C	0.627 ± 0.008	1.416 ± 0.009	0.353 ± 0.019
	Meta	0.626 ± 0.024	1.550 ± 0.016	0.373 ± 0.074
80	Meta-finetune	0.765 ± 0.010	0.940 ± 0.015	0.636 ± 0.042
	SBERT-P	0.704 ± 0.033	1.101 ± 0.011	0.523 ± 0.020
	SBERT-C	0.735 ± 0.017	1.094 ± 0.008	0.581 ± 0.042

effective at “warm-starting” scoring models on new questions since it is able to get a sense of how responses should be scored from scored responses to other questions. Again, we note that in-context examples changes the nature of the task from AS to finding similar responses; as a result, models can learn this task quicker and adapt to new questions using only a few examples.

SBERT-C, on the other hand, can barely work in few-shot learning settings, i.e., $n \in \{1, 3\}$. This observation is not surprising since SBERT-C does learn a scoring model from scratch and cannot work when the number of training data points is less than the number of possible score categories. The performance of SBERT-C starts to gradually increase when $n > 5$ but is still significantly worse than Meta-finetune.

Meta, the method for zero-shot learning, although fails to generalize well (only 0.533 in AUC and 0.1 in Kappa at $n = 0$) without seeing any training data, still significantly outperforms SBERT-C with $n \in \{1, 3\}$ and performs similarly to SBERT-P. This advantage only disappears at $n = 10$. To further illustrate this difference, we plot the three metrics vs. n for all methods in Figure 2. We see that Meta’s AUC and Kappa values are higher than that for SBERT-C until n reaches around 8, which indicates that even without re-training the model, it is more suitable for few-shot learning than SBERT-C on new questions.

4.5 Qualitative Error Analysis

In this section, we qualitatively analyze the prediction errors made by our ASAG method. We use the model trained on D_{clean} , with problem text + scale + examples as input into

MathBERT for our analysis.

4.5.1 Feature analysis

To analyze the difference between correct predictions and incorrect predictions, we extract several features that capture properties of the questions and responses to better understand the strengths and weaknesses of the trained ASAG method. As shown in Table 7, “Response math tokens” represents the percentage of math tokens in a response; “Response contains img/table” represents whether a response has images or tables; “Response length” represents the number of tokens a response; “score” represents the actual score given by the graders; “Number of graders” represents the number of graders that graded each response to the question; “question length” represents the number of tokens the corresponding question has and “question math tokens” represents the percentage of math tokens in the question.

Table 7: Features analysis between correct predictions and incorrect predictions. * means the difference is significant ($p_value < 0.005$).

Features (avg.)	Correct Prediction	Incorrect Prediction
Response math tokens (%)*	30.6	25.1
Response contain img/table (%)*	1.29	2.88
Response length*	17.4	29.5
Score*	3.25	2.13
Number of graders	2.53	2.48
Question length*	37.1	39.1
Question math tokens (%)	8.12	7.31

We observe a significant difference ($p_value < 0.005$) between values of the correct predictions and values of the incorrect predictions. We make the following observations:

- The scoring method is more accurate at scoring responses with higher percentage of math tokens and it becomes less accurate when there are higher percentage of plain texts.
- The scoring method is more accurate when the response contains images or tables that words can not represent.
- The scoring method is more accurate at scoring shorter responses.
- The scoring method is more accurate at scoring responses with shorter question description.
- The scoring method is more accurate when the average score of the response is higher. This observation indicates that the model is better at scoring responses with higher quality.
- There is no obvious distinction in grading accuracy for responses with different numbers of graders or to questions with different math tokens percentages.

4.5.2 Question topic and type error analysis

Table 8 lists the summarization of scoring accuracy on different question topics and types. We extract the topics and types from question text using BERTopic [20]. BERTopic is a topic modeling technique that leverages transformers

and term and document frequencies [33] to create easily interpretable topics. Overall, we see that the trained scoring method has better Kappa scores on questions that are primary text-based or involve equations. The result is not surprising since we adapted MathBERT, which likely sees many text-based questions during its pre-training stage. Questions that require students draw graphs in their response also have high Kappa scores; however this result is mainly due to the fact that most of these responses are given full credit, making them easy for scoring methods to make predictions. On the other hand, the trained scoring method has worse Kappa scores on estimation-type and (only a few) multiple-choice questions. This observation can be explained by language models not being trained to capture number sense and thus struggle at numerical reasoning [?]. For multiple-choice questions, the response, i.e., the multiple-choice option, is semantically meaningless, which does not provide meaningful context to the scoring method.

Table 8: Scoring accuracy on different question topics and types. Results are shown in increasing order of the Kappa score. * means the score is better than the average across all responses.

Topic	Type	AUC	RMSE	Kappa
Misc.	Multiple-choice	0.631	1.472	0.400
Math	Table calculation	0.659	1.345	0.445
Algebra	Estimation	0.702	1.310	0.536
Calculus	Estimation	0.716	1.241	0.546
Algebra	Table creation	0.731	0.823*	0.606*
Algebra	Equation writing	0.732	1.023	0.612*
Algebra	Graph drawing	0.734*	0.725*	0.629*
Math	Word question	0.735*	0.663*	0.647*
Calculus	Graph drawing	0.736*	0.610*	0.758*

4.5.3 Error type analysis

For this analysis, we choose a question with scoring accuracy below the average on our dataset to analyze the types of errors made by our trained scoring method. Table 9 shows selected responses with erroneous score predictions and the types of these errors. The question asks students to write an equation with a popular correct response $15/3 = 5$. We make the following observations on typical error types (apart from some obvious human grader errors, which we omit):

- The first error type indicates that our trained scoring method can still struggle on mathematical reasoning and handling numerical tokens. The incorrect responses “ $15*5=3$ ” and “ $5/3=15$ ” have the same numerical tokens but with different ordering and an incorrect operator token compared to the correct response, which completely changes their meaning. The trained scoring method tends to overestimate their scores. This observation suggests that we need base language models with stronger numerical reasoning abilities.
- The second error type indicates that our trained scoring method can struggle with spelling errors in student responses. When the word “equals” is spelled incorrectly in a student response, it does not affect the human grader’s ability to understand the student’s in-

attention. However, the trained scoring method puts a penalty on this spelling error.

- The third error type indicates that our trained scoring method may not recognize paraphrased responses. As shown in the examples, student may add text such as “I think that it is” which does not alter the meaning of the response; however, it adds noise and misled the prediction.
- The fourth error type indicates that our trained scoring method cannot handle responses in unparseable format such as an attachment.

5. CONCLUSIONS AND FUTURE WORK

In this paper, we have proposed a language model fine-tuning-based method for automatic short answer grading for open-ended, short-answer math questions. Our method has two main components: a base MathBERT model pre-trained with educational content on math subjects, and a meta-learning-based, in-context fine-tuning method that promotes generalization to new questions with a carefully designed input format. Experimental results on a large real-world student response dataset revealed surprisingly contradicting findings: Using MathBERT instead of regular BERT, which is not trained on mathematical content, results in a decrease in scoring accuracy, while the in-context fine-tuning method results in significantly improved scoring accuracy compared to existing methods, especially on previously unseen questions.

There are plenty of avenues for future work. First, the observation that MathBERT [35] cannot outperform BERT as the base language model suggests that there is a need to develop more effective models for mathematical language. One promising direction is perhaps taken by another simultaneously proposed version of MathBERT [31] that leverages the inherent tree structure of mathematical expressions. Moreover, the noisiness of human grading that we observed in our experiments suggests that there is a need to develop ASAG methods that take inter-rater agreement into account [43].

Second, there is a need to further improve the completeness of the context information we provide to the base language model. Several possible sources of additional contextual information include the grade level of the question, the common core standard codes, and mathematical skill/concept tags, which can all provide information on the level of the question. Additionally, we may even directly incorporate relevant mathematical content into the model’s input, e.g., by retrieving content chunks in textbooks or online resources using information retrieval methods [9]. However, a potential challenge that needs to be resolved is how to concisely pack all relevant contextual information into the model without exceeding the input length limit of language models (usually 512 tokens).

Third, in order to make ASAG methods more applicable in realworld educational scenarios, there is a need to thoroughly study the fairness aspects of these methods and ensure all students are treated fairly. There is a need to investigate how ASAG methods performs on different student populations; recent work has raised the concern that it is not clear that whether one should explicitly incorporate student

Table 9: Examples of scoring errors made by our trained method.

Question: Chelsea collects butterfly stickers. The picture shows how she placed them. Write a division sentence to show how she equally grouped her stickers. $_ \div _ = _$ Most frequency correct response : $15/3=5$			
Error type	Response	Grade	Predict

Meaningless response	see attachment	3	0

demographic information during model training [46]. Future work should explore how to incorporate fairness regularization into the training objective to promote methods that are fair across students [2, 34, 47, 48, 25].

ABSTRACT

Collaborative learning is a complex process during which two or more learners exchange opinions, construct shared knowledge, and solve problems together. While engaging in this interactive process, learners' satisfaction toward their partners plays a crucial role in defining the success of the collaboration. If intelligent systems could predict peer satisfaction early during collaboration, they could intervene with adaptive support. However, while extensive studies have associated peer satisfaction with factors such as social presence, communication, and trustworthiness, there is no research on automatically predicting learners' satisfaction toward their partners. To fill this gap, this paper investigates the automatic prediction of peer satisfaction by analyzing 44 middle school learners' interactions during collaborative coding tasks. We extracted three types of features from dialogues: 1) linguistic features indicating semantics; 2) acoustic-prosodic features including energy and pitch; and 3) visual features including eye gaze, head pose, facial behaviors, and body pose. We then trained several regression models to predict the peer satisfaction scores that learners received from their partners. The results revealed that head position and body location were significant indicators of peer satisfaction: lower head and body distances between partners were associated with more positive peer satisfaction. This work is the first to investigate the multimodal prediction of peer satisfaction during collaborative problem solving, and represents a step toward the development of real-time intelligent systems that support collaborative learning.

1. INTRODUCTION

Collaborative learning benefits learners in numerous ways, such as enhancing critical thinking [31], developing social skills [29], and improving learning gains [32]. During collaborative learning, partners may bring different ideas to solve a problem, defend and evaluate their perspectives, and have a dynamic interaction with each other to produce a shared solution [18]. This relationship between partners can be a decisive factor for the success of the collaboration and positive team experience [9], and the partners' satisfaction toward each other can have a significant impact on their task performance [51] and learning outcomes [20]. Previous literature suggests that students' interactions may not be productive and they may face challenges with their partner [25, 6], which could discourage them from working with partners in the future [44]. In a classroom setting, teachers may not have the resources to detect whether the partners in a team have positive attitudes toward each other and enjoy working together. Therefore, it becomes even more important to develop intelligent and adaptive technologies to predict peer satisfaction during collaborative activities.

Despite the increase in the development of techniques and models to analyze students' interactions during collaborative learning [49, 45], there is no research on automatically predicting peer satisfaction during collaboration. Current studies that analyzed learners' satisfaction during collaboration have revealed important factors such as social presence (sense of being with each other [46, 27]), frequency and quality of team communication [28], and mutual trust between group members [52]). However, most of these post-hoc studies relied on manual approaches (e.g., analyzing post-study attitude survey [22] or open-ended questions [28]). On the other hand, multimodal learning analytics research has created new opportunities to automatically analyze learners' interactions from multiple modalities (e.g., speech, facial expressions, body gestures), and provide insights into the learning process from different dimensions [2]. For example, recent studies successfully classified critical facets of collaborative problem solving process with multimodal features (linguistic, acoustic-prosodic, facial expressions, and task context) derived from groups of learners' collaborative dialogues [48]. However, multimodal learning analytics has not yet been used to automatically predict peer satisfaction from learners' interactions.

Aligned with this motivation, our goal in this paper is to investigate the automatic prediction of peer satisfaction during collaborative learning. We specifically address the following two research questions (RQs):

- RQ 1: What are the most predictive unimodal features of peer satisfaction during collaboration?
- RQ 2: Does multimodal feature fusion improve peer satisfaction prediction compared to the best-performing unimodal model?

To answer these research questions, we analyzed audio and video data collected from 44 middle school learners who worked in pairs on a series of collaborative coding activities. After participating in coding activities, each learner reported their overall satisfaction with their partners. To answer RQ 1, we examined the performance of the following features extracted from learners’ collaborative dialogues, including: 1) linguistic features indicating semantics from Word2Vec [35] and pre-trained BERT [15]; 2) acoustic features such as energy and pitch extracted with openSMILE [17]; 3) eye gaze, head pose, and facial AUs extracted with OpenFace [1]; and 4) body pose extracted with OpenPose [3]. We followed a state-of-the-art methodology [50] that preserves the sequential nature of the features across the collaborative session.

The experimental results revealed two significant predictors. The first significant predictor was head position (x-axis), generated from OpenFace, which was the horizontal distance of a learner’s head from the camera (located in the middle of two learners to collect video recordings). The second significant predictor was body key points (x-axis), generated from OpenPose, which was the the horizontal pixel location of a learner’s eight upper body key points (e.g., nose, neck, and shoulders). These results indicated that learners who had lower head and body distances from their partners were more likely to receive higher peer satisfaction scores. To answer RQ 2, we evaluated the model performance of several early-fused multimodal features, and the results showed that the multimodal features investigated in this study did not significantly improve the prediction accuracy of peer satisfaction compared to the best-performing unimodal feature.

This study provides two main contributions: 1) we present the results from extensive experiments evaluating both a variety of predictive features and a selection of sequential models; 2) and we identify two interpretable and meaningful learner behaviors that can be predictive of peer satisfaction. To the best of our knowledge, this is the first study to investigate the automatic prediction of peer satisfaction with multimodal features extracted from learners’ interactions.

The rest of the paper is organized as follows: Section 2 presents the related work; Section 3 describes the dataset used for this study; Section 4 details the features we investigated;. Section 5 elaborates on the peer satisfaction prediction models; Section 6 presents the experimental settings and results; Section 7 discusses the implications of experimental results; and finally, section 8 concludes the paper and discusses future work.

2. RELATED WORK

Interpersonal interactions and soft skills play an important role in students’ learning experiences and teams’ success during collaboration [11]. Previous research has emphasized that partners may have trouble while collaborating on a task together for a variety of reasons, and many social factors can have an impact on peer satisfaction. For example, So et al. [46] recruited 48 graduate students who collaborated on a healthcare project. They found that learners’ perceived social presence and emotional bonding were important factors for peer satisfaction. Zeitun et al. [51] examined the relationship between team satisfaction and course project performance among 65 groups of students. They found that team satisfaction (toward partners and their collaborative work) were positively related to group performance only for American students, and there was no significant difference in the satisfaction and performance regarding gender. Katuka et al. [26] analyzed the relationship between dialogue act and peer satisfaction from 18 pairs of middle school students. They identified six sequences of dialogue acts (e.g., questions, clarifications) that were positively related to satisfaction. Despite the insights of peer satisfaction provided by the aforementioned studies, most of these studies relied on manual approaches (e.g., post-study attitude survey or open-ended questions), which does not enable the automatic prediction of peer satisfaction.

In recent years, there has been an increasing interest in using multimodal learning analytics (MMLA) techniques that combine multiple data streams (e.g., speech and spoken words [41], text message and facial expressions [14]) to analyze student collaborative interactions. For example, Spikol et al. [47] used MMLA to estimate the success of collaboration with face tracking, hand tracking, and audio recording. They found that distances between learners’ hands and faces were two strong indicators of group performance, and lower distances indicated that it was more likely that successful collaboration occurred among students. Echeverria et al. [16] applied MMLA in a healthcare setting in which nurses collaborated in groups, with their audio, movement, and physiological data collected and analyzed. The authors demonstrated that integrating more sources of data multimodal data provided more contextual details of group activities during collaboration process. In another study, Liu et al. [30] used MMLA to understand learners’ knowledge model refinement process during collaboration. They were able to better predict learners’ knowledge models when they combined multiple data streams (i.e., audio, screen video, webcam video, and log files), which convey important contextual information about student learning. However, to the best of our knowledge, there is no research on automatic prediction of peer satisfaction using multimodal features during collaborative learning. Our study extends this body of MMLA research on learners’ interactions. We investigate different modalities (linguistic, acoustic-prosodic, and visual) for automatically predicting peer satisfaction.

Figure 1: *Left*: A sample script created with Snap!. *Right*: Two middle school learners collaborating on a pair programming task. In the captured moment, the learner in the left side of the frame is the *driver* and the learner on the right is the *navigator*; their collaborative interaction is video-recorded with a front-facing camera and audio-recorded with each learner wearing a lavalier microphone.

3. DATASET

3.1 Participants and Collaborative Activities

Our dataset was collected from 44 learners in 7th grade classrooms in a middle school in the southeastern United States during two semesters (Spring and Fall 2019). Out of 44 learners, 29 (65.9%) identified themselves as females and 15 (34.1%) as males. The distribution of race/ethnicity of these learners included 41.3% self-reporting as White, 26.1% Asian/Pacific Islander, 19.5% Multiracial, 8.7% Hispanic/Latino, 4.3% Black/African American, and 1.9% Other. The mean age was 12.1 with ages ranging from 11 to 13.

The learners collaborated on a series of coding activities in which they practiced fundamental CS concepts such as variables, conditionals, and loops using Snap! block-based programming environment [7]. The learners followed the pair programming paradigm, in which each pair shared one computer and switched roles between the *driver* and the *navigator* during the science-simulation coding activity (Figure 1). The *driver* is responsible for writing the code and implementing the solution, while the *navigator* provides support by catching mistakes and providing feedback on the in-progress solution [4].

3.2 Data Collection and Text Transcription

The collaborative coding session of each pair was recorded at 30 fps in 720p through a front-facing detached camera, and each child wore a lavalier microphone without active noise cancelling. The audio was recorded by digital sound recorders with a sample rate of 48KHz. After the audio/video data collection process was finished, an online manual transcription service [42] generated the textual transcript for each pair. The transcripts included three pieces of information for each spoken utterance: (1) *Starting Time*, in the form of *hour:min:sec*; (2) *Speaker*, in the form of *S1* (the learner sitting on the left of the video) or *S2* (the learner sitting on the right); and (3) *Transcribed Text*. Each collaborative coding session took around 30 minutes. In total, the corpus included 12 hours and 18 minutes of audio and video recordings, with 10,265 transcribed utterances.

3.3 Peer Satisfaction Post Survey

After participating in the collaborative coding sessions, each learner completed a peer satisfaction post survey. To the best of our knowledge, there is no existing validated survey for peer satisfaction in the pair programming context, so we developed a 6-item survey based on previous surveys on peer satisfaction. Sample questions in the peer satisfaction survey included: “My partner answered my questions well”, “My partner listened to my suggestions”, and “My partner often cut my speech”. Each of the six items in the survey was measured on a 5-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree).

Figure 2 (*Left*) shows the distribution of the peer satisfaction post survey responses from 44 learners. The distribution of the satisfaction scores shows that most of the learners agreed or strongly agreed that they were satisfied with the overall interaction with their partner. To determine whether to treat the six post-survey items as a single item or multiple items, we conducted a principal component analysis (PCA). The results of PCA suggested proceeding with only one derived outcome variable, which we refer to as *Satisfaction* score (the average score of six items). This derived outcome explains 52% of the variation across all six survey items, with an eigenvalue of 3.15. Figure 2 (*Right*) shows the distribution of the averaged *Satisfaction* score. The mean value of the *Satisfaction* score is 4.3 ($SD=0.6$) out of 5, with a maximum value of 5.0, and a minimum value of 2.2.

4. FEATURES

In this section, we introduce the feature extraction process from the audio (section 4.1), video (section 4.2), and language (section 4.3) modalities. Then we describe the feature padding process (section 4.4) that prepared the extracted features for model training. Table 1 shows the features this study investigated, and their corresponding dimensional details after the feature padding process.

Figure 2: *Left*: distribution of peer satisfaction post-survey items from from 44 learners. *Right*: distribution of the continuous averaged *Satisfaction* score (mean = 4.3, SD = 0.6).

Table 1: Utterance-Level Features

Modality	Feature Name	Vector Dimension*
Audio	Loudness	638, 704, 990
	Pitch	580, 640, 900
	Shimmer	116, 128, 180
	Jitter	116, 128, 180
	MFCCs	928, 1024, 1440
Language	Word Count	1
	Speech Rate	1
	Word2Vec	4,200
	Pre-trained BERT	768
Video	Eye Gaze Directions	784
	Head Directions	294
	Head Position (x-axis)	98
	Head Position (y-axis)	98
	Head Position (z-axis)	98
	Facial AUs	3,430
	Body Key Points (x-axis)	784
Body Key Points (y-axis)	784	

* For every audio-based feature, the three vector dimensions resulted from different speech lengths (29s, 32s, and 45s) after applying three different silence removal thresholds (-6, -16, and -30 dBFS) respectively. For language-derived features, the maximum number of spoken words was 42. For video-derived features, the maximum time length of video segments was 49s.

4.1 Audio-based Features

Simple acoustic-prosodic features (e.g., sound level, synchrony in the rise and fall of the pitch) derived from audio have proven to be effective in predicting learners' engagement level [49] and estimating group performance on solving open-ended tasks [47]. In our study, we extracted audio-derived features on the corresponding audio segment for each utterance. Because we only obtained the *Starting Time* of each utterance from the online transcription service, and not the *Ending Time*, the raw audio segments in our corpus also contain silence (background noise when a

learner stops talking) that elapsed before the next utterance started. To mitigate the potential negative influence of this silence in our audio segments, we used `pydub.detect_silence`, a function in the `pydub` [38] library to detect the time of end-of-utterance in a given audio segment. The function required a pre-defined parameter: silence removal threshold (any audio lengths quieter than this will be considered as silence). For each raw audio segment, we used three different silence thresholds to produce three different audio segments: -6 dBFS (half of the audio's maximum level), -16 dBFS (default setting of the function), and -30 dBFS (low enough to avoid losing actual speech lengths).

After removing the potential silence contained in raw audio segments, we used openSMILE v2.2, an open-source acoustic feature extraction toolkit, for automatic extraction of the following five types of audio-based features within a 20-ms frame and a 10-ms window shift. The five categories of audio-based features are as follows:

1. **Loudness** measures the energy level of the signal. For each audio frame, 11 loudness-related features were extracted.
2. **Pitch** measures the frequency scale of a signal. For each audio frame, 10 pitch-related features were extracted.
3. **Shimmer** measures how quickly the loudness of the signal is changing. For each audio frame, 2 shimmer-related features were extracted.
4. **Jitter** measures how quickly the frequency of the signal is changing. For each audio frame, 2 jitter-related features were extracted.
5. **MFCCs** (Mel-Frequency Cepstral Coefficients) measures the shape of the signal's short-term spectrum. For each audio frame, 16 MFCCs-related features were extracted.

Figure 3: An example of the video-derived feature extraction process for both learners in a specific video frame. *Left*: eye gaze direction (green vectors), head pose (blue 3D bounding boxes), and facial AUs (recognized later) extracted with OpenFace. *Right*: upper body key points (e.g., nose, neck, and shoulders) extracted with OpenPose.

4.2 Language-based Features

Linguistic features extracted from spoken utterances have been used to model collaborative problem solving skills and predict collaborative task performance [37]. In our study, multiple commonly used statistical and semantic linguistic features were extracted for each spoken utterance. The four categories of language-derived features are as follows:

1. **Word Count** For each utterance, word count was calculated as the number of words.
2. **Speech Rate** For each utterance, speech rate was calculated as the number of words divided by the number of elapsed seconds in the utterance, to produce words per second.
3. **Word2Vec** is a semantic method which learns word associations from the text, and groups similar words together in a vector space based on their semantics. We train our Word2Vec model with *gensim*, an open-source natural language processing library. The default settings of parameters were used, in which the dimension of each word embedding was set to 100, with a sliding window size of 5.
4. **Pre-trained BERT** is a language model trained on a large amount of data (e.g., texts from Wikipedia and books) in a self-supervised way. Similar to Word2Vec, BERT represents semantics of words in a vector space. In this study, we used the BERT-base-uncased model, which is a publicly available BERT model trained only on English texts with the hidden size of 768. With this pre-trained BERT, we generated one 768-dimensional vector for each utterance.

4.3 Video-based Features

A variety of features generated from video modality have been investigated in prior literature modeling collaborative problem solving. For example, eye gaze has proven effective in evaluating learners' attentiveness [43, 24] and learning performance [5, 40]; head pose has also been used for assessing learners' collaborative problem solving competence [13]; facial action units (AUs) have been used to measure both individual learners' tutoring outcomes [21] and interaction level during collaborative learning [33]. Body pose has been

used for analyzing learners' engagement level [39] and modeling collaborative problem solving competence [13]. In our study, video-derived features were extracted from the corresponding raw video segment of each utterance. We used the OpenFace v2.0 facial behavior analysis toolkit and OpenPose v1.7 body key points detection toolkit to extract the following four categories of video-based features (See Figure 3):

1. **Eye Gaze Direction** refers to the direction in which an eye looks. For each detected face per video frame, 8 eye gaze direction-related features were extracted. They included 3 eye gaze direction vectors (x direction, y direction, and z direction) for each eye, and 2 eye gaze directions in radians averaged for both eyes.
2. **Head Pose** refers to head position and direction. For each detected face per video frame, 6 head-related features were extracted with OpenFace, including three head position vectors (x direction, y direction, and z direction) representing the location of the head with respect to the camera in millimeters, and three head direction vectors in radius with respect to the camera. Since the front-facing camera was located in the middle of two learners during the data collection process, positive values of the x direction vector and the z direction vector indicate that the learner is sitting on the right side of the video and away from the camera, and vice versa. The head position features used in our study were the absolute values of the x , y , and z direction vectors, representing the spatial location of each learner's head from the camera.
3. **Facial AUs** refer to the movements of an individual's facial muscles. For each detected face per video frame, 35 facial AU-related features were extracted with OpenFace, including 17 facial AU intensity features (ranging from 0 to 5), and 18 facial AU presence features (0-absence or 1-presence).
4. **Body Pose** refers to the location of each joint (e.g., neck, shoulders) of the human body, which are known as key points that can describe a person's pose. For each learner appearing in each video frame, the 2D locations (x direction and y direction) of 8 body key

points, measured in pixels, were extracted with OpenPose. These included the locations of each learner’s eyes, nose, neck, and shoulders. OpenPose supports real-time detection of 25 full body key points (hand, facial, and foot key points); however, since our video recordings only captured learners’ upper bodies, OpenPose was not able to detect the locations of some body points such as hand and foot. Therefore, only 8 body key points related to learners’ upper bodies were extracted and used in this study. Because the resolution of our cameras was 720p, the maximum pixel value of body key points generated from OpenPose was 1280 pixels in the x direction, and 720 pixels in the y direction.

4.4 Feature Padding

Spoken utterances naturally vary in time length, and feature padding is an important step for ensuring the uniform size of model inputs before training machine learning models. We averaged the audio-based and video-based features across a small non-overlapping time window because they were extracted on the frame level. Following the feature aggregation methods used in prior works [47, 49], in which the average time windows of 500 ms and 1000 ms were chosen respectively, we selected the time window of 500 ms. We did not choose a longer window because audio-based features (e.g., pitch) could vary over a longer duration, which would lead to losing fine-grained details. Finally, post padding (adding zeros to the end of vectors) was applied on each averaged feature vector with the maximum time length (29s, 32s, and 45s) for different silence removal thresholds. For the Word2Vec-based feature, word embeddings were concate-

nated to form one feature vector for each utterance. Then, post padding was applied to the Word2Vec-based feature vector and the BERT-based feature vector with the maximum number (42) of spoken words.

5. PREDICTION MODELS

Figure 4 depicts the architecture of our peer satisfaction prediction model. For a collaborative coding session of a given pair (Learner A and Learner B), the model input is a session-level feature sequence $X = [x_0, x_1, \dots, x_{N-1}]$ for Learner B, in which N is the number of spoken utterances from the learner. For each element in X , we used the early fusion method to generate utterance-level multimodal feature $x_t = [a_t, v_t, l_t]$ by concatenating unimodal audio-derived feature a_t , video-derived feature v_t , and language-derived feature l_t . Before concatenating unimodal feature vectors into a single multimodal feature vector, we applied z-score normalization to all the features by subtracting their mean value and dividing by their standard deviation.

Our prediction model contains two stages: feature learning and regression. In the feature learning stage, we followed the current state-of-the-art methodology [50] that preserves the sequential nature of dialogue to learn the input feature sequence X . The sequential model is a two-layer LSTM network with 128 units. We obtained a final 128-dimensional hidden state h_T from the sequential model. During the regression stage of the model, we used h_T as input, and fully connected layers to output a continuous estimated satisfaction score \hat{y} , in order to approximate the actual *Satisfaction* score y rated by Learner A.

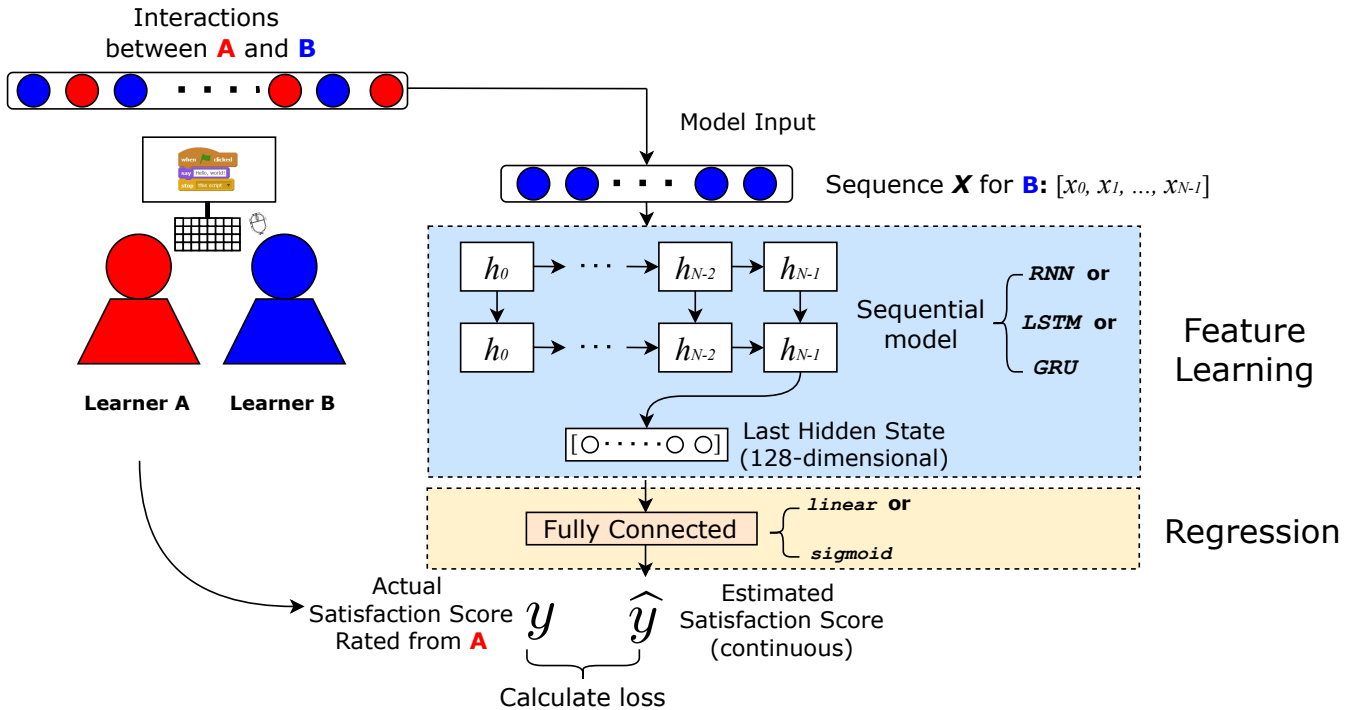

Figure 4: Architecture of the prediction model. For unimodal modeling, x_t ($0 \leq t \leq N - 1$) is a unimodal feature vector (audio a_t , video v_t , or language l_t). For multimodal modeling, x_t is a subset of an early-fused vector $[a_t, v_t, l_t]$ (normalized).

Table 2: Regression results of unimodal models. Two highlighted features: Head Position (x-axis) and Body Key Points (x-axis), significantly reduced the *MAE* compared to the baseline feature (*p-value* < .05).

Modality	Unimodal Feature	<i>MAE</i>	<i>p-value</i> (\hat{y}_{base} and \hat{y})	R^2 (y and \hat{y})
	Baseline	0.1953	—	0.07
Audio	Loudness	0.1981, 0.1790, 0.1796	0.31, 0.19, 0.12	0.02, 0.05, 0.07
	Pitch	0.2073, 0.1902, 0.1881	0.25, 0.14, 0.15	0.01, 0.15, 0.03
	Shimmer	0.1895, 0.1794, 0.1713	0.12, 0.19, 0.42	0.04, 0.12, 0.20
	Jitter	0.1983, 0.1896, 0.1853	0.14, 0.31, 0.31	0.01, 0.08, 0.06
	MFCCs	0.2341, 0.2405, 0.2318	0.19, 0.19, 0.24	0.01, 0.03, 0.03
Language	Word Count	0.1794	0.43	0.07
	Speech Rate	0.1790	0.19	0.29
	Word2Vec	0.1751	0.09	0.06
	Pre-trained BERT	0.1789	0.06	0.08
Video	Eye Gaze Directions	0.1689	0.10	0.21
	Head Directions	0.1583	0.09	0.23
	Head Position (x-axis)	0.1402	0.03	0.68
	Head Position (y-axis)	0.1902	0.21	0.15
	Head Position (z-axis)	0.1640	0.09	0.25
	Facial AUs	0.1927	0.19	0.11
	Body Key Points (x-axis)	0.1376	0.03	0.64
	Body Key Points (y-axis)	0.1761	0.39	0.10

MAE: aggregated testing absolute error for all data samples. y : actual satisfaction scores. \hat{y} : predicted satisfaction scores with each unimodal feature. \hat{y}_{base} : predicted satisfaction scores with the baseline feature. R^2 : another widely used metric to evaluate a regression task’s level of goodness-of-fit.

Table 3: Regression results of multimodal models. None of the multimodal features significantly outperformed the baseline feature.

Multimodal Feature	<i>MAE</i>	<i>p-value</i> (\hat{y}_{base} and \hat{y})	R^2 (y and \hat{y})
Baseline: Body Key Points (x-axis)	0.1376	—	0.64
Head Position (x-axis, z-axis)	0.1484	0.39	0.65
Head Position (x-axis), Head Directions	0.1355	0.17	0.68
Head Position (x-axis), Body Key Points	0.1367	0.10	0.68
Head Position (x-axis), Pre-trained BERT	0.1409	0.13	0.65

Recent research [50] has shown that the type of sequential model can play an important role for feature learning. Therefore, we also evaluated the performance of recurrent neural network (RNN) and gated recurrent unit (GRU) models to understand the influence of different sequential model architectures during feature learning. In addition, we evaluated the performance of two different output units, *sigmoid* and *linear* functions, to compare between linear and non-linear regression.

6. EXPERIMENTS AND RESULTS

6.1 Experimental Setups

We implemented the Python code¹ for our prediction models in Keras with a Tensorflow backend. We conducted five-fold cross-validation to train and validate the models. All labels (y) were normalized (ranging from 0 to 1) before the model training process because the *sigmoid* activation function was used to produce the predicted satisfaction scores \hat{y} . We used Adam optimizer with the learning rate of $1 \times e^{-3}$ to train the prediction model, which was trained for up to 100 epochs. The mean absolute error (*MAE*) was calculated for the loss function. After five rounds of cross-validation, we aggregated the *MAE* of each fold during the model testing process.

6.2 Investigating Unimodal Features

To identify predictive unimodal features, we compared the prediction accuracy of each unimodal feature with a randomly generated baseline feature. Followed a common method of generating uniform random baselines [12, 19], we used the Python function *random.uniform*(0, 1), which can be interpreted as white noise without any meaningful content. We then trained the model with the white noise to generate the random baseline results (error MAE_{base} and predicted scores \hat{y}_{base}). This low baseline allows us to measure the extent to which each feature predicts the outcome better than random chance. Next, we trained the model with each of the unimodal features from Table 1, and generated corresponding *MAE* and \hat{y} . A paired-samples *t*-test [34] between \hat{y}_{base} and \hat{y} checked whether adding that unimodal feature significantly reduced error compared to the random baseline. Table 2 shows the regression results of peer satisfaction prediction models trained on unimodal features.

For audio-derived features, the three values in each column (from left to right) resulted from different silence removal thresholds (-6, -16, and -30 dBFS). Although time-domain features (e.g., Loudness, Shimmer) performed better than frequency-domain features (Pitch, Jitter), as indicated by lower *MAEs*, the associated *p-values* showed that none of the acoustic and prosodic features significantly outperformed the baseline. For video-derived features, we identified two predictive unimodal features: learners’ head posi-

tions in the x direction (p -value = 0.03), and the locations of their body key points in the x direction (p -value = 0.03). Models trained on language-based features yielded similar $MAEs$ compared to the baseline model; therefore, none of the language-based features evaluated in this study were predictive for this task.

The feature space in our study is large compared to the relatively small corpus size. Therefore, identifying predictive unimodal features helped with filtering out noisy features that are not useful in predicting satisfaction scores. Next, we examined the performance of multimodal models by combining the unimodal features that were useful.

6.3 Examining Multimodal Features

For testing the performance of combining multiple features, we selected the two significant ($p < 0.05$) unimodal features (Head Position x-axis and Body Key Points x-axis). In addition, we also selected Head Direction and Pre-trained BERT, as their p -values are lower than 0.1 (a threshold that has been used to identify a weak trend or association [23]). We used the best-performing unimodal model trained on Body Key Points (x-axis) as the baseline (predicted satisfaction scores \hat{y}_{base}), and investigated the p -values of the paired-samples t -test between the predicted scores \hat{y} and the baseline results \hat{y}_{base} . Table 3 shows the regression results of peer satisfaction trained on unimodal features.

The results shown in column 2 of table 3 indicated that combining Head Position (x-axis) and Head Directions yielded the lowest MAE. However, none of these multimodal features significantly improved the regression performance compared to the unimodal model.

6.4 Comparing Different Model Architectures

To understand the influence of different sequential models during feature learning, and compare the performance between linear and non-linear regression models, we selected the best-performing unimodal model and examined how prediction accuracy varied under different model architectures.

Table 4 shows the experimental results with different model architectures. For the selection of different sequential models, three models provided comparable performances, with LSTM yielding a slightly lower MAE. As for the selection of different activation functions, the model predicting satisfaction score with a *sigmoid* activation function performed better than with a *linear* function. In addition, although we observed faster convergence speed with *linear*, *sigmoid* provided more stable training and testing performance (see Figure 5). As for the selection of the number of layers, the one-layer LSTM performed similarly compared to two- or three-layer LSTM.

7. DISCUSSION

This study investigates the prediction of peer satisfaction using multimodal features from learners’ interactions during collaborative learning activities. This section discusses the results with respect to our two research questions, as well as implications from comparing the performance of different model architectures.

Table 4: $MAEs$ under different architecture settings.

Sequential Model	LSTM	RNN	GRU
<i>MAE</i>	0.1376	0.1401	0.1382
Output Unit	<i>sigmoid</i>	<i>linear</i>	
<i>MAE</i>	0.1376	0.1741	
# of Layers	1	2	3
<i>MAE</i>	0.1359	0.1376	0.1384

Figure 5: Testing $MAEs$ under different activation functions (blue-linear, red-sigmoid). *linear* provided faster converge speed during training, while *sigmoid* provided lower MAE and more numerical stability during testing.

7.1 RQ 1: What are the most predictive unimodal features of peer satisfaction during collaboration?

7.1.1 Audio-based Features

In this study, we investigated several commonly used acoustic-prosodic features and the results showed that none of these features were significant predictors of peer satisfaction. Previous literature has associated learners’ peer satisfaction with their emotional bonding [46]. Acoustic-prosodic features have been widely used for detecting speaker emotion detection (positive, neutral, and negative) [10] and predicting learners’ task performance [47]. However, the results from this study indicate that the acoustic-prosodic features we tested may not have the explanatory power to predict peer satisfaction.

One potential reason for audio features not performing well in models is if there are periods of silence included in what the model thinks are periods of speech only. We examined several different silence removal thresholds (-6, -16, -30 dBFS) and the results indicated that this strategy did not help with peer satisfaction prediction. A higher silence removal threshold (e.g., -6 dBFS) could help reduce the negative influence from background noise; however, it is also more likely to remove learners’ speech. While selecting between and qualitatively examining different thresholds, we determined -30 dBFS was optimal for our corpus to balance between eliminating periods of silence without excessively cutting off speech. However, acoustic features under that threshold were not predictive of peer satisfaction.

7.1.2 Language-based Features

We examined several statistical (word count and speech rate) and semantic (Word2Vec and BERT) features from the language modality. Statistical features such as word count per utterance and speech rate have shown to be associated with learners’ active participation and turn-taking during collaboration [49]. The results from our study showed that there was a trend toward significance when more semantic information was added to the features (p-values for word count, Word2Vec, and BERT: 0.46, 0.16, 0.06); however, none of these models yielded statistically significant results for predicting peer satisfaction (Table 2). Previous literature also found several sequences of dialogue acts representing speakers’ intentions (e.g., questions followed by clarifications) that were positively related to peer satisfaction [26], but our results did not show a direct correlation between semantics and peer satisfaction. One potential reason may be that the semantic representation methods used in our study did not have the same explanatory power as dialogue acts to directly indicate learners’ intentions.

7.1.3 Video-based Features

Among the several video-based features extracted in this study, head position and body location on the horizontal axis were the only two predictive unimodal features. To better understand how the patterns of these two predictive features varied among learners with different satisfaction scores, we selected three groups of five learners and examined their sessions in more detail. The groups are as follows:

- High satisfaction group: five learners who received the highest scores (5.0 / 5.0).
- Average satisfaction group: five learners who received the exact score of 4.3 / 5.0 (mean peer satisfaction score of our corpus).
- Low satisfaction group: five learners who received the lowest five scores (all below 3.7 / 5.0).

Figure 6 shows the patterns of horizontal (x-axis) head distance from the camera, in meters, for the three groups of learners. For each group, we calculated their averaged Head Distance (x-axis) over whole sessions. Since the camera was positioned horizontally in the middle between two learners, if learners had lower head distance from the camera, this likely reflects that the learners were sitting closer to one another. From Figure 6 we could see that learners who received high satisfaction scores (green) had lower head distances over the collaborative coding sessions, compared to learners who received average (red) and low (blue) satisfaction scores.

Figure 6 also depicts the difference of the head distance variance over time across the three groups of learners. Learners who received high satisfaction scores (green) had lower head distance variance and fewer numbers of sharp distance increases over time, compared to learners who received average (red) and low (blue) satisfaction scores. A sharp head distance increase could happen when the learner became disengaged in the collaborative coding tasks (e.g., talking to learners in other groups). In comparison, for learners in the high satisfaction group (green), only a small range of head distance variance over time was observed.

In addition to head distance (x-axis), another predictive unimodal feature identified in our study was *body key points*,

Figure 6: Head Distance (x-axis) in Meters from OpenFace

such as the location of nose, neck, and shoulders. Figure 7 shows the patterns of neck location (x-axis) in pixels toward the camera for three groups of learners; locations for other body key points followed relatively similar patterns. The maximum neck distance from the camera that could be detected was 640 pixels (half of 1280 pixels) because the resolution of our cameras was 720p. Figure 7 shows that learners who received high satisfaction scores (green) sit closer toward the camera (they had closer distances to their partners) over the collaborative coding sessions, compared to learners who received average (red) and low (blue) satisfaction scores. Additionally, learners who received high satisfaction scores (green) had lower neck location variance over time, compared to learners who received average (red) and low (blue) satisfaction scores.

Figure 7: Neck Location (x-axis) in Pixels from OpenPose

The findings from Figure 6 and Figure 7 were aligned with previous literature that found learners’ perceived social presence and proximity significantly impacted their satisfaction, as well as group performance during collaborative learning [8, 36]. For example, a study conducted by So et al. [46] revealed that learners’ perceptions of physical proximity and psychological aspects of distance were both important factors in their reported satisfaction with their partner. In another similar study conducted by Spikol et al. [47], the

authors found that the distances between learners’ faces and between learners’ hands were two strong indicators of task performance when groups of college students were engaged in open-ended collaborative tasks.

7.2 RQ 2: Does multimodal feature fusion improve peer satisfaction prediction compared to the best-performing unimodal model?

In this study, experiment results in Table 3 from several multimodal models indicated that although using multimodal features (Head Position (x-axis) combined with Body Key Points) yielded lower *MAE* than the best-performing unimodal feature, there was no significant performance advantage of using multimodal over unimodal features. The potential reason may be that both head position and body key points represented learners’ spatial locations; therefore, combining these two unimodal features did not add extra useful information to predict peer satisfaction. Therefore, each of these two unimodal features alone could be used to predict peer satisfaction. However, the head pose feature extraction process with OpenFace was faster than OpenPose. OpenPose was computationally demanding, and required GPU acceleration to perform the body key points detection. Therefore, OpenFace may be a more practical feature extraction choice over OpenPose when deploying real-time learning support systems.

7.3 Implications from comparing different model architectures

The experimental results comparing performance of different model architectures showed that the three different sequential models (RNN, LSTM, and GRU) had similar peer satisfaction prediction accuracy; in addition, non-linear regression models yielded lower *MAE* than linear regression models. These results have a few practical implications for researchers in the educational data mining community seeking to conduct similar studies with the methodology presented in this study.

Although sequential models were able to represent the sequential nature of utterance-level features, the comparison between different sequential models (RNN, LSTM, and GRU) did not reflect significant performance differences. Given that GRU usually has a faster training speed than LSTM and RNN due to its simpler cell structure, GRU could be a better choice over RNN or LSTM for similar tasks. In addition, the comparison between different activation functions (*linear* and *sigmoid*) showed that the *sigmoid* regression model yielded lower *MAE* and provided more numerical stability during testing than the *linear* model. The reason may be that the satisfaction scores predicted in this study only ranged from 1 to 5, so the constrained output value range of the *sigmoid* function could better avoid large error values during training. On the contrary, there was no mechanism to prevent the *linear* activation function from predicting out-of-range satisfaction scores.

7.4 Limitations

The current work has several important limitations. First, we only studied peer satisfaction in the context of co-located pair programming, and analyzed recordings collected from

a relatively small corpus with 44 middle school learners; therefore, the predictive features found in this paper may not generalize well to group collaboration involving three or more team members, or to learners in other populations or learning environments, such as adults or online learning. Second, the LSTM-based feature learning process was black-box, which makes it relatively difficult to interpret what predictive information was learned from each unimodal feature. Finally, the effectiveness of video-derived features identified in this study relies heavily on the correct setup of the video recording process. Our dataset was collected from a natural and active classroom setting, and thus, OpenFace sometimes failed to detect both learners’ faces when they were not directly facing the camera, or in the case of occlusion. Even though we used wide-angle camera lenses for video recording student interactions, there were some cases in which some students were sometimes out of the recording range.

8. CONCLUSION AND FUTURE WORK

Learners’ satisfaction toward their partners plays a crucial role in group performance and learning outcomes. If intelligent systems could automatically predict peer satisfaction during collaboration, they could provide timely scaffolding for better learning experiences. In this paper, we investigated automatic prediction of peer satisfaction by analyzing 44 middle school learners’ collaborative dialogues. We compared a set of state-of-the-art multimodal learning analytics techniques with linguistic, acoustic-prosodic, and visual features extracted from students’ interactions. The experimental results revealed two significant predictors: head position and body location. Learners who had shorter head and body distances from their partners were more likely to receive higher peer satisfaction scores.

This study highlights several directions for future work. First, future work should examine the generalizability of the findings in this study using larger datasets, including data from online learning environments and multi-party interactions among groups of three or more learners. Second, although OpenFace and OpenPose support accurate detection of head pose and body pose, it remains challenging to integrate them into intelligent learning support systems for real-time analysis. Future work should investigate other methods and tools to detect learners’ pose features accurately and time-efficiently. Third, the satisfaction survey was administered post-hoc in this study. Future work could investigate potential variations in students’ attitudes that may occur during the ongoing collaborative process. Finally, it is important to investigate how intelligent systems can most effectively deliver feedback to learners during collaborative learning process. As we move toward predicting peer satisfaction in real time, we will be able to build and investigate systems that can significantly improve learners’ collaborative learning experience in classrooms.

ABSTRACT

What can eye movements reveal about reading, a complex skill ubiquitous in everyday life? Research suggests that gaze can reflect short-term comprehension for facts, but it is unknown whether it can measure long-term, deep comprehension. We tracked gaze while 147 participants read long, connected, informative texts and completed assessments of rote (factual) and inference comprehension (connecting ideas) while reading a text, after reading a text, after reading five texts, and after a seven-day delay. Gaze-based student-independent computational models predicted both immediate and long-term rote and inference comprehension with moderate accuracies. Surprisingly, the models were most accurate for comprehension assessed after reading all texts and predicted comprehension even after a week-long delay. This shows that eye movements can provide a lens into the cognitive processes underlying reading comprehension, including inference formation, and the consolidation of information into long-term memory, which has implications for intelligent student interfaces that can automatically detect and repair comprehension in real-time.

Keywords

Reading comprehension, Eye movements, Machine Learning, Long-term comprehension, Comprehension depth.

1. INTRODUCTION

Reading comprehension is the extraction of meaning from text. This activity takes place many times a day, whether reading the news, absorbing technical information at school or work, or reading a novel for pleasure. Difficulty in reading comprehension can slow the progression of such activities, and comprehension failures can lead to misunderstandings and inaccuracies. The rise of computerized reading via e-books, the Internet, and other media opens up the exciting possibility of intelligent interfaces that can track reading comprehension as it unfolds based on measurable signals (behaviors) from the reader [13, 51].

Eye-gaze is perhaps one attractive signal to explore because it provides a lens into cognitive processes [30, 48] and it can be passively and noninvasively recorded. In particular, there is a long history of using eye gaze in student-models of cognitive, affective, and social

processes during learning [8, 15, 61]. In the context of reading comprehension researchers have developed automatic models for skimming [3] and mind wandering (zone outs) [19] detection. These models have also been used for real-time intervention. For example, Mills et al. [41] designed an attention-aware reading intervention that prompted participants to re-read sections of text based on a real-time gaze-based model of mind wandering [19] and found this to improve reading comprehension. In addition, real-time modifications can be made to text content, such as adapting the text to be easier when comprehension difficulty is detected [53], or enabling gaze-contingent actions such as presenting a glossary for technical terms [3].

Whereas these examples focus on adapting the reading interface based on ongoing comprehension processes, such as mind wandering or comprehension difficulty, another possibility is to base adaptations on comprehension outcomes. For example, if gaze can be used to prospectively predict whether a student will comprehend a page or an entire text, adaptive interventions can be designed to address such deficits at their onset. Such a system would entail developing a model to monitor comprehension outcomes from gaze as a first step, a possibility we explore here. Specifically, we examine whether machine-learned models of gaze can be used to predict different types of comprehension outcomes (factual vs. those requiring inferencing) assessed at different time intervals (during a text, after a text, after multiple texts, and greater than a week). In addition to potential applications, the present research advances the empirical knowledge base of eye movements in reading comprehension, and to our best knowledge, is the first such study.

2. BACKGROUND AND RELATED WORK

2.1 Reading Comprehension

Most theories of reading posit that it involves hierarchically interacting levels of processing - from the sub-lexical and lexical levels [25] and the access of word-level meaning [45] to the formation of a literal then a more abstract meaning-based encoding of the text at the sentence-level (Figure 1 links a-c; [59]). Higher-order (or deeper) processing incorporates elaborative inferences from prior knowledge (Figure 1 n) [32] and integration across multiple sections within the text and even between texts (bridging inferences), forming a situation (or mental) model (Figure 1 d-g) [24, 39]. These above shallow and deep comprehension processes unfold in parallel [33] and interact with one another to provide a cohesive narrative of text. Both are critical in that shallow, perceptual encoding of information is important to construct the mental representations to support inferences from the text, and inferences are important to bridge ideas in the text into a cohesive narrative (Figure 1d; [34]).

It is therefore critical to develop models of comprehension that account for multiple levels of comprehension, which we address by focusing on varying depths of comprehension, such as rote (knowledge of factual content from text) and inference (deep) comprehension (for examples, see Table 2).

Comprehension also unfolds over timescales of milliseconds, seconds, minutes, hours, and beyond. For instance, reprocessing of remembered information can occur in milliseconds without re-fixating the part of the text that was not correctly encoded initially [6, 40], whereas comprehension of earlier sentences affects encoding of later content and vice versa (e.g., via bridging inferences [34]), a process that may unfold over seconds or even minutes. Further, memory traces acquired during reading one text may interfere with another [63] prior to being consolidated into long-term memory during sleep [43]. Thus, it is unclear if eye movements captured during the initial encoding of text (Figure 1 b,h) will be useful to predict comprehension at later stages after these intervening processes have unfolded (Figure 1 i-m). We address this by investigating the link between gaze and comprehension assessed at multiple time points.

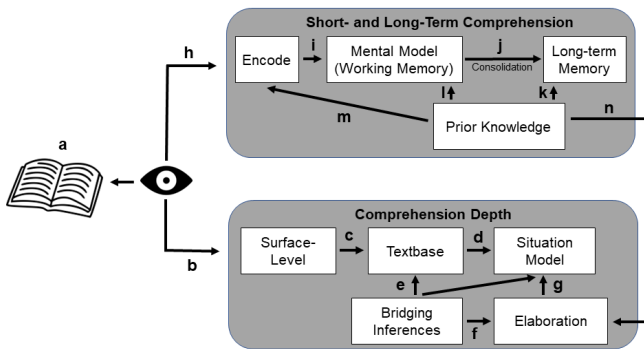

Figure 1. An overview of the process of reading comprehension.

2.2 Eye Movements During Reading

Theories of gaze control during reading shed light on the mechanisms linking cognitive processes and measurable gaze features [18, 50], particularly for lower-level lexical processes. For example, eye movements are determined to some extent by text properties, where fixations are shorter on more frequent [47] and shorter [49] words. But eye movements are also influenced by higher-level comprehension [5], for example the same word may be fixated for longer if it is contextually surprising versus expected

[38] or regressive eye movements can reconcile disparities in comprehension [9], such as in the case of ambiguous sentences [23] (but this can also occur covertly without a regression [7]).

Gaze has also been linked to several processes that support comprehension. In particular, attentional lapses (mind wandering) which are negatively associated with comprehension [14, 54] have been linked with fewer and longer fixations (see brief review by Faber et al. [20]). Similarly, skim reading manifests as fewer fixations [37] and fewer regressive saccades [42], but in contrast to mind wandering, these fixations are shorter than for normal reading [56].

Researchers have leveraged these findings to develop gaze-based models of reading comprehension as noted in Table 1. Whereas there have been attempts to model comprehension from other signals, such as facial expressions [58], we focus on gaze here. In general, most studies compute gaze statistics aggregated over time to give “global” measures at the level of an entire page, passage, or reader for use as features in shallow machine learning classifiers (e.g., Random Forest). For example, D’Mello et al. [16] used linear regression models to predict responses to multiple-choice questions targeting rote (factual) information of the text interspersed during reading trained on a small number of global gaze features grounded in the experimental literature. Similarly, Copeland and colleagues trained shallow neural networks to predict comprehension scores from gaze [10–12].

Deep neural networks are capable of modeling gaze behavior [35, 62], so it is plausible that an end-to-end system could be designed to predict comprehension. To this point, Ahn et al. [1] used convolutional neural networks (CNN) and long short-term memory (LSTM) models to model several reading comprehension metrics (passage- and participant-level comprehension, perceived difficulty, English language skill) from raw fixation-level data (location, duration, and pupil diameter) but their model performance was scarcely above chance and the results did not generalize to new readers.

To this point, a vast majority of studies do not provide evidence of generalizability to new people where data from the same participants are in either the training or test set (but not both). Further, as evident in Table 1, almost all studies focus on rote or inference comprehension or a combination of the two, which makes it difficult to compare the performance of gaze-based models for either type; comprehension is almost always assessed during reading or immediately after, but never after a longer delay when interference and memory consolidation processes unfold.

Table 1: Review of gaze-based computational models of reading comprehension

Study	Comprehension Type	Assessment Time	Participant-level Generalization	Small, predetermined feature set
Copeland & Gedeon, 2013	Rote	During reading	No	Yes
Copeland et al., 2014	Rote	Immediately after reading	No	Yes
Martínez-Gómez & Aizawa, 2014	Rote	Immediately after each text/section	Yes	Yes
Wallot et al., 2015	Rote	Immediately after reading	No	Yes
Copeland et al., 2016	Rote	Immediately after each text/section	No	Yes
Ahn et al., 2020	Rote and inference	Immediately after each passage	No	NA
D’Mello et al., 2020	Rote	During reading	Yes	Yes
Southwell et al., 2020	Rote (2 studies) and inference (1 study)	Roughly 30 minutes after reading	Yes	Yes

2.3 Current Study: Contribution & Novelty

As reviewed above, there is reason to suggest that gaze can provide an important signal to automatically measure comprehension during reading. However, despite some initial attempts towards this goal (Table 1), substantial items remain including: (1) differentiating the predictive value of gaze on different depths of comprehension; and (2) different time onsets from the initial reading of the text (where gaze data is acquired) and when comprehension is assessed; (3) developing models that generalize to new students, and (4) testing whether deep sequence learning models can improve comprehension prediction above standard classifiers.

We addressed these issues by testing whether gaze could be used to predict rote and inference comprehension (#1 above) assessed at four time points (during reading, after each text, after all texts, and at least seven days following reading; #2), using a large dataset of eye movements recorded as 147 participants read five long expository texts. Random forest models were used to evaluate whether a broad set of page-level gaze features (109 features total) could be used to detect reading comprehension on each page across depth and time by comparing them to two baseline models. We also tested a long-short-term memory (LSTM) deep neural network to examine whether temporal sequences of fixations could improve predictive accuracy (#4). Critically, participant-level cross-validation was used to increase the validity of the model on new participants (#3).

It should be noted that the present goal is more scientific in nature – to investigate the relationship between eye tracking and reading comprehension outcomes – rather than application oriented. As such, although we used a machine-learning predictive modeling approach [17], the goal was to use the models to investigate the question of the link between gaze and comprehension depth and durability (persistence across time) rather than to engineer the most predictive model. For this reason, we largely restricted the feature space to high-level eye gaze features and some contextual variables but did not include information on textual content and difficulty of the assessment items.

3. METHOD

3.1 Data Collection

Data was collected as part of a larger study investigating neurophysiology during reading comprehension. Only aspects germane to the present study are presented here. The data analyzed here have not been previously published.

Participants (N=147, age 23±6 years, 67% female, 1% other) were students from a large public University in the Western US. Participants were paid \$20 per hour plus \$10 for a follow-up survey via Amazon gift cards. All procedures were approved by the institution’s internal review board and all participants provided informed consent.

Binocular gaze was tracked using a high-resolution desktop-mounted eye tracker (SR Research EyeLink 1000+) with a sampling rate of 1000Hz. Stimuli were displayed on a 23.8”, 1920x1080 pixel display, and participants viewed the screen at a distance of ~90cm. A chin rest was used to minimize movement during the study.

Participants read five expository texts of around 1000 words each, where a single text was split into 10 pages. Each text was on the topic of behavioral research methods: Bias, Hypothesis, Casual

Claims, Validity, and Variables. The texts had a mean Flesch-Kincaid grade level (a measure of textual difficulty) of 13.2 indicating an advanced reading level [22] suitable for college students. Reading was self-paced in that participants pressed a key to advance to the next page but could not advance back to a previous page. On average, participants spent 5.5 minutes (1.8 SD) reading each text, for a total average reading time of 27.6 minutes (9.2 SD).

Reading comprehension was assessed via: 1) Rote items - four-alternative forced-choice item targeting factual knowledge explicitly presented in the text); 2) Inference items - a statement which is either a valid or false inference from the text, which the participant identified as ‘true’ or ‘false’ (see Table 2 for examples). Rote and inference questions were developed by researchers led by an instructor of a behavioral research methods undergraduate course. They were then piloted and refined using Mechanical Turk in order to calibrate the difficulty to the appropriate level. Items with less than 20% accuracy or greater than 80% accuracy were reexamined and either discarded or adapted based on patterns of responses. The final assessments and texts included in the study were tested on 10 unique participants per text.

Table 2: Examples of a rote question and inference items

Text	Question
“Occam’s razor, also called the principle of parsimony, teaches that hypotheses introduced to explain relationships should be as parsimonious as possible. We ‘cut away’ what is superfluous.”	(Rote Question) What is Occam’s Razor? A) The process by which we search for the simplest explanation for an observation (correct); B) The process by which we search for connections between facts; C) A tool used by those who search for truth; D) A book by the philosopher William of Occam
Sentence S3: Internal validity refers to whether the relationship between the variables is free of confounds Sentence S5: Content validity refers to the extent to which a measure represents all facets of a given construct.	(Inference Question) True or False: Internal validity is not a prerequisite for content validity. False (correct response because for a test to separately measure all facets of a construct (S5) it must be able to identify relationships free of confounds (S3)).

Both assessment items occurred at four time points: (A1) “during text” occurred immediately after reading the corresponding page, (A2) “after each” occurred after each individual text was completed; (A3) “after all” occurred once all five texts were read; and (A4) “delay” occurred a minimum of seven days after the reading session (Figure 2; median completion time 8.0 days, mean completion time 11.3 days after reading). The assessment items were linked to content covered on a particular page such that gaze on that page could be associated with a corresponding assessment item (Figure 2). At each time point, each participant received assessments corresponding to a randomized subset of two pages for each text from a pool of questions common to the A1, A2 and A3 assessments (Figure 2) but without overlap (e.g., if a page was selected for A1, then it could not be used for A2 and A3). A4 assessments were selected from a different pool of questions than A1-A3.

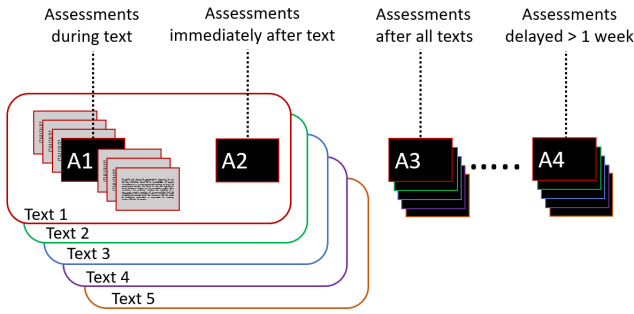

Figure 2. Four different timings of assessment questions. Black boxes indicate assessments, grey boxes indicate example pages within text, and colors indicate the five individual texts (and subsequently the corresponding text of the assessment questions).

3.2 Data Processing and Feature Extraction

Gaze data was processed with EyeLink’s event detection algorithm, using a velocity threshold of 30°/s and an acceleration threshold of 9500°/s². The right eye was used in the analyses if available, otherwise the left eye was used. No manual alignment of eye movements was done to address eye tracking errors as this would not be possible in a real-time application. Further, a pilot study comparing features (see Table 3) extracted from aligned vs. unaligned tested on the A1 (‘during text’) assessments yielded highly similar results.

Fixations and saccades greater than the 99th percentile across participants were removed to account for mis-parsed fixations and saccades (i.e., saccade amplitudes greater than 20°, durations above 600 ms, peak velocity below 5°/s or above 800°/s, distances over 1000 pixels, and fixation durations below 40 ms and above 3000 ms). The first and last fixations on a page were removed as these likely corresponded to orienting rather than reading behaviors.

Table 3. Gaze Feature Definitions

Feature	Description
Fixation Duration	Duration of a fixation in milliseconds
Fixation Count	Number of fixations on a page
Saccade Amplitude	Degrees of visual angle the eye travels during a saccade
Saccade Velocity	Saccade amplitude divided by saccade duration
Saccade Distance	Euclidian distance between saccade start and end points
Saccade Duration	Duration in milliseconds of a saccade
Saccade Relative Angle	Acute angle between the line segments of two saccades
Horizontal Saccade Angle	Angle between a saccade and the horizontal axis
Pupil Diameter (Z)	Diameter of the pupil, z-scored within-participant
Fixation Dispersion	Root mean square of distance from each fixation to the mean fixation position on a page
Horizontal Saccade Prop.	Proportion of saccades no greater than 30 degrees above or below the horizontal axis to the right or left
Forward Horizontal Saccade Prop.	Proportion of saccades no greater than 30 degrees above or below the horizontal axis only to the right
Blink Count	Number of blinks on a given page
Blink Duration	Duration in milliseconds of a blink
Dwell Time	Sum of the durations across all fixations that fell in a given interest area (i.e., the box bounding each word). Reflects the amount of time spent fixating on the words
IA Fixation Prop.	Total proportion of fixations that landed in a given interest area (e.g., 2 for word #12 “following” in Figure 3, 2/13 for the proportion)
Regression-In Prop.	Proportion of times an interest area was entered at the beginning of a regression. (e.g., 1 for #3 “start” in Figure 3, and 1/13 for the proportion)
Regression-Out Full Prop.	Proportion of times an interest area was regressed from (e.g., 2 for “experiment” #13 in Figure 3, and 2/3 for the proportion)
First Pass Regression-Out Prop.	Proportion of times an interest area was regressed from on the first pass (before having read any text past that interest area). (e.g., 1 for “experiment” #13 in Figure 3, and 1/13 for the proportion)
Regression Path Duration	Total time from when an interest area is fixated until it is exited to the right (also called go-past duration). This includes all the time spent regressing until that interest area is passed. (e.g., the sum of the first fixation on “experiment” #13 in addition to the sum of the 3 subsequent regressive fixations, and the last fixation on that same word in Figure 3).
Selective Regression Path Duration	Total gaze duration (duration of fixations and refixations) on an interest area before leaving the interest area to the right (e.g., 2 for the word “following” and the word “experiment” #13 in Figure 3).

The word “proportion” indicates these features were normalized by the total number of fixations on the given page. Prop. = Proportion

3.2.1 Gaze Features

Global (content-independent) gaze features (Table 3) were calculated as statistical functions over low-level features at the page-level (including min, max, mean, median, sum, skew, kurtosis, and standard deviation) and have been previously used to predict comprehension and mind wandering [4, 19, 55]. A second set of features captured the fixations corresponding to interest areas, which were rectangular boxes around individual words and punctuation computed with EyeLink Dataviewer (see example in Figure 3). The gaze models consisted of these 109 features plus three context features (see below). One goal of these features is to find participant-general patterns in gaze and comprehension, so to account for the variation in individual differences in fixation rates [26, 60], we normalized interest area features by the total number of fixations on a given page.

Figure 3. Hypothetical fixations ($n = 13$) and saccades on the text. The numbers indicate the interest area index for the word/punctuation they are above, the circles indicate fixations and the lines indicate saccades. The circles with darker outlines are the first and last fixation, for reference. The unfilled circles denote regressive fixations.

Table 4 includes summary statistics for a few key gaze features used in the present study, which are consistent with typical values observed during reading [46, 48]. The mean fixation duration was 210.30 ms, well in range of the 200-250 ms average during reading, and the mean saccade duration of 42.04 ms is close to the average saccade duration of 50 ms during reading [46]. Further, the average saccade amplitude in the study was 3.46 degrees, whereas the average during reading is reported to be 2 degrees [48]. This study does differ slightly in regressive fixations, as it is estimated that 10-15% of saccades are regressive during reading [46], where this study had 34%. There was also a slightly higher horizontal saccade proportional (95%) than previous studies (e.g., 85% in D’Mello et al. [16]).

Table 4. Gaze summary statistics computed over participants. IA = interest area.

Feature	M (SD)
Mean Saccade Amplitude	3.46 (0.45)
Total Scan Path Length	422.68 (105.61)
Fixation Dispersion	0.41 (0.03)
Mean Fixation Duration	210.84 (25.20)
Mean Saccade Duration	42.04 (8.94)
Horizontal Saccade Proportion	0.95 (0.03)
Mean Pupil Size (z)	0.11 (0.30)
Regression Fixation Proportion	0.34 (0.09)
IA Percent Visited	0.56 (0.08)
Proportion of Fixations in IAs	0.91 (0.06)
Mean IA Regression Path Duration	984.57 (450.88)
Mean Blink Duration	189.91 (229.87)

3.2.2 Baseline Models: Context Features, Shuffled Labels and Shuffled Fixation Events

Context features capture situational factors independent of gaze and were used as a baseline measure to gauge the added value of gaze features. They included reading rate (reading time divided by the number of characters on a page), text order, and the eye tracker calibration error. For a second baseline, we fit gaze models where comprehension scores were shuffled within each participant, preserving the distribution of the features, but breaking the temporal dependency between gaze and the comprehension. Additionally, the LSTM baseline models shuffled the units in the sequence of fixation events (see below), preserving the distribution of the features, but breaking the temporal dependency between fixation events.

3.3 Machine Learning Models

We chose Random Forest classifiers since they incorporate nonlinearity and interactivity among features and have good generalization properties. The random forest classifier was implemented in sklearn, with 100 estimators, minimum of 15 samples per leaf, and the maximum number of features set to the square root of the total number of features. The class weights of the models were balanced by setting the weights to be inversely proportional to the number of samples in each class. Note that no resampling was done on either the training or testing sets: setting the class weights to ‘balanced’ simply penalizes wrong predictions made on the minority class.

We also trained LSTM models (implemented in Keras) to examine to what extent the sequence of local fixation events can be used to predict reading comprehension. Each unit in the sequences represents a fixation event, which was described by five features: 1) fixation duration, 2) average horizontal (x) position, 3) average vertical (y) position, 4) average pupil size, and 5) the elapsed time since the end of last fixation. We also explored using other features, such as the position of the previous and next fixation, and the distance between the current and previous fixation, but this did not improve model performance. The maximum sequence length was set to 160 units, which is longer than 85% of the sequences. For those shorter than 160 units, 0s were filled at the beginning and for the longer ones, the last 160 units were kept. The LSTM network included a LSTM layer followed by two fully connected layers and used the binary cross entropy loss function. We tuned the following hyper-parameters: the number of hidden nodes in the LSTM layer (e.g., 8, 16, 32), the number of nodes in the fully connected layers (e.g., 8, 16, 32), batch size (e.g., 16, 32, 64), and dropout rate (e.g., 0, 0.2, 0.4). The hyper-parameters for each model were selected through a random search in 4-fold cross validation with 50% of data for training, 25% for validation, and 25% for testing.

3.4 Validation, Metrics, and Statistical Comparisons

We used four-fold cross-validation at the participant level to ensure generalizability to new participants [16]. Here, the dataset was randomly split into four folds, with the data from a given participant only being in a single fold. The process was repeated 10 times with a different random partitioning of the folds for each run. The same fold assignments were used to train the Random Forest gaze models and baseline models per run, but fold assignments were not preserved for the LSTM models as they were run in a different pipeline. For the random forest models, we only used participants who completed all assessments for a fair comparison across time ($N=122$). All participants (irrespective of whether they completed

all assessments) were used for the LSTMs to maximize the data needed for these data-intensive models (N=147). Because there was very little variability across runs, predictions were pooled for each participant from all runs prior to computing accuracy measures.

Performance was evaluated using the area under the precision-recall curve (AUPRC), which ranges from 0 to 1 with the ratio of true classes to total data (i.e., base rates) indicating baseline classification by guessing. The AUPRC was used because it is well-suited for class imbalance unlike the receiver operator curve (ROC) which may provide an overly optimistic view of model performance when classes are imbalanced [29]. AUPRCs were separately computed for each assessment type and time on a per-participant basis, resulting in eight values per participant per classification model.

We used linear mixed models [21] via the lmer package in R [2] to compare the percent improvement of AUPRCs over baseline ($100 * ((AUPRC - \text{base rate}) / \text{base rate})$). Mixed models are the recommended approach due to the repeated nature of the data (i.e.,

eight values per participant per model). Here, participant was included as an intercept-only random effect. We probed significant effects with the emmeans (estimated marginal means) package using a false discovery rate (FDR) adjustment for multiple comparisons and a two-tailed $p < .05$ significant criterion.

4. RESULTS

4.1 Observed comprehension differences across depth and time

We first considered how comprehension changed as a function of depth and time (Figure 4). To examine the extent to which each assessment measured the same construct, we first computed the proportion correct for each assessment for each participant. From here, we computed the Pearson correlation between the comprehension scores for each pairwise assessment (Table 5 upper diagonal). Overall, the average correlation was 0.23 and ranged from -0.13 to 0.54, suggesting that there was some overlap but also unique information in what each assessment measured.

Table 5. Pairwise Pearson correlations of comprehension scores and gaze model probabilities averaged over participants. The upper diagonal (white) contains the correlation between comprehension accuracies across depth and time. The lower diagonal (grey) contains the correlations between random forest gaze model probabilities across depth and time.

Assessment	Rote: During	Rote: After Each	Rote: After All	Rote: Delay	Inference: During	Inference: After Each	Inference: After All	Inference: Delay
Rote: During	-	0.33	0.42	0.35	0.38	0.13	0.08	0.11
Rote: After Each	0.19	-	0.54	0.37	0.26	0.23	0.17	0.11
Rote: After All	0.51	0.04	-	0.47	0.44	0.22	0.18	0.18
Rote: Delay	-0.01	0.18	-0.02	-	0.35	0.26	0.25	0.18
Inference: During	0.62	0.05	0.51	-0.03	-	0.17	0.16	0.14
Inference: After Each	0.02	0.21	-0.10	0.10	-0.02	-	0.20	0.10

Inference: Delay	0.16	0.07	0.30	-0.10	0.18	-0.28	-0.07	-

Next, we examined how averaged participant-level comprehension measures varied as a function of depth and time using the following linear mixed-effects model: $\text{proportion correct} \sim \text{depth} * \text{time} + (1 | \text{participant})$. There were significant main effects ($ps < 0.01$) and interactions ($ps < 0.07$). For the main effect of comprehension depth, the rote assessment scores were significantly higher than the inference assessments ($B = 0.05, p = 0.01$). We then probed the significant interactions using emmeans. For rote comprehension, the mean score during reading was statistically equivalent to the score after reading each text ($p = 0.10$) which were both statistically greater ($p < 0.05$) than assessments after reading all the texts ($p > 0.05$) and at delay ($p > 0.05$), suggesting the following pattern: [During = After Each] > [After All = Delay]. This suggested that as people read, rote comprehension was stable but dropped upon completion of reading. Inference comprehension was stable across the reading session but dropped at delay with the pattern of significance: [During = After Each = After All] > Delay.

Figure 4. Predicted comprehension score from the mixed model as a function of depth and time. Error bands represent 95% confidence intervals.

4.2 Gaze Models can predict short and long-term reading comprehension

Gaze vs. shuffled (Random Forest and LSTM). Our first comparison examined whether the random forest gaze models performed significantly better than the shuffled models across depth and time (Figure 5): percent improvement \sim model type (shuffled vs. gaze)*depth*time + (1|participant). Overall, there was a significant interaction between model type and time ($p < 0.001$). All other interactions and main effects were non-significant (all $ps > 0.05$). When probing the model type x time interaction, we found that the gaze models outperformed the shuffled models for all cases (Figure 5; $ps < 0.001$) except for the “after each” model ($p = 0.37$), though the trend was in the expected direction. When we repeated the analysis for the LSTM model, the interactions and main effects of interest were non-significant (all $ps > 0.28$), indicating that they performed at chance in all cases and was indistinguishable from the shuffled model. Given the chance performance of the LSTMs, we focus on the random forest model results.

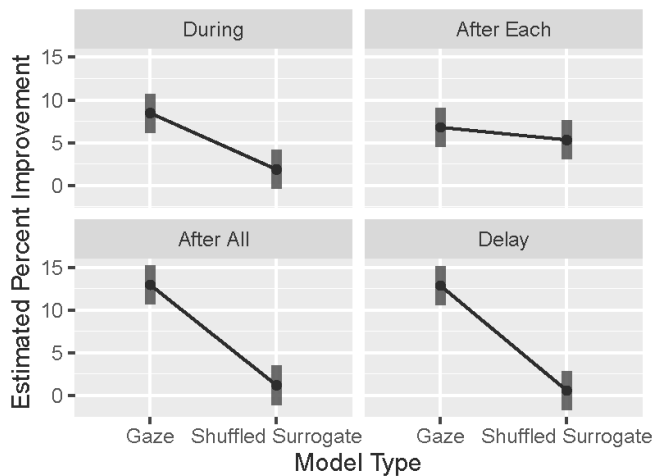

Figure 5. Gaze versus shuffled models. Comparison of the percent improvement for the gaze and shuffled models across time. Error bands represent 95% confidence intervals.

Gaze vs. context (Random Forest only). Our second analysis evaluated whether the random forest gaze models performed significantly better than the context models across depth and time (Figure 6): percent improvement \sim model type (gaze vs. context)*depth*time + (1|participant). Overall, there was a model by time interaction ($p = 0.002$), indicating that the gaze model outperformed the context model for all cases ($ps < 0.05$) except for the “after each” model ($p = 0.14$), though the trend was in the expected direction. Furthermore, there were no significant differences across time for the context model, as expected. However, for gaze, there were differences across time (Figure 6b). Specifically, the model performance for comprehension assessed after reading all texts was statistically equivalent to the delay model ($p = 0.90$) which was statistically higher than for assessments during reading ($p = 0.02$) which was in turn equivalent to assessments after each text ($p = 0.34$), suggesting the following pattern: [After All = Delay] $>$ [During = After Each]. There were no significant main effects nor interactions for comprehension depth, indicating similar patterns for rote and inference comprehension items.

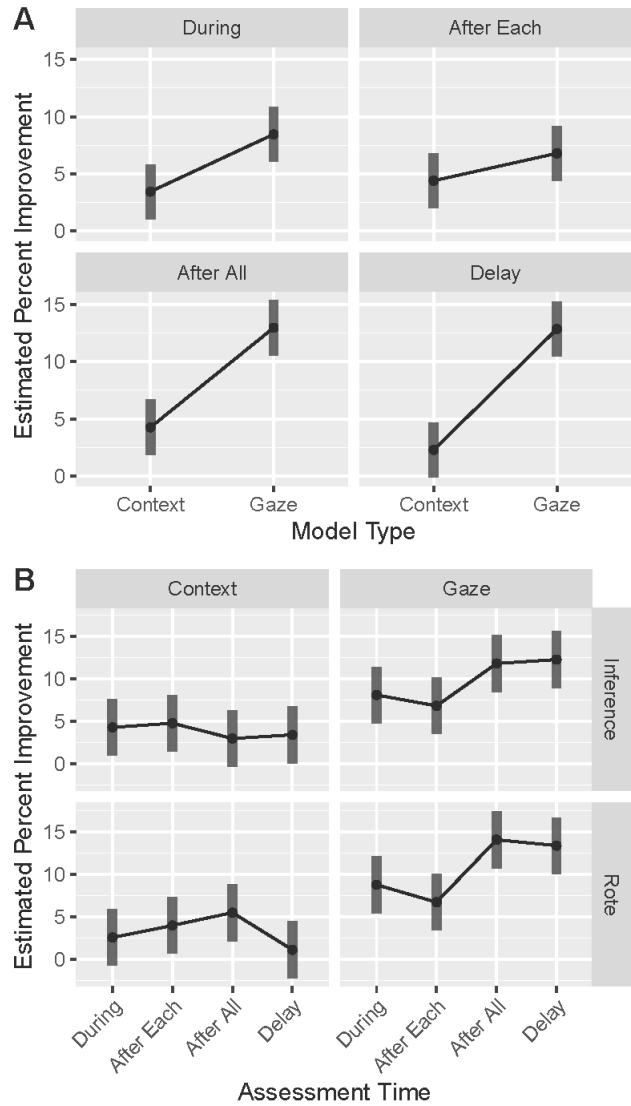

Figure 6. Comparison for percent improvement of gaze vs. context (A) across time and (B) across depth and time. Error bands represent 95% confidence intervals.

Table 6. Mean AUPRCs with 95% CIs computed over participants for the Random Forest models

Assessment	Gaze	Context	Base Rate
Rote: During	0.81 [0.80, 0.81]	0.77 [0.77, 0.78]	0.76
Rote: After Each	0.76 [0.76, 0.76]	0.74 [0.74, 0.75]	0.72
Rote: After All	0.75 [0.75, 0.76]	0.71 [0.71, 0.72]	0.68
Rote: Delay	0.75 [0.75, 0.75]	0.68 [0.68, 0.69]	0.68
Inference: During	0.80 [0.80, 0.81]	0.78 [0.78, 0.78]	0.75
Inference: After Each	0.78 [0.78, 0.78]	0.76 [0.76, 0.76]	0.73
Inference: After All	0.80 [0.80, 0.80]	0.74 [0.74, 0.75]	0.73
Inference: Delay	0.71 [0.70, 0.71]	0.65 [0.65, 0.65]	0.63

Model discrimination. To understand to what extent the random forest gaze model predictions were generally picking up on the same comprehension constructs, we computed the average model probabilities for each participant and assessment and correlated them (Table 5, grey diagonal). Overall, the average correlation was 0.10 and ranged from -0.28 to 0.62, suggesting that the models were

discriminating among the different comprehension assessments, with the highest correlation being between Rote During and Inference During, suggesting the model might be picking up on similar gaze patterns for both ‘During’ assessments.

4.3 Feature Analyses (Random Forest only)

We examined impurity-based feature importances from the Random Forest model to determine which aspects of gaze were most predictive of comprehension and whether the predicted features differed across comprehension types and delays. Here, we computed the correlation of the feature importances between each pairwise assessment for each run and then averaged across runs (Table 7). The grand average correlation excluding the diagonals was 0.15, indicating some overlap of feature importances across depth and time despite the broad range of features. Overall, the rote measures showed a mean $r_s = 0.23$, with a range from -0.01 to 0.35 (light grey in Table 7), with rote comprehension during reading showing the lowest correlations with the other rote assessments ($r_s = -0.01, 0.06$, and 0.16 compared to $r_s = 0.27, 0.30$, and 0.35 for the other rote assessments). Conversely, the inference comprehension measures showed a wide range of correlations with each other (from $r_s = -0.14$ to 0.57). This is in part due to the delayed inference assessments showing negative correlations with all other inference assessments ($r_s = -0.14, -0.05, -0.10$), while all other correlations

were positive, with inferencing assessed during reading and after reading all texts showing the highest correlation ($r = 0.57$). Correlations among rote and inference assessments showed a mean $r_s = 0.15$, with a range from -0.10 to 0.57 and the strongest correlations among the delayed rote assessments and inferencing assessed during the session (r_s from 0.26 to 0.57). Thus, the pattern of inter-associations among feature importances is mixed.

We then assessed which features were most important to comprehension across depth and time. To this end, we first computed the overall mean feature importances for each run across all assessments and averaged across runs. We then grouped and averaged each set of statistical features together to assess relative importance of each feature type. For example, for the “fixation duration” feature set, the feature importances for the eight statistical features of fixation duration were averaged together. We found that the top four feature categories were: the selective regression path duration (average importance = 0.0103), regression fixation proportion (average importance = 0.0097), calibration error (average importance = 0.0094), and interest area dwell time (average importance = 0.0094). Although these features were the most important, it appeared that all features contributed to model performance as they were all greater than zero (Figure 7).

Figure 7. Rank-ordered mean feature importance across assessments.

Table 7. Pairwise feature importance Pearson correlations averaged over runs

Assessment	Rote: During	Rote: After Each	Rote: After All	Rote: Delay	Inference: During	Inference: After Each	Inference: After All	Inference: Delay
Rote: During	-	-0.01	0.16	0.06	-0.01	0.10	-0.10	0.02
Rote: After Each		-	0.27	0.30	0.35	0.10	0.32	-0.05
Rote: After All			-	0.35	0.06	0.35	0.05	-0.03
Rote: Delay				-	0.57	0.26	0.46	-0.04

5. DISCUSSION

Our goal was to investigate the relationship between eye tracking and reading comprehension outcomes by identifying whether gaze-based models of reading could predict different depths of comprehension at varying degrees of delay. We discuss our main findings followed by applications, and limitations.

5.1 Main Findings

Beginning with *observed* rote and inference comprehension, we found that accuracies were highest during reading and dropped when assessed at seven days post-study, which is what we would expect. Nevertheless, the gaze-based Random Forest models could still predict both comprehension types significantly better than baselines during all stages of reading except for the “after each” assessment, which followed the same trend. Furthermore, we found a pattern such that gaze became more predictive of comprehension as time progressed within the main reading session, with performance peaking for assessments administered after reading all the texts.

As noted in Figure 1, theories of reading comprehension posit that readers first attend to and encode the text at the surface-level to form a text-based representation followed by a situational (mental) model via bridging inferences and elaboration, which is then consolidated into long-term memory. While there are reasons to expect that gaze should predict rote, short-term retention of information that simply requires attention to and basic encoding of the text (as others have shown – see Table 1), our results indicate that it is also related to the processes underlying deep, long-term comprehension which are typically viewed as internal cognitive processes that occur in the absence of eye movements [40]. To our knowledge, this is the first study to show that gaze during reading is predictive of deep, long-term comprehension since previous work has mainly focused on rote comprehension [55].

Second, while our models demonstrated participant-level generalizability (in contrast to prior work – see Table 1), the percent improvements of our models relative to baseline were admittedly modest. However, as indicated in the Introduction, the present goal was not to develop the most predictive model but to examine the predictive accuracy of a set of eye gaze features across comprehension depth and time. As such, we did not include many pertinent non-gaze features (e.g., text difficulty; item difficulty) that may be highly predictive when coupled with eye gaze.

It should be noted that D’Mello et al. [16] found that a gaze model yielded very high accuracies (AUROCs close to 0.9) for modeling rote comprehension during reading. One key difference is the D’Mello et al. study only measured rote comprehension with the items triggered in response to an automated mind-wandering detector. This may have engendered a very different reading strategy (and corresponding eye movement patterns) entailing skimming the text to identify targets for subsequent questions (the authors acknowledge this in Mills et al. [14]) than the more general reading strategies required here given the variety of comprehension measures. Thus, the high-accuracy scores reported in D’Mello et al. [16] might not generalize more broadly.

Third, there was overlap in feature importances across depth and time, with the top four predictive features being the selective regression path duration, regression fixation proportion, calibration error, and dwell time per interest area. It is possible these features capture measures of processing later in the time course of reading, and rereading text for comprehension repair, both of which are key to higher-level comprehension [9]. Dwell time, for instance, reflects the processing time (early and late), and in combination with selective regression path duration could be indicating processing difficulty later in reading a page (e.g., low selective regression path duration but high dwell time suggests difficulties only later on in the comprehension of a page [36]). Regression fixation proportion is also an important indication of comprehension repair [46, 52], and has been used in previous gaze models of comprehension [55]. Because it is difficult to interpret the direction of association of individual features in random forest models (due to interactivity), these patterns are speculative, and await further empirical data.

Historically, regressions have been one of the more difficult aspects of eye behavior to capture [48]. While it has long been posited that regressions occur when a reader experiences a difficulty in comprehension which triggers the reader to look back in the text to repair their comprehension deficit [9], several studies have linked an increase in regressions to better comprehension [28, 52], while others show the opposite effect [31]. Regression fixation proportion, the feature with the second highest average importance, indicates how often readers did not understand the text and acted to repair their comprehension [46], and might also be a way to distinguish better from poor readers, as better readers reread less and are more adept at redirecting their gaze efficiently [64]. Figure 8 shows an example of gaze behavior that leads to accurate and inaccurate comprehension. Note that in Figure 8A there are more regressions (seen as

long saccades cutting across multiple lines of text) and more reading in the middle of the text- an area which might have been giving the student some difficulty. On the other hand, the gaze on the page with inaccurate comprehension demonstrates a more even pattern of eye movements: possibly less attention to the text and less comprehension repair.

We also found that calibration error was predictive of comprehension. Indeed, prior work has found that greater pre-trial fixation dispersion is predictive of mind wandering [65]. Because mind wandering is negatively related to comprehension [14, 54], it might be the case that calibration error (and pre-trial fixation dispersion) is also negatively predictive of comprehension.

5.2 Applications

This research is a step towards gaze-based computational models of reading comprehension. Such models can be integrated into adaptive systems that trigger assessments and provide opportunities to correct comprehension deficiencies when lapses of comprehension are detected (similar to the gaze-based models that adaptively trigger interventions when mind wandering is detected [4, 13, 19, 27]). Given the modest accuracies obtained in the present study, the most immediate applications are in interventions that can be applied in a ‘fail-soft’ manner. These do not disrupt the student and do not pose any harm if comprehension is miss-classified. Interleaving questions during reading is one such example [57], as is encouraging re-reading at the end of a text or adaptively selecting post-reading assessments based on model-assessed comprehension during reading.

With further research, more fine-grained interventions that target different depths (rote vs. inference) and timescales (short- or long-term comprehension) are also feasible. For instance, if a student is preparing for an upcoming examination, models and interventions supporting long-term comprehension might be preferred compared to cases where short-term retention suffices (reading a short article). Other possible interventions include reducing textual difficulty or providing scaffolds when comprehension difficulties are detected [53] or even increasing difficulty when the reader is not being sufficiently challenged (e.g., the reverse cohesion effect [44] where good comprehenders benefit more from texts with lower cohesion).

In addition to direct intervention, the models also have applications with respect to assessment. For example, if the rote and inference models consistently (i.e., across multiple participants) predict high and low comprehension scores on a given page, respectively, this might suggest that there is a cohesion gap with respect to the content on the page that is impeding inference generation.

5.3 Limitations

Like all studies, ours has limitations. First, we only examined gaze on a particular page, thereby overly constraining the models. Therefore, there may have been other factors, such as gaze on the preceding page, that might have been relevant to reading comprehension but were not incorporated into the gaze models.

Furthermore, it is possible that the lab settings changed behaviors relative to how participants would behave in more ecologically valid settings. Specifically, participants donned other sensors and face masks to adhere to COVID safety procedures, which may have resulted in discomfort and unnatural reading behaviors (but see Table 4 which showed high horizontal saccade proportion and percent of fixations in interest areas indicating people were on task).

Next, the classes in the data were imbalanced, and we chose to not balance the classes since this might not capture real-world variation in comprehension. However, class imbalance might have introduced a confound when comparing model performance over time in that accuracies reflected the level of class imbalance rather than differences in comprehension depth and time. To address this possibility, we did test models on balanced classes and results did not change.

Although the present study demonstrated cross-participant generalization, participants only read one set of texts and therefore it is unknown whether the models would generalize to new texts. That said, because we used features which capture relative changes in gaze (e.g., angles) as opposed to absolute, stimulus-dependent values (e.g., coordinates), we think they are likely to generalize to similar contexts. To this point, prior work using similar global page-level features demonstrated cross-task-generalization for mostly rote comprehension after reading [55], but this is an empirical question for comprehension models at different depths and time delays.

Finally, the LSTMs yielded chance-level performance. This was despite using features that reflected relative changes in gaze (e.g., relative angles) in contrast to prior LSTM work that used absolute fixation coordinates [1]. It might be the case that there are not generalizable patterns in local gaze dynamics that are predictive of comprehension. Alternatively, and more likely, there might not have been sufficient data to learn these patterns should they exist given the relatively small number of training examples compared to the number of parameters in the LSTM models.

5.4 Concluding Remarks

Reading comprehension is a complex cognitive process that is critical to daily tasks. It unfolds across different depths and over time, raising the question of what eye movements known to index initial encoding of information can reveal about the processes underlying deep, long-term comprehension (Figure 1). Our results show, for the first time, that eye movements have the potential to provide an index into deeper inference-level comprehension assessed as late as a week after reading, indicating they capture far more than temporary surface-level encoding of a text.

ABSTRACT

A child's ability to understand text (reading comprehension) can greatly impact both their ability to learn in the classroom and their future contributions to society. Reading comprehension draws on oral language; behavioural measures of knowledge at the word and sentence levels have been shown to be related to children's reading comprehension. In this study, we examined the impact of word and sentence level text-features on children's reading comprehension. We built a predictive model that uses natural language processing techniques to predict the question-level performance of students on reading comprehension tests. We showed that, compared to a model that used measures of student knowledge and subskills alone, a model that used features of sentence complexity, lexical surprisal, rare word use, and general context improved prediction accuracy by more than four percentage points. Our subsequent analyses revealed that these features compensate for the shortcomings of each other and work together to produce maximal performance. This provides insight into how different characteristics of the text and questions can be used to predict student performance, leading to new ideas about how text and reading comprehension interact. Our work also suggests that using a combination of text features could support the adaptation of reading materials to meet student needs.

Keywords

Reading comprehension, text-features, early education, natural language processing, learner modelling

1. INTRODUCTION

Elementary students' ability to understand text, or their reading comprehension (e.g., [30]), supports their successful participation in both education and society [7]. It is well-established that reading comprehension is determined, at least in part, by children's skill in oral language [19], with strong impacts of oral language skills—at both the word and sentence levels (i.e., vocabulary and syntax)—on reading comprehension skills (e.g., [11]). We built on these ideas and tested whether automatically extracted indicators of vocabulary and syntax complexity would be indicative of reading

comprehension scores. To address this question, we extract features from a widely used standardised measure of reading comprehension [34]. Thus, we introduce various text-based measures that can be automatically extracted. After extracting these features, we trained and evaluated models. We then tested their relative performance and analyzed the added value of including all of these features in the context of a predictive neural network model. Our modelling approach could also be used to analyze new reading comprehension tests or tasks, enabling others to better understand how student knowledge and subskills interact with the characteristics of the text to influence reading comprehension.

The educational value of this work lies in informing the optimal selection of texts and questions to support the development of children's reading comprehension. Predictions on where mistakes would likely be made by individual students could be used to support downstream tasks, such as adapting systems so that both the comprehension questions asked and the assigned texts challenge students appropriately [57]. Further, interpreting the predictions made by such models and the model attributes may improve our understanding of what contributes to reading comprehension challenges, which could support the design of optimally effective interventions.

2. RELATED WORK

The single most widely cited theory of reading comprehension is the Simple View of Reading [19]. According to this theory, children's reading comprehension is determined by the product of their word reading and their oral language skills. Behavioural research since its development has made good progress in identifying the individual oral language skills that support reading comprehension. Two of the best-established lie in vocabulary, or knowledge of individual word meanings, and syntactic awareness, or the ability to reflect on or manipulate spoken sentences [5]. Each of vocabulary and syntactic awareness are strong predictors of children's levels of reading comprehension [54]. For instance, Deacon and Kieffer [11] showed that children's ability to manipulate sentences in Grade 3 predicted gains made in reading comprehension between Grades 3 and 4, a contribution similar in magnitude to that of word-level reading. There is an even larger body of research demonstrating the impacts of children's vocabulary knowledge on their ability to understand what they read [43]. Together, this body of work shows that individual differences in oral language skills—at both the word and sentence levels—are related to children's ability to understand the texts that they read.

But what about the features of the texts themselves?

Y. Nie, H. Deacon, A. Fyshe, and C. D. Epp. Predicting reading comprehension scores of elementary school students. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 158–170, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

It is well-established that the features of a text impact a person's comprehension of that text. These features can be identified manually, or we can use techniques from natural language processing (NLP) to identify the qualities of a text and extract their associated features. The field of NLP has developed many approaches that can be used to identify syntax, semantics, and word use. There are also methods that can identify the broader relationships in people's language use once those methods have been trained with corpora.

Of the techniques that do not require training with a corpus, are those that predominantly count elements of a text to derive measures that can then be used as features in a model. One widely-used tool that employs this approach to capture the syntactic complexity of sentences is Coh-Metrix. Coh-Metrix tracks the linguistic properties of a text using features such as the average length of words in a sentence or number of sentences in a paragraph [23]. The most recent version of Coh-Metrix also incorporates the scoring of connections between sentences, such as noun overlap between adjacent sentences and causal cohesion (sentences that are linked by causal connectives) [22].

Given the importance of syntactic complexity to reading comprehension, it is not surprising that Coh-Metrix has been used to extract the linguistic properties of texts to predict student reading comprehension scores in the context of the iStart tutoring system [1]. iStart provided training in active reading strategies (i.e., self-explanation) to support improved reading comprehension. In this case, features were extracted from student self-explanations and used to predict reading comprehension scores on the Gates MacGinitie test. These analyses provided insight into how the language produced by students can be used to predict their overall reading comprehension performance. Including the simple linguistic features that were extracted using Coh-Metrix accounted for additional variance in student performance, which demonstrated that the inclusion of such features has the potential to support learner modelling tasks.

Building on the idea of Coh-Metrix, AMOC aimed to automatically capture the semantic complexity and context of a text [8]. It uses similar approaches to those embedded within Coh-Metrix and adds semantic links using dictionary-like tools and Word2Vec. These links are then used to output a graph representation of the semantic model (context) associated with a segment of text.

Language models are a potential alternative approach to automatically capturing the syntactic and semantic or contextual features of a text. Existing language modelling approaches vary in complexity from relatively simple probabilistic representations of language (e.g., n-grams) to more complex neural network-based approaches (e.g., RNNs). All of these language modelling approaches require a corpus of data from which they can learn language-usage patterns.

Assuming you have access to a corpus, n-grams can be used to capture both the syntactic and semantic constraints in a text by determining the probability with which words are expected to follow one another. Mitchell et al [39] investigated using trigrams (i.e., n-grams of length 3) to analyze reading times and understand reading comprehension. They used these n-grams to estimate the lexical surprisal associated with a text and found a correlation between the surprisal measure and reading time. Similarly, a study by Hofmann et al [29] used a trigram language model to predict reading speed from eye-tracking data while acknowledging that trigrams do not account for long-range semantic effects (unlike AMOC and some more advanced language modelling approaches). The finding that reading time may be related to comprehension is not directly

measurable with n-grams; rather, they enable the extraction of measures, such as lexical surprisal, that can be used to predict reading time.

To better model long-range semantics and sentence meaning, recurrent neural networks (RNN) have been used to improve predictions of reading comprehension scores and reading times. Frank and Hoeks [18] used a specific type of RNN, called long short-term memory (LSTM), to correlate reading times with comprehension. Through this investigation, they found RNNs can capture both the structure and semantics of a long text thus improving reading time predictions. Transformer-based neural network models [53], such as BERT [15], have shown superior performance over RNNs when conducting various NLP tasks, such as neural machine translation [31] and sentiment analysis [38]. This suggests the use of transformer-based models may support improved performance when predicting reading comprehension scores.

Outside of the use of language models, other approaches to representing student performance (learner or student models) have been attempted in systems that rely on language as a primary source of interaction with the student. One project aimed to predict student scores on a post-test using the logs of student interactions from intelligent tutoring systems (ITS) that teach physics and probability using word-based problems [35]. Mao et al. [35] collected data from two ITSs and used the training content to predict student post-test results. They trained a Bayesian knowledge tracing (BKT) model to infer whether students had learned the intended units of knowledge (knowledge components). Their results showed BKT's prediction is more accurate than that of the LSTM on its own. A model that jointly used BKT and LSTM to predict post-test scores outperformed both individual models, suggesting the potential for combining different approaches to capturing student capabilities in relation to the complexities of the learning and assessment materials. This initial work has provided promising results by incorporating representations of the text as part of the prediction of student performance. However, the skill representations used by BKT models typically require the expert labelling of skills along with the careful development and sequencing of questions, and this sequencing is often specific to an ITS. Consequently, it cannot be easily generalized or applied to other prediction tasks.

Moreover, these types of approaches have yet to be applied to modelling student reading comprehension within e-learning systems. Within the instructional domain of literacy, previous attempts at modelling student skills or knowledge have focused on understanding student reading strategies [24], improving their vocabulary acquisition [14, 17], or improving reading proficiency (decoding and fluency) [2, 40], as steps towards supporting literacy. In these cases, the logs of student activities, their interactions with the system, and the texts they produce are used to model student knowledge and skills. These types of models are then used to provide feedback to students [13], inform teachers of student activities and skills, or adapt learning content [12, 13]. Consistent with the above modelling goals, the training provided by the e-learning systems that aim to support student literacy has tended to focus on exposure-based approaches [3, 12], stealth assessment during game play [17], and the training or modelling of reading strategies [17, 21]. In the research on the use of software to support reading proficiency, tests of reading comprehension have been used to evaluate the effectiveness of the system [1, 16, 40] rather than being an integral part of the content that is adapted.

We do not yet have a model that can predict student performance on comprehension questions by capturing students' underlying oral language skills while accounting for text features. A model that

could do this would support the selection of both texts and questions within an adaptive learning environment like an ITS. The present study is a first attempt at developing such a model. It asks, ‘What is the added value of including text features as input when predicting the correctness of question answering in reading tasks?’

3. METHODS

To answer the above question, we applied supervised learning to archival data from a study of children’s reading development. We compared models that include different features we extracted from a reading comprehension test to a baseline that only included measures of student oral language skills and language knowledge.

3.1 Participants

This study was approved by the Social Sciences and Humanities Research Ethics Board of Dalhousie University. All children participated with parental consent and child assent. We recruited Grade 3 students from a combination of urban and rural public schools in Nova Scotia.

There were 139 students with a mean age of 8.80 years at the time of testing ($SD = 0.29$; range = 8.15–9.37 years). Of these students, 74 were boys and 65 were girls. Based on parent-report, most children were native speakers of English; 4 spoke a language other than English at home.

Table 1 shows the children’s performance on standardized measures (see section 2.3.2 for details on these measures). Student scores suggest that participants were typically developing.

Table 1. Descriptive Statistics for the Individual knowledge and sub-skill measure scores

Measure Name	Rel.	Mean	SD	Min	Max
PPVT-M	.84	31.95	4.93	19.00	46.00
CTOPP	.93	23.01	6.10	8.00	33.00
Syntax Awareness	.74	9.57	3.27	2.00	16.00
TOWRE	.93	56.97	14.40	4.00	87.00
WISC	.91	13.17	2.31	8.00	20.00
WRMT-3	.97	60.97	12.72	3.00	83.00

Note. Raw scores are reported for all measures. Reliability (Rel.) was retrieved from the instrument manual. SD - standard deviation.

3.2 Procedures

The measures reported on here were completed as a part of a larger battery, presented in two individual sessions and one group session (up to 12 children). We only report measures relevant to the present study.

In session 1, participants completed the Sight Word Efficiency subtest of the Test of Word Reading Efficiency (TOWRE), amongst other measures.

Session 2 was completed an average of two days after the first individual session ($M = 1.93$, $SD = 1.39$; range: 1 to 9 days). Participants completed the Word Identification subtest of the Woodcock Reading Mastery Tests (WRMT), a modified version of Peabody Picture Vocabulary Test (PPVT-M), Digit Span from the Wechsler Intelligence Scale for Children (WISC), and Elision from the Comprehensive Test of Phonological Processing (CTOPP).

The group session was completed an average of just over 2 days after the first individual session ($M = 2.27$, $SD = 2.12$; range: 1 to 9 days). In the group session, children completed the Comprehension subtest of the Gates–MacGinitie Reading Tests.

3.3 Measures

3.3.1 Reading Comprehension Measure

To measure reading comprehension, we administered the Level 3 Comprehension subtest of the fourth edition of the Gates–MacGinitie Reading Tests¹ [34] according to manual instructions. The manual reports a reliability of .93 for this instrument. Students were given 35 minutes to read 11 short texts and answer the three to six multiple choice questions following each text.

We aim to predict whether students correctly answered individual questions for each of the texts from this test.

3.3.2 Individual Knowledge and Sub-skill Measures

To incorporate differences in student oral language skills and knowledge, we administered tests to assess their vocabulary, phonological awareness, working memory, word reading fluency, and word reading accuracy. The descriptive statistics for these measures are shown in Table 1, and the instruments are detailed below.

Vocabulary knowledge. To measure receptive vocabulary knowledge, a shortened version (51 items) of the PPVT-3 [36] was used. For each item, students chose which of a set of four black-and-white pictures referred to an orally presented word. This shortened version (PPVT-M) has been validated with Grade 1 to 3 children [11].

Syntactic awareness. This was measured with an 18-item task in which children corrected sentences based on Deacon and Kieffer’s framework [11]. For instance, children are presented orally with the scrambled sentence, “From the library were stolen the books.” and they were asked to fix the sentence so that it sounds right (in this case, “the books were stolen from the library”). Children were given 3 practice items prior to completing the test.

Phonological awareness. We measured phonological awareness with the Elision subtest of the second edition of CTOPP [55]. Participants were asked to repeat words without pronouncing certain syllables or phonemes (e.g., *bold* without /b/). Phonological awareness was measured because of its association with word reading and reading comprehension [10].

Working memory. Given established correlations of working memory with both reading comprehension and word reading in 9-year-olds (e.g., [5]), we measured it using the Digit Span subtest of the fourth edition of the WISC [56]. In this task, participants repeat a series of digits of increasing length in the order given or the reverse order.

Word reading fluency. We measured word reading fluency using the Sight Word Efficiency subtest of the TOWRE [51]. Participants were given 45 seconds to read a list of words as fast as possible.

Word reading accuracy. We measured word reading accuracy with the Word Identification subtest of the WRMT-3 [58]. Students read words that became increasingly difficult.

¹ The test content is available at <https://edinstruments.com/instruments/gates-macginitie-reading-tests-4th-edition-gmrt-4>

3.3.3 Text-based Features

We extracted both word- and sentence-level text-based features. The features included sentence complexity, rare word use, lexical surprisal, and sentence context. The descriptive statistics of all extracted features can be seen in Table 2. Since rare word use represents a proportion of the text, it produces a single input feature. Similarly, question complexity produces a single input feature because questions are one sentence long. In contrast, lexical surprisal and sentence complexity for the text, which contains multiple sentences, are represented using three features: mean, standard deviation, and maximum.

3.3.3.1 Sentence Complexity

Complex sentences increase working memory load, which makes reading comprehension challenging [20]. We used the depth of the parse trees from the text as a proxy for sentence complexity. Each parse tree identifies the grammatical constituents of a sentence and communicates an aspect of a sentence’s complexity through its structure.

Table 2 Descriptive Statistics for the Text-based Features

Feature Name	Mean	SD	Min	Max
Sentence Complexity				
Mean	8.41	0.88	7.18	10.33
SD	2.32	0.74	1.34	3.96
Maximum	12.33	1.75	10.00	16.00
Lexical Surprisal				
Mean	.44	.30	0	1
SD	.49	.26	0	1
Maximum	.56	.30	0	1
Rare Word Use	.46	.06	.35	.56
Question Complexity	8.37	1.94	6	13

Note. *SD* - standard deviation.

To obtain this sentence-level measure, we first tagged the sentences from each text in the reading comprehension test with their associated parts of speech (POS). From the tagged words, we built parse trees using a probabilistic context-free grammar (PCFG). Both tagging and parsing were performed by the CoreNLP tagging tool [52].

Figure 1 shows a parse tree for the “Snow turns blue when blue ice-worms live in it.” This sentence is taken from one of the texts that was used to measure reading comprehension.

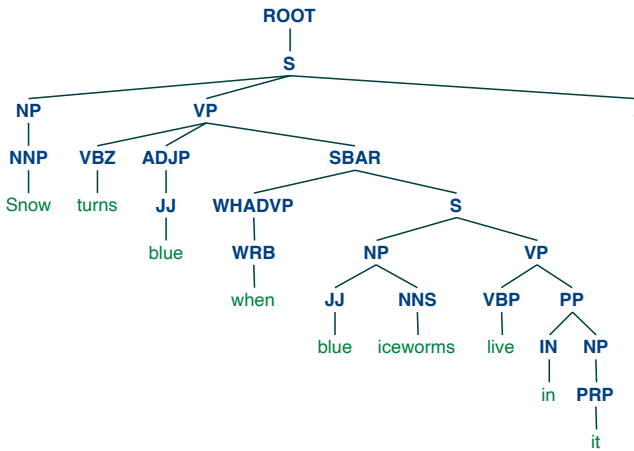

Figure 1. The parse tree with the highest probability for the sentence “Snow turns blue when blue ice-worms live in it.”

The PCFG assigns a probability to each potential parse of a sentence. The highest probability parse is selected; its associated tree is used to derive our measure of sentence complexity. We take the depth of the tree for each sentence in the text and derive three measures per text: the maximum tree depth, the average depth, and the standard deviation of tree depths. As an example, the parse tree in Figure 1 has a depth of 10.

3.3.3.2 Rare Word Use

The number of rare words in a text influences reading comprehension; one rare word can lead to a complete miscomprehension of a sentence [23]. Given this fact, it is important to capture the amount of rare word use in a text when assessing reading comprehension. We model vocabulary rarity by quantifying the percentage of rare words in each text of the test. This language feature is expected to represent the difficulty of the text on a vocabulary level.

To calculate the percentage of rare words, we first used the Children’s Book Test corpus [27] to compute all word frequencies. We then chose a cut-off threshold (700) for determining word rarity. The top 700 frequent words occupy 1.5% of all distinct words and account for 60% of the corpus content. The most frequent 700 words were extracted to form a common word list. We consider words rare if they are not contained in the common word list.

Figure 2. Word frequency in the Children’s Book Test dataset. The x-axis is in \log_2 scale. The dashed line is the cut-off at 700; any words with indices that exceed the cut-off are excluded.

To compute the percentage of rare words in a text, we count the number of rare word tokens (i.e., those that do not appear in the common word list) and divide that by the total number of word tokens in the text. This percentage is our measure of rare word use.

$$\text{Rare Word Use} = \frac{\text{rare word count}}{\text{total word count}}$$

3.3.3.3 Lexical Surprisal

The surprisal of a word in a sentence is related to the amount of cognitive work required for human comprehension of that word within the sentence [33], and it is predictive of reading times [46]. To model this word-level feature, we needed to determine the likelihood of one word appearing right after another word.

Since our prediction task is targeted towards Grade 3 students with elementary-level vocabulary, we built bigrams (n-grams of length 2) from the Children’s Book Test dataset [27]. We then derived the lexical surprisal value [25] for each sentence in the Gates-MacGinitie texts by computing the mean word-level surprisal. Min-max normalization [42] was used to ensure the values are on a similar scale to the other features. After extracting the surprisal of each

sentence in the text, we compute the mean, standard deviation, and maximum of all sentence surprisal values for the whole text. These normalized values are used for the lexical surprisal input feature.

3.3.3.4 Sentence Context

The sentence-context feature employs a prevalent method for representing text - a universal sentence encoder – which incorporates context, meaning, sentence complexity, and word order information [6]. The embedding represents the text in the form of a vector. To obtain these embeddings, we used the pre-trained MPNet encoder [49], which is a transformer-based language model. MPNet was used to encode both the text and questions into vectors with 768 dimensions. The generated universal sentence embedding was used to represent the general context of the texts.

3.4 Prediction Task

The goal of each model is to predict whether a particular student would answer a specific reading comprehension question correctly or incorrectly based on measures of their individual knowledge and sub-skills and the features of the texts (see Figure 3).

The input to our task includes features derived from the textual content of the Comprehension subtest of the Gates–MacGinitie Reading Tests and students’ individual knowledge and sub-skill measures that provide information about their oral language skills. Since each of these instruments provides scores on different scales, we applied min-max scaling normalization [41]. This allows all measures to be placed on the same scale, thereby facilitating comparisons. This type of normalization also facilitates model accuracy in classification tasks [4].

Of the questions students answered, 54 % are labelled correct and 46 % incorrect. Due to the limited size of our data (6,576 entries), all entries were used during model training and testing.

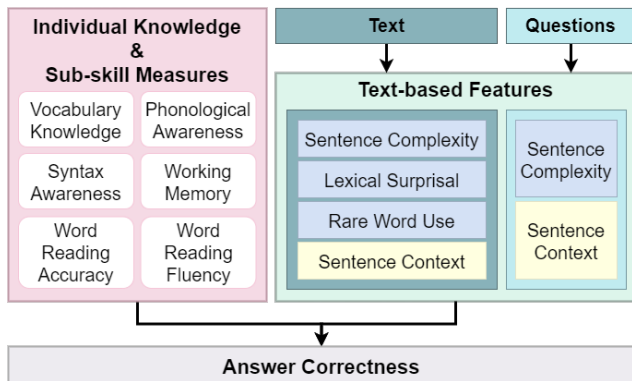

Figure 3. The features used in our prediction task, grouped by measure (child) and feature (text) source.

3.5 Models

3.5.1 Base Model

The Base Model is a fully connected neural network classifier that takes all sub-skill measures as input to predict whether a student will answer each question correctly. Given that the input layer is relatively small with 6 features, our network has two hidden layers each with 12 nodes.

3.5.2 Text-based Feature Models

Our proposed models augment the Base Model with the language features of the text. They incorporate four features: sentence complexity, vocabulary rarity, word surprisal, and context.

3.5.3 Base + Sentence Complexity Model

This model is a fully connected neural network that includes all sub-skill measures and sentence complexity text features as input. The network has two hidden layers, both of which have 18 nodes and use the ReLU activation function. Since we are predicting the probability of a binary event (correct/incorrect), a sigmoid layer follows the hidden layer. Loss is calculated using binary cross entropy. Adam optimization [32] is also used.

3.5.4 Base + Rare Word Use Model

This model is a fully connected neural network that includes all sub-skill measures and rare word use as input features. The network has two hidden layers, both of which have 14 nodes and use the ReLU activation function. Following the hidden layer there is a sigmoid layer. Loss was calculated using binary cross entropy and optimization was done using Adam.

3.5.5 Base + Lexical Surprisal Model

This model is a fully connected neural network that includes all sub-skill measures and lexical surprisal features as input. The network has two hidden layers, both of which have 18 nodes and use the ReLU activation function. Following the hidden layer, there is a sigmoid layer and the loss was calculated using binary cross entropy. Adam was used for optimization.

3.5.6 Base + Context

This model, shown in Figure 4, is a neural network that includes two parts, sub-skill measures (Base Model) and context as represented through sentence embeddings.

The six sub-skill measures are first passed through a 6x12 dense layer.

The sentence context part starts with two vectors: one represents the embeddings from the text and the other that of the question. Each vector is then passed through a 764x64 dense layer and transformed into 64 nodes.

We concatenate the sentence embedding and sub-skill measures into one fully connected layer followed by a hidden layer with 128 nodes. A sigmoid layer follows the hidden layer. Once again, loss was calculated using the binary cross-entropy function, and Adam optimization was performed.

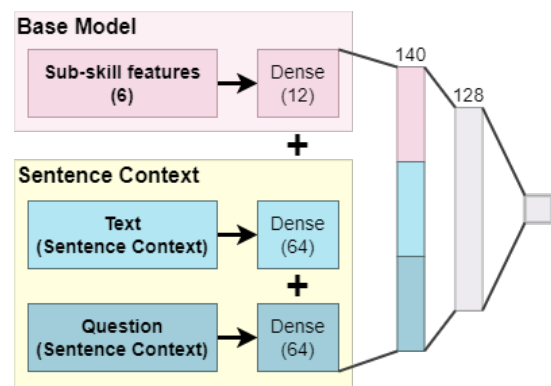

Figure 4. Neural network structure for the Base + Context Model. The “+” indicates the concatenation operation from the previous three dense layers.

3.5.7 Full Model

The Full Model (Figure 5) consists of all sub-skill measures from the Base Model, sentence complexity, vocabulary rarity, word

surprisal, and sentence context. This should allow us to best capture the language features of the tests that might affect children’s reading comprehension performance.

We manually tuned the number of nodes in each layer. Specifically, for the dense layer after concatenating sub-skill and text-based features, we tried {12, 24, 48, 96}; 24 nodes had the best performance. For the dense layers after vector embedding, we tested values among {32, 64, 128, 256} and picked 64. Both dense layers from the vector embeddings are kept at the same size, and no individual testing was done. For the last layer, where all three hidden layers were combined, we tested among {32, 64, 128, 256} for number of nodes and 128 nodes yielded the best result.

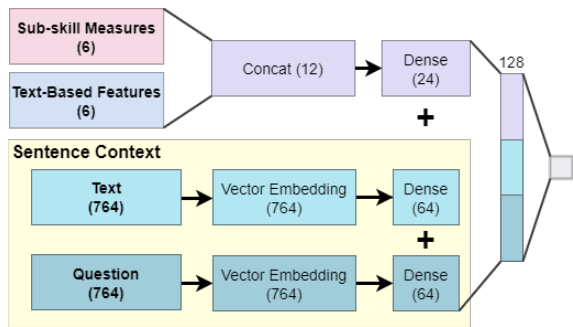

Figure 5. Neural network structure for the Full Model, where all measures and features are used as input. The “+” indicates the concatenation operation from the previous three dense layers.

3.5.8 Hyperparameter Tuning

For all of our models, we tested three learning rates: .01, .001, and .0001. The learning rate of .001 returned the best result for all models. Table 3 shows tuning details for the number of nodes in the two dense layers that are part of our models. We kept the node number the same for both dense layers during tuning.

Table 3. Hyperparameter tuning details

Model	Values Tested	Value Chosen
Base	6, 12, 24	12
Base + Sent. Complex.	9, 18, 36	18
Base + Context	64, 128, 256	128
Base + Rare Word Use	7, 14, 28	14
Base + Lexical Surprisal	9, 18, 36	18

Note. Sent. – Sentence, Complex. – Complexity

3.6 Model Evaluation & Analysis Procedures

We used k-fold cross-validation with $k = 10$ to evaluate all models. Since predicting whether a student answers a question either correctly or incorrectly is equally important, all models were optimized for accuracy during hyperparameter tuning. The whole training process is done within approximately two hours on a commodity machine after hyperparameter tuning.

We used McNemar’s test to determine whether there is a significant difference between the Base Model and all other models. McNemar’s test compares machine learning based classifiers in pairs by looking at the correct and incorrect classification each model makes. It can distinguish model differences even if the models yield similar accuracy results [37]. Bonferroni step-down correction was used to control for multiple comparisons; the adjusted p-values are reported.

Since it is not enough to determine which model performs best, we used integrated gradients [50] to examine feature importance. Integrated gradients quantitatively shows the effect each feature has on the final prediction. This measure evaluates the contribution of features (feature importance) to the prediction results of machine learning models. It does so by gradually increasing the values of the input features from those of a baseline. We used the value zero as our baseline since it represents zero information in our study. This method computes the integral of gradients with respect to inputs along the path from outputs to inputs in a neural network. Integrated gradients can provide insight into which features contributed to students correctly answering a question. A positive integrated gradients value shows an increase in the feature value that contributes to an increase in the output prediction value. A negative value indicates the opposite. The magnitude of the value shows how much the input feature influences the output. A value of zero means the measure or feature did not contribute to the prediction. There is no specific range for integrated gradients because the slope describing the relationship between the input and output (gradient) is not bounded.

4. RESULTS

4.1.1 What is the added value of including text features as input when predicting the correctness of question answering in reading tasks?

Model performance was measured through precision, recall, and accuracy (see Table 4). Chance accuracy for this prediction task was 54%. The average training and validation accuracy difference for all models during cross validation is under 2%.

Table 4. K-fold (k = 10) cross-validation results for each model as $M(SD)$.

Model	Precision	Recall	Accuracy (%)
Base	.665 (.012)	.737 (.011)	65.8 (0.76)
Base + Sent. Complex.	.696 (.017)	.751 (.015)	67.5 (1.17)
Base + Context	.713 (.014)	.738 (.017)	68.7 (0.91)
Base + Rare Word Use	.704 (.009)	.751 (.019)	68.1 (0.69)
Base + Lexical Surprisal	.691 (.014)	.756 (.019)	67.6 (0.74)
Full	.715 (.016)	.747 (.013)	69.8 (0.95)

Note. Sent. – Sentence, Complex. – Complexity

The full Model yields the highest accuracy and precision. It also had relatively high recall, suggesting the Full Model performs well. The Base Model had high recall but the lowest precision and accuracy. Adding any one of sentence complexity, rare word use, or surprisal to the Base Model was associated with an increase in precision while maintaining similar recall, demonstrating the potential for text-based features to support model prediction. Adding sentence embeddings to the Base Model resulted in the highest precision among all models except for the Full Model. However, it also had the lowest recall value. Thus, the model that included context, as represented through embeddings, made the lowest number of errors in its predictions of answering a question correctly. However, it also had the most prediction errors for questions that students had answered incorrectly.

The Full Model and Base + Context Model show significantly higher predictive accuracy than the Base Model (see Table 5). The performance of the remaining models did not show significant differences from that of the Base Model.

Table 5. Model comparisons using McNemar’s Test

Model 1	Model 2	McNemar Test Statistic	<i>p</i>
Full Model	Base Model	7.771	.025
Base + Context	Base Model	8.040	.024
Base + Sentence Complexity	Base Model	0.547	1
Base + Vocabulary Rarity	Base Model	2.972	.340
Base + Lexical Surprisal	Base Model	0.105	.746
Full Model	Base + Context	4.971	.026

Since the full model and Base + Context Model both outperformed the Base Model, we compared these top-performing models to see whether one outperformed the other. While the difference is

relatively small, the Full Model achieves higher performance than the Base + Context Model suggesting that representing many aspects of the text is important.

4.1.2 Full Model Features

We used integrated gradients to examine how much each text-based feature affected whether the model would predict that a student answered a question correctly. In Figure 6, the y-axis shows the value of integrated gradients for each feature, with large values indicating the feature has a strong influence on the model’s prediction. A positive value indicates the feature contributes to predicting a question is answered correctly. Negative values mean the feature supports the prediction of incorrect student answers.

The integrated gradient results for the Full Model show that an increase in maximum sentence complexity and mean question complexity helps the Full Model predict when students will be more likely to incorrectly answer a question (Figure 6). In contrast, predicting when students will correctly answer a question is supported by an increase in maximum (max) sentence complexity. Contributions from all other features are low.

Figure 6. Integrated gradient result for each feature from the Full Model. *M* – mean and *SD* - standard deviation

4.1.3 Sentence Complexity Features

Here we investigate how much the mean, standard deviation, and maximum values of sentence depth contributed to the prediction in the Base + Sentence Complexity Model.

As can be seen in Figure 7, the integrated gradient results do not show substantial contributions from any of the features when they are used on their own. To see if this finding is due to invariability among different instances, we plotted the feature value distribution across all texts (Figure 8). As shown by the values for texts two,

six, and eight, which are relatively high, a lack of variability fails to account for the limited contribution of this feature.

4.1.4 Lexical Surprisal Features

Here we investigate how much the mean, standard deviation, and maximum values of lexical surprisal contributed to the prediction when the Base + Lexical Surprisal Model was used. The integrated gradients results show both the mean and maximum of lexical surprisal contributed little to the prediction (Figure 9). Mean has a small positive impact while maximum has a small negative impact. Given the relatively small gradient, we checked variability across texts: Figure 10 shows that the mean lexical surprisal is relatively stable (its values range from .02 to .04) whereas the maximum lexical surprisal values vary considerably (~.02 - .12).

Figure 7. Integrated gradient result for each feature from the Base + Sentence Complexity model. *M* – mean and *SD* - standard deviation

Figure 8. Maximum and mean sentence complexity values for each text. The band represents the area within one standard deviation of the mean.

4.2 Error analysis

We compare the models that use text features as input to the Base Model because the Base Model does not incorporate any text features. Thus, it is not biased towards or against any of the readings or questions. By comparing model performance against that of the Base Model, we can see where a particular feature supports the task and where it performs poorly.

Base + Rare Word Use Model performed especially poorly in Text 7 compared to the Base Model. Text 7 is an expository paragraph containing scientific facts about snow colors. The rare word use feature of Text 7 has a high value of .550 where the average rare word use value across all texts (including Text 7) is .493. The most errors occur for question 30 in Text 7, which is an inference question where the answer is not explicitly stated in the text.

Among the questions where the Base + Rare Word Use Model outperformed the Base Model, Text 8 has the highest percentage of correct predictions. Questions 34 and 35 from Text 8 have a particularly high correct rate and rare word use rate. Both questions are non-inference questions. These differences in performance indicate that this model performs well in situations when the vocabulary is difficult and questions are direct.

Figure 9. Integrated gradient result for each feature from the base + lexical surprisal model. *M* - mean and *SD* - standard deviation

Figure 10. Mean and maximum lexical surprisal values for each text. The band represents the area within one standard deviation from the mean

Base + Sentence Complexity Model output differs in many places from that of the Base Model for Text 7. When comparing these two models on the Text 7 questions, we see that it is common for one of the models to correctly predict student performance when the other is incorrect. All three questions that belong to this text have high error rates in classification. The mean depth feature of this text is 10.3 whereas the average depth across all texts is 8.4.

Base + Context Model predictions disagreed often with those of the Base Model for Text 11, questions 44, 45, and 48. Question 44 and 45 are inference questions and question 48 uses a near synonym for a keyword from the text to assess comprehension. The Base + Context Model performed particularly well in Text 8, question 31 and 34; the answers to these questions can be explicitly found in the text. This differential performance suggests that adding sentence context information supports model performance when predicting student responses to non-inference questions.

Full Model prediction errors come from questions 44 and 45 from Text 11 in most cases. These errors are similar to those made by the Base + Context Model, but the Full Model performs slightly better: the percentage of prediction errors decreased from 22.5% to 18.5% (question 44) and 19.3% to 16.9% (question 45). The Full Model performed particularly well on Text 4, question 14 and 16. Text 4 is a relatively short narrative text containing sentences with simple structures, and the answer to both of the Text 4 questions is easy to find in the text.

5. DISCUSSION

To answer the research question, “What is the added value of including text features as input when predicting the correctness of question answering in reading tasks?”, we trained and evaluated models using information about students’ oral language skills and features from the texts they were reading as input. The developed models were used to explore how these features supported the prediction of student performance on reading-comprehension questions. The text-based features each provide a hidden representation of aspects of the text that were expected to affect reading comprehension. Individually, their inclusion does not appear to lead to strong model performance; however, their joint use supports prediction across a variety of text and question types.

It appears that the strengths identified when adding some features compensate for the weaknesses associated with adding others. For example, sentence complexity performs poorly when the vocabulary is challenging, which can be captured through the addition of the rare word use feature. Similarly, the context feature underperforms on inference questions, which seem to be better supported by the combined use of all features. Analyses of feature contributions to model performance (Section 5.1.2), and the error analysis (Section 5.2) indicate that the features interact. The complicated nature of how features supported the prediction task suggests that text characteristics need to be treated in a nuanced manner if we are to understand children’s reading comprehension or develop learner models that can be used to adapt reading materials to children.

5.1 Text-based Feature Contributions to Prediction

Each of the text features that we added appeared to improve model accuracy when they were used jointly (Full Model). The only text feature that supported improved model performance on its own was the sentence context feature that used sentence embeddings, and this model was outperformed by the Full Model that included sentence context as one of its text-based features. Given the relatively high contribution of sentence complexity features to the Full Model and the low contribution of most other text-based features (as identified using integrated gradients - Section 5.1.2), the sentence context and other features likely augmented the information provided by the sentence complexity feature.

The improved performance associated with adding sentence context information may be the result of it implicitly capturing several aspects of the text. Universal sentence encoders, which were used

to extract the sentence context feature, incorporate word order, sentence meaning, and grammar into a single vector so they implicitly capture some aspects of sentence complexity and vocabulary. They also implicitly capture aspects of the content domain through their representation of the surrounding text. The support provided by adding the sentence context feature parallels Hirsch's [28] findings on reading comprehension of elementary students. Hirsch found that a gap in reading comprehension appears (or is widened) when more advanced domains (e.g., math, science) are introduced. This effect of domain context was also found to be more influential when compared to differences in vocabulary size and decoding skills among students in elementary school. Our models accounted for the vocabulary knowledge (i.e., PPVT-M score) of children and added text-based features that represent the vocabulary knowledge needed to understand the texts (i.e., rare word use). This text-based feature only contributed to improved model performance when used in combination with sentence context. This lack of contribution by rare word use on its own suggests that Hirsch's domain influence findings can be partly captured through the sentence context feature.

The sentence complexity of both the text and the question contributed substantially to predictions when sentence complexity was used alongside other features even though this feature did not improve model performance when added to the Base Model by itself. This pattern suggests the sentence complexity of both the text and the question interacts with other features to produce meaningful predictions. That is, sentence structure by itself does not determine the difficulty students may experience when trying to understand a piece of text. This is consistent with our error analysis (Section 5.2) which identified high error rates for questions with low levels of rare word use and high levels of mean sentence complexity.

The rare word use feature improved prediction task performance (section 5.1.1), which is consistent with the lexical quality hypothesis [44]. Lexical quality is typically interpreted in relation to the role of high-quality word representations in reading comprehension; the flip side is that the presence of rare words will negatively impact reading comprehension because of their connection to the precision and flexibility of a mental representation of a word. Our rare word use feature provides a way to model the demands that a text will place on lexical quality, which will in turn be related to reading comprehension. That said, it seems that the most frequent prediction error emerged for inference questions accompanying a scientific information text with high levels of rare word use.

One's knowledge of vocabulary and exposure to language influence what one expects to see. Like with rare words, people can be surprised by the use of a relatively familiar word in an unexpected collocation or context [23]. The lexical surprisal feature was meant to capture this element of how we process language. In contrast to our expectations, the n-gram language model that we used to measure lexical surprisal did not appear to help predict performance on reading comprehension questions, either on its own or in combination with other text-based features. Its lack of contribution to predicting student correctness may be partly due to the limited diversity of content in the training corpus. For future work, the Corpus of Contemporary American English [9] is another publicly available dataset that could be used to model surprisal for children's readings. Additionally, using other language modelling approaches, such as a PCFG [46] or recurrent neural network grammars [26], to obtain surprisal measures might yield more accurate predictions since these language modelling approaches can output a more nuanced estimate of surprisal. It is also possible that rare word use and sentence context capture this aspect of language

processing for the target text. This suggests a need for follow up work that can help to tease apart the contributions of these vocabulary-related features.

Like the Base + Context Model, the Full Model is also less accurate when predicting correctness for inference questions. This shortcoming is mitigated by the inclusion of other text-based features that supported the prediction task. The analysis of feature contributions to this model (see Section 5.1.2) shows that the features that supported the prediction of a correct student answer (the mean and standard deviation of sentence complexity in a text) were different from those used to inform the prediction of which questions would be answered incorrectly (the maximum sentence complexity in a text and the sentence complexity of the question). This finding parallels those of Perin and Lauterbach [45], who found that there was consistency in the features that predicted strong performance in student writing and that different features predicted low student scores. The fact that none of the oral language skills captured through the individual knowledge and sub-skill measures supported the prediction of which questions a child would answer incorrectly suggests that Perin and Lauterbach's argument for there being many ways to perform poorly and only a few to perform well might be extendable to reading comprehension. When combined with the ability of text-based features to predict lower performance, this finding suggests text-based measures are needed to fully capture information about the reading-comprehension challenges that children face.

5.2 Implications for Understanding Reading

In addition to needing text-based features to predict when students will incorrectly answer a question, the error analyses showed that different text-based features were useful for predicting answer correctness for each type of reading comprehension task (inference, retrieval from text). This finding implies that we need to consider different features of a text when trying to understand children's inferring abilities or their ability to identify the content that is relevant to a question.

Beyond demonstrating the potential utility of these text-based features for predicting student answers to reading comprehension questions, these models and the approaches used can provide insight into the text-related challenges that affect students' reading comprehension based on their knowledge levels. Among these are the vocabulary used and whether its use matches that expected by a child based on their exposure to the language. It was expected that surprisal would support this prediction task since it has been predictive of reading times in some studies [46]. However, surprisal contributed little to model prediction, suggesting a need to further study the role of surprisal in children's processing.

The different contributions of features to the prediction task (see Figure 6), suggest that the sentence context feature augments information provided by the sentence complexity feature. Students tended to have poor comprehension when there was even just one very complex sentence, and higher mean sentence complexity showed less effect on the prediction result. This indicates that children's ability to answer a reading comprehension question is less affected when the sentences are more complex overall, compared to having a particularly complex sentence. The specific contributions of the mean, standard deviation, and maximum values of this characteristic of the text imply that all three measures should be used to better understand student reading abilities in relation to a text. Including the maximum sentence complexity helps to understand when students answer a question incorrectly and the mean and standard deviation help to understand when a question is

answered correctly. Combined, these provide a more robust view of how learners comprehend text.

5.3 Implications for Learner Modelling and Adaptation

As reported in our results, adding the sentence context feature to the Base Model supported better predictions of correct responses to a comprehension question. The sentence context feature also produced a better performing model when combined with the other text-based features. The underperformance of the Base + Context Model relative to the Full Model may be due to embeddings not having explicit representations of sentence complexity and lexical surprisal. The Base + Context Model's lack of explicit representation of these specific linguistic traits may be why our Full Model had the best performance.

The performance of the Full Model suggests that we can augment the learner modelling and adaptation process in educational technologies by using features that are automatically extractable from texts. This implication is further supported by the performance of the Base + Context model. The sentence context feature relies on a heavily data-driven approach to support prediction for non-inference questions that share a similar context with the text. Since the addition did not support the ability to distinguish student performance on inference questions, additional mechanisms will need to be found to support prediction for inference-based questions, which are usually harder for students to answer than non-inference questions [48]. In our case, the inclusion of multiple text-based features, specifically rare word use, helped mitigate the limitations of the context feature when inference-based questions were being predicted. So, this strategy can be used until a more powerful feature is found.

As suggested by the insights gleaned from the sentence complexity measures, these features should be included to better identify which questions might be within a student's abilities and which might not. This suggestion builds on Scott's findings from a study investigating sentence comprehension [47]. In both Scott's and our setting, measures of sentence complexity were more effective in prediction within the context of a specific domain. This may also suggest the benefit of including our sentence context features as they could reinforce domain information while also providing some information about sentence complexity and vocabulary use.

It is worth noting that, as part of the nature of all universal encoder models, the generated embedding is less interpretable by people even though it provides an effective representation of the text for predicting comprehension performance. This means more effort is required to evaluate how much specific features of the text affect the prediction task. Given the enhanced performance that is associated with the use of these embeddings, this effort is warranted when developing models for supporting the adaptive selection of texts and questions in an educational technology.

6. CONCLUSION

Student performance on reading comprehension tasks is often predicted using assessments of oral language skills, such as vocabulary knowledge or syntactic awareness. We extend this work by capturing features of text, which are rarely used in the prediction process despite an understanding that the characteristics of a text influence the ability to understand that text. In the present paper, we report

on data from grade 3 students to develop and test our prediction model. We test automated methods for extracting and incorporating text-based features from the content of a reading test to help predict whether a student will answer a reading comprehension question correctly.

The extracted text-based features were selected based on theories or evidence supporting their relationship with reading comprehension. Thus, they were designed to provide information about some of the aspects of a text that are expected to interact with children's oral language skills. Specifically, the selected features represent sentence complexity, vocabulary frequency, lexical surprisal, and context. They were all extracted using natural language processing techniques that include n-grams, a probabilistic context-free grammar, and a universal sentence encoder.

We used these features as inputs to neural networks that can self-update when given more student data or new texts are added. This mitigates the disadvantage where models with no text-based features have to be retrained fully every time a test is updated. Our model is also expected to better handle diversity across reading comprehension tests and student reading skill levels because it relies on general features of a text rather than solely relying on historical records of student performance. Since our model has clear separation between different categories of features at the input layer, new features and new data can be easily added which offers a starting point to identify what additional training might help improve student reading skills. To support the continued study of the role that text features play in reading comprehension, we have shared our approach to interpreting and analyzing the model (in section 5.4 and through GitHub²). This sharing will allow others to apply this approach to another test or population of learners.

To summarize, we extracted and tested text-based features at the word and sentence level to examine their impact on the reading comprehension of children. Those features were used as input to a model that predicts student performance on reading comprehension tests at the question level. Analyses of the tested models show that one of the employed text-based features (e.g., sentence context) improved model performance on its own while others did not (e.g., sentence complexity and lexical surprisal). The joint use of the text-based features resulted in a more than 4 % gain. Subsequent error analysis suggests each of these text-based features represents an important characteristic of the text, with their combined use resulting in the best performing model. Exploration of how these text-based features contributed to model performance provided insight into the complex relationships between text features and children's reading comprehension performance. Thus, the models and their analysis can support the design of better learning systems, the selection of appropriate reading materials, and increased understanding of the multi-faceted nature of student reading comprehension.

ABSTRACT

Stealth assessment in game-based learning environments has demonstrated significant promise for predicting student competencies and learning outcomes through unobtrusive data capture of student gameplay interactions. However, as machine learning techniques for student competency modeling have increased in complexity, the need for substantial data to induce such models has likewise increased. This raises scalability concerns, as capturing game interaction data is often logistically challenging yet necessary for supervised learning of student competency models. The generalizability of such models also poses significant challenges, and the performance of these models when applied to new domains or gameplay scenarios often suffers. To address these issues, we introduce a zero-shot learning approach that utilizes conditional generative modeling to generalize stealth assessment models for new domains in which prior data and competency labels may not exist. We evaluate our approach using observed student interactions with a game-based learning environment for introductory genetics. We use a conditional generative model to map latent embeddings of genetics concepts and student competencies to student gameplay patterns, enabling the generation of synthetic gameplay data associated with concepts and game levels that have not been previously introduced. Results indicate the zero-shot learning approach enhances the performance of the competency models on unseen game levels and concepts, pointing to more generalizable stealth assessment models and improved prediction of student competencies.

1. INTRODUCTION

Game-based learning has been shown to be effective at promoting student engagement and fostering enhanced learning experiences [7, 31]. These environments can complement traditional learning methods and help students acquire “21st century skills” such as digital literacy, creative thinking, and knowledge acquisition [4]. Further, game-based learning environments can enable educators to unobtrusively analyze student behavior through stealth assessment for the purpose of improving learning outcomes [9, 35]. Stealth assessment, offers a systematic approach for constructing data-driven models of student performance derived from evidentiary arguments [6, 29]. Despite these promising benefits, data-driven student modeling techniques are growing in complexity and often require large amounts of training data, which poses significant challenges.

Collecting sufficient data for training student models is often time and resource intensive, raising scalability concerns for stealth assessment frameworks [45]. Practitioners may also find that modeling student behavior in new domains, educational contexts, and populations is infeasible due to data sparsity issues. Further, circumstances may arise where there is no prior data to train stealth assessment models. Examples include where post-test surveys are impractical to administer, such as informal learning environments like museum exhibits, or if a learning concept or in-game problem-solving task is being deployed for the first time. These problems pose significant practical challenges for stealth assessment models.

Few-shot learning has been introduced as an effective method for classification tasks where labeled data may be scarce for certain classes or tasks [11, 23, 26, 45]. In particular, zero-shot learning (ZSL) refers to scenarios where no samples of a specific class are present at training. ZSL forms a mapping between the data and class labels present at training (“seen” data) and data absent from the training set (“unseen” data) using other attributes (semantic data) to bridge the gap between these two domains. ZSL can also address the aforementioned issues with stealth assessment by generating competent augmented data representative of the “unseen” classes, maintaining intra-class variance while promoting inter-class discrimination based on semantic relationships within the data [11, 45]. This allows for effective data augmentation that can be used to train downstream classifiers to make accurate inferences on data samples from new or unseen classes. Because these techniques

are designed to work in the absence of training data for new or unseen classes, they can be used to bootstrap new models and help mitigate the “cold start” problem where models make poor inferences due to this lack of class-specific training data [46].

In this work, we propose a generative zero-shot learning approach to improve stealth assessment models for predicting student competencies for certain gameplay levels and educational concepts missing prior student interaction data. We utilize conditional generative adversarial networks and embedding representations of introductory genetics concepts to learn latent mappings between student competencies and gameplay behaviors. By generating synthetic gameplay data conditioned on genetics concept descriptors, the generalizability of the competency models can be enhanced, leading to improved predictive performance. Our approach is evaluated using *Geniventure*, a game-based learning environment for teaching introductory genetics concepts to middle and high school students. Stealth assessment models induced with augmented student gameplay data are used to assess our generative ZSL approach. There are few zero-shot learning methods applied within educational domains [11, 22, 45]. However, to our knowledge there has not been prior work on addressing the unseen class problem in stealth assessment. We demonstrate that our approach is an effective method for addressing challenges with data sparsity and unseen class labels for student competency models in a game-based learning environment. Finally, we further show that our approach leads to improvement in the predictive performance of student competency models when compared against non-augmented baselines and alternative generative modeling techniques.

2. RELATED WORK

This work lies at the intersection of zero-shot learning and stealth assessment, particularly addressing approaches to student competency prediction for a range of genetics concepts, which is a subset of student modeling. We provide an overview of recent work pertaining to student modeling in game-based learning, with a focus on stealth assessment. Additionally, we provide a review of recent zero-shot learning research pertaining to student modeling, in addition to zero-shot learning using generative modeling approaches.

2.1 Student Modeling in Game-Based Learning

Student modeling has been shown to be effective at predicting complex learning processes such as engagement, flow, and the incubation effect [21, 32, 40]. More specifically, student modeling within game-based learning has been shown to positively impact deep learning and higher order thinking [19], promote self-regulated learning during gameplay [20, 34, 42], and address cognitive, affective, and social factors for fostering enhanced learning outcomes [3, 16]. Additionally, student modeling within game-based learning environments has been used to analyze and predict student competency levels in a variety of domains, including physics [41], literacy [40], and computational thinking. Student modeling in educational games has also been used to enable personalized and adaptive learning environments [5]. Spaulding et al. investigate the efficacy of transfer of learned cognitive models between two game-based learning environments [40]. The authors investigate the issue of negative transfer by utilizing Gaussian processes and an instance-weighting approach that considers the similarity between source and target tasks. Additionally, they address the aforementioned “cold-start” problem with a multi-task learning approach. Other studies have explored data-driven approaches for inferring student competencies by modeling their in-game progression through activity log data [12]. Similar data-driven approaches have

attempted to design student learning profilers that can inform practitioners in their design of adaptive gamified learning environments tailored to students’ interests and needs. One example is SPOnTo, a student profile ontology, that employs a multi-phase pipeline for student classification [29]. By predicting self-reported student type, intelligence type, and learning difficulties, the authors’ approach shows promise for personalized learning systems enabled by student behavioral patterns.

2.2 Stealth Assessment

There has been increased emphasis on developing effective and robust stealth assessment frameworks in recent years. By varying multiple input features (e.g., ECD model, sample size, data normality significance levels), Georgiadis et al. find that Gaussian Naïve Bayes and C4.5 models were effective for use in stealth assessment and were capable of handling different data distributions with extreme non-normality [14]. However, these models’ accuracy degrades as ECD models increase in complexity. Shute and Rahimi utilize stealth assessment to establish a link between creativity and the properties of well-established learning games that foster creative behavior and propose a creativity criterion [36]. Using Physics Playground and Bayesian networks, they show that their stealth assessment framework offers a valid measure for inferring creativity and was significantly correlated with other performance-based measures of creativity. In contrast to traditional approaches, deep learning-based methods such as long-short term memory networks (LSTMs) have been utilized as a method to model long-term temporal dependencies within student gameplay behaviors [18]. Min et al. employ LSTMs and n -gram based feed forward neural networks and compare their performance to competitive baselines [24]. By combining students’ pre-learning measures and interaction log data from a game-based learning environment, the LSTM-based approach outperformed both baseline methods and the highest performing FFNN using early prediction metrics. Akram et al. achieve similar results supporting the effectiveness of LSTMs as a student modeling technique [1].

2.3 Zero-Shot Learning

Zero-shot learning, first introduced as “zero-data learning” [23], considers the task of recognizing new classes whose instances may not have been seen during training. Recent advances in ZSL have largely been applied in the image and video classification domains, but relatively little work has explored its effectiveness in learning analytics. Wu et al. introduce the “ZSL feedback challenge” utilizing a dataset of 8 assignments with 800 unique solutions to propose a method for attributing feedback to specific sections of student code and to trace knowledge over time [45]. The authors achieve optimal performance by combining a rubric sampling technique with a multimodal variational autoencoder. Their framework can effectively track student growth over time and can provide feedback on non-compiled programs. In an alternative approach, Efremov et al. apply neural program synthesis, a reinforcement learning approach, to generate feedback and step-by-step hints for students from a partial solution [11]. They incorporate abstract syntax tree representations of student code with a tree-based bi-directional LSTM architecture to encode students’ inputs. The learned policy network outperforms state-of-the-art methods such as a continuous hint factory (CHF) and can provide feedback on specific lines of code.

Generative models are another method for approaching the ZSL problem. Mishra et al. introduce a conditional variational autoencoder conditioned on a class embedding vector to reduce domain shift across unseen classes [26]. The generative model is used to

Figure 1. Example challenges in *Geniventure* for the six gameplay levels.

produce synthetic training data that is utilized by a downstream classifier. Their generalized zero-shot learning approach is applied to five popular image recognition datasets and is able to achieve state-of-the-art performance using top- k and per class accuracy.

We contribute to this line of research by introducing a zero-shot learning approach to improve the generalizability of stealth assessment models. This work employs conditional generative adversarial networks for creating synthetic gameplay data from concepts for which there was no previous student interaction data available at training. We demonstrate that this method can improve predictive performance of student mastery within unseen game levels and educational concepts, highlighting its potential as a method for generalizing student competency models.

3. STUDENT GAMEPLAY DATA

Our generative ZSL method is implemented using a dataset captured from students' interactions with a game-based learning environment designed to teach genetics. By generating features from the students' gameplay trace data, we are able to induce student competency models without utilizing inherently intrusive or distracting methods such as external assessments or data capture through physical sensors. Student competencies for the different genetics concepts presented in *Geniventure* are quantified using a post-test knowledge assessment, with different questions corresponding to different concepts within the game's individual levels. These levels are divided into "seen" and "unseen" groups for evaluation of the ZSL data augmentation performance.

3.1 *Geniventure* Learning Environment

To evaluate the impact of our generative ZSL approach to student competency modeling, we use gameplay interaction log data captured from students engaging with *Geniventure*. *Geniventure* is targeted towards middle and high school students (ages 11-18 years) and the overall design of the game is guided by fundamental genetics concepts aligning with the Next Generation Science Standards [30]. In *Geniventure*, students are faced with the challenge of correctly breeding and studying virtual drakes, a model species of dragon [13]. In order to successfully produce the desired drake for each in-game exercise, students are required to learn and explore

genetics concepts such as heredity, dominant and recessive traits, and protein-to-trait relationships.

The game is comprised of 60 progressively difficult puzzle-like challenges that are divided into six distinct levels (Figure 1). Each level is divided into different in-game "missions", and each mission is comprised of the individual challenges. The types of challenges presented to the student varies widely across the different levels. *Geniventure* is designed to be played in a linear sequence, but students are allowed to attempt any challenge at any time, and also have the freedom to quit any challenge prior to completion.

For the first three levels of *Geniventure*, students are faced with the task of modifying the genotype of a presented drake to match a target phenotype (Figure 1, Level 1). These challenges require the student to understand several different genetics concepts and also correctly predict attributes of the target phenotype based on the current genotype. To determine whether the student correctly completed the challenge or not, the student selects the "Check" or "Hatch" button in the game's interface to submit their answer. At this point, the student receives binary feedback on whether the exercise was successfully completed or not. If the exercise was not successfully completed at this time, the student is presented with a hint to help reach completion. There are three hints available per exercise, with each hint becoming progressively more direct, a visual cue is also made available to the student at this time. The student is allowed to make additional changes and resubmit their proposed phenotype until the correct solution is reached, or until the student exits the exercise. The progressive hint mechanism exists for many exercises in *Geniventure*, although the structure and conceptual challenges in each exercise may vary widely. Level 2 further advances the challenge of matching a genotype to a specified phenotype by introducing dominant and recessive traits (Figure 1, Level 2), while Level 3 increases the complexity of the exercise by adding factors such as scale color, proteins, and cell modification (Figure 1, Level 3). Levels 4, 5, and 6 introduce increasingly complex concepts such as breeding, inheritance, and meiosis. Level 4 introduces more complexity to the breeding process through the use of gametes, epistasis, and more challenging inheritance patterns (Figure 1, Level 4). Level 5 presents students with the test cross concept, a genetic method for determine an organism's genotype

by crossing it with a fully recessive organism (Figure 1, Level 5). Level 6 builds on the prior concepts of the game while introducing additional concepts such as X-linked and polyallelic traits (Figure 1, Level 6). Certain levels introduce gameplay narratives or scaffolding that are not present in prior levels. For example, Level 3 uses a “pod-release gate” interface which varies from Level 4’s “Gamete Builder”, Level 5’s “Test Cross” interface, and Level 6’s “Clutch Breeder”. As a result, this may result in different problem-solving behavior distributions while labels for the new concepts are not available yet to train competency models and thus provides the motivation for investigating model generalization techniques such as domain adaptation or zero-shot learning.

3.2 Data Collection

Following Institutional Review Board (IRB) approval, the data corpus was captured from 462 consenting students across seven high schools and a middle school located in the Eastern United States from suburban, rural, and urban locations. Teachers led several different classroom implementations of *Geniventure* where students engaged with the game during instruction periods across multiple days. Prior to the first learning session, students took a pre-test knowledge assessment consisting of 28 questions related to the genetics concepts presented in the game. Following the conclusion of the last learning sessions, students took an identical post-test knowledge assessment addressing the same concepts to quantify students’ learning gain. The knowledge assessment was aligned with *Geniventure*’s competency model based on the ECD formulation of the game, and the assessment was also validated through multiple rounds of expert review and cognitive interviews with students. The knowledge assessment’s administration showed an internal consistency reliability of $\alpha=0.873$, and both the pre- and post-test were administered through the same online platform as the game. Logistical and technical issues were encountered during the data collections, which resulted in 38 students being removed from the data corpus due to missing knowledge assessment data and 108 students being removed due to missing gameplay log data. As a result, the data corpus is comprised of gameplay log data from 316 students. Student performance on the post-test ($M=19.33$, $SD=6.131$) was shown to be a statistically significant improvement over the pre-test ($M=14.41$, $SD=5.826$) according to a paired t -test ($t(316) = 14.663$, $p < .01$, Cohen’s $d = 0.823$). The distribution of completed challenges per student appears to be relatively normal (Figure 2), with most students completing between 50-150 challenges, with a range of 5 to 248 challenges ($M=95.89$, $SD=33.63$).

3.3 Feature Engineering

Features representative of students’ gameplay were engineered from the raw timestamped log files generated for each learning session. These log files contained action-level information about students’ in-game activity, such as moves made within a challenge, number of attempts, and number of hints received. Because of the differences in gameplay mechanics across the different levels and challenges, we generated nine generic, challenge-level representations of student activity to generalize the feature engineering process. The generic representations were: (1) level number of challenge, (2) mission number of challenge, (3) challenge number, (4) total time spent on challenge, (5) number of in-game actions taken during challenge, (6) number of hints encountered during challenge, (7) number of correct in-game actions taken during challenge, (8) number of wrong in-game actions taken during challenge, and (9) student’s completion status of challenge (0: incomplete, 1: complete with wrong answer, 2: complete with correct answer). From these representations, we also generate additional features to capture the temporal context of students’ activity across

Figure 2. Histogram of challenges attempted by students in *Geniventure*.

current and prior learning sessions. By accounting for all student challenges completed up until the current challenge, we calculated: (10) average time spent on individual challenges (seconds), (11) average in-game movements per challenge, (12) average correct in-game movements per challenge, (13) average incorrect in-game movements per challenge, (14) average number of hints received per challenge, (15) successful challenge completion rate, (16) failed challenge completion rate, and (17) unsubmitted challenge rate. For each challenge, a feature vector was constructed using these 17 features to serve as the input to the student competency models. It should be noted that these averages were computed separately across the “seen” and “unseen” gameplay data to protect against data leakage.

4. EVIDENCE-CENTERED DESIGN

Stealth assessment refers to non-intrusive methods for collecting evidence to induce student competency models [38]. This evidence captured from student interactions with various learning platforms is subsequently used to inform the evidence models, and subsequently competency models. The competency predictions generated from these models can be used to enable enhanced learning through adaptive mechanisms within the learning platforms. Stealth assessment can also be used to inform teachers and instructors in real time about students’ current learning trajectories to determine if dynamic interventions are necessary.

Stealth assessment is grounded in Evidence-Centered Design (ECD), a principled approach to assessment design that describes high-level models of a conceptual assessment framework and delivery architecture for assessment delivery systems [27]. ECD affords assessment designers a method for reasoning about student knowledge or skills while adhering to psychometric principles [28]. Historically, ECD has been utilized to guide the creation of various knowledge assessments, and more recently has been used to inform the development of stealth assessment models deployed within game-based learning environments [14, 24, 37]. Our approach to stealth assessment with the *Geniventure* learning environment is informed by the three following ECD models:

Task Model: This model defines the exercises or activities that students attempt to complete through interactions with the game-based learning environment. The task model within *Geniventure* is comprised of sixty distinct challenges that are split across the six in-game levels. Each challenge presents students with various genetics concepts such as inheritance patterns, breeding, and genotype-phenotype relationships.

Evidence Model: This model is shaped by the actions performed by each student within the game-based learning environment. This interaction data is representative of student behavior that is correlated with learning outcomes pertaining to specific concepts presented in the learning platform. In this work, the actions a student performs in *Geniventure* challenges, in addition to the outcome of each challenge, are represented by the evidence model and used to engineer features to train machine learning models used for predicting student mastery (or no mastery) of particular genetics concepts. The evidence model guides the competency model as it adjusts its modeling of students’ competencies as various in-game challenges are attempted.

Competency Model: This model pertains to the genetics concepts that are presented within *Geniventure* and attempts to model the machine-interpretable evidence from the evidence model in order to accurately predict students’ competencies for each concept. The primary objective of the competency modeling is to optimally map the evidence model to the competency model for each student. These concepts are derived from classroom learning objectives and state science standards through of expert review. Students’ competencies are captured and quantified from a post-test knowledge assessment administered to each student following interactions with *Geniventure*. The competency model and the post-test assessment are aligned using the same concepts presented in Table 1.

To generate the ground-truth competency scores for each student, individual responses to the items on the post-test assessment are summed across the different genetics concepts, with a single concept mapping to between one and six questions on the assessment. Each question considered in this study is graded as either 1 (correct) or 0 (incorrect). Competency scores are calculated for each concept by dividing the total number of correct responses for that concept by the total number of questions related to that concept. As a result, each competency score was within the range of 0 to 1 and serves as the target variables for the stealth assessment models.

5. ZERO-SHOT LEARNING

Zero shot learning (ZSL) is an extreme variation of unsupervised domain adaptation, which focuses on two distinct data sets extracted from two different domains and data distributions: a *source domain* and a *target domain*. The primary objective of unsupervised domain adaptation is to induce a generalizable model that is capable of accurately classifying samples from the two domains in instances where labels for samples in the target domain are not available during model training. However, ZSL expands on this concept by assuming that neither data samples nor labels for the target domain are available during the training process. For this work, we split the *Geniventure* dataset into seen (S) and unseen (U) domains by partitioning between in-game levels because different levels address concepts that correspond to different competencies according to the ECD model. The text descriptions of each ECD concept serve as the link between the seen and the unseen classes, commonly referred to in ZSL as “semantic embeddings” or “attribute vectors” and are known for both seen and unseen classes at training time. The seen domain serves as the “source” domain and the unseen domain serves as the “target” domain. Therefore, the ECD concepts (C) for this data corpus (X : data, Y : class labels) can be divided and formally defined as follows:

$$S = \{(x, y, c_y) \mid x \in X^S, y \in Y^S, c \in C^S\} \quad (1)$$

$$U = \{(x, y, c_y) \mid x \in X^U, y \in Y^U, c \in C^U\} \quad (2)$$

By framing the ECD competency modeling as a ZSL task, we seek to predict student competencies on unseen levels and concepts in situations where no prior gameplay data is available for those concepts, an example of the “cold-start problem”. For example, if we have concepts C1-C10 where C1-C7 have been previously presented to students in *Geniventure* and gameplay logs have been captured for these concepts (i.e., seen), we seek to use this available data to induce generalizable competency models that accurately predict student outcomes on concepts C8-C10, even though they

Table 1. In-game genetics concepts from ECD competency model.

Concept	Concept Description	Questions
C1	Only one dominant allele is needed to produce the dominant trait.	3
C2	Two recessive alleles are needed to produce a recessive trait.	2
C3	Create or select parental gametes to create an individual offspring with a specific phenotype.	4
C4	Set parental genotypes to produce a specific pattern of offspring.	6
C5	Use patterns in the phenotypes of a group of offspring to predict the genotype of the parents.	5
C6	For some traits primarily influenced by a single gene, both alleles will have some effect, with neither being completely dominant.	2
C7	Breed with a recessive animal to determine an unknown genotype (testcross).	2
C8	Different versions of a gene correspond to different versions of a specific protein.	2
C9	Proteins do work or have jobs to do in cells.	1
C10	Proteins are nanomachines; different proteins do different jobs.	1
C11	The function of a protein is determined by its shape.	1
C12	Different versions of a specific protein have different structures and different functions.	1
C13	Some traits have multiple alleles, which can form a ranked series in terms of dominance.	2
C14	Genes on the X chromosome are referred to as X-linked. Males receive only one copy of the X chromosome and pass on their X only to their daughters.	1
C15	Working from the phenotype, determine possible genotypes for an organism.	2
C16	Use a genotype to predict the phenotype for an organism.	2

have not been presented to any students and there is no prior gameplay logs or competency scores for these concepts (i.e., unseen). This allows for more generalizable student competency modeling and also enables ECD-based stealth assessment in circumstances where there are no prior ground-truth competency labels, such as when post-tests may be unavailable or impractical to administer. Examples include informal learning environments such as museums, or if a concept or level within a game-based learning environment is being deployed for the first time.

Because both the data and labels are not available at training time, a form of semantic data must be available for the ZSL framework to link between the seen and unseen domains. In this particular case, we use the text-based descriptions of each of the concepts to generate concept mastery embeddings used as conditional inputs to the generative ZSL models (Section 5.1). This allows the generative model to learn the non-linear relationships between the concept text embeddings, student competencies, and student gameplay patterns. As a result, the generative model generates synthetic gameplay data representative of each of the seen and unseen concepts which enhances the training and generalizability of the competency models.

The embedding representations for the genetics concept descriptions are generated using Sentence-BERT (S-BERT) [33]. S-BERT expands upon the original BERT model [10] by implementing the BERT model within a Siamese network architecture to facilitate the generation of fixed-length embedding vectors of sentences that are compared using distance metrics such as cosine similarity. This allows the S-BERT model to generate sentence-level embedding representations instead of single-word embeddings, making this model suitable for sentence descriptions of the genetics concepts. Additionally, the use of a common pre-trained language model such as S-BERT improves the generalizability of our approach, compared to manually crafted representations such as knowledge graphs.

5.1 Generative Modeling

To address the absence of training data and labels for the unseen concepts, we use semantic data (i.e., text descriptions of all concepts) to condition and train deep generative models, which facilitate data augmentation for this task. By employing text embeddings of the seen concept descriptions to condition the generative models, we can train the models to map the latent representation of each concept to particular patterns and features in the students’ gameplay data for the seen concepts. We can subsequently generate synthetic data to represent student gameplay for the unseen concepts using only the embeddings of the descriptions for each unseen concept. The augmented data is used to further train the competency models to increase the predictive performance during inference for the unseen concepts’ associated gameplay data.

Generative adversarial networks (GANs) have been frequently used as a data augmentation method due to their ability to generate high-fidelity data from noise vectors through zero-sum training of two deep learning components: a *generator* and a *discriminator* [15]. The purpose of the generator G is to generate synthetic data \tilde{x} based on a random probability distribution p_z , where z represents the latent space sampled by G so that $\tilde{x} = G(z)$, $z \sim p_z$. The objective is that \tilde{x} deceives the discriminator, whose purpose is to accurately distinguish between this “fake” data and real samples from the original data. The discriminator’s training loss from this binary classification is backpropagated through the generator and the discriminator, with the objective of both losses eventually reaching a Nash equilibrium. However, quantifying GAN convergence is an open-ended area of research and GAN models are often susceptible

to vanishing or exploding gradients, mode collapse, and other instabilities during the training process. One approach to mitigating this issue is a conditional GAN [25], which extends a traditional GAN architecture by providing associated data (“conditions”) to both the generator and discriminator’s input vectors. An example of such a condition is a class label or attribute that is associated with the desired augmented output of the generator. For this particular case, we use the S-BERT embedding vectors of the associated concepts as the conditions to our GAN model to generate synthetic gameplay data associated with both the seen and unseen concepts.

Traditional GAN architectures attempt to reach convergence by minimizing a divergence function such as the Jensen-Shannon (JS) divergence, which helps quantify the distances between two probability distributions $p_g(x)$ and $p_r(x)$, where p_g is the model distribution of the generator and p_r is the distribution of the real data. However, a common issue with these divergence metrics is that there exist sequences of distributions that do not converge under the JS divergence or where the gradient of the divergency eventually disappears, effectively halting the training of the generator during backpropagation. To address this issue, an alternative GAN architecture (W-GAN) was proposed that utilizes the Wasserstein distance, otherwise known as the “Earth Mover’s distance”, as a means to quantify the generator loss during training (Eq. 3) [2]. This metric is desirable as it is continuous and differential almost everywhere under the Lipschitz condition:

$$W(p_r, p_g) = \inf_{\gamma \in \Pi(p_r, p_g)} \mathbb{E}_{(x,y) \sim \gamma} [\|x - y\|] \quad (3)$$

where $\Pi(p_r, p_g)$ represents all joint distributions with marginal distributions of $\gamma(x, y)$ are $p_r(x)$ and $p_g(y)$, respectively. Because this equation is highly intractable, we use the Kantorovich-Rubinstein duality to simplify the calculation to be:

$$W(p_r, p_g) = \sup_{|f|_{L^1} \leq 1} \mathbb{E}_{x \sim p_r} [f(x)] - \mathbb{E}_{x \sim p_g} [f(x)] \quad (4)$$

As a result, we enforce a 1-Lipschitz constraint to the discriminator component. As a means to enforce this 1-Lipschitz constraint within the W-GAN, we introduce a concept known as “weight clipping” to the discriminator. This involves constraining the weights in the discriminator to be between the range of $[-c, c]$, with c being treated as an additional training hyperparameter. However, weight clipping is often volatile with respect to c and can cause W-GANs to converge much more slowly if c is too large but can also introduce vanishing gradients if c is too small. An alternative to the weight clipping is a “gradient penalization” method which proposes a penalty term added to the loss function that is parameterized by a penalty coefficient λ [17]. The gradient penalty term is based on weighted random sampling between the real and the generated samples from the generator. As a result, the final objective of our gradient-penalized W-GAN model (WGAN-GP) becomes the minimization of the following loss function for the discriminator D :

$$\mathcal{L}_{dis}(x, \tilde{x}; \theta_{dis}) = D_{\theta_{dis}}(\tilde{x}) - D_{\theta_{dis}}(x) + \lambda(\|\nabla_{\tilde{x}} D_{\theta_{dis}}(\tilde{x})\| - 1)^2 \quad (5)$$

where θ_{dis} represents the parameters of the discriminator, λ is the gradient penalty coefficient, and \tilde{x} is sampled from $\epsilon x + (1 - \epsilon)\tilde{x}$ with $0 \leq \epsilon \leq 1$, effectively representing any points sampled between the probability distributions, p_g and p_r .

We employ the WGAN-GP approach as a means to train a generator to produce realistic synthetic data representing students’ gameplay for unseen *Geniventure* levels in order to induce student competency models for the associated genetics concepts that have

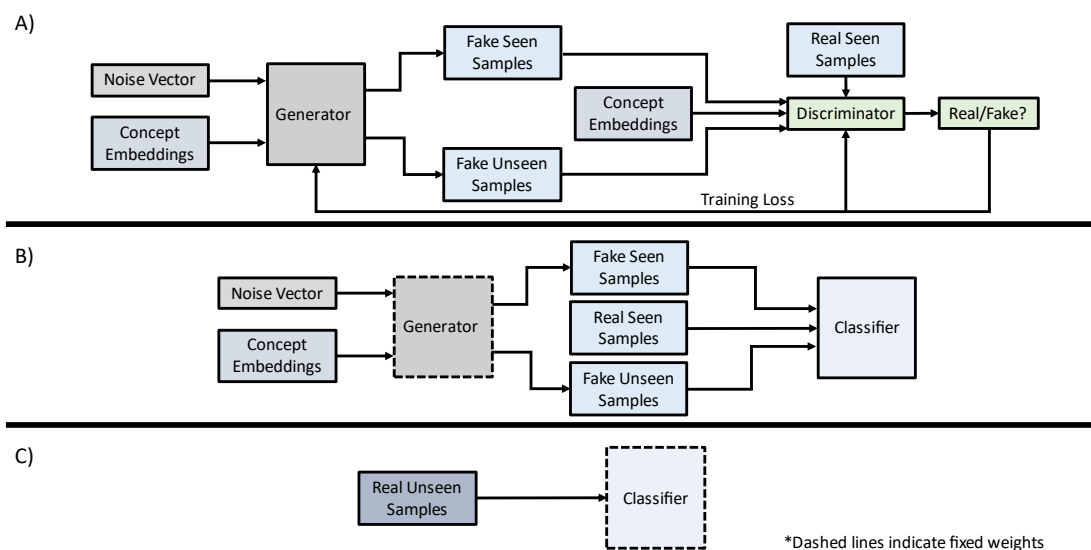

Figure 3. Visualization of data augmentation in generative zero-shot learning framework. (A) training process for conditional WGAN-GP augmentation model, (B) training process for student competency models with augmented data for unseen concepts, and (C) inference of trained competency model for real student gameplay on previously unseen concepts.

not been previously introduced. This model was selected due to issues with vanishing gradients during empirical evaluations of traditional GANs and WGANs within our ZSL framework. Additionally, we use a conditional variation of the WGAN-GP model in order to effectively map the latent representations of the augmented data representations to the word embeddings of the text-based descriptions of each genetics concept. This allows the synthetic data generation to be guided by the concepts associated with each data sample from the data corpus, while allowing for data to be generated based on the concepts associated with the unseen game levels.

6. METHODOLOGY

Our ZSL approach is evaluated across two different data splits. The first split involves removing any information from the ECD models associated with Level 6 (the last level) from the data corpus, which includes student gameplay (Evidence Model) from the challenges within the level (Task Model), as well as the student post-test scores (Competency Model) to items associated with genetics concepts associated with Level 6 (C13 and C14 serving as unseen concepts). The second split involves treating Level 5 and Level 6 as the “unseen” domain, which involves concepts C7, C13, and C14. The competency models are initially trained using the student gameplay features from the “seen” domain and a median split of the combined competency scores from the post-test items corresponding only to concepts associated with the “seen” *Geniventure* levels. To evaluate the ZSL performance, each competency model is evaluated using the gameplay from the unseen levels to predict student competencies from the post-survey items associated with the unseen concepts. This process is implemented to protect against data leakage, ensuring that the student competency models are induced using only data and labels from the seen levels as well as unseen, synthetic labeled data during the training phase, and any actual data or labels from the unseen concepts and levels are *only* presented to each competency model during the inference phase (Figure 3, C).

6.1 Student Competency Models

Five different classifiers were investigated as student competency models: a majority classifier, support vector machine (SVM), random forest (RF), Naïve Bayes (NB), logistic regression (LR), and

feedforward neural network (FFNN). Each of the models were implemented as binary classifiers to predict “high” and “low” categories of student performance based on a median split of the sum of the post-test score for each question related to either the seen or unseen concepts. Each of the models was evaluated using student-level cross-validation, to ensure against data leakage across validation folds. The median of the competency scores were determined based on the scores of the students within the training folds only as another means to protect against data leakage.

6.2 Model Evaluation

Hyperparameter tuning was performed using three-fold inner cross-validation within each iteration of the ten-fold outer cross-validation. The hyperparameters that were optimized were the regularization parameter and kernel (support vector machine; SVM), regularization parameter (logistic regression, LR), number of estimators (random forest; RF), and number of layers and nodes (feedforward neural network; FFNN). Hyperparameter tuning was not performed on the Naïve Bayes classifier and the majority classifier. Because multiple data samples exist per student and there is only one competency label per student, we generate a single student-level prediction by forward propagating all feature vectors for a given student through a trained competency model and averaging across all predictions for that student.

Because the use of the gradient penalty in the WGAN-GP stabilizes the training process and mitigates the need for extensive hyperparameter tuning, we focus only on tuning the number of nodes in the two hidden layers of the generator and discriminator using layer sizes of 32 or 64. This hyperparameter tuning also occurred within the nested cross-validation process described previously. The WGAN-GP’s learning rate was 0.001, with a dropout rate of 0.5 and hyperbolic tangential activation functions. The WGAN-GP (and FFNN competency model) was trained using 100 epochs while utilizing early stopping based on the model’s performance on the validation fold with a patience of 10 epochs. The noise vector size for the WGAN-GP was 32, and the number of generated synthetic data samples was set to be 50% of the original training dataset size. Because the concept mastery embedding vectors obtained

from S-BERT are high in dimensionality, we perform Principal Component Analysis on the embeddings to reduce the size to 32 components. The data was standardized within each cross-validation fold by subtracting each feature’s mean and dividing by the standard deviation of each feature as determined by the training folds.

To represent the students’ competencies within the semantic embeddings, a text description for each concept was preceded with either “mastery of” or “no mastery of” based on each student’s post-test performance relative to the median for each concept and these substrings were concatenated together to form a single comprehensive text string representing the student’s mastery of each of the seen concepts. For example, a concept mastery sentence for a single student might be “Mastery of *only one dominant allele is needed to produce the dominant trait*. Non-mastery of *two recessive alleles are needed to produce a recessive trait*. Mastery of ...” and so on for the seen concepts. These text representations are then passed through the pre-trained S-BERT word embedding model and, following the PCA dimensionality reduction described previously, are used as the conditional features for the generative models. To generate synthetic data following the generative model training, a similar process is followed to generate the text representations using the descriptions of the unseen concepts. As no student competency data actually exists for these unseen concepts currently, the preceding phrase “mastery of” or “no mastery of” is determined using a Bernoulli probability distribution where probability $p=0.5$. This allows the generative model to produce synthetic gameplay data representative of many possible mastery/non-mastery combinations of student competencies for the unseen concepts, thus enhancing the generalizability of the competency models for the unseen concepts.

To evaluate the performance of the WGAN-GP as the preferred ZSL generative model, we also investigate two alternatives: a conditional variational autoencoder (C-VAE) and a “target-only” baseline. The target-only baseline refers to a competency model that performs the inference on the data for the unseen *Geniventure* levels but does not undergo any form of ZSL-based data augmentation, which is a reflection of the target-only baseline in prior adversarial domain adaptation work by Tzeng et al. [43]. C-VAEs are similar to conditional GANs with regards to the use of conditional attributes [39]. A traditional VAE contains two components: an *encoder* and a *decoder*. The encoder learns latent representations of input data while the decoder seeks to reconstruct the original dimensionality of the data from the latent space representation. The VAE constrains the latent space representation to follow a pre-determined probability distribution by minimizing a loss function that consists of a reconstruction term and a divergence term. The reconstruction term quantifies the reconstruction error of the decoder component through a loss function such as root mean squared error and the divergence term quantifies the distance between the given probability distribution and the latent representation distribution. The Kullback-Leibler (KL) divergence is often used for this purpose. The conditional features are concatenated to the input features for the encoder as well as the latent representation vector that is passed from the encoder to the decoder. Because the encoder reduces the latent representation to a parameterized probability distribution, this allows the decoder to generate augmented data from this distribution.

7. RESULTS AND DISCUSSION

The ZSL approach was evaluated across two splits as described in Section 5. The results for Split 1 is shown in Table 2, while the

results for Split 2 is shown in Table 3. We select F1 Score and accuracy as our primary metrics to account for the relatively balanced class distribution due to the median split, while Area-Under-Curve (AUC) and Cohen’s Kappa [8] are used as secondary metrics. The optimally performing generative ZSL model for each split in terms of F1 Score is shown in bold. All evaluations were performed on a NVIDIA GeForce GTX 1080 TI GPU. Each evaluation took up to 100 minutes to complete the 10-fold cross-validation sequence.

In terms of the primary evaluation metrics, the WGAN-GP model appeared to induce the highest performance from the competency models across both data splits, outperforming both the C-VAE and the target-only baseline. It was noted that the performance across all models decreased for the split containing two “unseen” gameplay levels (Table 3) compared to one (Table 2), which is expected due to the decrease in training data available as well as the increased variance in the “unseen” dataset. However, the results overall point to the enhanced performance of the student competency models when additional synthetic data is generated from the WGAN-GP as a means to improve the training process.

Additionally, it was noticeable that the margin between the WGAN-GP and the other ZSL configurations widened from Split 1 to Split 2, which points to the relative scalability of our approach as the number of unseen concepts and in-game levels increase. It was also noted that the C-VAE was the lowest performing generative model and was also outperformed by the target-only baseline approach for both data splits. This is noteworthy as VAEs, including conditional variations, are the generative approach for prior generalized ZSL work [26, 44, 45].

However, we note in these prior works, the VAE models were trained on a multimodal dataset, which provides a more data-rich perspective compared to the stealth assessment data in this work. Additionally, although the work in [26] used a conditional variation of the C-VAE, the generative model appeared to suffer from mode collapse, a common issue in the training of generative models. However, one benefit of the WGAN (and the gradient-penalization modification) is additional mitigation against mode collapse during training, a possible explanation of why the WGAN-GP achieves the highest performance in our evaluations. A primary difference in this architecture is that the loss of the decoder in the C-VAE is the summation of the KL divergence and the reconstruction loss, compared to the WGAN component which strictly uses the Wasserstein divergence metric. This has potential for allowing the generative model to map between the semantic feature space and the augmented data more effectively, particularly as the augmented data from the WGAN-GP is restored to the original dimensionality instead of a latent space representation.

To further investigate the performance of the generative ZSL approach, we generate the confusion matrices for each of the models across both data splits (Figures 4 and 5). The confusion matrices are based on the inferences of each of the models based on the held-out test set within each outer cross-validation iteration, for a total of 316 student-level predictions. It should be noted that the results in Tables 2 and 3 were calculated across the outer cross-validation folds while the analyses conducted in Figures 4-7 were calculated across the entire dataset. Based on the results in the confusion matrices, we observe that high-performing students are more accurately classified compared to low-performing students. Additionally, it appears that the student competency models produced noticeably more false negatives as the unseen concepts increased. This occurred across all three evaluated ZSL approaches. In the case of the target-only baseline and the WGAN-GP model, the student competency models were able to retain a relatively similar

Table 2. Results of ZSL framework for Split 1.

ZSL Model	Classifier	F1 Score	Accuracy	AUC	Kappa
Target-Only	SVM	0.689	0.642	0.689	0.257
CVAE	RF	0.668	0.642	0.675	0.275
WGAN-GP	SVM	0.709	0.656	0.692	0.284

Table 3. Results of ZSL framework for Split 2.

ZSL Model	Classifier	F1 Score	Accuracy	AUC	Kappa
Target-Only	SVM	0.671	0.623	0.703	0.249
CVAE	FFNN	0.612	0.578	0.700	0.152
WGAN-GP	SVM	0.696	0.652	0.696	0.281

performance for correct identification of low-performing students across both data splits, but the C-VAE led to significantly decreased detection for low-performing students when evaluating from Split 1 to Split 2. Additionally, it is noticeable that the WGAN-GP was able to maintain relatively consistent performance for prediction of both high-performing and low-performing students across both data splits, which demonstrates the generalizability of this particular generative model.

To further evaluate the predictive value of the semantic embeddings of the student competencies with the various genetics concepts, we visualize the embeddings from each of the students using the principal components generated from the S-BERT embeddings. Using the t-distributed Stochastic Neighbor Embedding (t-SNE) plots for the low-performing and high-performing students (Figure 6), we are able to detect whether there are salient or underlying predictive patterns in the text representations of each student’s mastery of individual genetics concepts. Despite the use of PCA for dimensionality reduction for the original S-BERT embeddings, the representations of the semantic embeddings contain high dimensionality and thus poses a challenge for visualization. t-SNE attempts to address this issue by producing a representation of high-dimensionality data within 2D coordinate space. This is performed by constructing joint probability distributions to model the similarity between the original data points, and subsequently attempts to

minimize the KL divergence between these probability distributions and other probability distributions within 2D coordinate space. This process is expanded to distinguish between low-performing and high-performing students for the seen and unseen concepts (Figure 7). Figures 6 and 7 are generated using Split 2.

Figure 6 indicates that the use of semantic embedding representation of the students’ masteries of various genetics concepts may provide predictive context to the generative ZSL models when used as a conditioning input during training. Noticeably, there appears to be distinct separation between the semantic embeddings for high-performing students and low-performing students when calculated using all competencies, which points to the predictive value of using these embeddings for stealth assessment tasks. To provide analysis more similar to the ZSL framework, the semantic embeddings are generated for each group of low-performing and high-performing students by separating the embeddings for seen and unseen concepts (Figure 7). In this particular case, there appears to be notable separation between clusters of low-performing students and high-performing students, with overlap between the high-performing students across both seen and unseen concepts. As a result, this indicates that the use of the semantic embeddings alongside conditional generative modeling provides additional predictive value to guide the generation of augmented data for different students based on prior competencies. One aspect of note for Figure 7 is that the

Figure 6. t-SNE visualization of student competency S-BERT embeddings across all concepts.

plots of “High Unseen” and “Low Unseen” are based on the ground-truth competencies for the students on the unseen concepts, while in practice, this data is not available for training the stealth assessment models and the semantic representations are used by assigning “high” or “low” mastery of each concept at random and then generating a synthetic binary “label” based on whether at least 50% of the unseen concepts were labeled “high” or not. This allows the generative model to be conditioned on 2^n different combinations of student concept mastery where n is the total number of unseen concepts, and this allows the model to be trained using a higher number of mastery combinations than what is often available in datasets captured from game-based learning environments.

There are limitations to this work that should be noted. Although the zero-shot learning framework was based on seen and unseen domains across differing gameplay levels, the two domains were grounded in the same game-based learning environment. To further investigate the generalizability of the ZSL framework, our approach should be evaluated using unseen data and classes from entirely different learning environments. Additionally, Split 1 and 2 removed two and three concepts out of sixteen, resulting in 12-18% of the total data being treated as unseen data. Evaluations with more unseen in-game levels would provide more insight into the performance of our approach as the unseen domain increases. The class label for the seen and unseen domains were both based on binary labels of student mastery, but our method should also be evaluated in scenarios where the labels differ more widely (e.g., an additional unseen class in multi-class prediction). The binary labels

Figure 7. t-SNE visualization of student competency S-BERT embeddings across high/low and seen/unseen splits.

were utilized to convert our work to a classification task, but the level of granularity is much higher compared to regression, which

can negatively impact the adaptability of learner-sensitive mechanisms by grouping low-performing students and students performing near the median together. It was also noted that, as the unseen domain increased, the number of false negatives increased, which could lead to high-performing students receiving unnecessary interventions in user-adaptive settings.

8. CONCLUSION

Game-based learning holds significant potential for stealth assessment of student performance and knowledge acquisition. The capability to predict student mastery of particular concepts within game-based learning environments can enable mechanisms such as adaptive hint generation, personalized gameplay narratives and scaffolding, and gameplay-sensitive interventions in real-time. However, stealth assessment models often necessitate large amounts of data and labels, which presents logistical and scalability challenges. This prohibits the deployment of pre-trained stealth assessment models in domains where prior data and labels have not been collected, and questions remain regarding generalizability to different domains and educational content.

We propose a generative zero-shot learning framework to address the above issues. By using conditional generative models, we harness the predictive capabilities of textual representations of student mastery of different educational concepts. These representations are able to guide a Wasserstein Generative Adversarial Network in generating synthetic student gameplay data representative of in-game levels and genetics concepts that have not been previously presented and for which no prior gameplay data or student competency data actually exists. By mapping text embeddings of genetics concepts to the student gameplay data through the generative model, the resulting augmented data improves the predictive capacity of stealth assessment models for predicting student competency across different hidden gameplay levels. Our proposed model is shown to outperform an alternative conditional generative model and a baseline that excludes the zero-shot learning element. This indicates the potential for increasing the generalizability of student stealth assessment models through the generative data augmentation approach and for deploying pre-trained stealth assessment models in digital learning environments presenting new educational concepts, problem-solving tasks, and in-game levels.

There are many promising avenues for future work. Notably, our work focuses on zero-shot learning within a single game-based learning environment, and the natural extension of this work is the evaluation of our framework across different learning environments instead of separate in-game levels. Additional experimentation with a higher ratio of “unseen”-to-“seen” concepts would provide more insight into how the ZSL framework’s performance is maintained as the amount of “unseen” data increases in size and variance. More complex modeling for the stealth assessment, language embeddings, and generative models may provide additional benefit for the predictive capacity of our framework. Finally, the effectiveness of our approach should be implemented alongside student-adaptive interventions to determine the impact on learning outcomes and processes within run-time environments.

ABSTRACT

Interactive simulations allow students to discover the underlying principles of a scientific phenomenon through their own exploration. Unfortunately, students often struggle to learn effectively in these environments. Classifying students' interaction data in the simulations based on their expected performance has the potential to enable adaptive guidance and consequently improve students' learning. Previous research in this field has mainly focused on a-posteriori analyses or investigations limited to one specific predictive model and simulation. In this paper, we investigate the quality and generalisability of models for an early prediction of conceptual understanding based on clickstream data of students across interactive simulations. We first measure the students' conceptual understanding through their in-task performance. Then, we suggest a novel type of features that, starting from clickstream data, encodes both the state of the simulation and the action performed by the student. We finally propose to feed these features into GRU-based models, with and without attention, for prediction. Experiments on two different simulations and with two different populations show that our proposed models outperform shallow learning baselines and better generalise to different learning environments and populations. The inclusion of attention into the model increases interpretability in terms of effective inquiry. The source code is available on Github¹.

1. INTRODUCTION

In the past years, interactive simulations have gained increasing popularity in formal education [6] and have become integral parts of many science curricula [28]. These environments provide visualisations of abstract concepts, which can help students to better grasp them [34, 24]. On the other

hand, these simulations also allow students to explore new learning content and build knowledge in an active and independent way [33]. Since simulations are virtual learning environments, students can experiment freely without fearing any serious consequences of making mistakes - this property can often make them a preferred choice over real lab sessions. It has also been proved that the use of interactive simulations can support inquiry-based learning [25].

However, previous work has pointed out that many students struggle to learn effectively with interactive simulations [2, 21, 23, 10]. Indeed, navigating through interactive simulations purposefully can be challenging, especially when the number of controls and the level of complexity are high [1]. Therefore, providing adaptive guidance and feedback has the potential to improve students' learning outcomes. However, interactive simulations are often highly complex systems with a practically unlimited number of possible learning paths. Hence, defining (un-)productive inquiry behaviour in such environments is still an open issue.

Prior work has focused on identifying the key factors of productive inquiry behaviour in interactive systems from student log data by leveraging sequence mining and clustering techniques. For instance, [26] applied information theoretic sequence mining to identify behavioural differences of students using a virtual simulation for electronic circuits. In [4], the authors trained binary classifiers and logistic regression models on log data from virtual environments to categorise students by their science inquiry skills. Similarly, [27] used student log data as input for a linear regression model to predict the conceptual understanding students acquired after using physics and chemistry simulations. Latent Class Analyses models were able to identify different profiles in inquiry performance in two PISA science assessments involving interactive simulations [30]. The work in [20] employed clustering techniques to analyse students' inquiry strategies in an interactive simulation on circuit construction. Log data was manually tagged as ground truth to train a classifier on successive inquiry behaviour in [17]. Other research focused on the teacher and provided them with a dashboard displaying the mined student sequences [29]. A rule-based approach for classifying students' problem solving strategies in an interactive Chemistry simulation is described in [14]. In recent work, [32] assessed the effectiveness of data mining techniques guided by knowledge gained from qualitative observations to predict student's problem-solving skills in an interactive simulation.

However, most of the existing approaches have performed *a posteriori* analyses, requiring the complete log data entries as input to the models. This represents a major limitation, since it does not allow the system to provide feedback to the students while they are still interacting with the simulation. Their high complexity and lack of predefined learning trajectories makes building a student model for these environments a challenge. A popular approach to adaptive interventions in open ended learning environments is the use of a clustering-classification framework [19]. Students are clustered offline based on their interaction sequences and the resulting clusters are interpreted. The classification step is then done online: students are assigned to a cluster in real-time, as explored in [13, 11] for an interactive simulation for electrical circuit construction. Recently, [10] presented a novel pipeline for the early prediction of conceptual understanding in an interactive Physics simulation. They were able to robustly predict students' conceptual understanding in an interactive electronics simulation with only initial fractions of the log data. However, the approach was evaluated using only one data set from a single population (Physics undergraduates). To make such approaches more impactful, it becomes crucial to enable their generalisation across simulations and environments.

In this paper, we propose a new generalisable approach for predicting students' conceptual understanding based on sequential log data from interactive simulations. We leverage students' interaction data to extract meaningful features that encode both the state of the simulation and the action of the student. These features are then used as an input to models based on Gated Recurrent Units (GRUs), to predict students' conceptual understanding. In addition to a standard GRU model, we also propose an extension, the Self-Attention-based Gated Recurrent Unit model. We extensively evaluate our approach on two data sets from different contexts: the first data set stems from students of 10 different vocational schools interacting with a chemistry simulation. The second data set consists of physics undergraduate students using a physics simulation. With our experiments, we aim to address three research questions: 1) To what degree is interaction data within interactive simulations predictive for their obtained conceptual understanding? 2) Can our models predict students' conceptual understanding early on? 3) Is our approach transferable to another context involving a different population and simulation?

Our results demonstrate that our proposed models outperform previous approaches in terms of (early) predictive performance on both data sets. We further show that the inclusion of self-attention enables us to draw conclusions about productive inquiry behaviour in both simulations.

2. LEARNING ENVIRONMENTS

The PhET interactive simulations² allow students to explore natural phenomena using different parameter configurations and ideally infer the underlying principles on their own. A large body of research has focused on analysing students' inquiry strategies using these simulations, usually coupled with an explicit task to be solved using the simulation [35]. To evaluate the (early) prediction models presented in this

²<https://phet.colorado.edu/>

Figure 1: The two learning environments used in this study, the Capacitor Lab (A) and the Beer's Law Lab (B).

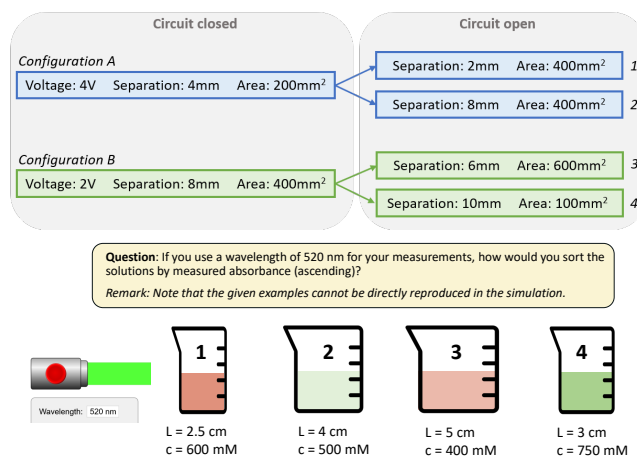

Figure 2: Ranking tasks for the two interactive simulations.

paper, we used a ranking task which we adapted to two different simulation environments. For each ranking task, the values of the variables presented in the task are outside the range provided by the simulation. Hence, students need to inquire the system to uncover the appropriate equations and plug in the numbers as answers in the ranking task.

Capacitor Lab. The PhET Capacitor Lab simulation³ provides students with the possibility to manipulate different parameters of an electric circuit (plate area, plate separation, applied voltage, open/close the circuit), to help them understand how each parameter influences the capacitance of a plate capacitor as well as the energy stored in that capacitor (see Fig. 1A). Previous work [10] designed an inquiry-based learning activity for this simulation using a ranking task. Specifically, students were asked to rank four different configurations according to the stored energy saved in the plate capacitor (see Fig. 2a). The four configurations were created by first loading the plate capacitor using two parameter configurations in a closed circuit (A and B), followed by opening the switch to disconnect the capacitor from the circuit and changing the parameters to obtain the final configurations to be ranked (1, 2, 3, and 4). The authors also suggested a tree-based approach to label the 24 possible solutions based on conceptual understanding. For this paper, we will use the binary labels suggested by [10] to divide students into a group with an **advanced understanding** of stored energy (i.e., for both open and closed circuits) and a second group with a conceptual understanding limited to the closed circuit, denoted as **limited understanding**.

³<https://phet.colorado.edu/en/simulations/capacitor-lab>

Figure 4: Our model building pipeline consists of three steps: we first extract the logs into sequences of events and states. We then categorise the states and events to build state-action sequences. Finally we feed the features into variations of GRU models.

Figure 5: Architecture of our GRU model with one unrolled GRU layer: the input features are fed sequentially into the recurrent cells of the GRU layer. The output shape of each layer is given: $|U|$ denotes the number of users, $\tilde{n} = \max_{u \in \mathcal{U}} \tilde{n}_u$, $cell$ the number of GRU cells, and f the number of features in the input matrix.

can occur naturally throughout a student’s interaction when the mouse moves from one element to the other [31]. The latter might introduce undesired noise and hinder student classification over their conceptual understanding, not unlike stop words negatively influence sentiment analysis tasks in the domain of natural language processing, as an example [15]. To maximise the retention of informative periods of inactivity, we therefore discard for each student $u \in \mathcal{U}$ their 60% of shortest breaks. We are left with $R_u = \{(e_0, s_0, d_0), \dots, (e_{\tilde{n}_u-1}, s_{\tilde{n}_u-1}, d_{\tilde{n}_u-1})\}$ with $\tilde{n}_u \leq n_u$, the final sequence of triplets of events e_m occurring in state s_m and of duration d_m for student $u \in \mathcal{U}$ at time $m \in [0, t_u)$. The new sequence contains \tilde{n}_u event triplets, i.e., *timesteps*.

3.3 Feature Extraction

The data logging of the PhET environments captures any click targeting an “interactive” component as well as the state of the simulation in case one of these “clicks” changes the value of a variable/multiple variables in the system. This fine-grained logging results in high dimensional simulation states s and a high number of different events e . Before creating feature vectors for each time step m , we therefore categorise the obtained events and states into meaningful components. We divide all possible *simulation states* into two groups: a) helpful or b) unhelpful to solve the problem. We then ponder whether some of the *helpful states* can be grouped such that the level of information received by the student is the same independent of the state within the group. We proceed in a similar way for the events. While this categorisation procedure is generalisable over different platforms, whether a simulation state or event is helpful depends on the actual task.

State-Action Categorisation for Capacitor Lab. For the Capacitor Lab activity, we use the state and action categorisation defined in [10]. By applying the above pipeline, we qualify each state $s_m \in (e_m, s_m, d_m)$ into one of the following groups: 1) closed circuit - stored energy displayed, 2) open circuit - stored energy displayed, 3) closed circuit

- stored energy not displayed, and 4) open circuit - stored energy not displayed. Since stored energy is the dependent variable in the ranking task, displaying the stored energy is essential for solving the task. The relationship between the parameters (plate area, plate separation, battery voltage) and stored energy differs for closed and open circuits. Moreover, we map each event $e_m \in (e_m, s_m, d_m)$ into one of the following actions: 1) manipulating battery voltage, 2) manipulating plate area, 3) manipulating plate separation, 4) break, 5) other (any other action).

State-Action Categorisation for Beer’s Law Lab. There are four independent variables that influence the dependent variable *absorbance* of the ranking task: the *laser colour*, the *solution colour*, the *concentration* of the solution, and finally the *width* of the container. Consequently, we categorise each state $s_m \in (e_m, s_m, d_m)$ into one of those 4 groups: 1) green-green (absorbance: displayed, laser colour: green, solution colour: green), 2) green-red (absorbance: displayed, laser colour: green, solution colour: red), 3) absorbance displayed (absorbance: displayed, laser colour: not green and/or solution colour: neither red nor green), 4) not observed (absorbance: not displayed). To solve the ranking task depicted in Fig. 2, students need to understand how the *width* and *concentration* interact with the *absorbance* when the *solution colour* is either red or green and when the *laser colour* is green, i.e., states 1) and 2). The *width* and the *concentration* share a linear dependency with the *absorbance* and are both colour agnostic. As long as the absorbance is observed, those relations can be discovered no matter the colour of the laser or the solution, i.e., state 3. Furthermore, we process each event $e_m \in (e_m, s_m, d_m)$ into one of those categories: 1) width (width slider is moved), 2) concentration (concentration slider is moved), 3) pdf (students are reading the instructions from the ranking task), 4) concentration lab (students are interacting with the second simulation available directly from the Beer’s law lab), 5) breaks, 6) other.

State-Action Sequences. After the categorisation step, each

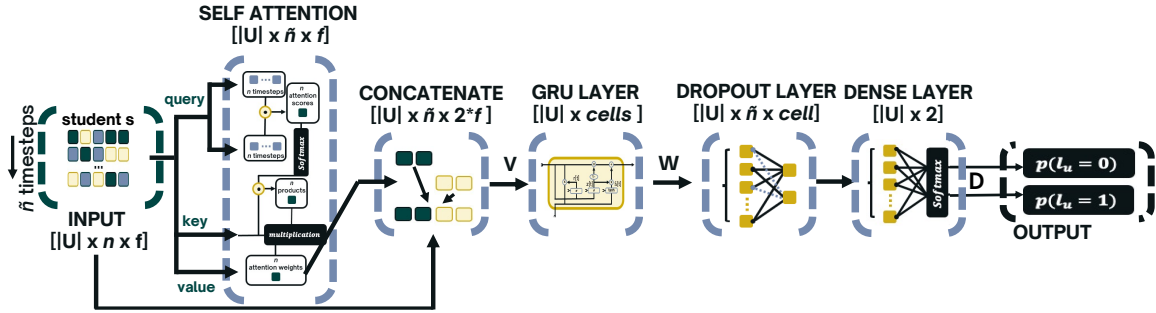

Figure 6: SA-GRU’s architecture with the attention mechanism. The output shape of each layer is given: $|U|$ denotes the number of students, $\tilde{n} = \max_{u \in U} \tilde{n}_u$, f is the number of dimension in the state-action features, and $cells$ is the number of GRU cells.

$e_m \in (e_m, s_m, d_m)$ will have been replaced by e'_m , its corresponding event category, and each $s_m \in (e_m, s_m, d_m)$ will have been replaced by s'_m , its corresponding state mapping. For each timestep m , we encode s'_m as a one-hot-encoded vector v_m^s of c_s cells (with c_s denoting the number of different state categories for the simulation), where all entries are 0 except the one corresponding to s'_m , which is equal to 1. We also transform $e'_m \in (e'_m, s'_m, d_m)$ into a one-hot-encoded vector v_m^e of c_e cells (with c_e denoting the number of different event categories for the simulation), where all entries are 0 except the one corresponding to e'_m , which is equal to d_m . Finally, for each time step m , we replace each triplet (e'_m, s'_m, d_m) by the concatenation of both vectors v_m^s and v_m^e . For each student $u \in U$, the interaction sequence R_u can now be formulated as $\{[v_0^s, v_0^e], \dots, [v_{t_u-1}^s, v_{t_u-1}^e]\}$. We then normalise the sequences on the v_0^e dimension resulting in the final action sequence F_u^{SA} for student $u \in U$.

3.4 Model Building

In this paper, we are interested in creating a conceptual understanding prediction model that can accurately predict the conceptual understanding label L_u for student u , given the extracted features F_u^{SA} . To this end, we rely on two types of models, both based on a *Gated Recurrent Unit* (GRU) network [8]. GRUs are a type of Recurrent Neural Networks (RNNs), whose specificity is to allow the transmission of information over time. To process sequential data, RNNs are composed of r recurrent cells arranged successively such that the output of one becomes the input of the next one, as illustrated on Figure 5. Their relative simplicity enables GRUs to handle smaller datasets (as those in our hands) than the more complex long short-term memory cells (LSTM), which contain an additional output gate [9, 18].

The first type of model is based on a GRU combined with a Dense layer (GRU), as shown in Figure 5. Specifically, the extracted features F^{SA} are fed into a neural architecture composed of a GRU, a dropout layer and a Dense layer (with Softmax activation) having a hidden size of 1. The model outputs the probability the student u will gain advanced (label 1) or limited (label 0) understanding.

The second type of model is based on a Self-Attention-based Gated-Recurrent-Unit (SA-GRU), as shown in Figure 6. In 2014, the concept of an *Additive Attention* layer, also called *Bahdanau attention* was introduced to improve statistical

machine translation [3]. Rather than using it to understand the context of words across languages, we use it to identify the pivotal moments in students’ interactions with the simulation. We first take the raw extracted features F^{SA} as the *query*, *key* and *value* input matrices to our self-attention mechanism implemented as in [16]. We then concatenate the attention output with the input features along each time step and feed this matrix to a GRU layer. Its latest output will directly be given to the dropout layer before passing through the final Dense layer which uses a Softmax activation (analogously to the GRU model). Though more complex than GRU and consequently more subject to overfitting on smaller datasets, SA-GRU’s attention weights can be used to understand what dimension of our features are important for the final prediction, and when that importance is emphasised over time. These aspects are fundamental to enable interpretability on such complex yet effective models.

4. EXPERIMENTAL EVALUATION

We evaluated our (early) prediction models on two data sets collected using the ranking task activities on the PhET Beer’s Law Lab and Capacitor Lab simulations (see Section 2). We used the data set that we collected using the Beer’s Law Lab activity as an *evaluation data set* to assess to what degree student interaction data within the simulation is predictive for their obtained conceptual understanding (RQ1) and whether our models are able to predict students’ conceptual understanding at the end of the task *early* on (RQ2). We then used the data that was collected by previous work [10] using the Capacitor Lab activity as a *validation data set* to assess the transferability of our proposed models to a different population and simulation (RQ3). In the following, we first describe the experimental setup used for our analysis, before describing each experiment in detail.

4.1 Experimental Setup

We compared the predictive performance of our models on the two data sets to baseline models used in prior work [10].

4.1.1 Data Sets

The evaluation and validation data sets were collected in two different classroom experiments (see Table 1).

Evaluation Data Set. Using the Beer’s Law Lab activity (see Section 2), we collected data from 448 laboratory technician apprentices of 10 different vocational schools in a European

	Beer’s Law Lab	Capacitor Lab
Number of students	254	193
Gender	Male: 53% Female: 43% Other: 4%	N/A
Region	A: 70% B: 30%	USA
Education Level	Vocational School	University
Field	Chemistry: 88% Other: 12%	Physics majors: 17% Science/Engineering: 83%
Mean time in simulation	507s	512s
Percentage label 1	44%	51%

Table 1: Statistics of the data sets used for the experiments.

country. The activity was performed directly in the classroom. We recorded students’ interaction logs (clickstream data) as well as their responses to the ranking tasks. For our experiments, we removed participants who did not answer the ranking task (23 students), with an extremely short task duration (less than 2 minutes), or with a low number of events (less than 10 events). The final data set used for the experiment therefore consists of 254 students. Prior to data collection, participants gave their informed consent to sharing the data for research, and all data was recorded in a completely anonymous way. Students could also participate in the learning activity without sharing their data for research. This study was approved by the responsible institutional review board (HREC number: 064-2021).

Validation Data Set. We used the data set collected by [10] on the Capacitor Lab Activity (see Section 2). It contains the interaction logs (clickstream data) and the ranking task responses of 193 undergraduate Physics students of a US university. Students were all in their first year of studies and completed the activity as part of a mandatory homework assignment. Data was recorded in completely anonymous way and students had to give their informed consent prior to data collection. Moreover, students could participate in the learning activity without sharing their data for research. This study was approved by the responsible institutional review board (HREC number: 050-2020).

4.1.2 Baseline Models

We assessed the performance of our sequential models to more simple baseline models. Random forest (RF) models were successfully used in previous work [10] to (early) predict students’ level of conceptual understanding gained through interacting with an interactive simulation. [10] experimented with neural network models and RF models with different type of features and did not find significant differences regarding predictive performance of the different model and feature combinations. We selected RF model with *Action Span* features (RF) as a baseline for our experiments, as this encoding is most similar to our action-state sequences. The *Action Span* features can be easily built from our state and action categories. For each time step m , the encoding of the triplet (e'_m, s'_m, d_m) is similar to a one-hot encoded vector, where all entries are 0 except the one representing $e'_m \times s'_m$ (state-action combination), which is equal to d_m . We therefore obtain a vector v_m of dimensions

$c_s \times c_e$. The raw interaction sequence R_u for student $u \in \mathcal{U}$ then becomes $I_u = \{v_0, \dots, v_{\tilde{n}_u}\}$. We flatten I_u by summing all vectors v_m , resulting in a vector where each cell represents the amount of time in seconds the student spent doing each type of state-action combination. We then normalise the vector by the total duration of the interaction so that the model does not consider the length of each interaction, but rather the proportion of time spent on each condition.

4.1.3 Optimisation Protocol

Both GRU and SA-GRU are relatively sensitive to *seeds* which have an influence on all weight initialisation. To temper the effects of randomness on the models’ training, we used a cross validation with seed mitigation to optimise the neural network models. The usual nested cross-validation optimisation protocol was conducted for the baseline RF model. We evaluated performance of all models using the macro-averaged area under the ROC curve (AUC).

Optimisation for RF. We optimised the RF model using a 10-fold nested cross validation stratified over the labels L_u . We use this step as an evaluation mean for the RF and as a basis for parameter optimisation for the GRU-based models. We ran the inner grid search on the following hyperparameters: the *number of decision trees* [3, 7, 9, 11, 13, 15, 17], the *split criterion* [*gini*, *entropy*], the *maximum depth* [5, 7, 9, 11, 13], the *minimum samples split* [3, 5, 7, 9, 11].

Optimisation for GRU and SA-GRU. For the two sequential models, we performed initial prototyping using a 10-fold nested cross validation (using the same folds as for the RF model) and a small number of seeds. We trained both the GRU and SA-GRU for 150 epochs, using a categorical crossentropy loss and an Adam optimiser. We tuned the following hyperparameters: dropout rate after the GRU layer [0.02, 0.05] and the number of cells [32, 64] in the GRU layers. The initial experiments demonstrated that: the selected hyperparameter values in the inner grid search were the same for a majority of the folds, the categorical cross entropy loss on the inner validation data set tended to converge after 20 – 30 iterations, and predictive performance of the models seemed to vary depending on the seed. We therefore decided to choose a fixed architecture for the GRU and SA-GRU models and limit the number of epochs to 30 for all our experiments. For Beer’s Law Lab the selected parameters were a dropout rate of 0.02 and 32 units for the GRU layer. For the Capacitor Lab, we also use 32 units in the GRU Layer and a dropout rate of 0.05. We evaluated the models using 10-fold cross validation (based on the same outer folds as the RF model). To mitigate the potential effects of randomness, we trained both models over n different seeds and averaged predictive performance across seeds. For our experiments on the full state-action sequences (see Sections 4.2 and 4.4), we used $n = 60$ seeds. Since we observed only minor differences in predictive performance across seeds, we reduced the number of seeds to $n = 10$ for our early prediction experiments (see Sections 4.3 and 4.4).

4.2 RQ1: Full Sequence Prediction

In a first experiment, we investigated whether our proposed models were able to predict students’ level of conceptual understanding based on their interaction data. We used

Figure 7: AUC of the GRU, SA-GRU, and RF models on the evaluation data set collected from Beer’s Law Lab. Predictions were made based on the complete sequential interaction data of the students.

the evaluation data set collected with the Beer’s Law Lab simulation to answer RQ1.

Predictive Performance. Figure 7 illustrates the predictive performance in terms of AUC for the GRU, the SA-GRU, and the RF baseline. Both sequential models outperform the RF baseline: using GRU and SA-GRU models we improve the AUC by 10% ($AUC_{GRU} = 0.77$, $AUC_{SA-GRU} = 0.76$, $AUC_{RF} = 0.70$). We also observe that the RF model exhibits a higher variability across folds than the two sequential models. For those, the minimum AUC is close to 0.70 ($AUC_{min,GRU} = 0.69$, $AUC_{min,SA-GRU} = 0.68$). In contrast, performance of the RF model drops below 0.6 based on the fold ($AUC_{min,RF} = 0.58$). We also performed a preliminary analysis on model bias according to protected attributes. Specifically, we grouped the students based on the available protected attributes and computed predictive performance in terms of AUC separately for the different groups. We found that the GRU model is slightly biased towards male students ($AUC_{m,GRU} = 0.78$, $AUC_{f,GRU} = 0.73$), while the two other models do not show any gender bias. All models show a bias in terms of region, with a higher AUC for region A ($AUC_{A,GRU} = 0.78$, $AUC_{A,SA-GRU} = 0.78$, $AUC_{A,RF} = 0.76$) than for region B ($AUC_{B,GRU} = 0.69$, $AUC_{B,SA-GRU} = 0.66$, $AUC_{B,RF} = 0.63$).

Attention Interpretation. While adding self-attention to the GRU does not increase predictive performance of the model (there is no significant difference in the performance of the GRU and SA-GRU model), the self-attention scores enable interpretation of the such black-box models. The heatmap in Fig. 8 shows the normalised attention scores for the SA-GRU model over 150 time steps. For each student $u \in \mathcal{U}$, we extracted the output (dimension: $n_u \times f$) of the self-attention layer of the SA-GRU model (see Fig. 6) and normalised it to make the attention scores comparable between models. We then averaged across all students. The number of students decreases rapidly with an increasing number of time steps (Fig. 7 (top)). In fact, for 90% of the students, $n_u \leq 150$.

We observe that the model seems to pay most attention to two of the states (*green-red* and *no absorbance*). The former state, *green-red*, indicates a green laser colour and a red solution colour while the absorbance is measured. As expected, exploring with this parameter setting is important for solving the ranking task. The latter state, *no absorbance*,

Figure 8: Normalized attention scores for the SA-GRU over 150 time steps (bottom). Number of students with $n_u \geq t$ for $t = 1, \dots, 150$ (top).

indicates that the absorbance (outcome variable of the task) was not displayed, which makes solving the task impossible. Also the two other states (*green-green* and *absorbance*) seem to have phases of higher importance over time. For the *no absorbance* state, we can see that the the model seems to pay less attention to it with an increasing number of time steps. Generally, the actual state of the simulation seems to be considered as more important than a specific action of the student. Regarding the action, the model seems to pay attention to state *pdf*, which refers to students checking the task description and hence the configurations to be ranked. Also experimenting with *concentration* and *width* seems to have some importance. Interestingly, the importance of taking a *break* varies over time steps. Finally, the model does not pay attention to the *concentration-lab* action.

In summary, this first experiment demonstrated that our proposed models yielded a 10% increase in AUC over the RF approach suggested in previous work [10]. Furthermore, the sequential models also exhibit a lower variance across folds. Finally, by adding self-attention to a GRU model, we were able to provide interpretations of what type of student exploration behavior will lead to successfully solving the task.

4.3 RQ2: Early Prediction

In our second experiments, we were interested in predicting students’ level of understanding *during* their interaction with the simulation. We therefore did not use all students’ full interaction sequences, but used partial interactions up to a time step l when the student went over that limit. Therefore to build the features $F_u^{l,SA}$ for student $u \in \mathcal{U}$, we only used the interactions I_u^l as a basis for building the features (see also Section 3.3). We trained all our models for $l = 30, 40, 50, 60$. We did not make predictions earlier as we did not expect a model to be able to accurately predict conceptual understanding after only a few student actions. We further limited $l \leq 60$ as the number of students decreases for higher time steps (see also Fig. 8 (top) which indicates the amount of remaining students per time step). At each time step l , we made predictions for students with state-actions sequences at each length l (e.g. $\tilde{n}_u \geq l$). For students with shorter sequences (e.g., $\tilde{n}_u < l$), we used the last available prediction. We used the evaluation data set collected with Beer’s Law Lab to answer RQ2.

Figure 9: Early predictive performance in terms of AUC for RF, GRU, and SA-GRU for the evaluation data set collected using Beer’s Law Lab for $t = 30, 40, \dots, 60$.

Predictive Performance. Fig. 9 illustrates the AUC of the different models for early prediction at $t = 30, 40, 50, 60$. We again observe that the RF baseline model performs inferior to the sequential models. It achieves an AUC of 0.59 after 30 time steps and manages to only slightly improve over time with an AUC of 0.61 after 60 time steps. The AUC of the RF is 0.70 for full sequence prediction (see Section 4.2), we therefore observe a strong increase in predictive performance when observing full sequences. It thus seems that the RF classifiers is not able to extract strong signal from early observations. The use of more elaborate sequential models leads to an up to 15% increase in AUC ($AUC_{30,GRU} = 0.67$, $AUC_{30,SA-GRU} = 0.68$, $AUC_{60,GRU} = 0.72$, $AUC_{60,SA-GRU} = 0.72$). Similar to the full sequences case, RF exhibits a much higher variance across folds than that our proposed models.

Attention Interpretation. Next, we investigated whether attention scores differed between an early prediction and a full sequence prediction model, i.e. whether the model paid attention to different features when making early predictions.

Figure 10 shows the normalised attention scores for the SA-GRU model trained to predict at time step $t = 30$. The scores in the heatmap were calculated following the same procedure as for the full sequences case (see Section 4.2). Similar to our findings on full sequences, we observe that the states generally seem to be assigned higher scores than the actions. While we again observe that the *no absorbance* and *green-red* states have relatively higher scores, we also observe that these scores vary over time. The scores of the *no absorbance* state clearly decrease over time. This finding might suggest that many students realise during their first 10 – 15 interactions with the simulation that the absorbance display should be turned on (by default, transmittance is displayed). In contrast, the scores of the *green-red* state increase over time, indicating that after being able to observe the outcome variable (absorbance), it is important to select the optimal colours for laser (green) and solution (red). For the actions, we observe the same picture as for the full predictions. The *concentration-lab* action gets little attention (it is probably also a rare action), while manipulating *width* and *concentration* gets similar attention over time. Checking the task description is mainly important early on. The model does not pay attention to *break* for the first 10 time steps. We hypothesise that “thinking” breaks do not occur often during initial interaction when students are still focused on understanding the task and have not yet started their exploration.

Figure 10: Normalised attention scores for SA-GRU trained for predicting at $t = 30$ time steps for Beer’s Law Lab.

In summary, our second set of experiments showed that in case of early prediction, the use of a GRU or SA-GRU model leads to even larger performance increases than in case of full sequences. Depending on the time step, we observe improvements in AUC of 15% compared to the RF baseline. Furthermore, the RF again shows high variability with drops in AUC down to 0.50. We are again able to provide meaningful interpretations of the attention weights, which is a promising basis for targeted intervention.

4.4 RQ3: Generalisation

In our last experiment, we were interested in assessing the generalisability of the developed models. While both learning activities were based on a ranking task, the underlying simulation as well as the population are different. We therefore evaluated our models on the transfer data set collected from the Capacitor Lab simulation.

Prediction on Full Sequences. We first evaluated the generalisability of the different model by predicting on the full interaction sequences of the validation data set. Figure 11 illustrates the predictive performance in terms of AUC for the GRU, the SA-GRU, and the RF baseline. We observe that all the models achieve a very high AUC for the Capacitor Lab data set. The sequential models achieve an AUC of 0.96 (GRU) and 0.96 (SA-GRU) respectively, while the AUC of the RF baseline is 0.95. Again the RF baseline model shows higher variability, achieving a minimum AUC of 0.86. For the GRU and SA-GRU models, we achieved a minimum AUC of 0.9 and 0.89 respectively. For Capacitor Lab, we ran the same bias analysis on protected attributes as for Beer’s Law Lab, showing that models are not biased with respect to field (the only known protected attribute for this data set).

While the SA-GRU model does not outperform the other two models, we again extracted the attention weights of this model and interpreted them. Figure 12 shows the normalised attention scores of the SA-GRU models over a 100 time steps. We chose to limit to 100 time steps as for 90% of the students $\tilde{n}_u \leq 100$. Again, the scores displayed in the heatmap were calculated using the procedure described in Section 4.2. Similar to our findings on Beer’s Law Lab, we observe that the states (*stored energy*, *closed circuit*) receive higher attention than the actions. For *stored energy*, attention scores increase up to time step 30 and then decrease again after time step 60. We assume that students needed some time to explore the simulation and figure out that the stored energy

Figure 11: AUC of the GRU, SA-GRU, and RF models on the validation data set collected from CapacitorLab. Predictions were made based on the full interaction data of the students.

Figure 12: Normalised attention scores for CapacitorLab for the SA-GRU over 150 time steps (bottom). Number of students with $n_u \geq t$ for $t = 1, \dots, 150$ (top).

display needs to be turned on (it is by default turned off in the simulation). For the *closed circuit* state, attention scores decrease over time, but there are always phases of increased activity. In order to be able to solve the ranking task, it is important to experiment with the closed as well as the open circuit, as detected by the model. The model also seems to pay attention to actions related to *voltage*, *plate area*, and *plate separation*, which are the other three components in the simulation that influence the stored energy. Moreover, *breaks* are important for different phases within the sequences. Hence, the model seems to detect when students take a thinking break and considers that as important.

Early Prediction. Next, we also trained the different models for early prediction on Capacitor Lab. Figure 13 shows the AUC of the evaluated models for prediction on $t = 30, 40, 50, 60$ time steps. We see that the AUC of the two sequential model is close to 0.80 already after observing 30 student interactions ($AUC_{30,GRU} = 0.8$, $AUC_{30,SA-GRU} = 0.81$). Predictive performance of the RF model is slightly lower ($AUC_{30,RF} = 0.76$). After 60 time steps, all the models achieve an AUC larger than 0.8 ($AUC_{60,GRU} = 0.9$, $AUC_{60,SA-GRU} = 0.9$, $AUC_{60,RF} = 0.88$). We observe that all three models show a similar variability under this task.

In summary, our results demonstrate that the proposed models can be transferred to a different learning environment and population. In case of full interaction data, the performance of the models is inline with the RF baseline, in case of early prediction, the sequential models outperform the base-

Figure 13: AUC of the GRU, SA-GRU, and RF models for early prediction ($t = 30, 40, \dots, 60$) on Capacitor Lab.

line. Furthermore, the addition of self-attention again enabled us to identify the key points in the exploration process.

5. DISCUSSION AND CONCLUSION

Interactive simulations used for inquiry-based learning activities are increasingly gaining traction as part of science education at all levels. It has thus become essential to understand how students navigate in such environments in order to provide them with targeted and well-timed feedback. To address this issue, we introduced a new data-driven approach to predict students’ conceptual understanding after solving inquiry-based learning tasks with interactive simulations. We leveraged log data directly recorded in these environments to extract meaningful features that were then used as input to models based on Gated Recurrent Units (GRU) to predict their conceptual understanding. In addition to a standard implementation of a GRU model, we also explored an extension, the Self-Attention-based Gated Recurrent Unit (SA-GRU) model, and compared their performance against a random forest (RF) classifier presented in prior work [10]. We evaluated our approach on two data sets collected from different populations (vocational and undergraduate students) who used two different environments (a chemistry and a physics simulation). We aimed at answering to three research questions: 1) To what degree is student interaction data within interactive simulations predictive for their obtained conceptual understanding? 2) Can our models predict students’ conceptual understanding early on? 3) Is our approach transferable to another context involving a different population and simulation?

To answer the first research question, we trained the proposed models using data collected from 254 first, second and third year lab technician apprentices who solved a ranking task using the PhET Beer’s Law Lab simulation. Using the complete log sequences of the students, both the GRU and SA-GRU models yielded AUC values of 0.77 and 0.76 respectively, outperforming the RF baseline model presented in previous work [10] by 10%. For both models, we also observed lower variance across training folds, indicating a higher robustness compared to the RF baseline. Previous research has highlighted that along with predictive accuracy, it is the interpretability of the models that can make a significant difference in improving student learning outcomes [12]. While adding the self-attention layer to the GRU models did not further improve their predictive performance, our analyses illustrated that they significantly enhanced the interpretability of the model results. For instance, analysing the attention scores of the SA-GRU model, we observed that the state s in which an action a is conducted is more important

than the nature of action a itself to predict conceptual understanding. Experimenting in a setting where the variable of interest is observed, and where the environment settings correspond to those present in the problem, is influential.

Our findings are in line with those of [32], who suggested that knowledge-grounded features that integrate qualitative observations are better predictors than purely actions-based features. From the attention score analysis, we also observed that taking breaks showed an interesting pattern with an alternating importance for the model over time. This result seems to indicate that taking breaks at specific moments during the activity may be predictive of the acquired understanding. These results are very much in line with those reported in previous work [26, 7], who illustrated that recurrently taking breaks for reflection and planning can be a powerful inquiry strategy in interactive simulations.

To address the second research question, we then trained the models with only initial sequences of the students' log data in order to evaluate their capabilities to early predict students' conceptual understanding. Naturally, the performance of all models dropped compared to the training on the full sequences. However, both the GRU and SA-GRU outperformed the RF baseline also in early prediction, with AUC values that were up to 15% higher and with lower variance across training folds. After only 30 time steps in the simulation, AUC values for the GRU and SA-GRU models already reached 0.67 and 0.68 respectively. Moreover, the analysis of the attention scores of the SA-GRU model showed that already after 30 time steps, meaningful interpretations could be made similar to those in the case of the models trained on the full sequences. This is a crucial result, since it enables the implementation of targeted interventions that could, for instance, support struggling students early on while they are still solving the tasks. Such interventions could potentially be implemented as automatic feedback that is directly displayed in the simulation, similar to approaches that have been adopted previously for other computer-based learning environments [5]. Another possibility could be to display the insights gained from the models to teachers using real-time dashboards [29, 22], to support them in preparing interventions for individual students and/or the entire class.

Finally, to answer our third research question we evaluated our approach on a second data set from [10]. It comprised log data from a different simulation (the PhET Capacitor Lab) that was used by a different population (undergraduate students attending a physics class). The goal of this analysis was to demonstrate that the functioning of our models is not restricted to a single context, but could be transferred to other populations and environments. In the case of training on the full sequences of log data, all three models performed very well with AUC values above 0.95. Since in this case the RF baseline already showed a good performance, the use of the GRU and SA-GRU models only increased the AUC by 1%. Similar to the results from the Beer's Law Lab data set, we found higher importance for states (stored energy toggled and circuit closed) in the attention scores of the SA-GRU model. The high attention scores for the stored energy state could be explained by the observations made in previous work using the same simulation. [22] found that despite the stored energy being the target outcome variable

of their task, not all students toggled the function to display it. Similarly, the stored energy state could have served as a useful feature to detect unproductive behaviour in our task. Moreover, while the design of the ranking tasks for both simulations was similar, the use of different circuit states (closed or open) in the Capacitor Lab might be more discriminatory for student performance than the color states in Beer's Law Lab. This could explain why for the Capacitor Lab the RF baseline also performed very well. Finally, when looking at early prediction, we observed again that GRU and SA-GRU exhibited better performances compared to RF despite the differences being smaller than for Beer's Law Lab. Variances across folds, however, were similar across models.

Our findings represent an important step towards a better understanding and modelling student behaviour in ranking-based inquiry learning activities within interactive simulations. Though the presented task is very specific, its key characteristics can be retained and transferred onto other interactive environments. Furthermore, the capabilities of the presented models to detect (un-)productive behaviour early on pave the way for more targeted interventions carried out by teachers or the system itself.

Nevertheless, this study also comes with certain limitations. First, the chosen labels for the Beer's Law Lab are only able to separate *struggling students* from *more advanced students*, giving us an indication of whether students can conduct inquiry rather than whether they have understood Beer's Law. Then, our preliminary bias analysis has indicated that some models show a slight gender bias (in case of the Beer's Law Lab simulation) and all models exhibit a geographic bias (also for the Beer's Law lab simulation). Therefore, further work on bias mitigation is needed. This includes understanding where the differences in predictions come from, as well as identifying any other confounding factors. Furthermore, while the presented methods were applied to two different data sets involving different contexts to illustrate its transferability, it can not be guaranteed that they are unreservedly applicable to any other inquiry-based learning situation involving interactive simulations. More research including larger and more diverse samples as well as different educational levels, simulations, and learning tasks are needed to consolidate the generalisability of our methods. This is particularly important in order to mitigate the risks of algorithmic bias that could be introduced. Furthermore, it needs to be acknowledged that measuring students' conceptual knowledge by means of a single outcome variable (i.e., the final ranking submitted) might be too limiting. While the number of possible rankings could be considered sufficiently high to filter out the effect of random answers, other measuring tools (such as quizzes or interviews) could be included to complement the analyses. Finally, it should be emphasised that before any interventions based on the proposed methods are being introduced, it is imperative that the main stakeholders (i.e., teachers and students) are involved. Only in this way the potential educational impacts of such approaches can be assessed, implying both positive and negative consequences for the concerned groups.

ABSTRACT

Predicting student performance in an academic institution is important for detecting at-risk students and administering early-intervention strategies. We propose a new grade prediction model that considers three factors: temporal dynamics of prior courses across previous semesters, short-term performance consistency, and relative performance against peers. The proposed architecture comprises modules that incorporate the attention mechanism, a new short-term gated long short-term memory network, and a graph convolutional network to address limitations of existing works that fail to consider the above factors jointly. A weighted fusion layer is used to fuse learned representations of the above three modules—course importance, performance consistency, and relative performance. The aggregated representations are then used for grade prediction which, in turn, is used to classify at-risk students. Experiment results using three datasets obtained from over twenty thousand students across seventeen undergraduate courses show that the proposed model achieves low prediction errors and high F1 scores compared to existing models that predict grades and thereafter identifies at-risk students via a pre-defined threshold.

Keywords

Grade prediction, machine learning, attention mechanism, long short-term memory network, graph convolutional network

1. INTRODUCTION

Learning analytics involves the process of collecting, analyzing, and reporting of data generated by learners in an education setting. It optimizes learning and the environment by gaining insights into the learning behavior and/or learner achievements [39]. Among the several sub-disciplines that learning analytics transcends across, prediction of academic performance has received increasing attention in recent years and remains one of the most challenging tasks. Grade prediction plays a central role in the development

of data-informed approaches for early-intervention strategies and it is therefore important to achieve a low prediction error—errors leading to high false alarms will result in reduced morale and inefficient allocation of resources while missed detection often results in sustained poor performance [29]. After grade prediction, at-risk students are identified as those whose performance satisfy a pre-defined set of conditions (e.g., those who score below the passing mark in one or more courses).

1.1 Existing Works for Grade Prediction

Prediction of academic performance in the form of grade point averages [15], examination grades [13], or academic achievements [25] can be achieved via a variety of sources. These sources include (but not limited to) online learning activities [22, 28, 44], co-curricular activity records [8], demographics [38], and course grades obtained from previous semesters [13, 23, 32, 34]. While online learning offers numerous opportunities for the exploitation of data associated with learning behaviors (in the form of clickstreams and/or online assessment results) [46], many academic institutions still rely on face-to-face instructions for some courses. Extraction of learning behaviors for these courses via audio/visual capturing devices may present challenges in terms of technological capability and privacy concerns. In addition, co-curricular activity records and demographic profiles may not be readily available due to the general personal data protection policies [3]. Therefore, grade prediction using past examination records as useful features [45] has been the main focus in recent years since examination results are often made accessible to policy makers, administrators, instructors, and student care support personnel involved in developing and administering intervention strategies.

Machine learning techniques have been proposed to predict grades of a given (pilot) course based on those achieved in historical (prior) courses. These models exploit the temporal dynamics of student performance across semesters from two aspects—consistency in academic performance and course importance [47]. These aspects have been modeled using a sequential model and the attention mechanism [24], respectively. Sequential models such as the long short-term memory (LSTM) has been applied to model long-term dependencies in online interaction [17] and to predict the grade point average of a given semester from marks obtained across various courses [33]. More recently, as opposed to predicting the aggregated performance for a semester, the LSTM was trained to predict the grade of each course [13]. In

this model, a vector representation of course grades achieved in each of the previous semester was used as input for the LSTM model.

Notwithstanding the above, a course-specific regression model that predicts the grade of a pilot course as a sparse linear combination of prior grades has been proposed [35]. Results presented highlight the detrimental effects of missing regressors for students who have yet attempted an “important” prior course. While modeling of the temporal dynamics of student performance along with the incorporation of the attention mechanism for grade comparison between students has been proposed [30], the intrinsic formulation of LSTM limits its ability to model short-term consistency [21]. Despite the use of knowledge distillation [27], such models do not consider peer performance among students.

In recent years, graph convolutional network (GCN) have been employed to generate meaningful feature representations. In contrast to the use of grade vectors in temporal modeling approaches, these representations model the transitions of grade distributions between courses across semesters [12]. Here, the performance of each student is considered for courses taken consecutively. More recently, nodes representing either students or courses have been used to construct student-course, student-student, and course-course graphs [23]. These graphs consist of edge links computed via grade distribution similarities; they do not model both the long- and short-term sequential information of each student.

While the above techniques achieve good prediction performance, the models are optimized independently and do not consider all the above-mentioned aspects jointly. A holistic approach toward predicting academic performance is important and motivated, in part, by Walberg’s theory of educational productivity. Apart from external variables such as quality of instruction and climate, student-centric variables that include prior achievement and student cognitive capacity will influence the academic performance of an individ-

ual [43].

1.2 The Proposed Model Architecture

Inspired by student-centric factors highlighted in Section 1.1, we propose an academic achievement-based grade prediction (A2GP) architecture that jointly models the (i) importance of prior courses, (ii) short-term consistency in academic performance across previous semesters, and (iii) benchmarking of student performance relative to their peers. With reference to Figure 1, the first module of the proposed architecture comprises an attention-based LSTM network that encodes the influence of prior course grades on the pilot course. This module is based on existing sequential models (such as LSTM) that have been employed to capture the temporal dynamics of past academic performance [13]. These models are motivated by studies that have established the association between course orderings and academic performance [9, 26]. Such an association is not surprising given that the constructivist approach has often been adopted for curriculum design, resulting in the influence of various prior courses on a pilot course [37]. Such a constructivist strategy has also shown to be effective in terms of academic achievement [2, 18] and improving content mastery that requires higher cognitive levels [1]. Temporal modeling of performance using LSTM is also in line with the Tinto’s Student Integration Model which posits that persistence in higher education is a temporal process [5], i.e., the ability to achieve learning outcomes of fundamental courses will influence that of other advanced or related courses. This is further justified if the prior course serves as a pre-requisite for the pilot course.

Compared to existing models that model long-term dynamics of academic achievements, the second module consists of a new short-term gated LSTM (STG-LSTM) that models short-term consistency in academic performance for each student. This module is motivated by the need to consider academic momentum that highlights the influence of workload (which varies across courses and semesters) on academic performance and the achievement of learning out-

comes [14]. Short-term consistency may also arise from academic performance being highly dependent on multiple (yet often convoluted) factors such as socio-economic, psychological, and environmental conditions that a student may face in the recent (past) semesters [36]. From developmental perspective, knowledge inquiry is known to evolve over a series of micro-development resulting in short-term variations in performance [7]. This also aligns with findings that demonstrate the positive effect of mastery and performance goals on short-term and long-term consequences of student achievement [10]. The identification of these patterns would therefore lead to more effective grade prediction.

Beyond representing the performance of a student over time, students are often deemed as at-risk if their performance is consistently below par compared to their peers. In particular, for courses perceived as easy which most students achieve a high grade, achieving a reasonable grade (e.g., Grade C) may still constitute as at-risk when most peers achieved a Grade A. Conversely, a Grade C may not be inferred as being at-risk when most peers achieved similar (or lower) grades for a course perceived by most as challenging. Accounting for such benchmarking of grades is important since such relative performance has shown to achieve lower grade prediction bias than one based on absolute grades [4, 41, 42]. In light of the above, the third module involves a graph convolutional network that models grade differences between student pairs across all prior courses taken by them. This module exploits information derived from students who perform similarly/dissimilarly across commonly taken courses and models such representation that describes the relative performance between students.

For grade prediction, learned academic achievement representations associated with temporal dynamics of past performance, short-term performance consistency of an individual, and relative performance against peers are synthesized via a weighted fusion layer. We formulate a learnable parameter in this layer that determines the relative emphasis of factors influencing the pilot course grade. Learning the weightings for these academic achievement representations is important to model the underlying characteristics of a dataset that contribute to the joint optimization of the model. Performance of the proposed A2GP architecture is evaluated over three student performance datasets obtained over seventeen courses from over twenty thousand students in a university. Results obtained highlighted that the A2GP model improves the performance of LSTM and GCN by 19.0% and 63.3%, respectively, in terms of F1 score for at-risk classification.

This paper is organized as follows: the problem statement and background formulations are described in Section 2. Technicalities of the proposed A2GP model are detailed in Section 3. Details of the datasets, as well as, the comparison analysis with discussions are described in Section 4 while Section 5 concludes the paper.

2. PRELIMINARIES

2.1 Problem Statement

The problem of grade prediction and at-risk detection from prior grades can be described by defining, for each student index i , the exam grade $x_{i,l,s}$ achieved for a prior course l

during semester s . Denoting L as the total number of prior courses, a $1 \times L$ grade vector for semester s is given by

$$\mathbf{x}_{i,s} = [x_{i,1,s}, \dots, x_{i,L,s}], \quad (1)$$

where $x_{i,l,s} = \phi$ is a null element corresponding to an unregistered course l in that semester. The prior course grades of a student across S number of semesters under consideration can then be represented as an $L \times S$ matrix

$$\mathbf{X}_i = [\mathbf{x}_{i,1}^T, \dots, \mathbf{x}_{i,S}^T]. \quad (2)$$

With the above, columns of \mathbf{X}_i form a sequence of vectors that encapsulates the ability of a student to achieve learning outcomes (measured by grades). Given the database of (student, course, grade) up to semester S , the aim is to predict grades for each student on courses he/she will be enrolling in the coming semester.

2.2 Modeling Long-term Dynamics of Academic Performance using LSTM

To model the academic performance across semesters, \mathbf{X}_i serves as features for the prediction of course grades in the forthcoming examinations [13]. The use of \mathbf{X}_i , therefore, allows the model to account for courses that a student has re-attempted. An LSTM unit in semester s is described by

$$\mathbf{h}_{i,s} = \text{LSTM}(\mathbf{x}_{i,s}, \mathbf{h}_{i,s-1}), \quad (3)$$

where the above compact form is defined by

$$\mathbf{f}_{i,s} = \sigma(W_f \cdot \mathbf{x}_{i,s} + V_f \cdot \mathbf{h}_{i,s-1} + \mathbf{b}_f), \quad (4a)$$

$$\mathbf{u}_{i,s} = \sigma(W_u \cdot \mathbf{x}_{i,s} + V_u \cdot \mathbf{h}_{i,s-1} + \mathbf{b}_u), \quad (4b)$$

$$\mathbf{o}_{i,s} = \sigma(W_o \cdot \mathbf{x}_{i,s} + V_o \cdot \mathbf{h}_{i,s-1} + \mathbf{b}_o), \quad (4c)$$

$$\tilde{\mathbf{c}}_{i,s} = \sigma(W_c \cdot \mathbf{x}_{i,s} + V_c \cdot \mathbf{h}_{i,s-1} + \mathbf{b}_c), \quad (4d)$$

$$\mathbf{c}_{i,s} = \mathbf{f}_{i,s} \odot \mathbf{c}_{i,s-1} + \mathbf{u}_{i,s} \odot \tilde{\mathbf{c}}_{i,s}, \quad (4e)$$

$$\mathbf{h}_{i,s} = \mathbf{o}_{i,s} \odot \tanh(\mathbf{c}_{i,s}). \quad (4f)$$

The variables \mathbf{u} , \mathbf{f} , \mathbf{o} and their associated subscripts denote the update, forget, and output gates, respectively. These control gates regulate information to be stored in the cell state $\mathbf{c}_{i,s}$ in (4e) allowing LSTM to achieve long-term memory [11]. The weight matrix for input $\mathbf{x}_{i,s}$ and hidden state $\mathbf{h}_{i,s-1}$ in different gate units are denoted, respectively, by matrices W and V . The variables $\tilde{\mathbf{c}}_{i,s}$ and \mathbf{b} are defined, respectively, as as the cell input activation vector and bias while σ and \tanh are the activation functions. The symbol \odot denotes element-wise multiplication. The ability of a student to achieve the course learning outcomes is therefore encoded in hidden states $\mathbf{h}_{i,s}$, which are then updated when grades for the new courses are made available. Predicted grade \hat{y}_i is then achieved via a fully-connected (FC) layer

$$\hat{y}_i = \mathbf{w} \cdot \mathbf{h}_{i,S}^T + b, \quad (5)$$

where \mathbf{w} and b are defined, respectively, as the weight vector and bias scalar for the FC layer.

2.3 Modeling Relative Performance using GCN

GCN has been applied to model the interactions between nodes in a graph network. As opposed to [12], where the GCN models transitions between courses across semesters, we define \mathbf{A} as the adjacency matrix such that its elements

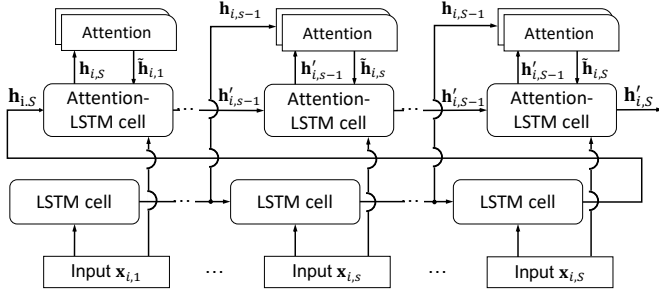

Figure 2: Modeling course importance.

$A_{i,j}$ denotes the similarity of prior grades between two students—a value of 1 is assigned between students i and j having exactly the same prior grades. The model incorporates a feature matrix \mathbf{F} with elements corresponding to first attempt grades that a student obtained over the past semesters for each prior course. Multiple layers of GCNs are then applied to \mathbf{A} and \mathbf{F} with the $(g+1)$ th layer being computed via [20]

$$\mathbf{Z}^{(g+1)} = \sigma \left(\mathbf{D}^{-\frac{1}{2}} \mathbf{A} \mathbf{D}^{-\frac{1}{2}} \mathbf{Z}^{(g)} \mathbf{W}^{(g)} \right). \quad (6)$$

Here, \mathbf{D} is the normalization matrix, $\mathbf{Z}^{(g)}$ is the input to the next layer, and $\mathbf{W}^{(g)}$ is the weight matrix. With the input of the first GCN layer being $\mathbf{Z}^{(0)} = \mathbf{F}$, the output of the last GCN layer is the student-specific graph embedding matrix

$$\mathbf{Z}^{(G)} = [\mathbf{z}_1^T, \dots, \mathbf{z}_K^T]^T, \quad (7)$$

where G is the number of GCN layers. Each node embedding (row) vector \mathbf{z}_i for each node (student) then serves as an input to the subsequent FC layer for grade prediction.

3. THE PROPOSED A2GP MODEL

3.1 Modeling Course Importance

Inspired by the attention mechanism in sequence-to-sequence models [24], the first module comprises an LSTM layer and the attention-LSTM layer to model course importance. To formulate the above and as shown in Figure 2, columns of the grade matrix \mathbf{X}_i in (2) serve as input sequences to the LSTM and the ability to achieve the course learning outcomes is therefore encoded in hidden states $\mathbf{h}_{i,s}$ defined in (4f).

The last hidden state $\mathbf{h}_{i,s}$ will be used to initialize the hidden state of the subsequent attention-LSTM layer. This layer is necessary to account for the influence of the various prior courses on the pilot course of interest. The attention mechanism in this layer can be described by first defining

$$\tilde{\mathbf{h}}_{i,s} = \begin{cases} \mathbf{h}_{i,s}, & \text{if } s = 1; \\ \mathbf{W}_h \cdot [\alpha_{i,s-1} \odot \mathbf{h}_{i,s-1}; \mathbf{h}'_{i,s-1}]^T, & \text{if } s > 1 \end{cases} \quad (8)$$

as the hidden activation vector, where $\mathbf{h}_{i,s-1}$ is the hidden state of the LSTM layer and $\mathbf{h}'_{i,s-1}$ is the hidden state of the attention-LSTM layer. Here, \mathbf{W}_h is the weight matrix that is to be trained, and the prime notation denotes for the attention layer. Therefore, the hidden activation vector $\tilde{\mathbf{h}}_{i,s}$ is

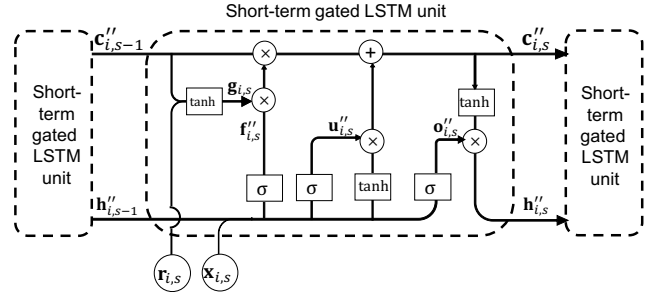

Figure 3: Modeling consistency in student short-term performance.

first initialized as the last hidden state $\mathbf{h}_{i,s}$ from the previous LSTM layer before being updated based on the learned semester-aware attention. Defining \mathbf{W}_α as the weight matrix, the semester-aware attention in (8) for semester s is given by

$$\alpha_{i,s-1} = \text{Softmax}(\mathbf{W}_\alpha [\mathbf{h}_{i,s-1}; \mathbf{h}'_{i,s-1}]). \quad (9)$$

The hidden state for the next unit $\mathbf{h}'_{i,s}$ (of this attention layer) is then computed using student prior grade $\mathbf{x}_{i,s}$ and the hidden activation vector $\tilde{\mathbf{h}}_{i,s}$ such that

$$\mathbf{h}'_{i,s} = \text{Attention-LSTM}(\mathbf{x}_{i,s}, \tilde{\mathbf{h}}_{i,s}), \quad (10)$$

where the Attention-LSTM($\mathbf{x}_{i,s}, \tilde{\mathbf{h}}_{i,s}$) is defined in the same form of LSTM($\mathbf{x}_{i,s}, \mathbf{h}_{i,s}$) in (3) except for the additional attention and hidden activation vector computed in (8) and (9).

We note from (8) that $\tilde{\mathbf{h}}_{i,1}$ is generated from $\mathbf{h}_{i,s}$, which encodes the academic performance over past semesters. This allows the attention-LSTM layer to incorporate both aggregated and semester-based information simultaneously when computing the semester-aware attention for each semester. The last hidden state $\mathbf{h}'_{i,s}$ of the attention-LSTM layer is then used along with short-term performance consistency and the relative performance representation (described below) for the grade prediction.

3.2 Modeling Consistency in Short-term Performance

Modeling short-term variations in academic performance is necessary since such variations may result from active (or the lack of) intervention strategies administered by the academic institution or changes in social-economic status that distracts students away from their academic pursuit [36]. In the second module, we formulate a short-term gated LSTM that employs, for each semester s , the average examination score computed across three consecutive semesters $s-1$, s and $s+1$, i.e.,

$$\mathbf{r}_{i,s} = \begin{cases} [0, \bar{x}_{i,s}, \bar{x}_{i,s+1}], & \text{if } s = 1; \\ [\bar{x}_{i,s-1}, \bar{x}_{i,s}, \bar{x}_{i,s+1}], & \text{if } 1 < s < S; \\ [\bar{x}_{i,s-1}, \bar{x}_{i,s}, 0], & \text{if } s = S, \end{cases} \quad (11)$$

where $\bar{x}_{i,s}$ is the average of non-empty elements in $\mathbf{x}_{i,s}$ defined in (1). Short-term performance averages are then em-

ployed to update information in the memory cell via

$$\mathbf{g}_{i,s} = \tanh(W_g \cdot \mathbf{r}_{i,s} + V_g \cdot \mathbf{c}_{i,s-1} + \mathbf{b}_g), \quad (12a)$$

$$\mathbf{c}_{i,s}'' = \mathbf{g}_{i,s} \odot \mathbf{f}_{i,s}'' \odot \mathbf{c}_{i,s-1}'' + \mathbf{u}_{i,s}'' \odot \tilde{\mathbf{c}}_{i,s}'', \quad (12b)$$

$$\mathbf{h}_{i,s}'' = \mathbf{o}_{i,s}'' \odot \tanh(\mathbf{c}_{i,s}''), \quad (12c)$$

where W_g and V_g are the weight matrices and b_g is the bias term for the short-term gate $\mathbf{g}_{i,s}$. The formulations of $\mathbf{f}_{i,s}''$, $\mathbf{u}_{i,s}''$, $\mathbf{o}_{i,s}''$, the input activation function $\tilde{\mathbf{c}}_{i,s}''$, and the hidden state $\mathbf{h}_{i,s}''$ are identical to those defined in (4). As shown in (12b), both $\mathbf{g}_{i,s}$ and the forget gate $\mathbf{f}_{i,s}''$ control information updates from previous cell state $\mathbf{c}_{i,s-1}''$. The last hidden state $\mathbf{h}_{i,s}''$ is used with other academic achievement representations in the fusion layer for grade prediction.

To gain insights into the above and with reference to Figure 3, the new short-term gate defined in (12a) utilizes $\mathbf{r}_{i,s}$ and $\mathbf{c}_{i,s-1}''$ to determine how short-term consistency in performance affects the cell state update. As opposed to (4a) where the sigmoid function is used, we employ tanh activation in (12a). This is to avoid sharp damp gradients during back propagation, gradient saturation, and gradient updates propagating in different directions when the sigmoid function is used [16, 31]. In addition, $-1 \leq \mathbf{g}_{i,s} \leq 1$ allows the module to model both the positive and negative relationship between performance variation and the cell states.

We also note from (12b) that the previous cell state $\mathbf{c}_{i,s-1}''$ is weighted by both the forget gate $\mathbf{f}_{i,s}$ and the short-term gate $\mathbf{g}_{i,s}$. As per conventional LSTM described by (4a), $\mathbf{f}_{i,s}''$ determines the amount of information to discard from the cell. The short-term gate incorporating $\mathbf{r}_{i,s}$ and $\mathbf{c}_{i,s-1}''$ encapsulates information pertinent to both short-term performance variation and long-term past performance before being passed to the next cell state. Unlike LSTM, where both the input activation $\tilde{\mathbf{c}}_{i,s}''$ and the previous cell state $\mathbf{c}_{i,s-1}''$ are weighted by a gate learned from the current input and the previous hidden state in (4e), only $\mathbf{c}_{i,s-1}''$ is weighted by $\mathbf{g}_{i,s}$ and $\mathbf{f}_{i,s}''$ in (12b). This is because the input gate $\mathbf{u}_{i,s}''$ does not cater for the removal of information from the cell state. Therefore, weighing the input gate $\mathbf{u}_{i,s}''$ by $\mathbf{g}_{i,s}$ in the second term of (12b) is ineffective. Furthermore, applying such weighting on the output gate $\mathbf{o}_{i,s}''$ may result in relevant information being lost in the next hidden state.

3.3 Modeling Relative Performance Against Peers

The third module models the relative performance between students by employing the graph convolutional layer. We first define a $K \times L$ prior score matrix across all students as

$$\mathbf{F} = [\tilde{\mathbf{x}}_1^T, \dots, \tilde{\mathbf{x}}_K^T]^T, \quad (13)$$

where K is the total number of students under consideration and $\tilde{\mathbf{x}}_i = [\tilde{x}_{i,1}, \dots, \tilde{x}_{i,L}]$ with elements $\tilde{x}_{i,l}$ being the first-attempt grade of the i th student for course l . Unlike (2) where grades across every semester are used in the first module, only first attempts are used for the construction of peer-performance graph since they better represent the ability of the student in achieving the learning outcome compared to his/her peers. In addition, the $\{i, j\}$ th element in the pro-

posed $K \times K$ adjacency matrix \mathbf{A} is given by

$$A_{i,j} = \begin{cases} 0, & \text{if } \|\mathbb{N}_{i,j}\| = 0; \\ \rho_{i,j}^{-1} = \left(\frac{\sum_{l \in \mathbb{N}_{i,j}} |\tilde{x}_{i,l} - \tilde{x}_{j,l}|}{\|\mathbb{N}_{i,j}\|} \right)^{-1}, & \text{if } \|\mathbb{N}_{i,j}\| > 0; \\ 1, & \text{if } \tilde{\mathbf{x}}_i = \tilde{\mathbf{x}}_j. \end{cases} \quad (14)$$

Here, we define $\mathbb{N}_{i,j}$ as the set of common courses that students i and j have taken and $\|\mathbb{N}_{i,j}\|$ as the number of such courses. Therefore, $\rho_{i,j}$ denotes the average grade difference that students i and j have achieved for these common courses. The above formulation implies that elements of the adjacency matrix $0 \leq A_{i,j} \leq 1$ correspond to the degree of similarity in academic performance between two students.

With \mathbf{A} and \mathbf{F} , the GCN encodes peer performance via graph representation $\mathbf{Z}^{(g)}$ computed using (6). We apply two GCN layers and the i th row of $\mathbf{Z}^{(2)}$ (denoted by \mathbf{z}_i) constitutes the graph representation corresponding to the relative performance vector for each node (i.e., for the i th student).

3.4 Weighted Fusion Layer and Grade Prediction

To determine the weighting for each academic achievement representation highlighted in Sections 3.1-3.3, a weighted fusion layer is employed. The fusion weight is learned by employing statistics associated with prior and semester average grades. More specifically, we define, for each student i , a 1×4 vector

$$\mathbf{d}_i = [\mu_i, \sigma_i, \mu'_i, \sigma'_i], \quad (15)$$

where μ_i and σ_i are the mean and standard deviation (STD) of non-empty elements in (2). The variables μ'_i and σ'_i denote the mean and STD of

$$\bar{\mathbf{x}}_i = [\bar{x}'_{i,1}, \dots, \bar{x}'_{i,S-1}], \quad (16)$$

where $\bar{x}'_{i,s}$ is the average of non-empty elements across two semesters $\mathbf{x}_{i,s-1}$ and $\mathbf{x}_{i,s}$. We note from the above that \mathbf{d}_i incorporates statistical properties associated with both long- and short-term consistency of a student. These features play an important role in influencing the contribution of each academic achievement representation $\mathbf{h}'_{i,S}$, $\mathbf{h}''_{i,S}$, and \mathbf{z}_i to the predicted grade. This dependence is expected given the student prior grade and the short-term consistency have been used as the input to each module to learn the representations.

To determine the weights in the fusion layer, we first define $p = 1, 2, 3$ as the index for the academic achievement representations. Given \mathbf{d}_i , these weights are learned via an FC layer given by

$$\beta_{i,p} = \mathbf{w}_p \cdot \mathbf{d}_i^T + b_p, \quad (17)$$

where \mathbf{w}_p and b_p are the trainable weight vector and bias for the p th academic achievement representations. The predicted grade \hat{y}_i for student i is then given by

$$\hat{y}_i = \mathbf{w} \cdot [\beta_{i,1} \times \mathbf{h}'_{i,S}; \beta_{i,2} \times \mathbf{h}''_{i,S}; \beta_{i,3} \times \mathbf{z}_i]^T + b, \quad (18)$$

where \mathbf{w} and b are defined, respectively, as the weight vector and bias scalar for the predictor. We employed the mean-

Algorithm 1 The proposed A2GP architecture

20: $\mathbf{d}_i = [\mu_i, \sigma_i, \mu'_i, \sigma'_i]$
21: $\beta_{i,p} = \text{FC}(\mathbf{d}_i)$ using (17)
22: $\hat{y}_i \leftarrow \text{FC}([\beta_{i,1} \times \mathbf{h}'_{i,s}, \beta_{i,2} \times \mathbf{h}''_{i,s}, \beta_{i,3} \times \mathbf{z}_{i,s}])$ using (18)
23: **end for**
24: **return** \hat{y}_i

square error loss function

$$\mathcal{L} = \frac{1}{K} \sum_{i=1}^K (y_i - \hat{y}_i)^2 \quad (19)$$

to compute the prediction loss for a total of K students. Similar to [13] [33], a student is classified as at-risk if his/her predicted grade for the pilot course is lower than the pre-defined threshold T , i.e., the classification label is computed by

$$\hat{\varphi}_i = \begin{cases} \text{At-risk,} & \text{if } \hat{y}_i < T; \\ \text{Non at-risk,} & \text{if } \hat{y}_i \geq T. \end{cases} \quad (20)$$

In line with Figure 1 that shows the proposed A2GP architecture, Algorithm 1 provides a formal description of the proposed model.

4. RESULTS AND DISCUSSION

4.1 Datasets

Three datasets have been collected from various departments in a local university with institutional review board (IRB) approval that includes the personal data protection policies. Since other open-source datasets employed for grade prediction do not include past snapshots of examination records, performance of the proposed A2GP model and baseline architectures is evaluated on the datasets from only this university. Seventeen courses across these datasets

Table 1: Number of students in the training and testing set

S: number of students

A: percentage of at-risk students

and their corresponding detailed information are illustrated in Table 1. The number of students denoted by ‘‘S’’ and the percentage of at-risk students denoted by ‘‘A’’ in each course for training and testing are also tabulated. These core courses have been offered to all undergraduates across the three engineering departments during their freshman and sophomore years. These datasets include grades obtained by students who are enrolled from academic year (AY) 2015 to 2019. In our context, the pre-defined threshold is $T = 40$ which refers to the passing mark of the university.

To reflect real-world deployment, we predict course grades using examination grades obtained in previous semesters. In particular, the model was trained using prior courses from AY2015 to 2018 and to predict grades for courses registered in AY2019. In this work, the prior grade matrix \mathbf{X}_i is of dimension 20×10 representing twenty prior courses and ten semesters across our dataset. While the undergraduate degree program requires eight semesters to complete, ten semesters were included since some students require a longer duration to graduate.

4.2 Implementation and Performance Metrics

The proposed A2GP model is trained using the Adam optimizer [19]. Hyper-parameters for each model were initialized using the Xavier initialization method [6] and the activation function is a rectified linear unit (ReLU). Adopting a systematic approach [40], the learning rate is first initialized with a small value, e.g., 1×10^{-7} , before being increased exponentially to a pre-defined upper-bound, e.g., 10. An optimal learning rate for the model is then determined from the range in which the model experiences the highest rate of decrease in model loss. This corresponds to 0.8×10^{-3} in our experiments.

Performance of the grade prediction models was evaluated via the mean absolute error defined by

$$\text{MAE} = \frac{1}{N} \sum_{i=1}^N |y_i - \hat{y}_i|, \quad (21)$$

which describes the average absolute error between the predicted and target grades for each grade prediction model. Classification performance of at-risk student detection was evaluated using the F1 score

$$F1 = \frac{2PR}{P + R}, \quad (22)$$

which is computed from the recall (R) and precision (P) scores. The recall score quantifies the number of correct at-risk predictions out of all actual at-risk students in the dataset while precision quantifies the number of correct at-risk predictions out of all detected at-risk students.

4.3 Performance Comparison in Terms of MAE and F1

While many grade prediction algorithms exist, we focus on models that rely only on prior grades obtained from previous semesters. This is important in our context since we cannot assume that all courses are offered online (for the extraction of clickstreams) or that we have access to audio-visual information in a physical classroom setting. To this end, we evaluate the proposed A2GP model on each pilot course by comparing its performance with two widely used classification algorithms (logistic regression (LR) and support vector machine (SVM)), and the LSTM [13]. We have also implemented two variants of the LSTM-based model (attn-LSTM [24] and STG-LSTM) and the GCN [20]. The attn-LSTM was implemented using (8)-(10) while the STG-LSTM is defined by (11)-(12). The GCN was modified from [20] by highlighting the relative performance using (14).

The performance of the models for each department in terms of MAE defined by (21) is tabulated in Table 2. With the predicted grades, at-risk classification performance in terms of the F1 score defined by (22) is tabulated in Table 3 for all predictive models under consideration. Results highlight that the proposed A2GP architecture achieves the lowest average MAE and highest average F1 score than all baseline models across all departments. Compared to the variants of LSTM, the LR and SVM models suffer from poor performance for since these two models do not consider the temporal information that is important for grade prediction.

Table 2: Performance comparison of different models using MAE (a lower value indicates better performance)

Methods	Dept. 1	Dept. 2	Dept. 3	Average
LR	0.121	0.137	0.123	0.127
SVM	0.124	0.138	0.121	0.128
LSTM [13]	0.113	0.129	0.111	0.118
attn-LSTM [24]	0.109	0.128	0.120	0.119
STG-LSTM	0.102	0.124	0.116	0.114
GCN [20]	0.109	0.121	0.115	0.115
The proposed A2GP model	0.104	0.119	0.109	0.111

Dept.: Department

It is also interesting to note that all models achieve lower grade prediction and at-risk classification performance for Departments 2 and 3 compared to Department 1. This is because Department 1 has a mandatory set of courses for all students while students from Departments 2 and 3 have the freedom to select courses not offered by their respective schools. Due to this difference in the course selection procedure, there are fewer commonly taken courses between students in Departments 2 and 3. Since GCN determines the relative performance of a student in comparison to his/her peers, an insufficient number of overlapping courses makes it more challenging to predict the grades for the pilot courses. On the same note, since there exist various combinations of courses taken by students from Departments 2 and 3, the LSTM-based models (attn-LSTM and STG-LSTM) are unable to identify similar sequences of temporal information among students. Therefore, diversity in the prior courses results in the poor prediction of a common pilot course grade.

In terms of at-risk classification for Department 1, the attn-LSTM model (with an F1 score of 0.324) achieves an approximate 17% improvement compared to LSTM. This improvement is attributed to attn-LSTM being able to detect the prior courses with higher importance compared to LSTM that equally weighs all courses to determine the grade for the pilot courses. The STG-LSTM model, on the other hand, accounts for the short-term fluctuation of student performance during the update of hidden states. This is in contrast to LSTM that updates the hidden state with equal importance applied to previous hidden states irrespective of any variations in performance. This results in a 10% reduction in the average MAE and 30% increase in an average F1 score for STG-LSTM over that of LSTM.

With regard to the non-temporal approach, since the GCN model constructs an input graph based on grade differences between student pairs (for identifying relative performance), variance of grades within a given dataset would determine the extent of distinguishability among the students. Figure 4 shows the relationship between the F1 score obtained using GCN and the standard deviation σ_{C_i} of the prior grades for

Table 3: At-risk prediction performance using F1 score (a higher value signifies better performance)

Figure 4: Relationship between F1 score of modeling relative performance against peer and average of σ_i .

all students. A smaller value of σ_{C_i} denotes a high similarity in performance among all students taking that course, implying that it is challenging for GCN to differentiate at-risk student performance from well-performing students (low F1 score). Therefore, we note that the ability of GCN for grade prediction is dependent on the underlying statistical properties of a dataset, resulting in varying performance across the courses for Department 1. We also note that GCN is not able to detect any at-risk students for some of the courses (reflected by the F1 score of zero in Table 1) since there were only few students who were actually at-risk. With most of the students achieving good grades in these courses, the performance variation among students is minimal, resulting in GCN not being able to identify relative performance differences.

Figure 5: Relationship between F1 score of modeling short-term performance and average of σ'_i .

Compared to the above models, the proposed A2GP model achieves the lowest average MAE of 0.111 and highest average F1 score of 0.351 across the three departments. These results highlight the importance of synthesizing the three dimensions associated with course importance, performance consistency, and benchmarking. Although the performance of individual modules (attention module and short-term gated module) are modestly higher in comparison to LSTM, A2GP includes a weighted fusion that adaptively determines the importance of each module depending on the relevance of the academic achievement representations to each dataset. Figure 6 illustrates the performance of our proposed A2GP model in terms of F1 score with a weighted fusion layer (implemented via (18)) or an equal fusion layer (where $\beta_1 = \beta_2 = \beta_3 = 1$). It is important to highlight that the weighted

Figure 6: F1 score across courses for model with/without weighted fusion.

Figure 7: Ablation of the proposed architecture.

fusion layer achieves significantly higher F1 scores for several courses with the remaining courses exhibiting similar performance as that of the equally weighted configuration. In particular, A2GP with weighted fusion (implemented via (17)) achieves an improvement of 0.263 F1 score for course $C_{1,2}$ over that of the equally fusion strategy.

As described in Section 3.4, the underlying statistics of student prior exam grades \mathbf{d}_i have been used to learn the fusion weights $\beta_{i,p}$. Figure 5 shows the variation of F1 with the mean of STD σ' defined by averaging σ'_i according to (15) over all students. Results plotted in this figure was generated by evaluating STG-LSTM over all courses offered by Department 1. A high value of σ' implies many students in this course exhibit short-term performance fluctuations in the past semesters. It can be seen that the F1 score reduces with increasing σ' . This implies that higher fluctuations in short-term student performance will pose a challenge for the model to detect at-risk students. To address limitations faced by individual models, the weighted fusion layer in the A2GP model de-emphasizes the aspects affected by the dataset while emphasizing other academic achievement representations which, in turn, aid the grade prediction process.

4.4 Ablation Test

Figure 7 shows results associated with an ablation test performed on the A2GP model. Here, at-risk prediction per-

formance is determined when each of the academic achievement representation is removed from the A2GP architecture. Among all three representations, the average performance across all courses reduces most significantly when attn-LSTM, i.e., $\mathbf{h}'_{i,s}$ is removed. This is due to the impact of identifying course importance on the entire cohort since constructivist approach is often adopted during curriculum development. The STG-LSTM model, on the other hand, is student-specific—fluctuation in individual performance depends on unique circumstances not generalizable for the other students. Therefore, the A2GP model is less sensitive to STG-LSTM compared to attn-LSTM. Removing GCN results in the least difference in prediction performance since different courses exhibit varying degree of grade spread, with some lacking sufficient information for GCN to discern among student performance resulting in an inappropriate representation. Nonetheless, incorporating peer performance will still be beneficial to A2GP model as seen in Figure 7.

5. CONCLUSIONS AND FUTURE WORK

An academic achievement-based grade prediction architecture is proposed for grade prediction and at-risk student detection. To utilize three important aspects in student prior performance—course importance, short-term performance fluctuation, and relative performance against peers, three modules have been formulated and fused. The first module learns the prior grade representation along with course

importance by employing the attention-based LSTM model. The new STG-LSTM in the second module is motivated by the need to model short-term fluctuation in academic performance. The third module is motivated by the need to model relative performance when detecting at-risk students—students are often deemed as at-risk if their performance is consistently below par compared to their peers. We evaluated the prediction performance of the proposed A2GP model by comparing its performance with baseline models. Results obtained showed that the proposed architecture outperforms existing at-risk detection algorithms across seventeen undergraduate courses from three departments. Improving the F1 score in at-risk student detection facilitates the administration of pre-emptive interventions by instructors, counsellors, or pastoral care managers.

There are possible avenues for future work. First, A2GP has been optimized for use with prior examination grades and has not been validated for online learning activities. Behavioral features associated with the consumption of online assets may provide additional (and often complementary) information that may aid grade prediction. Secondly, further investigations can be performed on the fusion weights defined by (17). These weights may offer insights into the importance of different representations influenced by characteristics that govern the cohort performance within each course.

ABSTRACT

In Automated Essay Scoring (AES) systems, many previous works have studied group fairness using the demographic features of essay writers. However, individual fairness also plays an important role in fair evaluation and has not been yet explored. Initialized by Dwork et al. [10], the fundamental concept of individual fairness is “similar people should get similar treatment”. In the context of AES, individual fairness means that “similar essays should be treated similarly”. In this work, we propose a methodology to measure individual fairness in AES. The similarity of essays can be computed using the distance of the text representation of essays. We compare several text representations of essays, from the classical text features, such as BOW and TF-IDF, to the more recent deep-learning-based features, such as Sentence-BERT and LASER. We also show their performance against paraphrased essays to understand if they can maintain the ranking of similarities between the original and the paraphrased essays. Finally, we demonstrate how to evaluate the performance of automated scoring systems models with regard to individual fairness by counting the number of pairs of essays that satisfy the individual fairness equation and by observing the correlation of score difference with the distance of essays. Our analysis suggests that the Sentence-BERT, as the text representation of the essays, and Gradient Boosting, as the score prediction model, provide better results based on the proposed individual fairness evaluation methodology.

1. INTRODUCTION

Automated Essay Scoring (AES) systems have been widely used in a vast number of educational institutions [25, 26]. However, there is a growing concern about the fairness issues in such a system so that no student should be treated unfairly [4, 5, 7, 16]. In recent years, many research studies have explored group fairness in AES with respect to demographic features, gender, race, socioeconomic status, and nationality of the writers [16]. Bridgeman et al. [4] studied the fairness of the essay scoring tool e-rater, and observed that in some cases, human and e-rater scores were incomparable across some subgroups. In particular, students’ essays from China tend to get higher scores from e-rater than from humans. The authors also mentioned that the rankings of subgroups would be different if machine scores were substituted for human scores. Additionally, Burstein and Chodorow [5] evaluated essays using the Test of Written English (TWE) and found that Arabic and Spanish speakers received relatively higher scores from humans, while Chinese speakers received higher scores from the machine. Although the differences between various ethnic groups are generally not large, they are still notable in some circumstances. Another study on the fairness of essay scoring system from the Analytical Writing Assessment to six subpopulation groups of GMAT[®] test takers was conducted in [12]. On the contrary, this study found that none of the subpopulation groups has an unfair advantage and is unfairly punished by the system. In addition, most of the work on automated essay scoring focuses on the effort of maximizing the agreement with the human raters, although human scores, which are treated as the gold standard for training a machine learning model, are not free from bias [1]. For group fairness, the availability of demographic features of the students is mandatory. However, privacy and legal concerns prevent the students’ personal information from being published, which is the main limitation in such works.

Besides group fairness, maintaining individual fairness for each graded essay is also important in AES systems. Initialized by Dwork et al. [10], the fundamental concept of individual fairness is that “similar people should get similar treatment”. In the context of AES, this concept is transformed into “similar essays should get similar treatment”.

To study individual fairness extensively in AES, we propose a methodology to assess the performance of automated scoring systems with regard to individual fairness. In our work, the similarity and dissimilarity of essays are computed using the distance metrics on the textual feature representation of essays. We investigate the performance of several vector representations of the essays, from the classical text features, such as Bag-of-Words (BOW) and Term Frequency - Inverse Document Frequency (TF-IDF), to the more recent deep-learning-based features, such as Sentence-BERT [21] and Language Agnostic Sentence Representation (LASER) [2]. However, these text representations of the essays are numerical vectors, and it is not easy for humans to interpret such results. Therefore, we highlight the importance of defining interpretable essay features, such as answer length, unique word count, spelling errors, and language errors, to help humans judge whether pairs of essays are similar or not.

The similarity score computed using the distance metric on the textual feature representation of the essays assigns a numeric value to each pair of essays, and the number of pairs can be very large. Consider if our dataset contains 1500 data points, then there will be 1,124,250 unique pairs. It makes the job of human evaluators in judging the similarity of each pair practically impossible. Therefore, we present two ways to compare how the distance metrics perform in measuring the essay similarities in the presence of this large number of pairs: firstly, by examining the extreme cases (most similar and most dissimilar essays), and secondly, by using aggregates of features differences. We further assess the quality of the essay vector representations and the distance metric by evaluating their performance against paraphrased essays.

Finally, we assess the performance of automated essay scoring models with regard to individual fairness using the proposed methodology. Firstly, we calculate the percentage of the number of pairs that satisfy the individual fairness equation (described in subsection 5.3.2) and observe that different text features have different distance distributions that affect the fairness results. Secondly, we categorize the essays based on the distance metric and visualize the score difference between different categories of essays. We observe that the score difference of more similar pairs is lower than the score difference of the less similar ones, as expected.

To the best of our knowledge, this is the first work that addresses individual fairness in automated essay scoring systems. The rest of the paper is organized as follows. In Section 2, we discuss the problem statement. In Section 3, we discuss the individual fairness assessment methodology for AES. Sections 4 and 5 cover the experimental settings and evaluation results, respectively. The paper is concluded in the last section with future directions.

2. PROBLEM STATEMENT

In this work, we aim to evaluate individual fairness in Automated Essay Scoring (AES) systems. Individual fairness in AES means that “similar essays should be treated similarly”, which raises several fundamental questions as follows.

1. How to define similar essays?
 - (a) How to measure similarity between essays? If the

similarity is computed using distance metrics on the text representation of essays, which text representation is good enough and which distance metric should be used?

- (b) How to make the evaluation of the distance metric interpretable for humans?
 - (c) Are there any limitations to the text representations of the essays?
2. How to define individual fairness in AES?
 - (a) How to define individual fairness in the presence of a large number of pairs of essays?
 - (b) Can we define individual fairness using the interpretable features of essays?
 3. How to evaluate individual fairness using essays’ similarity? Which machine learning model works best for maintaining individual fairness in essays evaluation?

3. INDIVIDUAL FAIRNESS ASSESSMENT METHODOLOGY FOR AES

To evaluate individual fairness in AES, we propose an end-to-end methodology from (i) selecting the text representation of essays to define the similarity, (ii) evaluating the performance of distance metrics, to (iii) evaluating the performance of the regression models with regard to individual fairness.

1. **Text Representation Selection.** To process the essays using a machine learning model, we first need to represent the essays in a vector format. In the field of Natural Language Processing (NLP), there have been proposed many methods to transform a text into a numeric vector, also known as the vector representation of the text. In this paper, we analyze several vector representations of essays, from the classical text feature, such as Bag-of-Words (BOW) and Term Frequency-Inverse Document Frequency (TF-IDF), to the more recent deep-learning-based extracted features, such as Sentence-BERT and LASER.
2. **Distance Metrics Selection.** There are many ways to calculate the distance of two vectors, and the most common distance metrics for textual data are cosine distance, Euclidean distance, Manhattan distance, and Jaccard distance. In our study, we choose cosine distance since it performs well for textual data, as shown in previous NLP studies [23, 6, 20].
3. **Evaluate Essay Similarity.** To evaluate the similarity of essays using distance metrics, we propose the following methods.
 - (a) **Define Interpretable Essay Features.** The text representation of an essay, generated using text representation API, provides a numeric vector that is not interpretable for humans. However, it is important that humans can also compare whether two essays are similar or not using interpretable features. Therefore, we define the interpretable essay features, which are discussed in detail in subsection 5.1.1.

- (b) **Extreme Cases.** In the presence of a large number of pairs, it is an impossible task for humans to examine each pair one by one. Therefore, we suggest a method to get a quick understanding of the performance of the distance metrics using the extreme cases based on the distance of essays. In this context, extreme cases are the most similar and the most dissimilar pair of essays. We also visualize the similarity (or dissimilarity) of a pair based on the interpretable essay features.
 - (c) **Aggregate of Features Differences.** Analyzing only the extreme cases is insufficient to make a concrete conclusion, as we can not judge the performance of the distance metrics of millions of pairs of essays only based on the nearest and farthest pairs. Therefore, to examine all of the essay pairs, we use aggregated feature differences computed using the normalized feature values. In this paper, we sampled 30,000 pairs of essays from three different similarity groups; lowest distant pairs (most similar), medium distant pairs (moderate similarity), and farthest distant pairs (most dissimilar). In each group, we average the score difference of 10,000 pairs of essays and compare this average score difference of all three groups. We visualize the average difference for different features that also help in understanding the dataset; more details are provided in Section 5.1.3.
4. **Evaluate the Distance Metric against Paraphrased Essays.** We further examine whether the text representation of the essays can recognize paraphrased essays and maintain their similarity ranking, as the original essay as well as its corresponding paraphrased essay should be treated similarly by an individual-fair AES system. To simulate this process, we compare the distance metric of the original essays and the paraphrased essays, and compare their similarity ranking. We measure the ranking quality using the Normalized Discounted Cumulative Gain (NDCG) score [13].
5. **Evaluate Individual Fairness.** The next step is to evaluate the performance of the scoring models with regard to the individual fairness measure. Individual fairness requires that the distance between two individual essays' outcomes is no greater than their distance according to the distance metric.
- (a) **Based on the Individual Fairness Equation.** We count the number of pairs that satisfy the *Lipschitz mapping* function by Dwork et al. [10] and represent what percentage of essays follows it.
 - (b) **Score Difference vs. Distance of Essays.** We study the correlation of score difference versus the distance of essays based on their text representation, as this is a quick method to check whether similar essays are treated similarly or not. If the system is fair, then the score difference between essays must correlate with their distance in the vector space. The average score difference in the group of similar essays should also be lower than the average score difference in the group of dissimilar essays. The expected condition from the visualization is a left-triangle-shaped (linear increment

in score difference as the distance of essays increases) graph for each scoring model.

4. EXPERIMENTAL SETUP

In this section, we introduce the experimental setup used in our work. We discuss the dataset, text representation of essays using several text encoding techniques in NLP, and regression models to predict the score of the essays that we use for the evaluation.

4.1 Dataset

We use the Automated Student Assessment Prize (ASAP) dataset¹, hosted by the Kaggle platform, and use the dataset of prompt 7. These essays were written by Grade-7 students. The total number of essays in this prompt is 1569 and had an average length of 187 words. The students were asked to write a story about a time when they were patient or about a time when someone they knew was patient or write a story in their own way about patience. Their answers were graded according to four rubrics: (i) ideas, (ii) organization, (iii) style, and (iv) conventions. Each essay was scored by two human raters on a 0 - 3 integer scale. Final scores were resolved by adding the rubric scores assigned by the human raters, resulting in a resolved rubric score between 0 and 6.

4.2 Text Representation of Essays

We use the following text representation methods for generating the vector feature representation of essays.

4.2.1 Bag-of-Words (BOW)

We first evaluate the performance of the BOW representation of essays in measuring the similarities between them since BOW is one of the classical textual features that has been widely used in NLP. BOW vector is constructed using a set of n-grams from the text. The n-gram is a contiguous sequence of n words from a given text or speech and is extensively used in NLP tasks. Specifically, n-grams are named *unigram*, *bigram*, and *trigram* when n is set to be 1, 2, and 3, respectively. In this paper, we generate our BOW features using unigram and bigram. For example, from a sentence 'Patience is important', the resulting n-grams are 'patience', 'is', 'important', 'patience is', and 'is important'.

Before creating n-grams, we implemented some text preprocessing techniques on the essays. We removed all non-letter characters and lemmatized the words using WordNet Lemmatizer from NLTK (Natural Language Toolkit) python library [3]. While building the vocabulary for n-grams, we ignored the terms that appear in less than three documents to remove the infrequently used terms. As a result, for each essay, we obtain a feature vector with a length of 14,974.

4.2.2 Term Frequency-Inverse Document Frequency (TF-IDF)

TF-IDF is a statistical measure that evaluates how relevant a word is to a document in a collection of documents. TF-IDF consists of two components, (i) Term Frequency (TF) that measures how frequently a term occurs in a document, and (ii) Inverse Document Frequency (IDF) that diminishes

¹<https://www.kaggle.com/c/asap-aes>

the weight of terms that occur very frequently in the document set and increases the weight of terms that occur rarely. Formally, TF-IDF is defined as follows.

$$tfidf_{(t,d)} = tf_{(t,d)} \times idf_{(t)} \quad (1)$$

where $tf_{(t,d)}$ is the number of occurrence of term t in document d , and according to the scikit-learn documentation, the $idf_{(t)}$ is computed as,

$$idf_{(t)} = \log \left(\frac{1+n}{1+df_{(t)}} \right) + 1 \quad (2)$$

where n is the total number of documents and $df_{(t)}$ is the number of documents that contain term t .

The resulting TF-IDF vectors are then normalized by the Euclidean norm. The effect of adding “1” to the IDF in the equation above is that terms with zero IDF, i.e., terms that occur in all documents, will not be completely ignored. Furthermore, the constant “1” is added to the numerator and denominator of the IDF as if an extra document was seen containing every term in the dataset exactly once, which prevents zero divisions. Before creating the TF-IDF vector, we applied the same text preprocessing techniques on the essays as the Bag-of-Words (BOW) vector. To create the TF-IDF vector, we use the scikit-learn library of TfidfVectorizer [18].

4.2.3 Sentence-BERT

We enrich our experiments by including more recent deep-learning-based features, besides the aforementioned classical text features. Sentence-BERT, which is introduced by Reimers and Gurevych (2019), is a modification of the pre-trained BERT [14] network using Siamese and Triplet network [21]. It converts a sentence into a 768-dimension feature vector and produces semantically meaningful sentence embedding. The embedding results can be used for similarity calculation. The Sentence-BERT representation has been proven to be able to separate the topics in the ASAP dataset very well [9].

4.2.4 Language-Agnostic Sentence Representations (LASER)

LASER was released by Facebook to support multilingual sentence representations to carry out various NLP tasks. They provide an encoder that was trained on more than 90 languages, written in 28 different scripts [2]. LASER includes all European languages, many Asian, Indian, Arabic, and Persian languages, along with numerous minority languages and dialects. All these languages are encoded by the same BiLSTM encoder with a shared BPE (Byte-Pair Encoding) vocabulary. Compared to Sentence-BERT, which produces a 768 length vector, LASER generates a 1024 dimensional sentence vector representation. The pre-trained LASER model is available online².

4.3 Regression Models & Evaluation Measures

We trained three regression models to predict essay scores: (i) Random Forest, (ii) Gradient Boosting, and (iii) Ridge Regression. We split the dataset into 80% training data and

²<https://github.com/facebookresearch/LASER>

Table 1: Essay Features

No.	Interpretable Essay Features
1	Answer Length (Character counts)
2	Word count
3	Average word length
4	Count of “good” POS n-grams
5	Number of overlapping tokens with the prompt
6	Number of overlapping tokens (including synonyms) with the prompt
7	Number of punctuation

9	Unique words count
10	Prompt – answer similarity score (SBERT representation)
11	Prompt – answer similarity score (BOW representation)
12	Language errors

20% testing data, and train the models using 5-fold cross-validation. We evaluate the performance of these models according to the three measurement criteria defined in [24]: (i) The agreement of scores between the human raters and the computer, which has been a long-established measure of the performance of automated scoring. The agreement is represented by the quadratic weighted kappa (QWK) [8]. (ii) The degradation from human-human score agreement. This measure helps to understand whether the human-automated scoring agreement is lower or higher than the human-human (rater 1 vs. rater 2) score agreement. (iii) The standardized mean score difference between human and automated scores.

5. EXPERIMENTAL RESULTS

In this section, we analyze the individual fairness of essays to answer the problem statements mentioned in Section 2. The fairness analysis is performed by evaluating the performance of different regression models on different text features.

5.1 Evaluating Essay Similarity

5.1.1 Interpretable Essay Features

In our experiment, to understand how the distance metrics perform, we need high-level feature representations of the essays, which make them easy for humans to interpret. We examine the similarity or dissimilarity of a pair of essays using twelve interpretable essay features as implemented by [9], shown in Table 1.

Six out of twelve features of the essays are extracted using EASE (Enhanced AI Scoring Engine) library³, written by one of the winners in the ASAP Kaggle competition. This feature set has been proven to be robust [19]. EASE produces 414-length features, but we exclude the features based on BOW vectors since they are not interpretable essay features. The considered six features are answer length, word counts, average word length, the number of “good” Part of Speech (POS) n-grams, the number of overlapping tokens between the prompt and the answer, and also the number of overlapping tokens between the prompt and the answer but including the synonyms. We generate the other six interpretable essay features from the answers. Those

³<https://github.com/openedx/ease>

are the number of punctuations, the number of spelling errors, unique word count, similarity scores between answer and prompt using S-BERT and BOW vector representations, and the number of language errors.

The interpretable essay features help in providing a higher-level description of each answer. For example, language fluency and dexterity can be estimated by the average word length and long words count, according to Mahana et al. [17]. Moreover, Larkey also mentioned that the number of long words could indicate the complexity of term usage [15]. Meanwhile, unique words count is useful to estimate the richness of vocabulary in the answer, and it can exhibit students' knowledge to use different words.

We measure the relevancy of an answer against the prompt using the degree of tokens overlap between the prompt and the answer (including their synonyms), and the cosine similarity value between the answer and the prompt using the Sentence-BERT and the BOW representation. Besides, we learn the grammar feature of the text, one of which is by measuring the number of good n-grams in the essay. The EASE library extracts the answer into its POS-tags and compares them with a list of valid POS-tag combinations in English. It defines the "good" POS n-grams as the ones that separate high- from low-scoring essays, determined using the Fisher test [11]. Additionally, we count the number of language errors in each answer using Language Tool Python library⁴. Finally, we also capture the mechanics of the text, which include aspects such as the usage of punctuation and the number of spelling errors found in the answer.

5.1.2 Extreme Cases

We use the dataset that consists of 1569 essays, which means that we obtain 1,230,096 unique essay pairs. The easiest and simplest way to get the first insight about the performance of the distance metrics is by examining the comparison between the most similar essay pair and the most dissimilar essay pair. We provide the visualization of each text feature in Figure 1, which highlights the similarity (or dissimilarity) for each of the twelve interpretable essay features, using the normalized feature values. Using this graph, we can observe in which aspects the essays are either similar or dissimilar.

BOW. Firstly, we inspect the comparison of extreme cases for BOW features. Figure 1 compares the difference of feature values between the most similar and the most dissimilar pair from the BOW representation of the essays. It is evident that it cannot distinguish the nearest pair and farthest pair of essays very well based on most of the features. BOW mainly focuses on the *Prompt Similarity BOW* feature.

TF-IDF. Secondly, we investigate the comparison of extreme cases for TF-IDF features. Here, both BOW and TF-IDF have the same essay pairs for the nearest and the farthest essays. This makes sense since the TF (Term Frequency) in the TF-IDF vector is actually the BOW vector, followed by the multiplication by the inverse document frequency (IDF), and then normalized by the Euclidean norm. So, it is not surprising if both of these vectors have similar pairs.

⁴https://github.com/jxmorris12/language_tool_python

Sentence-BERT. Next, we investigate the comparison of extreme cases for Sentence-BERT features. As opposed to the BOW representation, based on our twelve interpretable features, Sentence-BERT can provide a more clear distinction between the nearest and farthest pair for most of the features. It is noticeable that for the nearest pair, both values are almost the same, contrary to the farthest pair, which shows very different values.

LASER. Finally, we investigate the comparison of extreme cases for the LASER features. Figure 1 compares the difference in feature values between the most similar and the most dissimilar pair using LASER representation of the essays. It is evident that based on our twelve interpretable features, LASER provides the best distinction between the nearest and farthest pair for most of the features. The normalized feature values for all twelve interpretable features look close to each other for the nearest pair. In contrast, the normalized feature values for the farthest pair appears very dissimilar for all of the essay features, and visibly has the largest differences compared to the other text representations.

5.1.3 Aggregate of Feature Difference

In this section, to get a wider overview of the performance of the distance metrics, we conducted the evaluation using more than just the extreme cases. For the experiment, we sampled 30,000 pairs of essays from three different distance distributions: 10,000 pairs from the nearest distance pairs, 10,000 pairs from the medium distance, and 10,000 pairs from the farthest distance. For the medium distance, we collected 5,000 pairs before the median value and the other 5,000 after the median value. In this research, the expected condition is that the average of features' differences for all pairs in the nearest distance will be lower than the average of features' differences of all pairs in the medium distance. Consequently, the average of features' differences for the medium distance should be lower than those in the farthest distance.

The results are shown in Figure 2. The x-axis is labeled using numbers from 1 to 12 that refer to the twelve interpretable essay features in Table 1, in the same order. Consistent with the results of the extreme cases discussed before, LASER outperforms the other text representation of essays. Although for feature number 12 (*Language Errors*), it is not showing the expected result. This is also the case for the Sentence-BERT vector, with only one feature having an unexpected result (feature number 7: *Number of punctuation*). All of the other features for Sentence-BERT work well, even though mostly with smaller margins than those by the LASER vector.

The performance of Bag-of-Words (BOW) and TF-IDF representations is not as good as the deep-learning-based text representations. Some of the results are counterintuitive since the average of features' differences in the nearer pairs are larger than the farther ones. However, several of the essay features worked well as the exceptions, i.e., feature numbers 3, 8, 10, 11, and 12. The complete feature names can be referred to in Table 1. It is visible that BOW and TF-IDF have similar characteristics as also the case for the extreme cases in the subsection 5.1.2.

Figure 1: Nearest and Farthest Pair of Essays

5.2 Evaluation against Paraphrasing

We have evaluated the performance of the text representation with regards to their ability to measure similarities between essays. Our method proposes a further performance check concerning their ability to detect paraphrased essays. Students may write their answers using different words but still convey the same meaning. In this context, the scoring system should be able to perform consistently. We considered that two essays with the same content and arguments which were expressed using different words should be graded similarly.

We conducted this consistency check by inspecting whether the text features could maintain the similarity ranking between the original essays and their corresponding paraphrased essays. The rule is, if essay A is more similar to essay B than essay C , then the paraphrase of A also must be more similar to the paraphrase of B than the paraphrase of C .

For this purpose, the paraphrased essays were generated using the Spinbot API⁵. To understand how the API performed, a snippet of an essay along with its paraphrased version is shown below as an example:

Original essay. “One nice sunny day I was trapped in a doctors office with no air conditioning. this doctor’s office had @NUM1 chairs in the dirty waiting room. I was already cramed in the room with about @NUM2 people for @NUM3 minutes. I was trying to be patient but the patience was wearing off...”

Paraphrased essay. “One decent bright day I was caught in a specialists office with no cooling. this specialist’s office had @NUM1 seats in the grimy lounge area. I was at that point cramed in the room with about @NUM2 individuals for @NUM3 minutes. I was attempting to be patient however the tolerance was wearing off...”

During the experiment, we first sampled 100 essays each

⁵<https://api.spinbot.com>

Figure 2: Aggregate Features Differences for three Distance Groups

from the original version and the paraphrased version. For each sample, we calculated the cosine similarity values between that sample with all of the other (1569) essays in the dataset. Afterward, we created a similarity ranking in descending order, from the highest similarity to the lowest. We implemented the same procedure on the paraphrased essay. Therefore, we also obtained another descending-ordered similarity ranking from the paraphrased version. From these two rankings, we measured the ability to maintain the ranking using Normalized Discounted Cumulative Gain (NDCG) score [13]. Finally, we repeated the same procedure 100 times with the other sampled essays. In the end, we obtained one hundred NDCG scores from 100 samples. Then we calculated the average NDCG score. The whole method is depicted in Figure 3.

NDCG value ranges from 0 to 1, where score 1 means a perfect ranking. In document retrievals, a score of 1 indicates that the order of document hits in a search is perfectly ordered by relevance. We calculated the average NDCG scores of 100 samples against the other essays (1569) in the dataset for each of the four text representations of the essays. The results were satisfying, as all of them had an NDCG score of 1. This means that all of the vector representations had no problem in maintaining the ranking of similarities between the original essays and the paraphrased essays.

5.3 Evaluating the Individual Fairness

5.3.1 Regression Model Results

Table 2 describes the performance for all of the regression models using different text features. Based on the vector representations of essays, it is evident that all three regression models using LASER features provide the best results. While according to the regression algorithm, Gradient Boosting performs best for all text features, followed by Ridge Regression, and lastly, Random Forest.

5.3.2 Equation-based Evaluation

Speicher et al. [22] consider individuals who belong to different sensitive groups yet share similar protected attributes should have the same decision outcomes. For instance, essays having the same protected attributes must not be treated discriminatively based on the students’ gender or race.

Individual fairness requires that the distance between two individuals’ outcomes is less than their distance according to the similarity metric. A mapping of $M : V \rightarrow \Delta(A)$ satisfies the (D, d) -Lipschitz property if for every $x, y \in V$, we have:

$$D(M(x), M(y)) \leq d(x, y) \quad (3)$$

where, V is a set of individual essays, M is a function that assigns the essays into probability distribution over the outcomes A , D is a distance function that measures the difference in the outcomes, and d represents the similarity metric between two essays.

We applied cosine distance to create the distance metric. For prompt 7 in ASAP dataset, we obtained an $N \times N$ distance metric with $N = 1569$. To have the distance metric and outcome metric in the same scale, we used Min-Max normalization to rescale the feature values into the range of $[0, 1]$. Min-Max scaler is defined as:

$$x_{scaled} = \frac{x - x_{min}}{x_{max} - x_{min}} \quad (4)$$

where x is the original value, x_{min} is the minimum value, and x_{max} is the maximum value. The cosine similarity between two vectors A and B is:

$$\cos(\theta) = \frac{\mathbf{A} \cdot \mathbf{B}}{|\mathbf{A}| |\mathbf{B}|} = \frac{\sum_{i=1}^n \mathbf{A}_i \mathbf{B}_i}{\sqrt{\sum_{i=1}^n \mathbf{A}_i^2} \sqrt{\sum_{i=1}^n \mathbf{B}_i^2}} \quad (5)$$

For each text feature, we count the number of pairs of essays

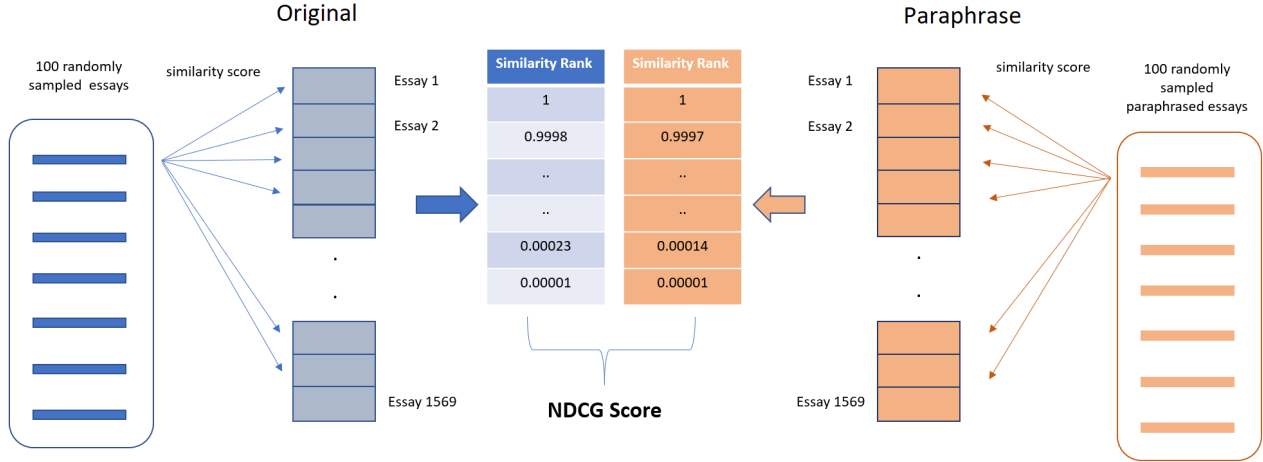

Figure 3: Ranking Evaluation from the Original and Paraphrased Essays

Table 2: Performance of Regression Models using Different Text Features

Features	Model	QWK Score	Human Agreement	Degradation	\bar{Z}
BOW	Random Forest	0.637	0.721	0.084	0.023
	Gradient Boosting	0.708	0.721	0.014	0.0063
	Ridge Regression	0.658	0.721	0.064	0.012
TF-IDF	Random Forest	0.602	0.721	0.120	0.001
	Gradient Boosting	0.703	0.721	0.018	0.004
	Ridge Regression	0.685	0.721	0.037	0.002
SBERT	Random Forest	0.618	0.721	0.104	0.036
	Gradient Boosting	0.722	0.721	-0.001	0.011
	Ridge Regression	0.699	0.721	0.022	0.028
LASER	Random Forest	0.713	0.721	0.009	0.0068
	Gradient Boosting	0.767	0.721	-0.046	0.0001
	Ridge Regression	0.758	0.721	-0.036	0.0024

Figure 4: Score and Distance Distribution

that satisfy equation 3. The dataset contains 1,569 essays, and therefore, there are 1,230,096 unique pairs of essays. Table 3 shows the proportion of pairs of essays that satisfy the individual fairness constraint for every vector representation of essays with its corresponding regression model. It is important to note that we should read the table row by row. For example, if we applied Bag-of-Words vector as the text features, Random Forest has a higher proportion of pairs that satisfy the individual fairness equation than Gra-

dent Boosting and Ridge Regression algorithms. If we use LASER, we can see that Ridge Regression outperforms the other algorithms with regard to the equation.

It is not possible to compare the performance between different vector representations since they work on different distance distributions. We can see their distance distribution in Figure 4. The orange curve is the distance distribution, and the blue one is the outcome distribution. To have a higher proportion of pairs that satisfy the equation, a major part of the blue curve should be on the left side of the orange curve, which will indicate that the outcome distance is lower than the vector distance. It is obvious that for BOW and TF-IDF vector, the majority part of the blue curve is on the left of the orange curve, which indicates that they had more pairs of essays that satisfy the equation. Meanwhile, LASER vector distance seemed to be more distributed on the left side, thus having more pairs with lower distances than the outcomes. It helps to explain why the proportion of pairs that satisfy the equation was much lower for LASER as compared to the other text features.

5.3.3 Score Difference vs. Distance of Essays

In the presence of a large number of pairs of essays, it is impossible for humans to examine each pair one by one. We propose a method based on a simple idea by using a visual

Figure 5: Average Score Differences for five Distance Groups

Table 3: The proportion of Pairs of Essays that Satisfy Equation 3 (in percentage)

Features	Random Forest	Gradient Boosting	Ridge Regression
BOW	99.4%	99%	99.2%
Tf-Idf	99.9%	99.9%	99.9%
Sentence-BERT	92.2%	94.7%	97.9%
LASER	51.7%	53.9%	67.8%

inspection of the distribution of score differences across different distance groups. Evaluating individual fairness is by looking at whether similar essays are treated similarly. It means that the score difference between essays must correlate with their distance in the vector space. The average score differences in the group of similar essays should naturally be lower than the average score difference in the group of dissimilar essays.

In our work, we presented the visualization of score difference vs. distance of essays in two scenarios, using data binning to (i) five groups (Figure 5) and (ii) one hundred groups (Figure 6). Firstly, we sorted the distance of all pairs of the essays in ascending order, from the most similar pair (the pair with the lowest cosine distance) to the most dissimilar pair (the pair having the highest cosine distance). For the data binning of five, we divided these sorted essays into five groups, with each group comprised of 20% of the whole data. For each group, first, we calculated the score differences of all pairs within that group. Afterward, we calculated the average value of those score differences. Lastly, we compared these average score differences of all five groups. We conducted this process for all of the regression models and text features of the essays. The results are shown in Figure 5. We can see that basically, all distance metrics with all three

models could produce the correct proportion of score distance and vector distance, except for the Ridge Regression algorithm on Bag-of-Words (BOW) vector, which appears flat, which means that the score difference was not correlated with the vector distance. Therefore, this does not follow the expected condition for individual fairness and is not recommended.

The exact same procedure was then repeated, but instead of dividing the whole sorted pairs into five groups, we divided them into one hundred groups to get a smoother graph. The results are shown in Figure 6. Now, we can observe a smoother increase in score differences. In Figure 5, we observe that the graph for Ridge Regression using the BOW vector appears flat. Sentence-BERT has the best shape of the increment of score differences since it grows in a gradual and consistent manner. For LASER, it shows a smooth increment at the beginning but flattens a bit towards the end and suddenly rises significantly. Moreover, if we look at the graph carefully, there is even a drop in score differences after reaching the peak by the Gradient Boosting and Random Forest algorithms. Although, this phenomenon is not seen in the Ridge Regression algorithm. TF-IDF vector exhibits a smooth increasing behavior similar to the Sentence-BERT vector. The only slight difference is that there are sharp increases at the right-most part (most dissimilar pairs). This visualization method helps quickly understand the individual fairness performance of a combination of a regression model and a text representation vector.

5.4 Discussion

We are looking for a combination of text features and regression model that has a better overall performance with respect to different aspects of our methodology. On the one hand, for the text features, they should perform well in these criteria: (i) the ability to discriminate between the most

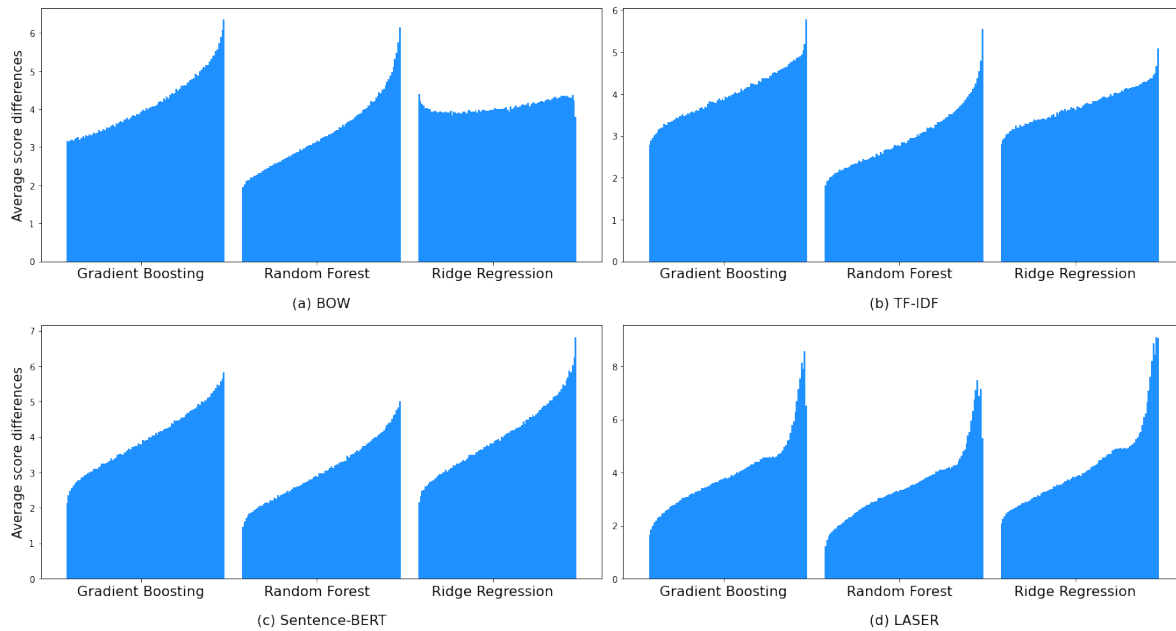

Figure 6: Average Score Differences for 100 Distance Groups (from left to right: the nearest pairs to the farthest pairs)

similar and most dissimilar pair of essays (extreme cases), (ii) the aggregate of features differences, and (iii) the ability to maintain the ranking of similarities between the original and paraphrased essays. On the other hand, the regression models should have good capabilities in these aspects: (i) the proportion of pairs that satisfy the individual fairness equation, and (ii) the correlation of score difference with the distance of essays. Ultimately, both of them must have a high agreement between the system scores and the human scores, measured in Quadratic Weighted Kappa (QWK). According to the acceptance criteria for an essay scoring model from Williamson et al. [24], the QWK must be at least 0.7.

Based on the proposed methodology, we analyze the outcomes of experimental results. LASER has the highest agreement (QWK) score compared to the other text features, as shown in Table 2. However, it performs inadequately for the proportion of pairs of essays that satisfy the individual fairness equation. Meanwhile, BOW and TF-IDF have the highest scores, as illustrated in Table 3. Nevertheless, they did not show better performances than Sentence-BERT and LASER in terms of discriminating the extreme cases and the aggregate features differences.

Finally, we observe that an automated essay scoring model trained using the Gradient Boosting algorithm on Sentence-BERT vector representation of essays has a better overall performance than the other combinations. It has exceeded the acceptance rate of the QWK score (0.722), performed well in discriminating the extreme cases and the aggregate of features differences, has a high percentage of pairs that satisfy the individual fairness equation (94.7%), and has the smoothest linear increment of score differences across the linearly divided distance groups as reflected in Figure 6. However, it is noteworthy to mention that selecting the combination depends on the priority given to a specific evaluation aspect when developing an essay scoring system.

6. CONCLUSION

In this work, we studied individual fairness in the Automated Essay Scoring (AES) system and proposed an individual fairness evaluation methodology. In practice, it is a challenging task to define the similarity of essays. We used the numerical text representation of essays to compute the similarities between answers. Next, we compared the performance of different scoring models using different text representations with regard to individual fairness. Our proposed methodology suggests that we look for the combination of the text representation of essays and score prediction models that achieves well-balanced results in several evaluation aspects. Based on the experiment results, we observed that the combination of Sentence-BERT and Gradient Boosting had overall better results than the other combinations.

The proposed methodology provides flexibility to be used with any text representations of essays and any score prediction models. Moreover, it is further expandable for a more robust evaluation process. One can assess the performance of the distance metrics not only against the paraphrased essays but also against noised textual data. For example, whether an AES system can perform well on the negation of essays is still a challenging problem in the NLP domain. It will be interesting to observe whether the essay features and distance metrics can be used to differentiate pairs of essays that have similar syntactic features but different semantics. Another interesting question for future study is how individual fairness relates to and contributes to group fairness. For instance, two students with and without a disability might provide very similar essays, but the scores need to reflect the extra effort and time of the student with the disability. In this context, it would be unfair to only take essays rather than individuals into account to measure fairness in AES.

ABSTRACT

In this paper, we propose a novel approach to combine domain modelling and student modelling techniques in a single, automated pipeline which does not require expert knowledge and can be used to predict future student performance. Domain modelling techniques map questions to concepts and student modelling techniques generate a mastery score for a concept. We conducted an evaluation using six large datasets from a Python programming course, evaluating the performance of different domain and student modelling techniques. The results showed that it is possible to develop a successful and fully automated pipeline which learns from raw data. The best results were achieved using alternating least squares on hill-climbing Q-matrices as domain modelling and exponential moving average as student modelling. This method outperformed all baselines in terms of accuracy and showed excellent run time.

Keywords

computer science education, domain modelling, student modelling, Q-matrix, mastery score, task-sequencing

1. INTRODUCTION

The idea of mastery learning was first proposed by Bloom [3] as an educational philosophy based on the belief that nearly all students can master a studied subject when given enough time and support. Nowadays, the term more commonly refers to an educational approach where test questions assess certain concepts and a mastery of prerequisite concepts is required before moving to harder concepts [11]. A con-

cept or skill (we use these terms interchangeably) can be thought of as a unit of knowledge that is assessed by a question; for example, a mathematics question might assess the concepts of "addition" and "subtraction", or a programming question might assess the concepts of "print statements" and "strings" [7]. A common application of this approach is for task sequencing in intelligent tutoring systems, where remedial questions for students are selected based on concepts they are weak at [11]. These approaches can also be used for providing automated feedback to students and hint generation [8]. But how do we know the full set of concepts in a set of questions? How do we know which questions assess which concepts? How do we measure the extent to which a student has "mastered" each concept? There are two distinct but related fields of research that attempt to answer these questions—domain modelling and student modelling [12].

Domain modelling is concerned with knowing the full set of concepts in a set of questions, and knowing which questions assess which concepts. This mapping of questions to concepts can be represented as a **Q-matrix**, a m questions \times k concepts matrix, where each entry is either 1 or 0, with 1 representing that the question in the row assesses the concept in the column [13]. Several previous studies have proposed methods for generating a Q-matrix based on student performance data on question sets; e.g. Barnes [2] introduced a hill-climbing algorithm, and Desmarais et al. [5] proposed a method in which Alternating Least Squares (ALS) method is used to refine an expert-designed Q-matrix.

Student modelling is concerned with measuring the extent to which a student has mastered a concept, or how to generate a **mastery score**. For instance, Corbett et al. [4] introduced Bayesian Knowledge Tracing, which uses a Markov model with two hidden states (a concept is either 'known' or 'unknown' by a student), with further refinements to this technique proposed by Pardos et al. [9] and Yudelson et al. [14].

In this paper, we aim to combine domain and student modelling in a single, automated pipeline. In other words, is it

possible to go from domain modelling to student modelling in a single pipeline on a single dataset, and thus predict future student performance? Solving this problem would be of significant benefit for intelligent tutoring systems, for example for task sequencing. Using only historic student performance data on questions, it would be possible to automatically generate a mapping between questions and concepts, and generate a mastery score for each student for each concept. This can then be used to sequence remedial tasks for students, i.e., for recommending tasks which assess the concepts at which the students were the weakest, with minimal human input.

This study attempts to explore this question, and has three main contributions. First, it provides an implementation and analysis of a pipeline that includes different combinations of three domain modelling and three student modelling techniques, where the results are based on predicting future student performance using the mastery score. Second, it performs this analysis on large datasets from an online programming course - 6 datasets across 2 years with 3 levels of expertise (beginners, intermediate and advanced), with a total of 144 questions and 28,466 students - demonstrating consistent results across all datasets. Third, it introduces a new Q-matrix generation technique - ALS on Hill-Climbing Q-matrix. The results show that the proposed technique is the most successful student modeling - it is best combinations of domain and student modelling in 5/6 cases.

2. RELATED WORK

2.1 Domain Modelling (Q-matrix Generation Algorithms)

A Q-matrix is a mapping between questions in a set, and the skills or concepts that they assess [13]. An example is shown in Fig. 1. Such matrices are used to determine the probabilities that certain skills are learned by a student, and to select and sequence tasks in mastery learning environments. While Q-matrices are traditionally designed by experts, we have to consider disagreement between experts, the amount of time and effort needed to do this process manually, as well as disagreement between expert opinion and what students

actually experience.

Barnes [2] introduced an algorithm that can derive a Q-matrix from student response data. The algorithm initializes a $m \times k$ matrix (m being the number of students, k the number of skills) with random values for each cell in range $[0, 1]$. Given the current Q-matrix, it computes, for each student, the binary knowledge states which best describe the student’s actual test responses. Then, hill-climbing is performed to improve the Q matrix given the current knowledge state estimate. This is repeated until convergence, and repeated for different numbers of concepts.

By contrast, Desmarais et al. [5] propose to let an expert design the initial Q-matrix, and then optimising via the ALS method. This is motivated by expressing the $m \times n$ matrix of student responses R (n being the number of students) as a product of two matrices Q and S ; the Q matrix being an $m \times k$ matrix as before, and the S matrix being a $k \times n$ matrix that represents student mastery profiles. The ALS method minimizes the squared error $\|R - Q \cdot S\|^2$ with respect to Q and S in an alternating fashion until convergence.

In this paper, we propose a new method which combines hill-climbing and ALS, called ALS on Hill-climbing Q-Matrix. It uses a hill-climbing algorithm to derive an initial Q-matrix, and then ALS to refine it. We evaluate the performance of three methods: Hill-climbing Q-matrix, ALS on Expert Q-matrix and ALS on Hill-climbing Q-matrix.

2.2 Student Modelling (Mastery Score Algorithms)

Once a Q-matrix is known, the students’ learning process can be described by modelling which skill is mastered at what time by which student.

Kelly et al. [6] conducted a study to determine the accuracy of two methods, namely N -Consecutive Correct Responses (N -CCR) and Knowledge Tracing (KT) [4] in detecting concept mastery in students. The study defined mastery of a concept as a binary attribute. N -CCR is a simple algorithm that considers a skill mastered once a student gives N consecutive correct responses on questions related to the skill. By contrast, KT models student knowledge as a latent variable in a Hidden Markov Model, with the parameters updated based on whether or not the student gets each question in a sequence of questions correct or wrong (more detail on this below). The algorithm computes the probability that a student has mastered a skill after each observation of a correct or incorrect answer. The study concluded by stating that 3-CCR was the better approach for next-problem correctness, and 5-CCR was the better approach for predicting performance on a transfer task, with both methods being more accurate than knowledge tracing.

However, N -CCR has drawbacks which are not discussed in the paper. Consider two students who answered a sequence of 6 questions, and assume we consider 5-CCR, with the vectors representing the correctness of the answers of each student being $[0, 0, 0, 0, 0, 0]$ and $[1, 1, 1, 1, 0, 1]$. 5-CCR would determine that both students have the same level of mastery, which can be argued is not true. One way to mitigate this is to introduce a method where more recent answers

Table 1: Dataset statistics

	Questions	Students
Beginners-2018	29	7956
Intermediate-2018	25	4756
Advanced-2018	22	731
Beginners-2019	28	8662
Intermediate-2019	25	5423
Advanced-2019	15	938

carry more weight in determining the measure of mastery. The exponential moving average (EMA) technique [10] estimates the mastery of a student after answering the t th question via the expression $\sum_{\tau=0}^{\infty} r_{t-\tau} \cdot w_{\tau}$, where $r_{t-\tau}$ is 1 if the student answered question $t - \tau$ correctly and 0, otherwise, and where $w_{\tau} = (1 - \lambda) \cdot \lambda^{\tau}$ is a weight for past states, with $\lambda \in (0, 1)$ being a hyperparameter that controls how fast this weight decays into the past.

Corbett et al. [4] introduced the concept of Bayesian Knowledge Tracing (BKT). BKT assumes that a concept is a latent binary variable (either mastered or not mastered by a student) in a Hidden Markov Model, with observations also being binary (a student can get a question correct or incorrect). There are 4 parameters in this model; the probability $p(L_0)$ that a student has mastered the skill prior to attempting the first question, the probability $p(T)$ that a student will master the concept after one opportunity to apply the concept in a question, the probability $p(G)$ that a student will get a question correct given they have not mastered a concept ('guess'), and the probability $p(S)$ that a student will get a question incorrect given that they have mastered a concept ('slip'). One model is built for each concept k , assuming that the concepts assessed in a given question are known.

In this paper, we will evaluate all three approaches: N -CCR, EMA and BKT.

3. DATA AND PREPROCESSING

The data used in this study was provided by Grok Academy (groklearning.com) and comes from three online Python programming courses for high school students. In total it comes from 28,466 students and includes 144 questions. In this learning platform, students complete coding tasks and receive automated feedback in the form of passed test cases and feedback about the failed cases, e.g. comparison between the expected output and the student's output.

Our study uses a total of 6 datasets from 2 years (2018 and 2019), with each year having one set of questions from 3 difficulty levels (beginners, intermediate and advanced). Table 1 summarises the dataset statistics.

For each student, we collected a 'trace' of all their submissions on each question. A student may submit solutions multiple times for a question, each time getting feedback in terms of expected vs actual program output, and the number of test cases passed. However, domain and student modelling approaches typically require a single binary value of correctness for each student on each question. To obtain such a value, we used 1 if the average number of passed test

Table 2: Runtimes for generating 10 Q-matrices (with 1 to 10 concepts) per dataset via hill-climbing

Dataset	Hill-climbing Q-matrix Runtime
Beginners-2018	5 hours
Intermediate-2018	4 hours
Advanced-2018	30 minutes
Beginners-2019	7 hours
Intermediate-2019	5 hours
Advanced-2019	45 minutes

cases per submission exceeded the median, and 0, otherwise. For example, if a student attempts a question 3 times and passes 0/10, 5/10 then 10/10 test cases, then we take the average over the 3 attempts, which is 5/10, and map this to 1 if 5/10 is larger than the median value over all students for this question.

4. METHOD

There are two main steps, namely domain modelling and student modelling. The first step infers the relation between questions and concepts in a form of Q-matrix. The second step builds a model to predict a student's future performance based on their past responses.

We consider three algorithms for domain modelling, namely Hill-climbing Q-matrix [2], ALS on Expert Q-matrix [5], and ALS initialized with Hill-climbing Q-matrix. The last one is our proposed method and it combines hill-climbing and ALS algorithms. Further, we consider three algorithms for student modelling, namely N -CRR, EMA, and BKT. The pipeline for each combination of domain modelling and student modelling components is as follows.

First, infer a Q-matrix using the domain modelling component. Second, for each student, extract one sequence of correct and wrong responses to questions that are related to that skill. Finally, use the student modelling component to model the mastery of each student for each skill.

For prediction, we consider the mastery score after responding to the t th question and predict a successful response if the mastery score exceeds a threshold. Our evaluation measure is the RMSE between the mastery scores and the actual responses.

5. EXPERIMENTAL SETUP

Combining each domain modelling algorithm (Hill-climbing Q-matrix, ALS on Expert Q-matrix, ALS on Hill-climbing Q-matrix) with each student modelling algorithm (N -CCR, EMA, BKT) yields nine combinations. We evaluate each combination on each data set from Table 1. For brevity and lack of space reasons, we discuss in detail the 2018 datasets but provide only the best results for the 2019 datasets.

Using hill-climbing, we generate 10 Q matrices for each dataset with $k = 1$ to $k = 10$ concepts. The runtime needed for the Q matrix generation is shown in Table 2.

To evaluate the student modelling, we use five-fold cross validation over students. For N -CCR and EMA, we also

Table 3: Performance of the three baselines (RMSE) on the 2018 data sets

Baseline Method	beginner	intermediate	advanced
random	0.7065	0.7054	0.7131
majority	0.6576	0.6447	0.5270
BKT-1	0.4899	0.4880	0.4280

Table 4: Performance of BKT, EMA and N -CCR when combined with Hill-climbing Q-matrix - RMSE on Beginners-2018 dataset

n_con	BKT	EMA (λ , RMSE)	N -CCR (N , RMSE)
1	0.4453	0.1, 0.1487	1, 0.1482
2	0.4316	0.1, 0.1588	1, 0.1594
3	0.4352	0.1, 0.2476	1, 0.2484
4	0.4391	0.1, 0.2261	1, 0.2276
5	0.4368	0.1, 0.2274	1, 0.2286
6	0.4351	0.1, 0.2280	1, 0.2293
7	0.4340	0.1, 0.2193	1, 0.2208
8	0.4318	0.1, 0.2114	1, 0.2131
9	0.4305	0.1, 0.2463	1, 0.2491
10	0.4309	0.1, 0.2389	1, 0.2417
(sec)	54.1	49.7	48.5

evaluate the results for different hyperparameter values: N from 1 to 10 and λ from 0.1 to 0.9.

Additionally, we compare the performance with three baselines, namely random guessing (random), predicting the majority label for each question (majority), and BKT with a single concept per question (BKT-1).

All six techniques were implemented in Python. For hill-climbing, ALS, N -CCR, and EMA we used our own implementation, and for BKT we used the pybkt toolbox [1].

6. EXPERIMENTAL RESULTS

6.1 Beginners-2018

The performance of the three baselines on the 2018 datasets is shown in Table 3. We can see that the most accurate baseline on all 3 datasets is BKT-1, followed by majority and random.

Table 4 shows the RMSE for BKT, EMA, and N -CCR on the Beginners-2018 dataset for Q-matrices that were generated via hill-climbing; the best results are shown in bold. For EMA and N -CCR, we only report the results for the best-performing values of λ and N (the results for other hyperparameter values are shown in Table 5). Each row represents the results obtained for a certain number of concepts. Here, it is interesting to see that, for EMA and N -CCR, the best Q-matrix is the one with only 1 concept, while, for BKT, the best Q-matrix had 9 concepts. The RMSE stays relatively stable for the different Q-matrices for BKT. For BKT and N -CCR, the RMSE stays relatively stable only for Q-matrices with 3 concepts and above. The last row of the table shows the prediction runtime; we can see that all methods were fast and had similar prediction runtime - 48-54 seconds.

Table 5: Hyperparameter values of EMA (λ) and N -CCR (N) vs RMSE for n_con = 1 when combined with Hill-climbing Q-matrix on Beginners-2018 dataset

λ (EMA)	RMSE	N (N -CCR)	RMSE
0.1	0.1487	1	0.1482
0.2	0.1624	2	0.1742
0.3	0.1857	3	0.2068
0.4	0.2148	4	0.2524
0.5	0.2470	5	0.3067
0.6	0.2809	6	0.3231
0.7	0.3159	7	0.3059
0.8	0.3523	8	0.3893
0.9	0.3927	9	0.4257

Table 6: Performance of BKT, EMA and N -CCR when combined with ALS on Expert Q-matrix - RMSE on Beginners-2018 dataset

n_con	BKT	EMA (λ , RMSE)	N -CCR (N , RMSE)
8	0.3908	0.3, 0.1874	1, 0.2176
(sec)	12.3	6.78	6.24

It is also interesting to note that, regardless of the number of concepts, $\lambda = 0.1$ and $N = 1$ are the best-performing hyperparameters for EMA and N -CCR, respectively (see Table 4). In other words, it was always best to predict the performance on the next question based on the question immediately before it. Table 5 provides more details about the impact of the hyperparameters $\lambda = 0.1$ and $N = 1$ on the RMSE. We see a clear trend: as λ and N increase, RMSE rises as well.

Next, we evaluate BKT, EMA, and N -CCR on the Q-matrix derived by ALS when initialized with an expert Q-matrix. The expert Q-matrix covers eight skills (refer to Fig. 1). Table 6 shows the results, indicating that EMA with $\lambda = 0.3$ performs best. Table 7 shows the performance of EMA and N -CCR for different hyperparameter choices. For N -CCR we observe the same trend as before, for EMA we observe that low λ -values generally perform better, with a minimum at 0.3.

Finally, we evaluate BKT, EMA, and N -CCR on the Q-

Table 7: Hyperparameter values of EMA (λ) and N -CCR (N) vs RMSE for n_con = 8 when combined with ALS on Expert Q-Matrix on Beginners-2018 dataset

0.8	0.2289	8	0.2106
0.9	0.2971	9	0.2348

matrix derived by ALS when initialized with a hill-climbing Q-matrix. Table 8 shows the results. Again, EMA with $\lambda = 0.3$ performs best. Indeed, the results for EMA with $\lambda = 0.3$ are better than any other result we obtained across all domain modelling approaches. Interestingly, different λ values are optimal, depending on the number of concepts.

In Table 9, we see that the RMSE of N -CCR steadily worsens as N increases. By contrast, the RMSE for EMA has a minimum at $\lambda = 0.3$ and increases for smaller or larger values.

6.2 Intermediate-2018

From Table 10, it is interesting to note that the best models use Q-matrices with more concepts than seen in the previous dataset. For BKT, 3 concepts is optimal, for EMA and N -CCR it is 10 concepts. We also observe that, for EMA and N -CCR, the more concepts we consider, the better performance gets (considering only the model with the best parameters), which is something that we did not observe in the previous dataset. While N -CCR still selects 1 as the best N for all the Q-matrices, for EMA, most of the Q-matrices give either 0.3 or 0.2 as the best λ .

From Table 11, we can see that λ s of 0.1, 0.2 and 0.3 actually have very similar RMSE, with 0.4 and above steadily worsening in RMSE as λ increases. N -CCR exhibits the pattern of RMSE worsening as N increases.

Table 10: Performance of BKT, EMA and N -CCR when combined with Hill-climbing Q-matrix - RMSE on Intermediate-2018 dataset

8	0.3930	0.4, 0.2815	1, 0.1977
(sec)	8.01	4.95	4.33

Table 14: Hyperparameter values of EMA (λ) and N -CCR (N) vs RMSE for n_con = 8 when combined with ALS on Expert Q-matrix on Intermediate-2018 dataset

λ (EMA)	RMSE	N (N -CCR)	RMSE
0.4	0.2815	1	0.1977
0.5	0.2821	2	0.2009
0.3	0.2821	3	0.2093
0.2	0.2837	4	0.2145
0.6	0.2844	5	0.2205
0.1	0.2861	6	0.2247
0.7	0.2899	7	0.2365
0.8	0.3018	8	0.2481
0.9	0.3265	9	0.2636

From Table 12, we see that, across all algorithms, the per-skill RMSE is not uniform at all. For example, for N -CCR, skill 8 has an RMSE of 0.1071, while skill 0 has an RMSE of 0.3925. This can be interpreted as being caused by a large variance in student proficiency for certain skills, or that some skills are a lot harder to learn than others.

From Table 13, we see that N -CCR performs better than EMA. N -CCR has chosen 1 as the best N , while EMA has 0.4 as the best λ .

From Table 14, we see that—while there is no pattern of worsening RMSE as λ increases for EMA—the first 7 values of λ have very very similar RMSE (differences lesser than 0.01). For N -CCR we see that RMSE steadily worsens as N increases. It is also interesting to note that the worst N -CCR model (RMSE = 0.2636) performs better than the best EMA model (RMSE = 0.2815).

From Table 15, we see again that per-concept RMSE has high variance, more so with EMA and N -CCR than BKT. Skill 7 has the highest RMSE when EMA is used, with an RMSE of 0.5888. Meanwhile, the skill with the worst RMSE

Table 15: Per-concept RMSE for BKT, EMA and N -CCR (best models) on Intermediate-2018 dataset

Skill	RMSE (BKT)	Skill	RMSE (EMA)	Skill	RMSE (N -CCR)
0	0.4071	0	0.2691	0	0.1854

(sec)	27.2	31.8	30

Table 17: Hyperparameter values of EMA (λ) and N -CCR (N) vs RMSE for n_con = 1 when combined with ALS on Hill-climbing Q-matrix on Intermediate-2018 dataset

λ (EMA)	RMSE	N (N -CCR)	RMSE
0.3	0.1782	1	0.1854
0.4	0.1787	2	0.1877
0.2	0.1790	3	0.1889
0.5	0.1801	4	0.1896
0.1	0.1813	5	0.2198
0.6	0.1830	6	0.2220
0.7	0.1900	7	0.2248
0.8	0.2092	8	0.2289
0.9	0.2582	9	0.2335

for N -CCR is skill 2 which only has an RMSE of 0.2748.

It is interesting that, compared to the hill-climb Q-matrix without ALS refinement, the results in Table 16 show that ALS on Hill-climbing Q-matrix perform best when using Q-matrices with a smaller numbers of concepts.

From Table 17, we see the familiar pattern of N -CCR selecting 1 to be the best N regardless of number of concepts, while EMA has many different values of λ being the best for different numbers of concepts. The largest λ found is 0.6 when we use the Q-matrix with 5 concepts - this yields an RMSE of 0.2608, which in fact is better than even the best BKT model by a decent margin.

6.3 Advanced-2018

From Table 18, it is interesting to see that a large number of concepts (6) was best for EMA and N -CCR as compared to the Beginner and Intermediate datasets. BKT, on the other hand, performed best with only 2 concepts. The optimal λ and N were at 0.1 and 1, respectively.

Another interesting finding is that a different N is optimal for N -CCR, depending on the number of concepts. For 1 or 2 concepts, the optimal N is 2 instead of 1.

From Table 19, we do see the pattern for both EMA and N -CCR where performance worsens as the respective parameters increase in value, with RMSE increasing rapidly

Table 18: Performance of BKT, EMA and N -CCR when combined with Hill-climbing Q-matrix - RMSE on Advanced-2018 dataset

Table 22: Hyperparameter values of EMA (λ) and N -CCR (N) for n_con = 9 when combined with ALS on Expert Q-matrix on Advanced-2018 dataset

λ (EMA)	RMSE	N (N -CCR)	RMSE
0.4	0.3116	1	0.4160
0.3	0.3119	2	0.4173
0.5	0.3122	3	0.4186
0.2	0.3129	6	0.4274
0.6	0.3143	7	0.4274
0.1	0.3145	4	0.4286
0.7	0.3190	5	0.4286
0.8	0.3283	8	0.4323
0.9	0.3447	9	0.4327

as λ rises to 0.8 and 0.9.

From Table 20, we see that per-concept RMSE is relatively stable for EMA and N -CCR as compared to the previous dataset, with BKT in fact having very close RMSE between the two concepts. This could be interpreted as concepts having less variance in difficulty, though we have to keep in mind that this is the Advanced dataset, which has the least number of students by far (731) compared to the Beginner and Intermediate datasets of the same year (7956 and 4756). It also has the least number of questions (22) compared to Beginner and Intermediate which have 29 and 25 respectively.

From Table 21, we can see that performance across all 3 algorithms with 9 concepts from an expert Q-matrix passed through ALS is worse compared to the previous Hill-climbing Q-matrix method. N -CCR with an N of 1 performed worse than EMA with an λ of 0.4.

From Table 22, we see that there is no pattern of worsening performance as parameters increase for both EMA and N -

CCR. While both methods don't show much of a difference between their best and worst parameter values (within 0.03 difference for both methods), it is worth noting that the worst EMA model still outperforms the best N -CCR model.

From Table 23, we see much more variance in per-concept RMSE as compared to the previous method, though we do have to consider that this method simply also has more concepts. An extreme example of this can be seen in the table for N -CCR, in which skills 0 to 6 all have the same low RMSE of 0.1843, while skill 7 and skill 8 have RMSE values of 0.7709 and 0.8846 respectively. It could simply be that 9 concepts is too many for this dataset, even though the expert deems 9 to be the correct number, with ALS not zeroing-out any concepts.

From Table 24, we see that applying ALS on the Hill-climbing

Table 26: Per-concept RMSE for BKT, EMA and N -CCR (best models) on Advanced-2018 dataset

Skill	RMSE (BKT)	Skill	RMSE (EMA)	Skill	RMSE (N -CCR)
0	0.3346	0	0.2235	0	0.2248

2	0.3565	2	0.1723	2	0.1843
3	0.3801	3	0.1723	3	0.1843
4	0.3352				

Q-matrices (see Table 20) reduced the number of concepts that was optimal, from 6 to 4, and in fact also improved the RMSE, for EMA and N -CCR. For BKT this increased the number of optimal concepts from 2 to 5.

It is also interesting to see that for the Q-matrix with 1 concept, the best λ for EMA is 0.7, which is the largest we have observed so far. Across the other Q-matrices the optimal λ also varies.

In addition, Table 24 shows that N -CCR has a large variance in the optimal values for N across the different numbers of concepts as compared to previous results.

From Table 25, we do see that RMSE worsens as N increases for N -CCR. Meanwhile, for EMA, RMSE stays relatively similar for the first 6 values of λ , then worsens quicker beyond 0.6.

Table 26 shows us that RMSE stays very stable across the different concepts across all 3 algorithms - very different from when we had 9 concepts (see table 25). This shows us that the optimal number of concepts is in fact small for this dataset, much smaller than the number of concepts designed by an expert.

6.4 2018 Summary

For all three datasets, the best models are EMA together with the novel Q-matrix method of applying ALS to the Hill-climbing Q-matrices (refer to Table 27). This combination does not need any expert opinion or human input, and can be fully automated, provided that example student responses are given. Also note that the runtime is relatively quick.

6.5 2019 Summary

For the 2019 datasets, 2 out of 3 datasets have ALS+Hill-climb as the best Q-matrix method, and 2 out of 3 datasets have EMA as the best Mastery Score method. All 3 combinations of Q-matrix and Mastery Score methods can be automated and require no human input.

In fact, the only Q-matrix method which requires human input is the ALS+Expert method which, of course, has the first step of initialising a Q-matrix by getting an expert to manually create one from inspecting the data/questions.

7. OVERALL RESULTS DISCUSSION

7.1 Automation

Recall that we have 3 Q-matrix generation methods - Hill-climbing, ALS on an expert-initialized Q-matrix, and ALS on a hill-climbing-initialized Q-matrix (novel combination of the first two methods). The first and third methods do not need human input and need only response data, while the second method does need human input as the initial Q-matrix is initialised by an expert.

One of the goals of this study was to investigate methods of automating the whole pipeline from data to domain modelling to student modelling to prediction (which can then be used for task sequencing), which means that it would be

Table 27: Summary of 2018 results - best models and baselines

	Best Baseline RMSE	Best Method Q-matrix : Mastery Score : RMSE : n_concepts : runtime (sec)
Beginners-2018	0.4899	ALS+Hill-climb : EMA : 0.1319 : 1 : 55.8
Intermediate-2018	0.4880	ALS+Hill-climb : EMA : 0.1782 : 1 : 31.8
Advanced-2018	0.4280	ALS+Hill-climb : EMA : 0.1899 : 4 : 6.09

Table 28: Summary of 2019 results - best models and baselines

	Best Baseline RMSE	Best Method Q-matrix : Mastery Score : RMSE : n_concepts : runtime (sec)
Beginners-2019	0.4629	ALS+Hill-climb : EMA : 0.1243 : 1 : 59.8
Intermediate-2019	0.4832	Hill-climb : EMA : 0.1130 : 1 : 37.1
Advanced-2019	0.4427	ALS+Hill-climb : N-CCR : 0.0790 : 1 : 6.4

best to require as little human input as possible at any point in the pipeline.

With this in mind, it is encouraging that, out of the 6 datasets, the best performing combinations of Q-matrix and Mastery Score algorithms all use either ALS on Hill-climbing Q-matrix or just a Hill-climbing Q-matrix, both of which do not need human input. All 3 Mastery Score algorithms do not need human input.

In fact, 5 out of 6 combinations use ALS on Hill-climbing Q-matrix which is our proposed novel method. As we have seen in the previous results, in most datasets, applying ALS on the Hill-climbing Q-matrices will bring about an improvement in RMSE on most Mastery Score algorithms, as compared to using Hill-climbing Q-matrices without ALS.

7.2 Runtime

One drawback of ALS on Hill-climbing Q-matrix is that it first requires calculating the Hill-climbing Q-matrices, which, based on our setup with multiprocessing on 10 cores, would take a few hours on the largest of our datasets (see Table 2). However, we must consider that this can be run offline and only needs to be run once.

In a real life scenario, we start with some historical data to generate the Q-matrices. Hill-climbing would take a few hours, and then applying ALS on the resulting Q-matrices would only take a few seconds.

Once this is done, then this Q-matrix can be used in conjunction with EMA or N-CCR (which perform better than BKT in our experiments) on any new student responses to predict their mastery of each concept. This only takes a few seconds. Predictions on mastery of concepts can then be used for things such as task sequencing - for example, if we identify that a student is weak at certain concepts, then we can recommend other questions which test that same concept as remedial questions.

The Q-matrix can then be updated once sufficient new data has been accumulated by running the algorithm from scratch with the new data. Again, the long runtime doesn't really matter since this can be run offline, and until it is done

running, the old Q-matrix can be used.

7.3 BKT Performance

It is interesting that, for all the datasets, BKT performed worse than EMA and N-CCR. One explanation for this could be the variance in student skill. One limitation of BKT is that, when the parameters are fit on the data, what is really being captured are patterns in the average difficulty of the questions in the dataset. As such, it is best used when students are of a similar skill, whereas student skill in our data set varies wildly, even within one difficulty level (Beginner, Intermediate, Advanced). EMA and N-CCR are much simpler algorithms, and perhaps the issues that affect BKT do not affect these two algorithms quite as much.

8. LIMITATIONS AND FUTURE WORK

8.1 Q-matrix Interpretability

One limitation of the best Q-matrix generation algorithm (ALS on Hill-climbing Q-matrix) is interpretability. With a Q-matrix that is designed by an expert, obviously it would be clear what each concept actually represents - e.g. the labels can be "for-loops", "while-loops" etc.

However, when the Q-matrix is learned from data without human intervention (as in the case of ALS on Hill-climbing Q-matrix), each concept only has an index as a label. Interpreting what each concept represents would require an expert to inspect the Q-matrix together with the questions and responses.

Nevertheless, it can be argued that this is beyond the scope of this study, since we are concerned only with whether the process can be automated, and if the pure-automation approach performs better than the expert-initialised approach (any combination with ALS on expert Q-matrix) with respect to predicting future task performance.

8.2 Alternative Preprocessing Methods

Our algorithms require the student response data to be in the form of one response per question, with the response being either correct or wrong. This is not really the case for our data, where a programming question allows multiple attempts not a single one, and correctness is measured

based on how many test cases are passed. To deal with this, we aggregated the student's attempts into a single score as explained in the preprocessing section. Other methods for preprocessing and aggregation of the student's score can be explored in future work and may result in better performance.

8.3 User Testing

An interesting direction for future work would be user testing. In this study, we measured the performance of a model by its ability to predict future task performance for a question on the same concept using the mastery score, with the hope that this could then be used for task-sequencing. It would be interesting to test this method in a real intelligent tutoring system for sequencing remedial tasks and see the proportion of students who agreed that the questions that were recommended for remedial were targeting concepts that they felt weak at. Or in other words, to test if the students agreed that the system recommended the right questions, which was one of the evaluation methods used in [2].

9. CONCLUSION

This study investigated if it is possible to combine methods from domain modelling and student modelling in a single automated pipeline that could go from raw response data on a set of questions, to learning the mapping from concepts to questions, and predicting future task performance for a student, given the student's responses to questions for a given concept.

We experimented with combinations of three Q-matrix generation methods (domain modelling) and three Mastery Score methods (student modelling), and performed experiments on 6 large datasets containing data from students learning to program in Python for 2 years (2018 and 2019) at three different levels (beginner, intermediate and advanced).

We found that for 5 out of the 6 datasets, the best combination of domain modelling and student modelling used our proposed method, ALS on Hill-climbing Q-matrix, as the domain modelling algorithm. For the last dataset (Intermediate-2019), the best method was Hill-climbing Q-matrix. For 5 out of the 6 datasets, the student modelling algorithm in the best combination was EMA, while for the last dataset (Advanced-2019) N-CCR was the best method.

Since none of the best combinations used ALS on Expert Q-matrix as the best domain modelling technique, we conclude that it is possible to fully automate the pipeline from raw data to task sequencing with no human input, relying only on learning from data. The results are promising, in terms of both prediction accuracy and runtime, and are consistent across the datasets from the two different years and three levels.

10. ACKNOWLEDGEMENTS

We would like to thank Grok Academy for providing the datasets used in this study.

ABSTRACT

Regular expression (regex) coding has advantages for text analysis. Humans are often able to quickly construct intelligible coding rules with high precision. That is, researchers can identify words and word patterns that correctly classify examples of a particular concept. And, it is often easy to identify false positives and improve the regex classifier so that the positive items are accurately captured. However, ensuring that a regex list is complete is a bigger challenge, because the concepts to be identified in data are often sparsely distributed, which makes it difficult to identify examples of *false negatives*. For this reason, regex-based classifiers suffer by having low recall. That is, it often misses items that should be classified as positive. In this paper, we provide a neural network solution to this problem by identifying a *negative reversion set*, in which false negative items occur much more frequently than in the data set as a whole. Thus, the regex classifier can be more quickly improved by adding missing regexes based on the false negatives found from the negative reversion set. This study used an existing data set collected from a simulation-based learning environment for which researchers had previously defined six codes and developed classifiers with validated regex lists. We randomly constructed incomplete (partial) regex lists and used neural network models to identify negative reversion sets in which the frequency of false negatives increased from a range of 3%-8% in the full data set to a range of 12%-52% in the negative reversion set. Based on this finding, we propose an interactive coding mechanism in which human-developed regex classifiers provide input for training machine learning algorithms and machine learning algorithms “smartly” select highly suspected false negative items for human to more quickly develop regex classifiers.

Keywords

Qualitative coding, Regex, text classification, neural network, recall, false negative density, negative reversion set

Data mining, as Baker (2010) described, is the “field of discovering novel and potentially useful information from large amounts of data”[2]. A critical challenge in *educational data mining* (EDM) is extracting information from text data. In education settings, text data might come from team chats in collaborative learning environments[4], conversations between computer agents and human learners[12], team discussions, notes, essays and reports in virtual internship[8, 10], etc. Traditionally, qualitative coding is the first and most important step in analyzing text data[11, 6]. But as the size of data increases, manual coding becomes expensive and in some cases impossible. Machine learning (ML) based text classification methods thus play an important role in EDM.

1.1 Challenges in Automated Text Classification

Unsupervised ML, such as *topic modeling*, can automatically extract collections of words that might serve as topics in text data[3, 5]. Supervised ML, such as neural network text classification algorithms[13, 1] can be trained on a subset of manually coded data to predict coding for the remainder of the data. While such ML algorithms can quickly code large data sets, they have disadvantages that may lead to biased classification. For example, unsupervised ML algorithms often generate topics that occur with high frequency. Codes with relatively low frequency are often missed or vaguely represented[7]. Supervised ML algorithms, on the other hand, rely on human coded data, thus bias in training data will be inherited by machine learning models. Moreover, in some circumstances, the amount of human-coded data required to produce a reliable classifier using supervised ML methods can be prohibitive.

A third approach to automated coding is to use human-developed *regular expressions* (regex). Humans are often able to quickly construct intelligible coding rules with high precision. That is, researchers can identify words and word patterns that correctly classify examples of a particular concept. It is often easy to identify *false positives* and improve the regex classifier so that the positive items are accurately captured. However, ensuring that a regex list is complete is a bigger challenge. Because the concepts to be identified in data are often sparsely distributed, examples of *false negatives* are difficult to identify. This causes the low-recall problem in regex based classifiers. That is, the regex based classifiers often miss items that should be classified as positive.

In this paper, we explore the possibility of constructing an interactive coding mechanism in which human-developed regex classifiers provide input for training machine learning algorithms and machine learning algorithms provide cues for human to construct better unbiased regex classifiers.

2. OVERVIEW OF CODING PROCESSES

2.1 Manual Coding

Manual coding of text data is a complex process. Done well, it requires researchers to intensively read their data to discover and construct appropriate theories and develop codes that reflect those theoretical machinery [11, 16, 15]. Hand coding typically begins when text data is segmented into meaningful units, or *items* of data. Codes are then induced by sorting and interpreting observations item by item. A grounded coding process iterates through three coding phases: *open coding*, *axial coding* and *selective coding*. In open coding, a researcher goes through the data to identify preliminary concepts. The concepts are then compared and categorized in axial coding. Once a conceptual framework is established, the researcher focuses on a fixed set of codes in the selective coding phase and identifies which items each code occurs.

Key to the process of manual coding is identifying a precise *definition* for each code (usually accompanied by examples from the data). However, coding depends on how individual researchers understand each code: there are no rules specified that convert text into code in a deterministic way.

To address this concern, manual codes are validated, either through a process of social moderation (sometimes call *dual coding*) in which two or more coders come to agreement about each code for each observation in the data, or using some form of *interrater reliability* (IRR) that quantifies the rate of agreement between two coders.

Because manual coding requires that at least one human rater codes each item of the data and includes triangulation with at least one more human rater, the results from manual coding are considered the most accurate (compared with machine coding methods) and often serves as the gold standard or *ground truth* to which other coding methods are compared.

Despite this advantage in terms of coding validity, manual coding can only be applied to data sets with relatively small size. Thus researchers turn to a variety of machine-based or machine-augmented coding techniques.

2.2 Keyword/Regex-based Coding

In the selective coding phase, when the size of a data set is too large for manual coding, researchers may turn to rule-based automatic coding [9]. Rules can be expressed in terms of text patterns described by regexes [14]. The simplest form of regex is a word, such as “teach”. If this word is used to represent a code “Education”, then the code “Education” occurs if and only if the text contains the string “teach”. Thus, if a text contains the words “teacher”, “teachers”, “teaches” or “teaching”, the code occurs, because “teach” is a sub-string of all these words. Regexes use a set of operators to specify complex patterns. The most frequently used operators

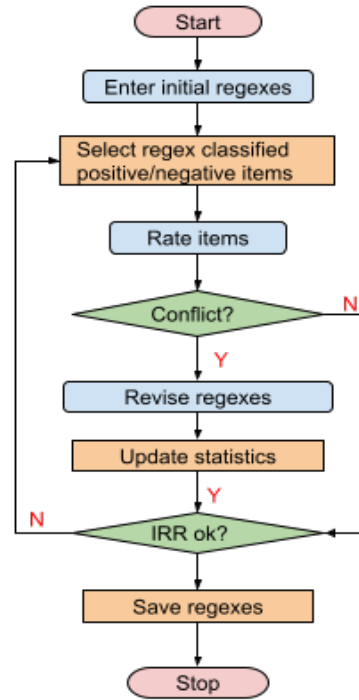

Figure 1: nCoder flowchart.

include the pipe symbol “|”, period “.”, brackets “[]”, and star “*”. The pipe symbol “|” is used to compose alternative strings. For example, the regex “teach|student|school” matches a text containing any of the strings “teach”, “student” or “school”. A period “.” indicates an arbitrary text character and brackets “[]” indicate a range of characters (e.g., [aeiouy] indicates any vowel in English), and the star “*” indicates an arbitrary repetition of the previous character. So the regex “my favorite vowel.*[aeiouy]” would code for the text “my favorite vowel” followed anywhere in the text string by a vowel. In this way, very complicated patterns can be represented by a single regex(see, e.g., <https://www.regular-expressions.info/tutorial.html>).

One powerful publicly available tool for regex-based coding is nCoder (<https://app.n-coder.org/>). nCoder uses an *active machine learning* approach to generating a regex-based classifier. Figure 1 shows the typical work flow of nCoder. A researcher starts from an initial regex list. nCoder uses that regex list to select a set of items to present to the researcher for rating. The set may proportionally include items that the regex list classified as positive or negative. nCoder then allows the researcher to rate the items and compares the researcher’s rating with the regex classification. When conflict occurs, the researcher may revise the regex list, change his or her rating, or leave the conflict unresolved. Inter-rater reliability (IRR) between the researcher and the regex classifier is then computed based on hypothesis testing. nCoder may present another set of items and repeat the rating-testing process. The process continues until the researcher and regex classifier reach a satisfactory level of agreement. The developed regexes are saved before the process terminates.[16].

The convergence of the above procedure depends on what data items are presented to the researcher. If a presented item is one that the human and regex classifier have agreement, no information is provided to the human to improve the regex list. Rather, it is the items where the two ratings conflict that help improve the regex list. This conflict may occur in two ways: one is *false positive*, in which the regex coded positive but the human coded negative; the other is *false negative*, in which the regex coded as negative but the human coded as positive.

Conceptually, we can partition a data set D into two sets: a positive set $\tilde{P} \subset D$ of the items that would be coded as positive by current regex, and a negative set $\tilde{N} = D - \tilde{P}$ that would be coded as negative by the regex list. False positive items are a subset of the positive set \tilde{P} (because a false positive requires that the regex codes an item as positive); and false negative items are only in the negative set \tilde{N} (by similar reasoning).

Notice, however, when the frequency of a code is low (that is, there are few items that should be coded positive), the probability of sampling a false positive item from the positive set \tilde{P} may be much higher than sampling a false negative item from the negative set \tilde{N} . Thus, it is more difficult for the active machine learning system to present users with false negatives, potentially allowing the regex development procedure to converge on a regex list with high precision but potentially lower recall (see the definition of precision and recall in section 3.4).

2.3 Machine learning-based Coding

Machine learning algorithms can be applied to both code discovery and selective coding. In the domain of code discovery, unsupervised machine learning algorithms, such as topic modeling, can automatically extract from a data set lists of related words that might potentially serve as codes. However, research shows that in most cases these word lists do not produce codes of interest to qualitative researchers without further refinement. But topic modeling *can* help identify missing codes by providing potential keywords for coding[5].

One popular approach to using ML for selective coding is LSTM (Long Short Term Memory) neural network models. These models take as input a set of coded data items, and return an algorithm that can predict coding for the rest of the data. Figure 2 shows the model used in this study. A text data item enters from the input layer as an ordered word list. The embedding layer represents each unique word by a vector. The ordered vectors are input to a bidirectional LSTM layer that creates two vector representations of the input data line. The two vectors are merged into a single vector representation and 50% of the nodes are removed in the dropout layer to control over-fitting. The sigmoid layer converts the vector into a class probability output, which indicates for each item how likely the model thinks it should be coded positive. The probability values are then converted to a binary coding value using a cutoff threshold, say, 0.5. That is, when the probability is greater than 0.5, the item is coded as 1, otherwise 0. (Readers interested in more details about LSTM models can find more information in neural network publications such as [13].)

Table 1: Manual, Regex and ML Coding

	Manual	Regex	ML
Evidence	Explicit	Explicit	Implicit
Precision	High	High	Medium
Recall	High	Low	Medium
Coding size	Limited	Unlimited	Unlimited
Cost	High	Low	Medium

This kind of neural network model can represent very complicated patterns of words that serve as indicators for a code. However, it usually requires a large number of coded data items to train a neural network model to reach an acceptable accuracy; thus preparing the training data for the neural network model could be expensive. Moreover, like many other machine learning models, neural network models are a *black box*: the output is hard to interpret. When a neural network model flags the occurrence of a code in a data item, it can be hard (and often impossible) for a researcher to determine what specific evidence the algorithm used to make its decision. This makes it difficult for qualitative researchers to establish a theory with clear interpretation. In addition, it makes it difficult for researchers to understand potential biases in the codes and to warrant to end users that the result of the coding is fair.

2.4 Combining manual, regex and ML coding

Table 1 summarizes the advantages and disadvantages of the three coding methods we have discussed so far. In what follows, we construct and test an approach to coding that integrates these three methods together into a single process, in which we iterate between manual coding and regex coding to train a regex list. Then we use the data coded by the regex list to train the neural network model. The disagreements between regex coding and neural network coding are presented back to the researcher to further refine the regex coding. We will show that this combination helps solve the low recall problem in regex coding.

2.5 Approach

For a given data set D and a code c , let a human rater’s classification be $D = P + N$, where P is the set of positive items (i.e., items in which code c occurs) and N is the set of negative items. The plus sign “+” denotes the union of two sets. In practice, the number of items in P is usually much smaller than in N (i.e., $|P| \ll |N|$), because researchers are often interested in codes that do not occur with high frequency.

Of course, for a given item $x \in D$, the coding algorithm cannot determine whether $x \in P$ or $x \in N$ without asking the human rater. Therefore, it is impossible for an algorithm to sample a new item from P (or N) unless they have already been classified by the human rater. In this sense, the sets P and N are *unsamplable*, while the set D is *samplable*. That is, a machine algorithm can choose an item $x \in D$ but it cannot choose with certainty whether sample $x \in P$ or $x \in N$.

Consider a regex classifier that classifies the data set $D = \tilde{P} + \tilde{N}$. Since the machine knows the classification of all

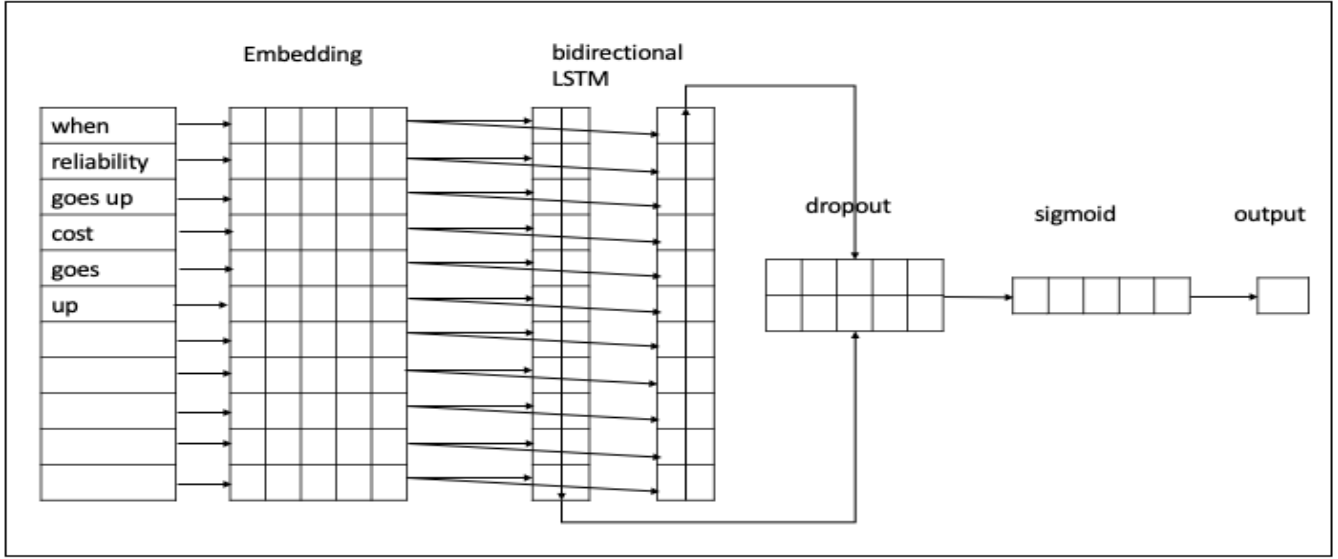

Figure 2: LSTM neural network model for text classification

items in D , the sets \tilde{P} and \tilde{N} are samplable. The regex classifier is perfect if $P = \tilde{P}$. In reality, however, this is rarely the case.

The data set D thus can be decomposed as the union of four sets (from now on we use the notion XY to denote the intersection of the sets X and Y):

$$D = P\tilde{P} + P\tilde{N} + N\tilde{P} + N\tilde{N}$$

where

- $P\tilde{P}$: true positive set of the regex classifier relative to human;
- $P\tilde{N}$: false negative set of the regex classifier relative to human;
- $N\tilde{P}$: false positive set of the regex classifier relative to human; and
- $N\tilde{N}$: true negative set of the regex classifier relative to human.

Notice that, since P and N are unsamplable, none of the above sets ($P\tilde{P}$, $P\tilde{N}$, $N\tilde{P}$, or $N\tilde{N}$) is samplable.

As described above, the performance of the regex classifier development process depends on its ability to present users with false positives $N\tilde{P}$ and false negatives $P\tilde{N}$. When $\tilde{P} \ll \tilde{N}$, the false negative items are less *recoverable*, in the sense that the probability of sampling a false negative item is much smaller than false positive.

Let us use an example to show this. Suppose the data size is $|D| = 10,000$ and a regex classifier identified 1000 positive items $|\tilde{P}| = 1000$ with 500 false positive and 500 false negative: $|N\tilde{P}| = 500$ and $|P\tilde{N}| = 500$. Since the false positive

items are in the samplable set \tilde{P} , we can sample from \tilde{P} to find false positive items. The probability of sampling a false positive item from \tilde{P} is $500/1000 = 0.5$. On the other hand, false negative items are in the samplable set \tilde{N} , which contains $10000 - 1000 = 9000$ items. The probability of sampling a false negative item from \tilde{N} is $500/9000 \approx 0.056$.

The above example shows that, when developing a regex classifier, it is hard for the machine to find false negatives — that is, to find examples of items that the human would classify as positive but the regex classifier does not. This means that positive cases outside of the scope of the current regular expression list are difficult for the regex classifier to identify, which causes the low recall problem.

Here we ask whether it is possible to use a neural network model trained from the regex coded data to identify false negative items. For example, if a regex list for the code “education” contains “teach”, “student” and “school”, a neural network model may be able to tell that the items containing “class”, “book” should be included in the positives. Thus, if we sample items that the regex classified as negative but neural network model classified as positive, we may be able to increase the probability of finding examples that the human rater would code as positive but the regex classifier would not.

Consider a neural network model that classifies $D = \tilde{\tilde{P}} + \tilde{\tilde{N}}$. The regex false negative set $P\tilde{N}$ is decomposed by the neural network classifier as

$$P\tilde{N} = P\tilde{\tilde{P}} + P\tilde{\tilde{N}}.$$

We are mostly interested in the items that regex classifies as negative but neural network model classifies as positive. We call the set of such items *Negative Reversion Set*, which

can be written as

$$\tilde{N}\tilde{P} = P\tilde{N}\tilde{P} + N\tilde{N}\tilde{P}.$$

Notice that the negative reversion set $\tilde{N}\tilde{P}$ is the intersection of the regex negative set (items coded negative by the regex) \tilde{N} and the neural network positive set (items coded positive by the neural network) \tilde{P} . Since both \tilde{N} and \tilde{P} are samplable, the negative reversion set $\tilde{N}\tilde{P}$ is samplable.

2.6 Research question

In what follows, we ask two research questions:

2.6.1 RQ1

Is the probability of finding a regex false negative item higher from the negative reversion set $\tilde{N}\tilde{P}$ than from the regex negative set \tilde{N} ? In other words, are the false negatives denser in the negative reversion set $\tilde{N}\tilde{P}$ than in the regex negative set \tilde{N} ?

We define the false negative density d_A of a set A as the proportion of the number of false negative items in the set A . That is,

$$d_A = \frac{|P\tilde{N}A|}{|A|}.$$

Thus, the false negative density of a negative reversion set $\tilde{N}\tilde{P}$ is

$$d_{\tilde{N}\tilde{P}} = \frac{|P\tilde{N}\tilde{P}|}{|\tilde{N}\tilde{P}|},$$

and the false negative density of a regex negative set \tilde{N} is

$$d_{\tilde{N}} = \frac{|P\tilde{N}|}{|\tilde{N}|}.$$

Using the notation of false negative density, the mathematical form of this research question is whether or not the following equation holds:

$$d_{\tilde{N}\tilde{P}} \gg d_{\tilde{N}} \quad (1)$$

2.6.2 RQ2

If a set A is found dense with false negatives, does it also has an acceptable false negative recovery rate?

Sampling false negatives in a denser set certainly helps. However, it is also important that the denser set should be large enough to include a certain proportion of false negatives. We define the *false negative recovery rate* r_A of a set A as the proportion of false negatives included in the set A , that is

$$r_A = \frac{|P\tilde{N}A|}{|P\tilde{N}|}. \quad (2)$$

So, we ask whether or not the false negative recovery rate of the negative reversion set $r_{\tilde{N}\tilde{P}}$ is large enough.

Table 2: Code definition.

Code	Description
CONSTRAINTS	Referring to inputs: material, processing method, surfactant, and CNT.
PERFORMANCE	Referring to attributes: flus, blood cell reactivity, marketability, cost, or reliability.
COLLABORATION	Facilitating a joint meeting or the production of team design products.
DESIGN	Referring to design and development prioritization, tradeoffs, and design decisions.
DATA	Referring to or justifying decisions based on numerical values, results tables, graphs, research papers, or relative quantities.
REQUESTS	Referring to or justifying decisions based on internal consultant’s requests or patient’s health or comfort.

2.6.3 General method

To answer these questions, we investigate a text data set with full regex lists developed and validated for multiple codes. The full regex lists coded data is used as “true human ratings”. We then randomly sample a partial regex list from the full regex list of each code. Partial regex lists are treated as the regex classifiers under development. Neural network models are built from the data coded by these partial regex lists. So, given this data set, we are able to obtain “human ratings” (actually full regex list coding), regex classifier (actually partial regex classifier) and neural network classifier (trained on partial regex classifier). The negative reversion sets are then determined from these three classifications. We are then able to compute the false negative density and the false negative recovery rate of the obtained negative reversion sets to get the answers to our research questions.

3. METHODS

3.1 Data

The data used in this study consists of 50,818 participant utterances collected from novice engineering design teams participating in an engineering virtual internship *Nephrotext*, in which students worked as interns at a fictitious company that designs and manufactures ultrafiltration membranes for hemodialysis machinery used to treat end-stage renal failure[8]. Table 2 shows the definition of six codes defined by previous researchers, including *Tech Constraints*, *Performance*, *Collaboration*, *Design*, *Data* and *Requests*.

Using nCoder tool (<https://app.n-coder.org/>), researchers developed and validated the regex lists. Table 3 shows the regex list for each code, together with “base rate” (BR) and kappa values. The base rate of a code was the proportion of items in the data set the code occurred. The kappa values

Table 3: Regex lists for each code, the base rates (BR), and the kappas between human rater 1 (H1) and human rater 2 (H2), human rater 1 and computer (C) and human rater 2 and computer.

were computed on the ratings from two human raters (H-1, H-2) and the regex classifier (C). Because of the high kappa values, we considered these regex lists as “complete” and represent the “true classification” by human raters. In the discussions below, we use “full regex classification” to replace “human classification”.

We decomposed the items in the regex lists if they were connected by a pipe symbol “|”. For example, if an item was “r1|r2”, then it was decomposed as two items “r1” and “r2”. Of course, all items in the list for a given code could be composed back as a single regex by re-connecting them with a pipe symbol “|”. We decomposed the regex in this way so that we could more meaningfully sample partial regex lists.

3.2 Data splitting

The data set D was randomly split into a training set S and a test set T , each of which consisted of 25,409 items. The training set S was used for sampling items to train neural network models, while test set T was used for computing final results.

3.3 Coding by three classifiers

3.3.1 Full regex coding

Full regex lists for the six codes were used to code the whole data set D , which formed the “true classification” of the whole data $D = P_D + N_D$. Consequently, the training set S and the test set T are also “truly” classified as $S = P_S + N_S$ and $T = P_T + N_T$. Under this classification, the positive rates (base rates) for the six codes range from 7% to 16% (see Table 3).

3.3.2 Partial regex coding

For a given code, a partial regex list was constructed using the following procedure:

1. Start with an empty regex list $L = \{\emptyset\}$ and full regex list R_c for a code c ;
2. Randomly select a regex $r \in R_c$ and add it to the partial regex list L ;
3. Code the whole data set D by the partial list L to produce $\tilde{P}_{D/L}$;
4. Compute the number of positive items $|\tilde{P}_{D/L}|$ coded by L ;
5. If $|\tilde{P}_{D/L}| > \frac{|P_D|}{2}$, end the procedure; otherwise go back to step 2.

Through this procedure, the number of positive items classified by a partial regex list L is equal to or greater than half of the true positive items. Each partial list L decomposed the training set and test set into the following samplable sets (for parsimony, we define $\tilde{P}_A \equiv \tilde{P}_{A/L}$):

- \tilde{P}_S : regex positives in training set;
- \tilde{P}_T : regex positives in test set;
- \tilde{N}_S : regex negatives in training set; and
- \tilde{N}_T : regex negatives in test set.

3.3.3 Neural network coding

In this paper, the neural network models were trained based on the classification of partial regex classifiers. For a given partial regex classifier and a given sample size n , a random sample $s_n \in S$ with size n was taken from the training set. Each item in the sample contained two fields: the text field X and the classification value Y (1 when the regex list was matched and 0 otherwise). The text field X is used as the input and the partial regex classification value Y is used as the output to train a predictive LSTM neural network model. The testing set was then coded by the predict function of the LSTM model, with the cutoff probability 0.5. Thus, the neural network model classified the test set into the samplable sets:

- \tilde{P}_T : neural network positive in test set; and
- \tilde{N}_T : neural network negative in test set.

3.3.4 Sample size and repetition of partial regex lists

In training the neural network models, we used five different sample sizes: $n = 100, 200, 400, 800, 1600$. In order to reduce the random effect in partial regex construction, 12 random partial regex lists were drawn for each code using the partial regex construction procedure. So, for each of the six codes, the test set had the following classifications:

- 1 “true classification” $T = P + N$;
- 12 partial regex list classification $T = \tilde{P}_i + \tilde{N}_i$, ($i = 1, 2, \dots, 12$);
- 60 neural network classification (12 partial regex list, 5 sample sizes each) $T = \tilde{P}_{in} + \tilde{N}_{in}$, ($i = 1, 2, \dots, 12; n = 100, 200, 400, 800, 1600$).

In the notions above, \tilde{P}_i and \tilde{N}_i were the positive and negative set, respectively, classified by the i^{th} partial regex for the given code; and \tilde{P}_{in} and \tilde{N}_{in} were the positive and negative set, respectively, classified by the neural network model trained on the i^{th} partial regex list with sample size n .

3.4 Performance metrics

Before moving on, we define three measures for the performance of classifiers: *precision*, *recall* and *Cohen’s κ* . For a given classifier, denote the *proportion* of true positives, false positives, false negatives and true negatives by tp, fp, fn and tn , respectively.

- The **precision** of a classifier is the ratio of true positive to the sum of true positive and false positive, namely

$$precision = \frac{tp}{tp + fp}.$$

- The **recall** of a classifier is the ratio of true positive to the sum of true positive and false negative, namely

$$recall = \frac{tp}{tp + fn}.$$

- The **Cohen’s kappa** κ of a classifier is the ratio of the difference between observed probability and chance probability to one minus chance probability, namely,

$$\kappa = \frac{p_o - p_c}{1 - p_c}.$$

where

$$p_o = tp * fp,$$

and

$$p_c = fp * fn + (1 - fp) * (1 - fn).$$

4. RESULTS

4.1 Single model comparison

Table 4 shows an example classification on code “Tech Constraints” with its full regex list, one randomly constructed partial regex list and one neural network model trained from the partial regex list with sample size 400.

In this example, the classification of the test set by the full regex classifier, which was considered the “true classification”, yielded 3976 positive items (set P) and 21,431 negative items (set N). Notice that there were far more negative items than positive items. The partial regex classifier correctly identified 2,133 positive items (set $P\tilde{P}$). However, it falsely classified 1845 positive items as negative (set $P\tilde{N}$). Since the partial regex was a subset of the full regex list, any item matched by the partial regex was in turn matched by the full regex. In other words, any item not matched by the full regex was not matched by the partial regex. Thus, no negative item was falsely classified as positive (set $N\tilde{P}$); and the partial regex classifier agreed with the full regex classifier on all 21,431 negative items (set $N\tilde{N}$). As a result, the partial regex got a larger negative set $\tilde{N} = P\tilde{N} + N\tilde{N}$ with a total of 23,276 items. The false negative density in the negative set \tilde{N} was thus $d_{\tilde{N}} = 1845/23276 \approx 7.92\%$.

The third column of the table shows the classification results of the neural network model trained on the data classified by the given partial regex list with sample size 400. There were 1170 items that were correctly classified by both partial regex list and the trained neural network model (set $P\tilde{P}\tilde{\tilde{P}}$). 963 positive items were correctly classified by the partial regex list but falsely classified as negative by the neural network model (set $P\tilde{P}\tilde{N}$). Most interestingly, there were 288 positive items that were falsely classified as negative by the partial regex list but correctly reversed as positive by the neural network model (set $P\tilde{N}\tilde{\tilde{P}}$). 1557 positive items were falsely classified as negative by both the partial regex list and neural network model. For the 21,431 negative items, the neural network falsely classified 302 items as positive (set $N\tilde{N}\tilde{\tilde{P}}$) and correctly classified 21,129 items as negative (set $N\tilde{N}\tilde{\tilde{N}}$).

The negative reversion set $\tilde{\tilde{N}}$ was the union of the sets $P\tilde{N}\tilde{\tilde{P}}$ and $N\tilde{N}\tilde{\tilde{P}}$, which contained 288 correctly reversed items and 302 falsely reversed items. Therefore, the false negative density in the negative reversion set $\tilde{\tilde{N}}$ was $d_{\tilde{\tilde{N}}} = 288/(288 + 302) \approx 48.81\%$, which was much larger than the density in the regex negative set $d_{\tilde{N}} = 7.92\%$.

Table 4: An example of false negative recovery for Tech Constraints with training size 400.

Full Regex	Partial Regex	Neural Network
$P(3976)$	$P\tilde{P}$ (2133)	$P\tilde{P}\tilde{\tilde{P}}$ (1170)
	$P\tilde{N}$ (1845)	$P\tilde{P}\tilde{N}$ (963)
		$P\tilde{N}\tilde{\tilde{P}}$ (288)
		$P\tilde{N}\tilde{\tilde{N}}$ (1557)
$N(21,431)$	$N\tilde{P}$ (0)	$N\tilde{P}\tilde{\tilde{P}}$ (0)
	$N\tilde{N}$ (21,431)	$N\tilde{P}\tilde{N}$ (0)
		$N\tilde{N}\tilde{\tilde{P}}$ (302)
		$N\tilde{N}\tilde{\tilde{N}}$ (21,129)

Figure 3: False negatives density in partial regex negatives versus in negative reversion set.

This example gives us a positive answer to our first research question. That is, the false negative density in the negative reversion set is much higher than in the regex negative set.

To answer the second question, we computed the false negative recovery rate in the negative reversion set. From Equation 2, we had $r_{\tilde{\tilde{N}}} = 288/1845 \approx 16\%$.

If our goal is to find all false negatives, this number is not very high, because 84% false negatives are still sparsely distributed in the regex negative set \tilde{N} . However, we argue that this number is large enough for constructing iterative methods, which we will talk more about in the discussion section.

4.2 Average false negative density

The above example showed false negative density and the false negative recovery rate in the negative conversion set for one code, one random partial regex list and one neural network model with sample size 400. To answer our research questions more reliably, we computed the average false negative density for each code with 12 randomly drawn partial

Table 5: False negative recovery rate, training size=400

Code	$P\tilde{N}\tilde{P}$	$P\tilde{N}\tilde{N}$	r (%)
Tech Constrains	195.83	1579.67	11.03
Performance	270.17	1338.00	16.80
Collaboration	23.75	900.58	2.57
Design	76.67	1908.17	6.53
Data	19.67	1027.67	1.88
Requests	38.25	615.25	5.85

Figure 4: False negative density in negative reversion set for all sample sizes.

regex lists. The results show that the false negative density for all codes were several times higher in the negative reversion set $\tilde{N}\tilde{P}$ than in the regex negative set \tilde{N} . Figure 3 shows the results for sample size=400. While the density $d_{\tilde{N}}$ in the regex negative set ranged from 3% to 8%, the density $d_{\tilde{N}\tilde{P}}$ in the negative reversion set ranged from 12% to 52%. For example, the density for the code “Performance” increased from $d_{\tilde{N}} = 7\%$ to $d_{\tilde{N}\tilde{P}} = 52\%$.

4.3 Average false negative recovery rate

For each code, we computed the average false negative recovery rate over 12 randomly drawn partial regex lists. Table 5 shows, with neural network training size=400, the number of items in sets $P\tilde{N}\tilde{P}$ and $P\tilde{N}\tilde{N}$ and false recovery rate as percentages. The average false negative recovery rates ranged from 1.88% to 16.88% and the average number of false negative items included in the negative reversion set ranged from 19.67 to 270.17.

4.4 Sample size effect

In the above, we only showed the results for the neural network models trained from sample size $n = 400$. Figure 4 and Figure 5 show the average false negative density and false negative recovery rate in the negative reversion set for each code as a function of neural network training size. For the codes “Tech Constraints”, “Collaboration” and “Design”,

Figure 5: False negative recovery rate for all sample sizes.

the density change was very small after size 400. For code “Performance” and “Requests”, the density for larger training size was larger. However, they suffered from reduced false negative recovery rate.

We also computed Cohen’s kappa between different models. Figure 6 shows the mean Cohen’s kappas for each code as functions of sampling size for neural network model. The kappa means were computed over the 12 partial regex lists for each code. The blue lines are the kappas between full regex and partial regex lists. They are horizontal lines because they have nothing to do with the sample size. The green lines are kappas between partial regex lists and neural network models. As sample size increases, the green lines increases. That indicates that neural network models could be close to the partial regex list model as the sample size increases. For codes “Tech Constraints” and “Performance”, the green lines even go beyond the blue lines when the sample size is large. This is normal because the neural network models were trained from partial regex list. The red lines are kappas between the full regex and neural network models. Although the red lines also increase, they never go beyond the blue lines. That indicates that, although neural network models may help identify items missed in partial regex list, they don’t perform better than the regex classifier from which they are trained.

5. CONCLUSIONS

In this study, we used neural network models trained from partial regex classifier to help identify the false negatives from partial regex classifiers. The so called *negative reversion* set $\tilde{N}\tilde{P}$ was of our most interest in this study. This set consisted of conflict items that the partial regex classifier coded as negative but the neural network classifier coded as positive. Since the neural network classifiers was trained from the data coded by the partial regex classifiers, the negative reversion sets were actually error sets - the *false positive* sets relative to the partial regex coded data. That is, the neural network models didn’t correctly predict how the par-

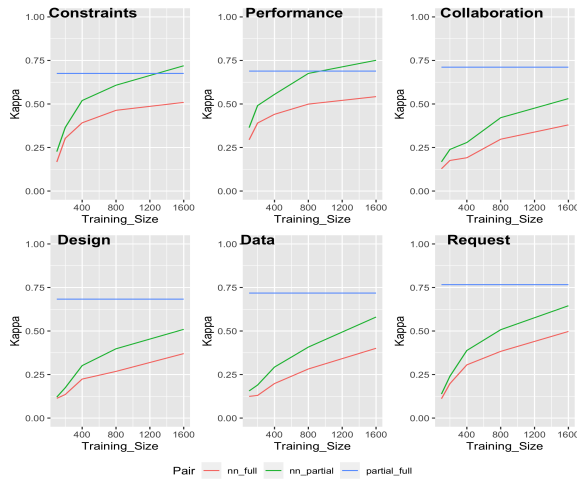

Figure 6: Kappa as functions of training size between three pairs of coding: partial regex and full regex coding, neural network and full regex coding, and neural network and partial regex coding.

tial regex classifiers code such items. However, our study showed that this “error set” had a much higher density of regex false negatives. This indicates that the neural network models had some ability in detecting the error contained in the training data. It is unclear how this happened. Our current theory is that, since the neural network model was built on semantic representations (word embedding layer captures the word meaning and the LSTM layer captures the word order information), it could be able to detect certain violations of semantic consistency. For example, if “table” and “chair” are included in a partial regex list, the neural network model may suggest that “furniture” shouldn’t be excluded.

The results show the differences of the density increases among codes. The increased density in the false negative reversion set doesn’t correlate to the original density in the regex false negative set. The source of the difference is unknown. However, the fact that the density in the false negative reversion set is from 3 to 12 times higher suggests that this technique could improve classifier performance.

The results showed that false negative recovery rate ranged from 2% to 17%, depending on the specific code and neural network training size. This indicates that, while it is easier to find false negative items from the negative reversion set, many false negative items remain in other sets. We suggest that, when searching for false negative items, the negative reversion set and the whole regex negative set should both be considered.

The training size issue in this study is more complex. In general, more training data results in better neural network models. However, in our case, we are expecting a larger “error set” $\tilde{N}\tilde{P}$. When the training size is too large, the “error set” shrinks and thus reduces the false negative recovery rate. From our study, it appears that a training size of approximately 400 is adequate.

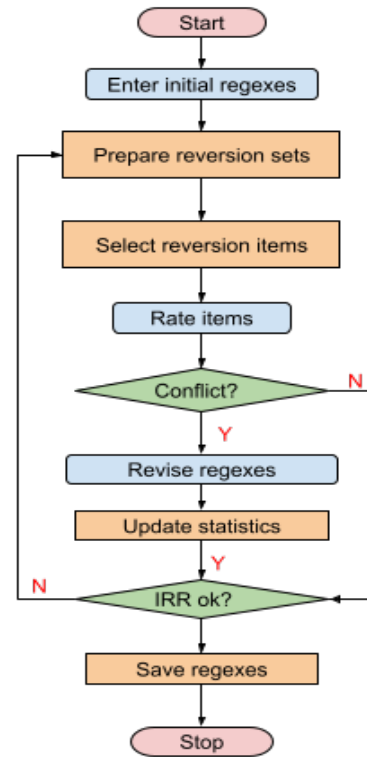

Figure 7: Neural network assisted regex development.

More generally, our study is limited by the use of one specific data set, six specific codes, and a specific ratio (1:2) between the partial regex and the full regex. In practice, the partial regex corresponds to the regex list under development and the full regex corresponds to the human understanding of the code. When the partial regex is close to the “full regex”, the density in the negative reversion set may become small.

While, of course, training the neural network models from manually coded data would produce a better predictor, it would require a human rater to code a large number of items. But, as we argued above, even if enough manual coding could be provided, training a neural network model directly from the manually coded data will result in a classifier that is hard to interpret and defend. Instead, we suggest using an imperfect neural network model to augment regex-based classification, so that when a regex classifier codes a positive item, it will be clear to researchers and end users why each item has been coded.

The last but not least, we didn’t use real human coding in this study, which limited our investigation on false negative items only, because a partial regex classifier will never have false positive prediction in relation to a full regex classifier. However, in the case of real human coding, false positives are likely to occur. Similar to the negative reversion set, we may define a positive reversion set as the set of items for which the regex classifier coded as positive but the human rater coded as negative. It could be the case that the positive reversion set also contains denser false positives. However, this is less important when the positive rate is small.

To conclude this paper, we propose the following iterative procedure for better development of regex classifiers (see Figure 7):

1. The user enters initial regex list for development;
2. A machine learning model is trained based on the initial regex list classification and prepares reversion sets;
3. The computer selects highly likely conflict items suggested by machine learning model;
4. The user rates the item ;
5. If a conflict occurs, the user resolves the conflict and updates the regex list;
6. The computer computes agreement statistics (IRR) based on the ratings from the user, regex list and neural network model;
7. If the statistics show that the IRR is not high enough, go back to the reversion set preparation step and reiterate the process;
8. If the statistics show high agreement, end the process.

ABSTRACT

Student grade prediction is a popular task for learning analytics, given grades are the traditional form of student performance. However, no matter the learning environment, student background, or domain content, there are things in common across most experiences in learning. In most previous machine learning models, previous grades are considered the strongest prognosis of future performance. Few works consider the breadth of instructor features, despite the evidence that a great instructor could change the course of a student's future. We strive to determine the true impact of an instructor by analyzing student data from an undergraduate program and measuring the importance of instructor-related features in comparison with other feature types that may affect state-of-the-art student grade prediction models. We show that adding extensive instructor-related features improves grade prediction, when using the best supervised learning classifier and regressor.

Grade Prediction, Student Performance Prediction, Feature Analysis, Instructor Features, Learning Analytics

1. INTRODUCTION

Student performance prediction is a useful service for multiple educational stakeholders in a university and other educational contexts. For example, it is a frequent feature in learning analytics software, like in early-warning systems [6], curriculum personalization [5], cultivating student study skills [13], characterizing course difficulty [31], and can be incorporated into Intelligent Tutoring Systems [22], Massively Open Online Courses [26], and Learning Management Systems [17]. It makes sense that a student would want to use their predicted grade in future courses for short-term course planning, or if an instructor or advisor would want to predict the grades of their students as an early indication of which students are likely to need more assistance.

N. Ong, J. Zhu, and D. Mosse. Towards including instructor features in student grade prediction. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 239–250, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

Intuitively, it would appear that student history would be sufficient to predict future grades. However, in a classroom environment, the student and their past grades are not the only factors that dictate the student's performance. The specific course for which the grade is being predicted and the particular instructor can also affect the outcome of the student's efforts. It is common knowledge that students have varying strengths and weaknesses that interact with courses and their materials. This is reflected in machine learning (ML) models that attempt to carry out student grade prediction by including course-based features. Furthermore, the content of the course and the student's ability to retain the information and skills they learned can also have an impact on student performance (e.g. [27]). Similarly, it is also known that instructors can have a monumental impact on students. For example, good teachers can improve standardized testing scores in reading and math [20]. When considering a teacher's motivation level, there is a direct link to students' academic achievement [4]. Furthermore, it is a common anecdote for someone to be able to point to a teacher that had greatly affected who they became later in life, usually by reinforcing positive traits or shielding from negative influences (e.g. [9]). Yet, an instructor's impact on a student's performance has not been fully explored, quantitatively and in ML models.

In this paper we take a first step to characterize the feature space that can describe the instructor effect on student grade prediction. We experiment with several ML algorithms, using a dataset with thousands of student data records from a large, public university, and show that adding extensive instructor-related features improves grade prediction. Our evaluation shows that GradientBoost is the best supervised learning classifier and regressor, and we will use it to compare instructor-based features with other feature types.

2. PREVIOUS WORK

Student performance prediction is a popular research subject, given its varied applications and approaches. Some works have approached the problem of binary classification of student performance (e.g., predicting pass/fail), to focus educators' attention to the needy students. However, our focus is on overall prediction of the Grade Point Average (GPA) of the final grade in a course, along with a corresponding 5-class breakdown of the grade¹, to explore the possible effect that instructor features have over a course's

¹The categories and corresponding GPA values can be found in Table 3.

final grade. Many works also attempted to train models that predicted multi-class classification (e.g., categorical/letter grading) or regression (e.g., percentage) [1], but with no attempt to include instructor characteristics.

Recent published work in grade prediction has focused on experimenting with different ML models, using features such as student characteristics, domain content, or other course characteristics. Morsy and Karypis [19] focused on assigning knowledge component vectors for each course, paired with a student’s performance in those courses, to inform a regression model, and attained up to 90% accuracy for some predictions with leeway up to 2 half-grades away². Polyzou and Karypis [25] employed Matrix Factorization, previously found in recommendation systems, and focused on historical student grades as the primary feature category, achieving an average error between 2 to 3 half grades. Widjaja et al. [34] combined a Matrix Factorization model, Factorization Machines (FM), with a Long Short-Term Memory neural network, using multiple course and student features, achieving an error between 1 to 2 half grades. None of these works included instructor-based features. For comparison, we will use an FM [29] model as one of our baselines.

Most research to date in this area focuses on past student performance, student-based features, and more recently on course-based features, like in the examples given above. Polyzou [24] went further in an attempt to enumerate student grade and course-based features, but applied the models only to predicting several binary classifications (e.g. will the student fail the course?). They found that for some classification tasks, some feature types improved the performance, while in other classification tasks, they made things worse.

Given that our focus is to add instructor features, we examined works that included them. Ren et al. [28] used only an instructor’s ID when training a neural collaborative filtering model and achieved an error within two half grades. Zhang et al. [35] had a feature list that included 4 instructor-based features (that were grouped with course-based features), namely “teacher’s seniority, teacher’s age, teacher’s title, [and] teacher’s nation.” They applied a variation on a Convolutional Neural Network, achieving an F1-score of 0.805 for a 5-grade classification task. Hu et al. [14] included three instructor features in their datasets, namely instructor’s rank, tenure status, and average GPA over all of the courses they taught in the dataset; they achieved an average error up to 1 grade level difference with regression. Sweeney et al. [32] used 4 instructor features, classification, rank, tenure status, and a bias term introduced in their model, features which focused on their official positions rather than experience, and achieved an error range of two half grades. Each of these works haphazardly included a few instructor features. Only Sweeney et al. analyzed the instructor features’ effects on the performance of their chosen models, and found that the instructor’s bias feature was the third-most important feature, yet was only one-third as important as the student’s bias feature. Our work makes headway in instructor-based features, and examines the number and importance of such features in more detail.

²We define *half grades* to be when the grade changes by one step (e.g., from A to A⁻ or B⁺ to A⁻), while a *full grade* change is when the letter changes (e.g., from A to B)

3. DATASET

3.1 Program Curriculum

The dataset is taken from a computer science (CS) four-year, undergraduate degree program at the main campus of a large American public university. This university has four independent satellite campuses that may offer similar courses, but do not offer the same curriculum. However, it is common for students to transfer from satellite campuses to the main campus and enroll in the CS degree, and some courses students took at the satellite campuses can be transferred into the main campus’ CS program with approval from the main campus undergraduate program director.

Courses in the program are split into three categories: mandatory, electives, and a capstone. There are 8 mandatory courses that all students who intend to graduate with a CS degree must take (unless students will enter with Advanced Placement/International Baccalaureate CS credit or transfer courses from other campuses). For electives, students pick at least 5 upper-level CS courses that pertain to their interests and strengths. Each course may or may not contain prerequisites, and if they do, they tend to be other CS courses. Some mandatory courses have co-requisites, meaning certain courses may be taken at the same time. Students must pass each course with a grade of “C” or higher; if a student does not reach this threshold, they are given the opportunity to retake the course up to two additional times. The last grade that the student received for a course, regardless if it is higher or lower than any previous attempt, is the final grade recorded for the course. The capstone is a project-oriented course as a culmination of the CS curriculum, but not relevant to this research.

Instructors are given flexibility in how they wish to teach their course, as long as they follow the generalized syllabus that is agreed upon by the area faculty for that course. The syllabus contains a list of topics that instructors are expected to cover, but does not prescribe the depth that the instructor must reach for each topic. Should instructors believe there are additional important topics not covered by the generalized syllabus, they are also free to add them into their course. A specific order is similarly not imposed by the generalized syllabus, but topics tend to build on each other naturally, common in STEM fields (e.g. [15]), which imposes a soft ordering. However, due to individual preferences on how to present concepts to students, instructors have the freedom to conduct their courses differently. Given different degrees are offered on satellite campuses, we expect that in the same course, satellite instructors will present their concepts differently from instructors in the main campus.

The main campus CS degree program also is involved in a college-in-high-school (CHS) program, where the CHS program director and a faculty liaison provide materials to high school teachers, and if the student earns a passing grade given by the high school teacher, they qualify for college credit, as if the student took the course at the university. The material high school teachers receive is more structured than the generalized syllabus that instructors for undergraduate students receive, and the university provides training for those teachers to ensure the material that is taught is at the same level of rigor as what is expected for the undergraduate course. The high school teachers assign the final grade,

Total	Out-of-State	868	23.8
		3,646	100.0

which are recorded in the official university transcripts.

3.2 Summary Statistics

Transcripts of 3,646 students, all of whom enrolled in at least one of the first two computer science major mandatory courses (since those two can be taken in any order and have no prerequisites) were retrieved from the university registrar. Records spanned between August, 2006 and December, 2019, for a total of 186,316 grade records. Not all students have completed the degree program, but the university does not have an official denotation for when students have decided they no longer wish to pursue their studies at the university or are taking a break from their studies.

3.3 Data Cleaning

To retain consistency, students enrolled in the computer engineering (CE) program, which for a time took many

of the same mandatory courses of the CS program, but with a different passing grade requirement, were removed from the set, leaving 3,122 students. We further cleaned the dataset by removing all non-CS courses and non-letter grades (e.g. “Withdraw”, “Satisfactory”, etc.), leaving 28,150 “fully-cleaned” grade records. Basic statistics can be found in Table 1.

4. METHODOLOGY

Our goal is to generate a supervised ML model that can predict a student’s grade for a target CS course in a given semester of their undergraduate career, and use that model to run a comparison between the different feature types (i.e., to figure out which feature types contribute the most to the best prediction), which will include instructor features.

4.1 Features

We include four types of features in our models: Student Characteristics, Student Grade History, Course Characteristics, and Instructor Characteristics, as detailed below. There are 571 features altogether. The first feature that we include with any model we will train is the target course number, to indicate which course the training grade label came from.

4.1.1 Student Characteristics

Student Characteristics are features that describe the student themselves that are not directly related to their courses. We include a student’s ethnic group, gender, math and verbal SAT scores, ACT scores³, high school GPA, whether they are the first in their family to attend college, and whether they are an in-state or out-of-state student. Furthermore, with the anecdotal knowledge that instructors have particular jargon, preferences, and quirks, we add a feature indicating if the student has ever encountered the same instructor for the target course, or if the instructor was the same for the target course’s prerequisite, in the belief that a student who encounters the same instructor again has a better understanding of how to satisfy the instructor’s requirements. This provides a total of 9 features.

Demographic breakdown of the students in the dataset can be found in Table 2.

4.1.2 Student Grade History

Student Grade History features are a simple enumeration of all CS courses a student has taken in their undergraduate career. Each course is represented by a pair of features, the grade they received as a GPA value (e.g., 4.0 instead of A), and the semester number they took the course relative to the first CS course they took, which includes the summer term. As an example, assume a student took their first ever CS course, CS 101, in the spring term and received a B⁺, and took CS 102 in the fall term of the next school year and received a A⁻; the resulting grade and semester pairs for CS 101 and CS 102 would be (3.25, 0) and (3.75, 2), respectively. We use relative semester value given that students

³The SAT and ACT are common standardized exams that high school students take for entry to an American undergraduate program. For this university, these scores are not required, and are given 0 if no score is provided. Note that 0 is not a valid score for either exam.

have other general education requirements to fulfill not related to the major, and thus can choose to delay taking CS courses, or take the initial CS courses more leisurely. This provides a total of 218 features. Note that each feature will be considered independently when training the models.

The grading scale, GPA-equivalent, and distribution of grade records can be found in Table 3.

4.1.3 Course Characteristics

Course Characteristics describe the courses. We generate these characteristics for the target course, which will be the direct context that the model can use in the grade prediction task. We include the target course’s semester relative to the student’s first semester taking a CS course and maximum enrollment size. We also compile the history of grades for the target course before the semester the student completed the course by providing the parameters that describe their fitted distributions over the GPA-equivalent conversion. We provide the Weibull distribution, which can be described over three parameters: location, shape, and scale, aside from the normal distribution’s mean and standard deviation. Lastly, we derived a feature to denote whether the target class started in the morning (AM) or afternoon and evening (PM). For completeness, we also provide the maximum enrollment size for all courses the student has taken. This provides a total of 117 features.

4.1.4 Instructor Characteristics

Instructor Characteristics describe a target course’s instructor, and were chosen here as an attempt to reflect the instructor’s tendencies and experience, which, under our hypothesis, may have an effect on student performance. We generated the cumulative number of students taught by that instructor in any course to characterize the instructor’s experience. In addition, we include the instructor’s official rank at the time of the target course. In understanding an instructor’s grading behavior, we consider the instructor’s past history of assigning grades, in an attempt to capture how “demanding” the instructor is, by including features that describe the distribution of the instructor’s given grades. We generated the Weibull distribution parameters, location, shape, and scale, along with the mean and standard deviation, for the collection of grades that the instructor has assigned for the target course, for all courses they have ever taught, and for grades they have given for only morning or evening classes. For completeness, we include the instructor’s ID as a base feature for every course the student has taken (or null if the student has not taken the course at the time of the target semester), representing the history of instructors that the student has encountered. This provides a total of 226 features.

Relating to instructor’s official rank, the CS department under study has several official teaching positions, namely “Teaching Fellow,” “Part-Time Instructor,” “Lecturer,” “Senior Lecturer,” “Visiting Lecturer,” “Visiting Professor,” “Assistant Professor,” “Associate Professor,” and “Full Professor.” We opted to merge “Teaching Fellow” with “Part-Time Instructor,” given their duties are exactly the same, but the former corresponds with PhD students. Each instructor’s rank was consistent with the position they held at the beginning of the semester that they taught a course. In addition,

we included another category, “High School Teacher,” to indicate teachers who taught through the college-in-high-school program, given students who are enrolled in the program may have a CHS course (or several) on record. Finally, we include a “Satellite Instructor” title, given the courses taught at the satellite campuses are different, despite the true title that those instructors have.

4.2 Comparison Metrics

We compare the models using weighted average F1-score (Weighted F1) for classification, as well as mean absolute error (MAE) and root mean square error (RMSE) for regression. We also conduct cross-metric comparisons for completeness. For computing MAE and RMSE for each classifier, we converted the predicted letter grade directly into their corresponding GPA value. For computing Weighted F1 for each regressor, we took the predicted value output, which represents an expected GPA, converted it to the closest letter grade, and dropped the plus or minus, where applicable. Conversions between GPA values and letter grades can be found in Table 3.

The F1-score formula is defined as

$$F_1 = 2 \cdot \frac{\text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}} = \frac{\text{TP}}{\text{TP} + \frac{1}{2}(\text{FP} + \text{FN})}$$

where TP is the true-positive rate, FP is the false-positive rate, and FN is the false-negative rate. For multiclass classification, weighted average F1-score formula is defined as

$$\text{Weighted } F_1 = \frac{\sum_c n_c \cdot F_1(c)}{\sum_c n_c}$$

where $F_1(c)$ is the F1-score for class c , and n_c is the number of data points that are part of class c . This metric gives more weight towards correctly predicting larger-sized classes.

The MAE is defined by the following formula

$$\text{MAE} = \frac{\sum_{i=1}^n |y_i - x_i|}{n}$$

where y_i is the value predicted by the algorithm, x_i is the true value, and n is the number of data points. MAE can be preferred for grade prediction because the absolute distance can translate directly into GPA values without additional penalty for significant wrong predictions.

The RMSE is defined by the following formula

$$\text{RMSE} = \sqrt{\frac{\sum_{i=1}^n (y_i - x_i)^2}{n}}$$

where y_i , x_i , and n have the same definitions as those in the MAE formula. As opposed to MAE, RMSE penalizes large errors, which can be useful in spotting cases where excellent grades are predicted as failing grades, and vice versa.

Note that higher values of Weighted F1 mean the model is better, while for MAE and RMSE, lower values mean that the model is better.

4.3 Data Preparation and Model Selection

Recall that the task is to predict the grade of a student for a target course. Towards that aim, we first clean the dataset

Table 3: Grade class, university’s letter grade, GPA equivalent, and final grade percentage required for the letter grade, along with the percentage of grade records that were given the letter grade and percentage of records for the combined classes.

Class	A		B			C			D			F
Letter Grade	A ⁺ /A	A ⁻	B ⁺	B	B ⁻	C ⁺	C	C ⁻	D ⁺	D	D ⁻	F
GPA	4.0	3.75	3.25	3.0	2.75	2.25	2.0	1.75	1.25	1.0	0.75	0.0
Grade Threshold (%)	92.5	90.0	87.5	82.5	80.0	77.5	72.5	70.0	67.5	62.5	60.0	0.0
Grade Records (%)	28.9	8.7	9.4	18.2	5.7	5.7	11.4	1.0	1.2	3.1	0.5	6.3
Class Records (%)	37.6		33.3			18.1			4.8			6.3

as described in Section 3.3, and then compile the features for each student, ensuring that the feature vector is consistent with the known information at the time they would be taking the course, so that future information cannot inform past courses. For example, if the student is taking CS 102 in the third semester, then only grades from before the third semester will be part of the input. Note that, for the purposes of training the algorithms, we ignore prediction for CS courses offered for non-majors, given that CS students are unlikely to be taking those courses, especially after they have already started taking the mandatory courses. As a result, the total dataset transformed into 25,354 rows, an average of 7.7 transcript moments (or courses and grades) per student considered. The dataset was randomly split 80-20 for training and testing, respectively.

We decide to compare several classifiers and regressors, as described below. We use implementations by Scikit-learn [23], unless otherwise noted. For the classification task, we only require the models to predict from the five letter grades (i.e. {A,B,C,D,F}, where +/- is dropped). For the regression task, we train the models to predict GPA values using the university’s scale (found in Table 3).

We train five different classifiers: majority classification (Majority) as a baseline, decision tree model (DT), K -neighbors model ($K = 2, 2\text{Neigh}$), AdaBoost classifier (AdaClass), and GradientBoost classifier (GradClass). To reduce variability, we utilize five-fold training; we tested typical cross-validation, “soft” voting, and “hard” voting [21]. We explain the first two here for completeness, and we report soft voting because it yielded the best results. In typical 5-fold cross-validation (we assume 5 folds in this paper), five mutually-exclusive and equally large portions of the training set are generated, the classifier is trained on four folds of the data and validated on the fifth, generating a model instance. This procedure is repeated five times, generating 5 different classifier model instances trained on different subsets of the data. We then select the instance with the best performance, and use that model to label new input. In five-fold soft voting, rather than selecting one instance, we average across all instances, and the class with the highest average is the label assigned to the input.

Due to the imbalance of the classes (see Table 3 for a breakdown), we attempted class-balancing via upsampling and downsampling (e.g. SMOTE [8]). However, in the final models trained, we do not perform any rebalancing, because while all models improved on the “C,” “D,” and “F” classes, they did not improve enough to offset the loss of performance in the “A” and “B” classes.

We train seven different regressors. Following the lead of previous works that utilize regression models, we opt to use a Matrix Factorization technique, specifically FM, using a Python wrapper [18] of an existing package [30], along with Linear Regression (LinReg). We also include the regression version of the decision tree model, using both mean-squared error (DT(MSE)) and mean-absolute error (DT(MAE)) to determine the best split, and the K -neighbors model ($K = 2, 2\text{Neigh}$). Finally, we also use the AdaBoost regressor (AdaReg), and GradientBoost regressor (GradReg). We train each model five times, and take the average result.

Using the results from Table 4, the GradientBoost classifier performs the best because it provides the highest weighted average F1-score on the testing set, and has a slight edge on MAE and RMSE over the AdaBoost and decision tree classifiers. When selecting a regressor, the F1-score is less representative due to the prediction of continuous GPA values; even though FM performs better on the weighted average F1-score, we select the GradientBoost regressor because it provides the lowest RMSE and ties with FM on MAE.

5. DISCUSSION

5.1 Individual Feature Weights

Referring to Figure 1, we see that for classification, “instructor_grade_weibull_loc” has the largest feature weight; this feature describes one of the parameters for the fitted Weibull distribution, namely “location.” Location for the Weibull distribution is analogous to the mean for the normal distribution. In our case, the “instructor_grade_weibull_loc” summarizes the instructor’s grades for the target course across all semesters in the dataset before the target semester. Similarly, for regression, the instructor’s mean grade for the target course instead factors as the most-predictive feature. With grading strategies like curving or partial credit, it is easy to see how the instructor’s (subjective) grading style can affect the final grade. We also notice that the difference in contribution between the top-two features is quite large. The difference between the top contributor in classification (approx. 0.16) and the second contributor (approx. 0.10) greatly exceeds the difference between the remaining consecutive features (<0.02). A similar effect can be seen in regression, where the top contributor has a feature importance that is more than double the second feature. This shows that the grades that an instructor is likely to give in a target course is a strong predictor of what kind of grade the student is likely to achieve in the target course. We examine the distribution type in more detail in Section 5.3.

Six out of the top 10 features are grades that the student achieved in the given course number. In this case, all 6 courses are mandatory (out of 8 total) for CS majors to

Table 4: Comparison between different models. Italics represent the best among only classifiers or regressors, while bold represents best overall.

		Training			Testing		
		Weighted F1	MAE	RMSE	Weighted F1	MAE	RMSE
Classifiers	Majority	0.20	1.07	1.55	0.20	1.07	1.55
	DT	0.55	0.57	1.00	0.48	0.65	1.05
	2Neigh	0.68	<i>0.46</i>	<i>0.94</i>	0.40	0.83	1.24
	AdaClass	0.51	0.63	1.02	0.49	0.66	1.06

	2Neigh	0.57	0.47	0.66	0.38	0.86	1.16
	AdaReg	0.27	0.80	1.00	0.27	0.81	1.00
	GradReg	0.44	0.66	0.88	0.44	<i>0.66</i>	0.89

take at the university. The second-most predictive feature for both classification and regression are also for the same mandatory course. It seems intuitive that these courses would provide insight into how students would do in future courses, emphasized by the idea that the curriculum requires students to take these mandatory courses first. However, it is likely that the importance of each course is inflated simply because of the mandatory requirement, and as a result provides the initial information that is necessary to predict courses earlier in a student’s undergraduate career. This type of result may not hold as strongly in a major that does not provide a mandatory course schedule.

High school GPA rounds out the top-three. This is consistent with previous literature that indicates that the overall grades received by an incoming student can predict success at the university level [16], from student retention (e.g. [12]) to higher freshmen grades (e.g. [10]). The combined verbal and math score for the SAT also stands out as one of the top features, but is not as predictive as high school GPA, which consistent with the literature [3]. Typically, college-preparedness features are assumed to only have the most impact upon arrival at the university, which is why the typical benchmark for student success that uses these features tends to be freshmen grades. From our work here, it may suggest that these features are more representative of student success throughout the student’s undergraduate career.

While not as predictive as some of the top features, “target_semester” appears as a top-15 feature for both classification and regression, which may suggest that the timing in which a student takes a particular course in their major in relation with other major courses is correlated to their success. However, it is not clear what the causal link may be; it is reasonable to hypothesize that students who take courses in close succession are likely to do better, but it may also be the case that students who do better are more likely to take courses in quick succession. There is also a likelihood that delays in taking courses due to repeating failed courses may be captured by this feature.

5.2 Feature Type Comparisons

To provide a proper comparison between feature types (each of which is detailed in Section 4.1), we choose to retrain

and retest GradientBoost over each feature type by itself to contrast them with the model trained over all feature types. Given our goal in this paper is to determine the impact that instructor features have on grade prediction models, we also compare a model trained with all feature types except for Instructor Characteristics. We perform the same validation techniques as mentioned in Section 4.3 (5-fold soft vote for classification and 5-run average for regression).

We can see that the Student Grade History feature category continues to be the main feature type for student grade prediction. From Table 5, we note that for all comparison metrics, either the classifier or regressor trained with only Student Grade History features outperforms all other singular feature type trained models. Furthermore, when training GradientBoost over all features, Figure 2 shows that Student Grade History features provides the highest feature weight among all categories. Along with the discussion about course grades from the section above, this provides further evidence to confirm previous research indicating that past student grades are a good predictor for future grades.

Instructor Characteristics comes closely in second, on many of the same angles presented for Student Grade History. From Table 5, we note that the classifier and regressor trained with only Instructor Characteristics has a similar performance with Student Characteristics and outperforms Course Characteristics on all comparison metrics. In terms of feature weights, we also see in Figure 2 that Instructor Characteristics comes closely in second and is almost on par with Student Grade History in the classification task. While individually, an instructor’s grade distribution retains the highest feature weight (as seen in Figure 1), collectively, they still fall short of Student Grade History.

To provide assurance that Instructor Characteristics helps with student grade prediction, we compared two feature sets when training and testing GradientBoost, one trained with all features, and one trained without Instructor Characteristics. Results in Table 5 indicate that for both classification and regression, GradientBoost performs better when Instructor Characteristic features are included. We further examine the classification confusion matrix in Figure 3; in comparing Figures 3a and 3b, we see that adding Instruc-

(a) Top 15 features for GradClass

(b) Top 15 features for GradReg

Figure 1: Top 15 features on average utilized by the GradientBoost model when training over all features. Features with names like “grade_(num)” describe the grade that the student received in the indicated course number. Features that start with “instructor_grade” each describes a parameter of the instructor’s grade distribution. “pm” (e.g. in “instructor_pm_grade_mean”) further indicates the grade distribution assigned by the instructor for courses that start in the afternoon or evening.

(a) Top feature categories for GradClass

(b) Top feature categories for GradReg

Figure 2: Top feature categories on average utilized by the GradientBoost model when trained over all features. Feature categories are described in Section 4.1. “target_course” is the feature that describes which course the grade label comes from during training or should be assigned to during testing.

tor Characteristics does have a general positive effect on the accuracy of the classification, given that the number of correct classifications (numbers on the diagonal) increases, and the number of incorrect classifications (numbers not on the diagonal) decreases. Furthermore, we also note that the total misclassifications that are one grade away (adjacent to the diagonal) increases, while the total misclassifications elsewhere decreases. This further confirms that instructor features do have a positive impact in overall classification, not just in singularly increasing recall or precision.

5.3 Grade Distributions and Representation

We tested 103 different distribution types (implemented by SciPy [33]), as well as the logit-normal distribution [2], over the full dataset to determine which kind of distribution best represents the grades’ GPA-equivalent values. We evaluated each distribution using the sum of squared error, and the best fit was the Weibull distribution, which can be represented by three parameters, location, shape, and scale. For every relevant grade distribution, we fit a Weibull distribution to the corresponding grouping, and each parameter was then considered an independent feature. Overall, 10 features were derived from the normal distribution, and 15 were derived from the Weibull distribution. In addition, out of the 25 total features, 5 were Course Characteristics (all grades

ascribed to the course up to the target semester, regardless of instructor), and 20 were Instructor Characteristics.

There is some controversy about using the normal distribution for representing grades [11], so we briefly investigated the effect of having only the Weibull distribution or the normal distribution represent the grades. We retrained and retested the GradientBoost classifier and regressor with the same procedure in Section 4.3 (5-fold soft vote for classification and 5-run average for regression), both of which are reported in Table 6. From the results, having at least one representation of grade distribution provides some benefit over not having a representation at all, with no difference in performance between the distribution type. Having both provides little-to-no benefit, so it is easy to conclude that it does not matter which grade distribution representation is included, so long as a representation is expressed in the feature set.

Feature weights provided a different angle with which to determine any effects that may stem from the different kinds of distributions. We first examined the effect that historical grades and their distributions had on future grade prediction by examining the weights of those features separately from the main categories. Figure 4 shows that Student Grade History grades and Instructor Category grade distributions

Table 5: Comparison between different feature types. The fifth category combines the first three feature categories together. Italics represent the best among singular feature type, while bold represents best over any category. Note that the “All Features” section mirrors the results from Table 4.

Feature Category	Model	Training			Testing		
		Weighted F1	MAE	RMSE	Weighted F1	MAE	RMSE

(a) Classification

(b) Regression

Figure 4: Top feature categories on average utilized by the GradientBoost model when grades and grade distribution features are separated from their original categories. Feature categories are described in Section 4.1. Categories with the suffix of “Grades” are only features from the category prefix that use GPA as their values, while categories that end with “Non_Grades” are the remaining non-GPA-based features.

(a) Classification

(b) Regression

Normal distribution features only

(c) Classification

(d) Regression

Weibull distribution features only

Figure 5: Top 15 features on average utilized by the GradientBoost model when varying the type of distribution of grades.

would be the top two feature categories, if they were on their own. We then compared the effect that having a singular distribution type has on feature weights, to see if there were any notable changes. Figure 5 shows that no matter which distribution type is being used, the mean or the Weibull distribution’s analogous parameter, location, will remain the top feature overall. However, it is important to note that for the regression task, GradientBoost assigns a much higher weight to the mean than to Weibull’s location parameter,

and even the sum of all three Weibull distribution parameter feature weights, indicating a stronger preference for the normal distribution for regression. We also see this effect appear when both distributions are used, as seen in Figure 1; classification prefers Weibull’s location parameter, while regression prefers the mean. This may provide evidence that the mean captures information that overlaps with more features, more so than the Weibull distribution, given that the performance does not noticeably increase. As for feature

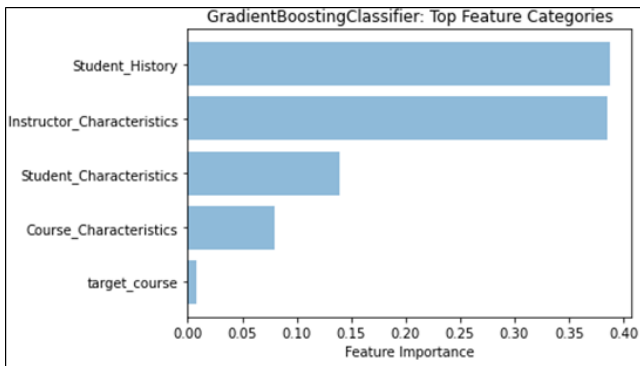

Figure 6: Top feature categories on average utilized by the GradientBoost classifier model when only using the normal distribution to describe grades. Feature categories are described in Section 4.1. “target_course” is the feature that describes which course the grade label comes from during training or should be assigned to during testing.

categories, no placement change was noted. However, in Figure 6, we see that the total feature weight for Instructor Characteristics is almost on par with Student Grade History during classification, further emphasizing the role that the normal distribution can have on predictive models.

5.4 Implications

While our model still has room for improvement for student grade prediction, there are several key items that can be derived from this research.

First, instructor-based features have a place in student grade prediction. The Student Grade History feature type continues to provide the most predictive power for grade prediction, and Instructor Characteristics follows closely behind in second place, while other feature types lag behind.

Second, the distribution of instructor grades is an important feature class to include in future student grade prediction models. It may not matter what kind of grade distribution representation is needed, despite prior research into the “appropriate” distribution, but the parameters for the normal distribution may assist with feature selection, given its high weight in the regression task.

Third, given the strong importance of the distribution of grades that an instructor assigns in their courses, more research is needed to determine the best way to either reduce the impact that instructors have on final grades through teaching ability or subjective measures, or conversely, ensuring that the grades that instructors assigned are truly unbiased and dependent only on the student’s performance in the course. Indeed, it is a long-standing question about the reliability and validity of grades themselves as a measurement of knowledge, given the significant variability in assigning them [7]. One could attempt to expose some of these subjective items by measuring student satisfaction for the instructor, characterizing the instructor’s teaching style, or determining the instructor’s efficacy when utilizing learning management systems, but those would all require additional data collection beyond what a university might readily

have access to.

Lastly, there is still significant room for improvement in explainable student grade prediction. One area where significant work has been done is in Knowledge Tracing to diagnose student issues while they complete a course. Intuitively, understanding how students are doing within a course will ultimately determine how students will do overall, given the knowledge dependency within the course, which is especially important in STEM majors. While Knowledge Tracing does provides additional insight, the effort for training a model significantly increases due to the variation in course content material; it remains to be seen if Knowledge Tracing-adjacent or domain-agnostic Knowledge Tracing features can be generated to assist with generalized student grade prediction without introducing an extra heavy burden.

6. CONCLUSION

In attempting to characterize the relationship between instructor features and predicting a student’s grade, we first enumerated the feature space in grade prediction, with additional emphasis on generating features that describe an instructor’s history and experience in teaching. These features were then extracted from over 13 years and thousands of students’ grade records from a large, public, American university, and used to train and test several supervised ML models. From our experiments, the GradientBoost algorithm, both as classifier and regressor, has the best performance when compared with other supervised ML models.

We then used GradientBoost as our comparison algorithm between different features and feature types, in order to determine the utility of features that define an instructor in a grade prediction model. First, we noted that the distribution of grades that an instructor gives, specifically the mean or the Weibull distribution’s analogous parameter, location, is a major factor in grade prediction. Upon further review, it was found that the distribution representation does not make a major difference in the performance of the model. We then grouped features by type and found that Instructor Characteristics has the second-highest combined feature weight, closely behind Student Grade History. We further trained GradientBoost with and without Instructor Characteristics, and found that Instructor Characteristics contributed to better predictions of student grades for both classification and regression. Therefore, we strongly insist that future ML models should include features that describe Instructor Characteristics, or at the very least, features that describe the distribution of grades that an instructor assigns to a course.

ABSTRACT

Gaming the system, a behavior in which learners exploit a system's properties to make progress while avoiding learning, has frequently been shown to be associated with lower learning. However, when we applied a previously validated gaming detector across conditions in experiments with an algebra tutor, the detected gaming was not associated with learning, challenging its construct validity. Our iterative exploratory data analysis suggested that some contextual factors that varied across and within conditions might contribute to this lack of association. We present a latent variable model, *item response theory-based gaming detection* (IRT-GD), that accounts for contextual factors and estimates latent gaming tendencies as the degree of deviation from normative behaviors across contexts. Item response theory models, widely used in knowledge assessment, account for item difficulty in estimating latent student abilities: students are estimated as having higher ability when they can get harder items correct than when they only get easier items correct. Similarly, IRT-GD accounts for contextual factors in estimating latent gaming tendencies: students are estimated as having a higher gaming tendency when they game in less commonly gamed contexts than when they only game in more commonly gamed contexts. IRT-GD outperformed the original detector on three datasets in terms of the association with learning. IRT-GD also more accurately revealed intervention effects on gaming and revealed a correlation between gaming and perceived competence in math. Our approach is not only useful for others wanting to apply a gaming assessment in their context but is also generally applicable in creating robust behavioral measures.

1. INTRODUCTION

Assessing students' engagement levels or motivation from their interaction behaviors in digital learning environments is a compelling challenge both practically and theoretically. Practically, valid behavioral assessment of student engagement can drive adaptations that adjust to students' needs, leading to greater learning and motivation; theoretically, valid behavioral assessment of student engagement can be used to better understand when and why interventions or system designs work for enhancing student learning or motivation. One frequently explored behavioral indicator of student engagement is "gaming the system", which is defined as "attempting to succeed in an educational environment by exploiting properties of the system rather than by learning the material and trying to use that knowledge to answer correctly" [6]. Many studies have demonstrated that gaming the system (abbreviated as *gaming* in this paper) is associated with poor learning outcomes in the short term or the long term [2, 5, 12, 30]. Prior research suggests that interventions directly targeting gaming can reduce gaming behaviors [4, 33] and improve learning [4], demonstrating the practical value of gaming detection. Recent work [28] has also shown that the positive effect of learning with an educational game was fully mediated by lower levels of gaming the system, showcasing the theoretical value of gaming detection for understanding how a specific intervention influences learning.

Past research has leveraged two classes of approaches to model gaming behaviors: knowledge engineering where experts develop rational rules that identify gaming behaviors [21, 25, 26] and machine learning where the model designer creates a set of features first and then a supervised learning algorithm is used to select features for predicting human coded gaming labels [6, 32]. Mainly the emphasis has been put on student features [21, 25, 26], such as how students utilize help (e.g., help abuse [1]) and make errors (e.g., systematic guessing [32]). Task or system features have been investigated to a limited extent although they have been found to be important contextual factors for gaming. For example, [8] found that system features explained more variance in gaming behaviors than student characteristics on a year-long log dataset with 22 different lessons of Cognitive Tutor Algebra. In particular, the results showed that gaming was more frequent in lessons that were abstract, ambiguous, and had unclear presentation of the content or task. Another study [22] also found that differences in gaming behaviors were more strongly associated with the learning

environments than with student populations. Some machine-learned models have incorporated one or two task features in the initial set of features [6, 32]. For example, [32] included features related to question types (top-level or follow-through helping questions) and interfaces (multiple-choice or textbox) in the initial feature set, yet they did not mention whether these features remained in the final model. Meanwhile, in knowledge-engineered gaming detectors, task features typically are not (explicitly) considered [21, 25], i.e., rules to identify gaming behaviors are described in a task type-independent way. Such limited consideration of task features may limit the generalizability of gaming detectors to new contexts with task or system design substantially different from that of the original context. In addition, some research has identified cases where detected gaming behaviors were not harmful [6, 12] or were even good learning behaviors [31], further suggesting the necessity to look carefully into the contexts for identifying or interpreting gaming behaviors. However, such unconventional findings (unconventional in the sense that gaming has frequently been shown to be associated with lower learning) still have not received enough attention in the development of gaming detectors.

Obtaining a student-level gaming estimate has been valuable for studying the relation between student attributes and gaming or intervention effects on gaming. Prior work has predominantly used direct aggregation of detected (or observed) gaming by computing the proportion of gamed transactions or the average of predicted probabilities of gaming for each student [6, 22, 27]. However, [13] showed that the observation-level simple average failed to reveal correlations between motivation and gaming (except for one motivational measure), while a simple latent variable model that estimated a latent gaming tendency for each student controlling for the effect of curricular sections on detected gaming yielded strong associations between a range of motivational measures and gaming tendencies. Inspired by this prior work, we identified an overlooked connection between existing behavior modeling paradigms and knowledge modeling paradigms: latent variable models widely used for estimating student abilities or knowledge levels can also be used to obtain more valid student-level behavioral constructs, thanks to their capacity to account for both task and student features in a single framework. One widely used latent variable modeling paradigm for knowledge assessment in psychometrics is *item response theory* (IRT) [14]. IRT models the observed correctness on each item (e.g., problem steps) of each student as a function of item difficulty and student ability. Instead of using the proportion of correctly answered items as the measure of student ability, IRT accounts for item difficulty in estimating latent student abilities. In essence, students are estimated as having higher ability when they can get harder items correct than when they only get easier items correct. IRT models have been further extended to model dynamic student knowledge by considering the temporal aspect [17], and also by decomposing items into knowledge components (e.g., skills, concepts) shared across items [11].

With the increasing demand of learning engineering efforts towards building effective, engaging learning systems, the generalizability, interpretability, and development cost of gaming detectors are becoming increasingly important. Recent studies [23, 24] compared three previously separately validated gaming detectors across multiple systems: a knowledge-engineered model [25], a machine-learned model [7], and a hybrid model [24] that combines both knowledge engineering and machine learning. In particular, the knowledge-engineered model was developed by using cognitive task analysis to elicit knowledge about how experts code students as gaming or not in Cognitive Tutor Algebra [19]. It

consists of 13 patterns of students' systematic guessing and help abuse behaviors. The comparisons [23, 24] focused on predictive performance of expert labels of gaming in held-out test sets in the original data and two new datasets collected from two other learning environments [3, 27]; the comparison also considered the interpretability of models. Results showed that the knowledge-engineered model achieved greater generalizability to new datasets and interpretability than the machine-learned model, and achieved comparable to slightly better generalizability and interpretability than the hybrid model. Although there was initial cost (higher than that of the machine-learned model) in developing the knowledge-engineered model, it could be directly used in new datasets without further cost (since actions that match any of the 13 patterns can be directly labeled as gaming). However, one may need to retrain the machine-learned or hybrid model (that needs a machine-learned model as input), given the much lower (and even unacceptable) predictive performance of the machine-learned model than the knowledge-engineered model on new datasets [23]. Thus, this knowledge-engineered gaming detector [25], which is referred to as KE-GD in this paper, appears to be the best choice (to build on) among the three detectors, considering generalizability, interpretability, and development cost in a new context altogether; it also represents a broad class of behavioral detectors that are built based on rational rules specified by experts. However, predictive performance of expert labels is only one aspect of construct validity; the establishment of construct validity of a gaming detector also requires examining the association between detected gaming and learning. Past studies [23, 24, 25] have not examined the association between detected gaming by KE-GD with learning, while other studies on other detectors have frequently shown that a higher detected gaming level is associated with lower learning [5, 15, 20, 21, 28].

In this work, we propose a latent variable model, *item response theory-based gaming detection* (IRT-GD), that estimates a latent gaming tendency for each student accounting for contextual factors (i.e., task and student features): students are estimated as having a higher gaming tendency when they game in less commonly (or frequently) gamed contexts than when they only game in more commonly (or frequently) gamed contexts. IRT-GD builds on a previously validated knowledge-engineered gaming detector (KE-GD) that focuses on students' action features and the predictiveness of human labels. We started with applying KE-GD on a dataset collected from experimentation with an algebra tutor, and examined the association between detected gaming and learning, an important aspect for the construct validity of gaming measures. Observing the lack of association with learning, we conducted an iterative exploratory data analysis, and found that this lack of association might result from some contextual factors not considered in KE-GD that varied across and within conditions. Without complex human feature engineering, we integrated contextual factors as predictors in a mixed effect model predicting whether a transaction was detected as gaming by KE-GD, and extracted the student random intercepts as the latent gaming tendencies. We compared KE-GD and IRT-GD by the association with learning in nine contexts, obtained from three datasets and three condition configurations per dataset. Finally, we demonstrated two applications of IRT-GD: to study whether there was a difference in the level of gaming between the two conditions from our experimentation with the tutor, and to explore the relation between gaming and motivation. The development and evaluation process of IRT-GD is explained as follows.

2. DEVELOPMENT OF IRT-GD

2.1 The Tutor

We used datasets collected from an algebra intelligent tutoring system for middle and high school students [18]. Students learn about writing algebraic expressions in story problems in various task (problem) formats: writing an expression in a textbox with dynamic scaffolding steps that appear if a student fails in the original question (*text* format); writing expressions in a table where the main question step and scaffolding steps are accessible at any time and are all required (*table* format); explaining a set of expressions extracted from a given equation by choosing the matching textual description from a dropdown menu for each expression (*menu* format); and given an equation, writing a set of expressions that match a given set of textual descriptions (*flipped-menu* format). These tasks also vary in the complexity of the expressions involved (e.g., one or two operators).

The algebra tutor was continuously redesigned and tested in three experiments with different student populations across three years. In each experiment (eight sessions over four weeks), we compared two versions of the tutor corresponding to two conditions differing in task design and sequencing. The control (CT) condition, corresponding to the original tutor, provided a *normal deliberate practice* schedule. Students received *full* tasks representing the full version of the problem requiring filling in all steps (including scaffolding steps) given a cover story. There were three consecutive units: the first unit contained all the table tasks, the second unit contained less complex menu and flipped-menu tasks, and the third unit contained more complex menu and flipped-menu tasks. Steps were labeled with coarser-grained knowledge components (KCs; skills). Students received individualized practice until reaching mastery of all KCs in a unit before moving on to the next unit. Across the three experiments, the design of the control condition remained the same. The experimental (EXP) condition, the *data-tuned adaptive* condition, corresponds to a redesigned tutor with redesign decisions drawn from data mining outcomes of student log data. It provided an *intense deliberate practice* schedule with task design and sequencing based on a refined, larger KC model revealing hidden difficulties (i.e., original KCs were split to differentiate easier and harder use cases). *Focused* tasks were introduced to reduce over-practicing easier KCs and target particularly difficult KCs. Examples of focused tasks include: text format tasks asking for the final expression without the mandatory intermediate steps required in table task; text format tasks that further remove the story and focus on learning algebraic grammar rules; and simpler menu and flipped-menu tasks with equations less complex than the original equations. There were three or more learning units where different task formats or task types (full or focused) were interleaved in each unit. Students received individualized practice until reaching mastery of all KCs in a unit before moving on to the next unit. Across the three experiments, the design of the experimental condition was continuously refined aiming at promoting greater learning. Our prior work has shown that the experimental condition led to better learning outcomes compared to the control condition [18]. Here, we are interested to see whether intense deliberate practice (i.e., the experimental condition) also led to higher behavioral engagement, particularly lower levels of gaming the system, and also whether gaming was linked with motivation. We started our investigation with the first dataset collected from the first experiment explained below.

2.2 A Previously Validated Knowledge-Engineered Gaming Detector Did Not Generalize

We chose a previously validated knowledge-engineered gaming detector, KE-GD, as the starting point for studying students' behavioral engagement when using the algebra tutor. KE-GD contains 13 interpretable patterns modeling systematic guessing and help abuse. For example, one pattern is "the student enters an incorrect answer, enters a similar and incorrect answer in the same part of the problem and then enters another similar answer in the same part of the problem". It is coded as "incorrect \rightarrow [similar answer] [same context] & incorrect \rightarrow [similar answer] & [same context] & attempt", consisting of constituents such as "[similar answer]" (judged by Levenshtein distance), and action types such as "attempt" (correct or incorrect) or "help". If a sequence of transactions (i.e., student-step interactions considering multiple attempts per step) matches any one of the 13 patterns, then all transactions involved are labeled as gaming. Details of the patterns and the validation of KE-GD could be found in [23, 25].

We used KE-GD to label transactions as gaming or not and then examined the construct validity of detected gaming in our dataset. We defined two metrics of construct validity in the current study, both of which evaluate the association between gaming and learning. The primary metric was the correlation between gaming levels and normalized learning gains over students. For each student, we computed a gaming level using the proportion of gamed transactions (referred to as *proportion of detected gaming* or *detected gaming (proportion)*) for KE-GD, or the estimated gaming tendency for IRT-GD (explained in Section 2.3.2); we computed the normalized learning gain using the widely adopted formula, $(posttest - pretest) / (1 - pretest)$. We used Spearman correlation (ρ) because it is less sensitive to outliers than Pearson correlation. As a supplementary metric, we conducted a regression analysis predicting posttest scores controlling for pretest scores and gaming levels over students and examined the coefficient of the variable of gaming levels. We considered negative correlations and coefficient values at a significance level of 0.10 as acceptable construct validity. Prior studies have used significance levels of 0.05 and 0.10 for correlation analyses involving behavior measures [5, 13, 31].

Two observations emerged. First, the detected gaming proportion 18% (last column in Table 1) was much higher than the previously reported proportions (3.5% in [13] and 6.8% in [25]) of the same detector in other math intelligent tutoring systems. Second, there was a lack of association between detected gaming and learning (correlation: $\rho = -.02$, $p = .86$; regression coefficient: $b = 0.07$, $p = .69$), challenging KE-GD's construct validity in our context.

Table 1. Statistics of the Fall 2019 dataset including the proportion of gamed transactions (considering all attempts of all steps) detected by KE-GD.

#stu	#transaction (tx)	#tx of 1st attempts of steps w/ KCs	Avg proportion of gamed tx over stu
129	98,176	32,419	.18 ($SD = .08$)

2.3 Identifying and Integrating Contextual Factors to Improve Construct Validity

Next, we conducted iterative exploratory data analysis on the first dataset to identify contextual factors that might explain the lack of association between detected gaming by KE-GD and learning, and

integrated the contextual factors through latent variable modeling analogous to item response theory modeling, explained as follows.

2.3.1 Identifying the effect of task formats

One notable feature of our dataset compared to other datasets for developing gaming detectors is that it was collected from experimentation with two conditions with substantial differences in task design and sequencing. So, we first conducted a moderation analysis to test whether the condition moderated the relation between detected gaming and learning. We constructed a regression model predicting posttest scores for each student given the pretest scores, the condition indicator, detected gaming proportion and an interaction term between the condition and detected gaming proportion. The interaction was significant ($b=-0.98, p=.007$) and the control condition showed a relation opposite to theoretical prediction: higher proportion of detected gaming was associated with higher posttest scores (Figure 1).

Figure 1. The interaction plot between the condition and detected gaming proportion of the regression model predicting posttest scores with pretest scores controlled for.

To understand this interaction, we started an exploratory data analysis on the overall dataset to examine when and how students gamed according to KE-GD. We used the unit of analysis normally used for modeling student learning, knowledge components (KCs), for better drawing insights into the relation between gaming and learning. We used the KC model previously validated for this dataset [18] based on model fitness. It includes 26 KCs shared by both conditions. We first examined whether students gamed much more on some KCs than on others, and if so whether there was a pattern in this variation. A pattern emerged (see Figure 2) showing that students gamed substantially more on KCs required in menu and flipped-menu formats than those required in table and text formats. Meanwhile, we knew that the control condition positioned menu and flipped-menu tasks in later units, whilst the experimental condition interleaved menu and flipped-menu tasks with text and table tasks in earlier units. Having in mind that higher detected gaming was associated with higher posttest scores in the control condition (Figure 1), we wondered whether this association was because students with higher abilities (who usually also have higher posttest scores) progressed faster to later units and thus accessed a higher proportion of menu and flipped-menu steps, which were highly-gamed contexts, than students with lower abilities. We approximated students' abilities by pretest scores and investigated this relation. Indeed, as shown in Figure 3, students with higher pretest scores in the control condition accessed a higher proportion of menu and flipped-menu steps than students with lower pretest scores (which was not the case for the experimental condition), and as a result, they might appear to game more than students with lower pretest score. Thus, the positive association between detected gaming and posttest scores in the control condition was spurious due to a confounder, the proportion of highly-gamed format steps a

student accessed. The association between detected gaming revealed by KE-GD and posttest scores was biased. If we introduce task formats to account for (part of) the detected gaming, then this bias may be reduced.

Figure 2. Detected gaming proportion by KCs averaged over students. 95% confidence intervals are plotted. (Only first attempts of steps with KCs are considered.)

Figure 3. Correlations between pretest scores and proportion of highly-gamed formats (menu, flipped-menu) per condition.

2.3.2 The basic latent variable model accounting for task formats

Based on the first set of exploratory data analyses, we formulated a basic latent variable model, the simplest form of our proposed IRT-GD, that explains detected gaming by both task formats and students' latent gaming tendencies, analogous to explaining item performance by both item difficulties and students' latent abilities in Rasch model [14], the simplest form of item response theory (IRT) models. To illustrate our model, a student with a high proportion of detected gaming due to having a high proportion of menu steps will not be estimated as having a high gaming tendency if he or she does not game more than the average level of the student population on format steps. The model predicts the binary detected gaming label per transaction (i.e., an attempt on a student-step) G asserted by KE-GD, given the student identity and the current format (using a generalized linear mixed model):

$$\text{Detected gaming: } G \sim (1|\text{Student}) + \text{Format} \quad (1)$$

$$\text{Gaming tendency: } \alpha = \exp(\theta) \quad (2)$$

where the student identity is modeled as a random factor and the format of the current step is modeled as a fixed factor. Formula (1)

is written using the syntax of R’s lme4 package for better replicability; a formal mathematical description is that the log odds of a transaction being labeled as gaming by KE-GD is a linear function of the student’s identity (of which the coefficient is the student’s random intercept θ) and the current format. In formula (2), a student’s gaming tendency α is obtained by exponentiating the student’s random intercept θ from formula (1), converting log odds scale to odds scale. This basic model improved over KE-GD in terms of the sign and strength of the association with learning (Table 2 row #1), but the statistical significance was insufficient, demanding further investigation.

2.3.3 Identifying other contextual factors

Based on prior literature, we hypothesized that students’ prior and dynamic knowledge levels (i.e., learning) might also account for detected gaming. The theoretical foundation can be found in several studies: [29] showed that avoiding help and failing repeatedly (which may be considered as systematic guessing, a form of gaming) is associated with better learning than seeking help on steps for which students have low prior knowledge; [31] suggested that the behavior of bypassing abstract hints in search of a concrete solution (traditionally considered as help abuse, a form of gaming) may be an engaged learning behavior where students use bottom-out hints as worked examples; [13] also suggested that detected gaming can be a desirable adaptive learning behavior when students encounter challenges far beyond their abilities. Students’ dynamic knowledge levels were often included as features in machine-learned gaming detectors [6, 32] but absent in KE-GD. Thus, we conducted further exploratory data analysis to examine the effect of prior knowledge (approximated by pretest scores) and dynamic knowledge (approximated by practice opportunities) on detected gaming. More specifically, since we had already identified task formats as an important contextual factor, we hypothesized that there might be interactions between prior knowledge and formats, as well as between practice opportunities and formats, on detected gaming.

Figure 4. Correlations between pretest scores and detected gaming proportion per task format over students (considering all attempts of all steps).

Figure 4 shows that on flipped-menu and menu formats, students with lower pretest scores gamed much more than students with higher pretest scores, while this was not the case for other formats. Figure 5 shows that on table formats, students were more likely to game on earlier than later opportunities and reduced gaming quickly over opportunities. Discussion of these findings can be found later in Section 5. Based on this second set of exploratory data analysis, we integrated the discovered contextual factors into a latent variable model explained below.

Figure 5. Correlations between practice opportunities and detected gaming per task format. Each point corresponds to the average proportion of detected gaming at an opportunity over students (considering all attempts of all steps). The blips at the end of the curves are due to small sample sizes.

2.3.4 The full latent variable model accounting for critical contextual factors

Based on the second set of exploratory data analyses, we identified two groups of contextual factors that might be important to explain general gaming behaviors: the first group captures the effect of pretest scores adjusted by formats; the second group captures the effect of learning adjusted by formats. We then estimated students’ latent gaming tendencies accounting for these contextual factors. The underlying rationale of our model can also be explained as follows. Since the proportion of detected gaming is usually a low proportion of a full dataset under a study (typically less than 7% in past studies and less than 20% in our datasets), it is sound to assume that a model describing well the detected gaming behaviors of a full dataset captures the *normative* behaviors of a population, and the deviation from the normative behaviors represents the intended gaming construct. Essentially, students are estimated as having a higher gaming tendency when they game in less frequently gamed contexts than when they only game in more frequently gamed contexts according to the general behaviors. This is analogous to IRT models where students are estimated as having higher ability when they can get harder items correct than when they only get easier items correct. The full formulation of our latent variable model IRT-GD is as follows (using a generalized linear mixed model):

$$\begin{aligned} \text{Detected gaming: } G &\sim (1|\text{Student}) + \text{Format} \\ &+ \text{Pretest} + \text{Pretest:Format} \\ &+ \text{Opportunity} + \text{Opportunity:Format} \end{aligned} \quad (3)$$

$$\text{Gaming tendency: } \alpha = \exp(\theta) \quad (4)$$

Formula (3) is written using the syntax of R’s lme4 package for better replicability; a formal mathematical description is that the log odds of a transaction being labeled as gaming by KE-GD is a linear function of the student’s identity (of which the coefficient is the student’s random intercept θ), the format of the current step, the student’s pretest score, the interaction between the pretest score and the format, the practice opportunity count of a format of the student (note that all steps of a task are considered as having the same opportunity count of the corresponding format), and the interaction between the opportunity count and the format. Except for the student identity modeled as a random factor, all other predictors are

modeled as fixed factors. In formula (4), a student's gaming tendency α in odds scale is obtained by exponentiating the student's random intercept θ from formula (3).

Table 2. Associations between gaming tendencies estimated by different variants of IRT-GD and learning. Correlations with normalized learning gains and coefficients of gaming tendency variables in regression predicting posttest scores are reported ($p < .10$: boldfaced and italicized; $p < .05$: boldfaced).

ID	Level	Predictors	Cor with NLG	Post~ Pre+G
1	Format	(1 Stu)+F	$\rho = -.07$ $p = .44$	$b = -.02$ $p = .31$
2	Format	(1 Stu)+F+Pre	$\rho = -.14$ $p = .11$	$b = -0.03$ $p = .16$
3	Format	(1 Stu)+F+Pre+Pre:F ¹	<i>$\rho = -.16$</i> <i>$p = .07$</i>	$b = -0.03$ $p = .14$
4	Format	(1 Stu)+F+Pre+Pre:F+Opp	<i>$\rho = -.16$</i> <i>$p = .07$</i>	$b = -0.03$ $p = .14$
5	Format	(1 Stu)+F+Pre+Pre:F+Opp+F:Opp (The final chosen model)	<i>$\rho = -.18$</i> <i>$p = .04$</i>	<i>$b = -0.04$</i> <i>$p = .09$</i>
6	Format	(1 Stu)+F+Pre+Pre:F+Opp+F:Opp (1st attempts of steps w/ KCs)	<i>$\rho = -.26$</i> <i>$p = .00$</i>	<i>$b = -0.08$</i> <i>$p = .01$</i>
7	KC	(1 Stu)+K+Pre+Pre:K+Opp+K:Opp ² (1st attempts of steps w/ KCs)	<i>$\rho = -.25$</i> <i>$p = .00$</i>	<i>$b = -0.07$</i> <i>$p = .01$</i>

Table 2 shows the construct validity metrics of full models (row #5-#7) as well as reduced models (row #1-#4) of IRT-GD. All the seven variants reached higher validity than KE-GD in terms of having stronger associations with learning, and the three full models reached desirable statistical significance (row #5-#7). The five predictors increasingly strengthened the association (except when adding the single opportunity term in row #4 before adding the interaction term) and were necessary for reaching acceptable validity in this dataset. In formulating the full models, we explored two other configurations: one that used KCs as the unit (row #7) and fit the model using first attempts of steps with KC labels (without modifying the detected gaming labels associated with these transactions); another that used the same data subset as the KC-level model to fit the model but maintaining the unit of format. We found that a format-level modeling worked as well as the KC-level modeling, when using the same subset (row #6 vs. #7). We also found that using the subset with only first attempts of steps labeled with KCs could improve validity compared to using all attempts of all steps (row #6 vs. #5) in this dataset. However, using all attempts of all steps does not require additional KC labels, so we chose to fit IRT-GD with all attempts of all steps for potentially greater generalizability. The final chosen model for the rest of the paper was the one in row #5 in Table 2. We further examined the fitted parameters of the chosen model (Table 3) and found that they had high consistency with the patterns observed in our exploratory data analyses (note that some differences may be due to the differences in statistical methods and data processing used in the two kinds of analyses). We thus concluded the formulation of IRT-GD for valid gaming detection in our tutor.

¹ In R's lme4 package, a colon : is used to denote an interaction term.

² We treated the KC variable as a random factor. R formula:
G~(1|Stu)+(1+Pre+Opp|K)+Pre+Opp.

Table 3. Parameters of the chosen full model of IRT-GD (row #5 in Table 2). Categorical variables were dummy coded and continuous variables were standardized for reducing multicollinearity. The coefficients are in log odds scale.

3. GENERALIZABILITY OF IRT-GD

In the previous section, we conducted exploratory data analysis and validity evaluation on the same dataset and on a single dataset, which might risk overfitting to the dataset. In this section, we tested the generalizability of IRT-GD to two new datasets. We looked into conditions separately and together for all three datasets, resulting in nine contexts across different populations and designs of the system. The two new datasets were collected in 2020 Spring (20S) and 2021 Fall (21F) from the second and third experiments with the tutor with some design changes derived from data mining in the experimental (EXP) condition: new units were introduced for providing focused practice on prerequisite KCs; a lower proportion of menu and flipped-menu tasks was positioned in earlier units compared to the first dataset; a new task format was introduced in the 21F dataset involving interactions with animations. The four task formats identified in the first dataset were still present in the two new datasets. On the other hand, the control condition remained the same.

Table 4 shows statistics of all datasets including detected gaming by KE-GD. Again, the detected gaming proportions were high (16%) in the new datasets. When applying both KE-GD and IRT-GD to the nine contexts (see Table 5), IRT-GD consistently outperformed KE-GD in reaching higher associations with learning in all nine contexts, except one (21F dataset the EXP condition) where the correlation of IRT-GD was slightly weaker but of the same level of significance as KE-GD. In particular, when examining both conditions together and the EXP condition, IRT-GD reached high construct validity (i.e., $\rho < 0$ and $p < .05$) in all six contexts, while KE-GD only reached construct validity in half of the contexts. When examining the control condition, IRT-GD also improved on KE-GD by reversing positive correlations to the theoretically consistent negative correlations for all datasets and reached acceptable significance on the 20S dataset, although the correlations did not reach acceptable significance in other datasets. We conducted further investigation next.

3.1 Identifying deeper task format effects for refining the input detector

To understand and address the lack of validity of IRT-GD in the control condition in two datasets (Table 5), we conducted further investigation on the 19F dataset where IRT-GD showed the weakest association with learning. We wondered whether the bottleneck lay in the input detector KE-GD. If the gaming labels (i.e., values of the dependent variable for fitting IRT-GD) were too noisy, it would be hard to get accurate tendency estimates by any means. If we decompose a gaming label, it is the union of 13 gaming labels corresponding to 13 gaming patterns defined in KE-GD. Could some of the patterns under some formats be better considered as not gaming in our control condition context? In other words, we hypothesized that there might be deeper task format effects in students' interaction patterns. We conducted a third set of exploratory data analysis where we examined the associations between detected gaming proportions of each of the 13 patterns from KE-GD with learning under each format. We used a *local* normalized learning gain computed using tasks related to a specific format rather than all tasks in the pretest and posttest. The results in Table 6 suggest that on different formats, the same gaming pattern could be helpful or harmful for learning, supporting our hypothesized deeper format effect. To account for this contextual factor, we updated the detected gaming labels from KE-GD in the control condition by using the union of only the patterns that were negatively associated with learning (regardless of statistical significance) for each format while maintaining the labels of the experimental condition. This was a change in the dependent

variable rather than the predictors in IRT-GD. We used the updated dataset to fit new IRT-GD variants, referred to as IRT-GD-PR, and estimated gaming tendencies for the control condition and the overall dataset. Table 7 shows that IRT-GD-PR achieved acceptable validity for the control condition and also boosted the validity for the overall dataset compared to IRT-GD and KE-GD. We leave for future work to further improve and test this local refinement method.

4. APPLICATIONS OF IRT-GD

In this section, we demonstrated two applications of IRT-GD. We used the estimated gaming tendencies from IRT-GD to study whether there was a difference in the level of gaming between the two conditions from our experimentation with the tutor, and to explore the relation between gaming and motivation.

4.1 Intervention effects on gaming

Our prior work [18] has shown that the data-tuned adaptive condition (that provided intense deliberate practice) led to greater learning outcomes compared to the control condition (that provided normal deliberate practice) in the first experiment (19F dataset); we are interested to see whether the intervention also led to higher behavioral engagement, particularly lower levels of gaming the system. We conducted a regression analysis predicting levels of gaming over students given the condition indicator on the three datasets. The two detectors had contradicting results on the 19F and 20S datasets. On the 19F dataset, KE-GD showed that the intervention led to significantly higher levels of gaming while IRT-GD showed that there was no statistical difference (Table 8 the 2nd column). The suggested intervention effect of increased gaming levels by KE-GD contradicted the previously validated intervention effect of improved learning, since higher levels of gaming are usually associated with lower learning. Thus, IRT-GD more accurately revealed the intervention effect on this dataset. We hypothesized that this could be due to KE-GD not being able to account for the task format effect. We computed the proportion of highly-gamed formats over transactions and the normalized learning gain per student per condition. We found that the EXP condition had a higher average proportion of highly-gamed formats (Table 9 the 2nd column), consistent with our hypothesis. On the

20S dataset, KE-GD showed that the intervention led to significantly lower levels of gaming while IRT-GD showed that there was no statistical difference (Table 8 the 3rd column). However, both conditions have similar normalized learning gains, and the control condition had a much higher average proportion of highly-gamed formats (Table 9 the 20S columns). This again suggests that KE-GD provided biased gaming assessment by using direct proportion of gaming without accounting for formats. This set of analyses shows that IRT-GD more accurately revealed intervention effects on gaming than KE-GD in our experiments.

Table 8. Intervention effects on gaming examined by regression predicting gaming proportions or tendencies given the condition variable (Control: 0, Experimental: 1). Coefficients of the condition variable are reported.

4.2 Motivation and gaming

The investigation of the relation between motivation and gaming contributes to understanding why students game and developing behavioral measures of motivation. Prior work [9] indicated that students' attitudes and interest towards the domain was related to detected (observed) gaming frequency. More recent work [13] applying a simple latent variable model identified strong associations between several motivational measures and estimated gaming tendencies. Our investigation of the relation between motivation and gaming adds to the limited empirical evidence in this space. On our datasets, motivational surveys with four scales (Table 10) were collected at the first and the last sessions of each month-long experiment. Each question used a 7-point Likert rating; responses for each scale were averaged to present students' motivation along the scale. Table 11 shows correlations between motivational measures from surveys and estimated gaming tendencies over students. Among the four scales, only perceived competence in math (PC) showed consistent significant correlations with gaming and only in the experimental condition across three datasets; the sign of the correlations was negative as theoretically predicted. The correlations between PC and gaming did not appear to be due to students' abilities approximated by pretest scores, because we did not find correlations between pretest scores and gaming tendencies. To understand why PC was only associated with gaming in the experimental condition that provided intense deliberate practice but not in the control condition that provided normal deliberate practice, we compared objective difficulties measured by the proportion correct of first attempts and subjective difficulties measured by the difference between the final and the initial values of PC between the conditions (Table 12). We found that the experimental condition had lower objective difficulties but higher subjective difficulties. We discussed the results in the next section.

Table 10. Motivational survey inventory.

Scale	Question
Perceived competence in math (PC)	How good at math are you?
	Compared to most of your other school subjects, how good are you at math?
Math utility value (UV)	How important is it to you to learn math?
	How important do you think math will be to you in the future?
Interest in math (IM)	How interesting is math to you?
Interest in tutor (IT)	How excited are you to do math on a computer?

5. DISCUSSION AND CONCLUSION

In this paper, we demonstrate a latent variable model for more valid and robust gaming assessment, item response theory-based gaming detection (IRT-GD), that estimates latent student gaming tendencies accounting for contextual factors. We started with applying a previously validated knowledge-engineered gaming detector (KE-GD) to a dataset collected from an algebra tutor with varying task design and sequencing across conditions. However, the detected gaming level by KE-GD was not associated with learning, challenging its construct validity in our context. We conducted exploratory data analyses and identified contextual

factors that could capture the normative interaction behaviors of the population that might explain this lack of association. We then built an IRT-GD model that explains detected gaming from KE-GD by both contextual factors and students' intrinsic gaming tendencies; it estimates a student-level latent gaming tendency as the degree of deviation from normative behaviors of a population across contexts. We tested the generalizability of IRT-GD and found that it outperformed KE-GD on three datasets across different contexts in construct validity measured by associations with learning. Our approach is not only useful for others wanting to apply a gaming assessment in their context, but is also generally applicable in creating more robust behavioral measures.

There are two notable features of our approach that may be particularly relevant for anyone building or using behavioral detectors. One is that our modeling approach adapts an existing behavioral detector to new contexts without complex feature engineering, which may be attractive for the learning engineering community to maximally build on past methods and adapt them to new contexts. For example, the learning effect on detected gaming is incorporated through practice opportunity counts without an additional process to estimate dynamic knowledge as in [6, 32]. Another feature is that our modeling and evaluation approaches do not require extra human labeling and focus on the association between the behavior measure and learning. Many past works constructed and validated detectors solely by predictions of human labels; although human labels have undeniable merits, they may contain bias. For example, in the development of KE-GD [25], experts examined each clip, which consists of five consecutive actions, from a set of clips randomly selected from log data and decided whether the clip would be coded as gaming or not. A clip was shown in a textual format giving *individual-level* information about the actions *within* the clip (e.g., each action's time, the problem context, the input entered, the relevant skill, whether the input was right, wrong, a help request or a "bug?"), and experts made judgements about gaming without *population-level* information (e.g., the median time of the step of the population), or information *outside* the clip from previous or future clips. This may increase the speed and ease of labeling, yet it may risk introducing bias. For example, if the student did not deviate much from the general behavior of the population or if the student could get a similar step correct in a future clip on their first attempt, then it may be better to label this clip as not gaming. Thus, behavioral detectors validated solely by predictions of human labels looking at isolated clips may not always reliably capture unproductive or harmful behaviors for learning. Our approach reduces bias and enhances the support for learning when applying a behavioral detector by considering contextual factors that were not considered in the original human labeling process, but are important for identifying behaviors harmful for learning. Although further examination of generality, stability, and reliability (as elaborated later) of IRT-GD may be needed to strengthen the validity claim of our approach, we think current evidence suffices to suggest that IRT-GD and our latent variable modeling approach can *enhance* (rather than replace) existing behavior measures for more valid and most robust behavioral assessment. One may consider using IRT-GD and our latent variable modeling approach when an existing behavior measure lacks validity in a specific context.

We identified strong contextual factors, i.e., the task format and its interaction with students' practice opportunities, aligning with previous research. The menu format led to the highest detected gaming, which coheres with prior work hinting at the high propensity of the multiple-choice format (which also involves selecting an option given a set of options) for triggering detected

gaming. One explanation may be that the cognitive cost [16] in making attempts in menus is low since it does not require typing, and different descriptions may only have subtle differences, so students might have developed a trial-and-error strategy with genuine engagement. This explanation could also be applied to the second highest gamed format, flipped-menu, where students might enter several expressions extracted from a given equation corresponding to a description rather than writing expressions from scratch as in other formats. Cognitive cost of a format is implicitly considered in IRT-GD and may be worth more attention for others developing gaming detectors. Meanwhile, students more likely decreased detected gaming as their prior knowledge levels increased on menu and flipped-menu formats compared to other formats, suggesting that certain game-like learning strategy (e.g., a trial-and-error strategy) may only be likely when the cognitive cost is low and students are of low prior knowledge. Moreover, we found that students decreased detected gaming faster on the table format over successive practice opportunities than on other formats, suggesting the reasons for students to game on this format might be different from the reasons they gamed on menus or flipped-menus. Examining the interface, one explanation may be that there are no clear instructions on how to fill in the various cells of the table, e.g., under the column labeled as "Show your work", it is not clear whether a student could enter $15+10$ (graded as wrong) instead of $3*5+10$ (the correct answer). This coheres with prior work suggesting that students gamed more when the presentation is unclear [8], and that students may game as a way to obtain worked examples [31]. Further analysis on student answers may support our hypothesized explanations. A final remark regarding task formats is that in the tutor we studied, the interpretation of task formats requires caution since a task format is not only coupled with a specific interface design (as the name *format* suggests), but also a specific scaffolding design (e.g., fixed or dynamic scaffolding) as well as specific KCs. A future direction is to study them separately through experimentation.

In a context where IRT-GD did not reach statistically significant associations with learning, we conducted local refinement of the input detector, KE-GD, by considering deeper format effects, i.e., the interaction between formats and specific interaction patterns. Our refinement led to acceptable validity and further confirms the importance of task features and demonstrates the flexibility of our latent variable approach. A next step is to test whether this local refinement approach is robust in other contexts. In some contexts, KE-GD already reached acceptable validity, although IRT-GD further improved on it by reaching stronger associations with learning. A next step is to apply IRT-GD to other learning environments and to study more automatic ways to identify contextual factors important in a specific context.

One aspect that needs further examination is whether and how well a fitted IRT-GD model extrapolates to unseen students or formats. This aspect is especially relevant to online intervention where the tutor has to react to gaming as designed for new students or formats. In Section 4, we conducted one kind of generalizability checking where we used the same independent variables in the IRT-GD model for the first dataset to construct IRT-GD models for new datasets fitted to the complete set of the new datasets. The new format (*animation*) was handled through adding a new dummy coded variable. We showed that the structure (i.e., predictors) of IRT-GD generalizes to new students and new versions of the system. This checking is most relevant if one uses IRT-GD to conduct offline student-level analysis as was done in Section 4. However, we have not examined how well a fitted IRT-GD model extrapolates to unseen students or formats, i.e., predicts detected

gaming or estimates gaming tendencies for unseen students or formats, which is important when using IRT-GD for online intervention. In theory a fitted IRT-GD model can extrapolate to an unseen or newly seen student: we first plug in the values of the fixed factors which equates to using the population mean to obtain a prediction; after observing at least one data point of the new student, we can (repeatedly) reestimate the parameters with the accumulated data with a random intercept added for the new student. Meanwhile, the extrapolation to unseen formats is also feasible: we can first treat a new format as a seen, similar format, and after observing at least one data point of the new format, we can (repeatedly) reestimate the parameters with a parameter fitted for the new format³. A promising modification of IRT-GD that enables greater generalizability is to replace the dummy coded format variables with a variable that describes key properties of formats, e.g., *whether a response set is given or can be easily inferred*. As for the question of *how well*, we plan to test the “online” predictiveness of IRT-GD used in the aforementioned ways for extrapolation as a next step.

A related examination that could further support the validity of IRT-GD is to examine the stability and reliability of estimated gaming tendencies. To examine stability, we may check whether gaming tendencies estimated from the first half of students’ temporally ordered interactions correlate with those estimated from the second half of the student interactions, i.e., whether students who tend to game more earlier also tend to game more later. To examine reliability, we may check whether gaming tendencies estimated from interactions of a set of formats correlate with those estimated from interactions of other formats, i.e., whether students who tend to game more in some formats also tend to game more in other formats. The higher the validity and reliability, the higher the truthfulness of the underlying assumption of IRT-GD about a latent, stable gaming tendency construct and the soundness of the identified contextual factors.

Although we have focused on a student-level gaming estimate by IRT-GD, it can also give a transaction-level gaming estimate for online intervention. For example, we can first fit an IRT-GD model to past data using the full formulation. Then, we can apply the fitted model without using the random student intercepts to predict whether an average student may game (as defined by KE-GD) on a step according to current contextual factors. Then we compare this population-level prediction (considering an interval of uncertainty) to the gaming label by KE-GD to identify cases where gaming is not acceptable, i.e., deviating too much from the norm, and finally activate the pre-designed intervention.

One seemingly conflicting result with prior studies is that we did not find an association between gaming tendencies with pretest scores (Table 11), where prior studies have shown that lower prior knowledge levels were associated with higher gaming frequencies [5, 20]. This is because IRT-GD already includes pretest scores and relevant interactions as predictors for detected gaming. IRT-GD is intentionally designed to extract latent gaming tendencies that are not (primarily) triggered by prior knowledge, but by other factors such as students’ motivation or metacognitive skills. This may lead to tutor design that focuses on promoting students’ motivation or metacognition. However, our latent variable modeling approach is flexible in that one could consider dropping the pretest scores

³ Treating a categorical variable with few levels as a random factor may lead to imprecise estimates [10]. Thus, we do not consider this as a next step when the number of formats is small (e.g., <10).

related predictors if they are interested in gaming tendencies triggered by prior knowledge.

One finding seemingly less consistent with prior work and harder to interpret is the link between motivation and gaming. We found a negative correlation between perceived competence in math and gaming in the experimental condition (i.e., the intense deliberate practice condition), consistent with the reported negative correlation between self-efficacy in math and gaming in [13], but we did not find any correlations between other motivational measures and gaming, such as students’ interest towards the domain and gaming reported in [9, 13], or any correlations in the control condition (i.e., the normal deliberate practice condition)⁴. Rather than prematurely attributing the general lack of correlation between motivation and gaming to the lack of validity of estimated gaming tendencies, we hypothesize several reasons. There may be interactions between different student attributes (measured or unmeasured in the current study) or between student attributes and system attributes not considered in a simple zero-order correlation we did here. Additionally, the motivational survey was deployed at the first session but was used to correlate with month-long accumulated behaviors. After all, there is still limited empirical evidence of the relation between motivation and gaming, so further investigation is needed. To explain why there was a negative correlation between perceived competence in math and gaming in the intense deliberate practice condition but not in the normal deliberate practice condition, we conducted a preliminary exploration and found that the objective difficulty (measured by the proportion correct of first attempts) of the intense deliberate practice condition was lower than the normal deliberate practice condition but the subjective difficulty (measured by perceived competence in math) of it was higher. One hypothesis is that the patterns of successes or failures may matter more than the proportion of success for students’ perceived competence. The intense deliberate practice driven by a more fine-grained and larger KC model may have more constantly pushed students to work on their weak spots in new tasks (i.e., put them on the edge of competence), challenging their perceived competence. It may be worth considering letting students to occasionally work on already mastered skills to boost their perceived competence, or preparing students better for desirable difficulties or failures. Combining this finding with the finding that intense deliberate practice alone did not reduce gaming tendencies, one promising direction is to introduce motivational interventions or designs that could maintain or promote perceived competence or self-efficacy in the task domain under intense deliberate practice, to reach a potential multiplier effect of both cognitive and motivational interventions.

ABSTRACT

Collaborative problem solving (CPS) is a 21st-century skill essential for learning gains, workplace success, and tackling increasingly complicated global problems. Group diversity plays a vital role during collaborative activities, especially in a digital space. Although CPS involves dynamic communication behaviors, few studies have considered the impact of cultural diversity on the complex and reoccurring discourse involved in CPS tasks. In this study, we explore team conversations during a CPS task to understand the role of cultural diversity on team communication patterns. First, we characterized team dialogues with an existing CPS framework; then used recurrence quantification analysis (RQA) to quantify group communication and capture recurrent patterns. Finally, we compared the patterns across groups with varying degrees of cultural diversity. Our results suggest that groups with higher levels of cultural diversity, compared to more homogeneous groups, had a higher number of group messages, spent more time in group discussions, and demonstrated greater convergence and complexity in communication patterns. These intricate and complicated communication patterns support the notion that cultural diversity can produce both positive and negative outcomes and may explain the perception of cultural diversity in teams as a “double-edged sword”.

Keywords

cultural diversity, collaborative problem solving, recurrent quantification analysis, group dynamics

1. INTRODUCTION

M. A. Samadi, J. G. Cavazos, Y. Lin, and N. Nixon. Exploring cultural diversity and collaborative team communication through a dynamical systems lens. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 263–275, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

Collaborative problem solving (CPS) involves individuals working together to solve a problem and promotes division of labor, sourcing information from different perspectives and backgrounds, and increasing innovation and creative solutions that stem from the presence of multiple group members [52]. CPS has been identified as a key 21st century skill [9, 80] that plays a pivotal role in both workplace [22] and educational environments [12]. Furthermore, CPS has increasing international importance and has been shown to be an essential skill needed across several domains to solve complex environmental, social, and public health problems [52, 29]. From a socioeconomic perspective, the rise of complicated global issues requires innovative solutions derived from individuals working together and generating solutions from diverse perspectives [22]. In professional environments, employers often report problem-solving [49, 60] and collaboration [49] as skills that are essential for the success and employability of recent college graduates. In educational contexts, CPS is also a key component for successful teamwork and student learning [52, 27, 28]. Positive collaborative interactions have been shown to improve student psychological and performance outcomes [1, 35, 34, 44, 42, 41, 18, 20, 62].

Given the pivotal role of collaboration across multiple disciplines, it is unsurprising that an increasing number of studies have explored which team attributes are important for successful CPS outcomes. For example, studies have considered the impact of group size [68, 45, 57], group diversity [33, 66, 6, 21, 7, 75], and personality differences [37, 32] on team performance. This area of research has consistently highlighted that team diversity in general, and cultural diversity in particular, play a critical role in successful team collaboration [66, 7, 75, 33]. Notably, this line of previous work has generally focused on measuring the effects of team diversity on static post-collaboration measures (e.g., performance outcome) [66, 33, 77]. However, there have been limited research efforts devoted towards understanding the role of diversity from a more dynamic, process-oriented perspective, which are fundamental to collaborative interactions [19, 16, 42]. As such, current studies on diversity in teams are limited in offering insight on many interdependent aspects within collaborative interactions such as negotiation, coordination, and regulation, among others. In order to explore

how these fine-grained collaborative interactions are influenced by diversity, more nuanced techniques are needed.

To address this gap, we use a dynamical systems lens to explore cultural diversity in teams and team communication patterns [58, 15, 79]. Specifically, we apply recurrence quantification analysis (RQA) [78] to quantify team dynamics, and capture recurrent patterns of interaction amongst the members. Using this novel approach, we aim to uncover low-level temporal patterns in CPS communication and variations therein across groups with different levels of cultural diversity. Group communication is inherently interdependent and research has shown that group composition factors are associated with different aspects of social and cognitive processes during collaborative interactions [20, 19, 42, 55, 11, 10, 17]. Therefore, we are motivated to examine whether cultural diversity as a team composition factor is associated with different collaborative communication dynamics and structures.

The remainder of the paper is organized as follows. First, we review the literature on diversity in teams and the impact of diversity on team outcomes and communication. Second, we provide an overview of the current practices in quantifying communication in CPS tasks and the previous work related to RQA in the context of teams and group dynamics. Third, we present our methodological approach including a description of our CPS task, the qualitative coding of CPS skills exhibited in group communication, and the RQA measures. Finally, we present our RQA analysis results with regards to cultural diversity in groups as well as discuss our findings and their implications for understanding communication behaviors in CPS.

2. RELATED WORK

2.1 Diversity in Teams

Diversity in teamwork and its impact on group's performance outcomes has been studied extensively across multiple disciplines and contexts (c.f. [33, 21, 72, 77, 66], for meta-analyses on this topic). However, studies have demonstrated mixed findings on the impacts of team diversity on various team outcomes. Horwitz & Horwitz, 2007 found a positive association between task-related diversity in groups and performance, yet no direct relationship between demographic diversity and group performance. There is some evidence to show that diversity in groups can result in positive outcomes, such as increased innovative and creative ideas [33, 66]. However, other studies suggest that diversity can result in negative outcomes such as increased conflict and lower group cohesion [65, 66]. Although the direct impact of diversity on team outcomes remains unclear [8, 66, 77], several studies have demonstrated that different sources of diversity (personality, cognition, gender, race, ethnicity, etc.) can impact groups to varying degrees [59, 33]. The impact of diversity is often associated with the type of diversity: surface-level diversity (i.e., easily observable attributes such as gender, race, ethnicity) v.s. deep-level diversity (i.e., less overt attributes such as personality, cognition, values/beliefs) [59, 31]. Initially, surface-level attributes may influence group dynamics, but over time deep-level attributes may become more salient and influential [59]. Considering the interactions among the participants in this study and many other collaborations are short-term

(20-minute discussions), surface-level diversity and cultural diversity in particular can prove to be highly influential on group interactions. In the current study, we focus on a surface-level attribute, cultural diversity operationalized by ethnic compositions in group, and its relationship to the communication dynamics during CPS.

2.2 Cultural Diversity in Teams: A Double Edged-Sword

Although there are various forms of group diversity, cultural diversity has often been of particular interest to scientists because of the increased globalized and interconnected workforce [7, 71]. Moreover, an array of collaboration technologies and online platforms enable distance teamwork, and create greater collaborative opportunities for individuals with different cultural backgrounds [22, 29]. Previous studies suggest that the role of cultural diversity on team performance is nontrivial. However, the effect of cultural diversity on group performance is mixed. These effects are often mediated by factors such as creativity, conflicts, communication effectiveness, social integration, and satisfaction [66]. For example, although culturally diverse teams benefit from higher levels of creativity and satisfaction, they also suffer from lower social integration and more conflicts [66]. In addition, it is commonly assumed that people with different cultural and ethnic backgrounds are likely to hold different views and priorities when communicating with others [65, 14]. Following this assumption, higher degrees of cultural diversity in groups may contribute to more complex interpersonal dynamics and information sharing behavior. To extend our understanding of communication patterns associated with cultural diversity, we took on a dynamical system lens to examine structural and temporal processes in CPS discourse.

2.3 Quantifying the Impact of Cultural Diversity

The literature on cultural diversity in teams covers a wide range of domains and collaborative contexts. Existing studies have extensively focused on static team or individual outcomes such as performance [70, 76], number or quality of ideas generated [50, 53], decision-making tasks [81, 40, 64], achieved learning [24], and psychological measures such as learner experience and attitude towards group interactions [54]. These studies have extended our knowledge on the relation between cultural diversity and the end product of the collaboration. However, few studies [69, 73] have considered how cultural diversity impacts more dynamic aspects of the group collaboration process, such as language and group discourse. For example, Tenzer et al., (2014) found that cultural-based language differences can impact group perceptions of trust and competencies. CPS is inherently interactive and dynamic. Collaborative interactions involve reoccurring and interrelated discourse as teams exchange ideas, negotiate, and share information. Thus, it is necessary to unpack collaborative process with regards to cultural diversity compositions. To address this gap, our study focuses on the fine-grained temporal communication patterns across cultural diverse and culturally similar groups.

2.4 Quantifying CPS Communication in Teams

Collaborative problem-solving involves dynamic interpersonal exchange and shared cognitive behavior of individuals [19, 12]. Successful CPS requires multiple skills and subskills for effective communication stages, including negotiation, information sharing, coordination and so on. Language is considered a less intrusive means compared to traditional survey sampling to reveal cognitive processes of the human mind. A number of existing assessment frameworks have been developed to identify and capture CPS skills from interactive dialogues. For example, the Programme for International Student Achievement (PISA) [52], identifies a framework with three social competencies (i.e., establishing and maintaining shared understanding, taking appropriate action to solve the problem, and establishing and maintaining team organization) and four cognitive processes (i.e. exploring and understanding, representing and formulating, planning and executing, and monitoring and reflecting). This framework was first introduced by OECD to evaluate CPS skills during various computer-simulated assessment tasks, highlighting important aspects unique to collaborative interactions mediated by computers. Other CPS frameworks that subsequently surfaced follow similar ontology. For instance, Liu et al. (2016) [43] proposed a framework that conceptualizes four broad CPS skills: sharing ideas, assimilating and accommodating knowledge/perspective taking, regulating problem solving ideas, and maintaining positive communication. Andrews-Todd & Forsyth mapped out more nuanced skills under the social and cognitive domains [2]. More recently, some researchers propose to conceptualize CPS interactions as a continued sociocognitive spectrum, in contrast to the previous dichotomous view on social and cognitive processes [18]. Through this lens, CPS practices could best be described as sociocognitive in nature, allowing more opportunities for adopting computational methods to meaningfully capture natural language patterns of learners. Increasingly, studies have suggested that natural language processing and other artificial intelligence techniques are effective ways to measure CPS skills [13, 74]. Given this trend, researchers have called for more efforts towards developing and adapting innovative data mining methods to effectively quantify CPS patterns and make sense of learner communication behavior [38].

2.5 Communication in Teams as a Dynamical System: RQA

Communication and CPS skills can be considered a dynamic and complex system [46, 23, 36]. Several methods can be used to quantify and analyze group dynamics. However, Knight, et al. (2016) point out that each are limited by a lack of consideration for time dependencies and therefore oversimplification of group dynamics [36]. RQA, on the other hand, is a non-linear dynamical systems approach that enables the evaluation of recurring patterns across times [78]. RQA has been widely used recently to study social interactions, group communication, and group dynamics [3, 4, 36, 25, 26, 15, 67]. For example, Fusaroli & Tylén (2016) took advantage of RQA and cross-recurrence quantification analysis (CRQA) to analyze dyadic conversations patterns and subsequent performance. Based on RQA and CRQA, they defined measures of interactive alignment, interpersonal syn-

ergy, and self-consistency. Interpersonal synergy serve as a significant predictor of performance suggesting the importance of complimentary conversations between the dyads. This dynamic system approach, to our knowledge, has not yet been applied to investigate the communication group dynamics in culturally diverse and homogeneous teams.

In the current study, we use RQA to measure structural components of groups' conversations. Specifically, we focus on time-series data that map CPS skills exhibited in student discourse based on the ontology presented in Andrews-Todd et. al., [2]. RQA results can be visualized using a recurrence plot. The recurrence plot gives a visual representation of the components of each time-series data and plots their recurrence over time. Figure 1 provides an example of RQA in the context of CPS skills. Figure 1A depicts chat discussions during a typical CPS task. Each color in the chat discussion depicts a coded CPS skill (e.g., information sharing) that results in a times series of skills used labeled in Figure 1B. Figure 1C illustrates a recurrence plot based on the chat discussions in Figure 1A. The CPS skills on X and Y axis correspond to the temporal sequence of chat utterances and each dot is an instance in which the CPS skill has recurred in the group conversation. The central diagonal line represents the sequence of CPS skills plotted against themselves, also known as the line of identity (LOI). The recurrence of a skill code used previously in the conversation is represented by dots in the recurrence plot. The recurrence points along with their patterns and alignment provide insight to structural components of group communication. For example, the recurrence of Sharing Information (green) took place at time points four, five, nine, and eleven and the recurrence of Shared Understanding (orange) on times three and eight are recurrence points.

Of particular interest, is any group of dots that create a diagonal line and that are not part of the LOI. A diagonal line of length l is an indication of a recurring pattern of l skill codes in the same sequence. For example, the sequence Monitoring (purple), Shared Understanding (orange), and Information Sharing (green) creates a diagonal line of length 3. These exhibited CPS skills occurs back to back at position, two, three, and four and then again at seven, eight, and nine, thus creating a recurrence of CPS skills.

3. CURRENT WORK

CPS tasks involve dynamic discourse and communication between groups. Therefore, by understanding how cultural diversity impacts these dynamic communication patterns and CPS skills, we can gain insight on the impact of cultural diversity beyond outcome measures such as CPS performance. The current study investigates how cultural diversity in teams impacts group communication behaviors from a dynamical system lens. We explore the linguistic CPS patterns that emerge in culturally homogeneous and diverse groups of undergraduate students as they complete an on-line CPS task. Specifically, we aim to explore the following research questions:

RQ1: Does cultural diversity impact structural components (as captured with RQA) of a group's conversation?

RQ2: How does cultural diversity impact structural compo-

4. METHODS

4.1 Participants

A total of $N = 514$ undergraduate students from a large university in the U.S. southwest participated in the study. Participants were randomly assigned into teams to take part in a Hidden Profile CPS task (described below). In total $N = 129$ teams were included in the study. Teams are predominantly four person groups with a few exceptions that consist of three or five people. In this study we consider four-person groups only for the sake of consistency in analysis. Over a half of our participants were female ($N = 347$), and most of them were freshman ($N = 342$) or junior ($N = 128$). The average age of the participants was 19.5 years, with the 90% of the participants between the ages 18 to 22 years old. Of those participants who reported their race and ethnicity (497 out of 514), 62 (12%) of the participants were White, 9 (1.7%) were Black or African American, 209 (40.6%) were Asian or Asian American, 162 (31.5%) were Hispanic or Latino, and 9 (1.7%) were multiracial. Out of 502 participants who reported their first language the breakdown was as follows: 142 English, 152 non-English, and 208 bilingual. Additionally, over half of students ($N = 277$) identified as first-generation students.

4.2 Procedure

Participants were randomly assigned into teams of four individuals to complete a decision-making task on the Education Platform for Collaborative Assessment and Learning (EPCAL) [30]. EPCAL is a platform by Educational Testing Service that provides a collaboration space for participants to communicate, for teachers or organizers to manage the participants and team formations, and for researchers to study team collaboration in a computer-mediated environment. Prior to beginning the task, participants were asked to complete a background survey to collect information on race, gender, education level, and native language. Next, students were prompted with a problem (e.g., “choose the best apartment”) and were asked to rank three options based on positive features (e.g., “this apartment is at a prime location”) and negative features (e.g., “the rent is expensive”). Teams were randomly assigned to one of four decision-making scenarios including ranking apartments, professors, party venues, and job candidates. Each individual was provided with different features relevant to the problem. In the team discussion phase, participants synchronously chatted with other teammates to share information that they held in order to achieve the optimal ranking. The group communicated through text-based and communication lasted for 20 minutes.

4.3 CPS Skills: Qualitative Coding

In an attempt to qualitatively annotate the utterance data, we adapted the CPS framework from [2]. We removed one cognitive skill code, exploring and understanding, given that it was not as eminent in our data set and was less relevant to our CPS task. The resulting CPS skills are divided into social and cognitive interactions. Each social and cognitive category includes four CPS skill codes, resulting in eight skill codes in total. Social skills include maintaining communication (SMC), sharing information (SSI), establishing shared understanding (SESU), and negotiating (SN); while cognitive skills consist of representing and formulating (CRF),

planning (CP), executing (CE), and monitoring (CM). Table 1 present the definitions and examples of each CPS skill.

CPS skill coding was completed at the chat utterances level and each utterance was assigned one primary code (i.e. eight CPS skill codes aforementioned) and 29 subskills that correspond to each high-level CPS skill. For the purpose of this study, we only focused on the eight main CPS skills. Four undergraduate research assistants were trained as raters to coded the content of students’ discourse (7,711 total utterance events). Raters were trained on the adapted CPS framework. Then, we retrieved a random sample of 20% of all utterances in the data and assigned each rater to code independently. All raters discussed their codes and address any discrepancies. The inter-rater reliability (Kappa = .81) achieved among all raters is considered high (Kappa > .60; [39]). Next, the remaining 80% of the data were split evenly into four groups. One of the four trained raters coded each of these four groups independently.

4.4 Recurrence quantification analysis

We used recurrence quantification analysis (RQA) to visualize and quantitatively assess students’ behaviors within a CPS environment. Specifically, we used PyRQA Python framework¹ [56] to run RQA experiments efficiently. Exploring the recurrence of human behavior would help us better understand how underlying communication patterns occur, and how the phases and dynamics of a system change over time. The time series data required for RQA can be categorical or continuous.

4.4.1 Recurrence plot

Recurrence plot gives us a visual two-dimensional representation to discover repetition, recurrence, and underlying patterns across time from a one-dimensional time series data. For a time-series data t of length ℓ , the recurrence plot R is a $\ell * \ell$ matrix consisting of 0, 1 values, where $R_{i,j} = 1$ is an indication of recurrence between t_i and t_j ($t_i = t_j$). An example of this process is provided in Figure 1.

4.4.2 Recurrence quantification

Visually, the recurrence plot provides valuable qualitative information about the group dynamics and the structure of the dynamical system. However, RQA’s quantified measures, calculated based on the recurrence plot, allow us to quantitatively evaluate a dynamical system beyond visuals and qualitative observations. The following provides a brief description of the main metrics of RQA (for more information on RQA measures see [78, 47]).

- **Recurrence Rate:** Recurrence rate (RR) shows the rate and the density of recurrence points in a recurrence plot. It is calculated by dividing the recurrence points by the total number of cells in the plot which is the length of the time series squared. Higher recurrence rate would show a higher frequency of repetition in actions and the system to revisit previous states. RR ranges from 0 to 1, while 0 shows a system without

any recurrences, and 1 shows a fully recurrent system.

$$RR = \frac{1}{\ell^2} \sum_{i,j=1}^{\ell} \mathbf{R}(i, j) \quad (1)$$

- **Determinism:** Determinism measures the distribution of recurrence points that form a diagonal line. In other words, determinism is the percentage of recurrence points that align on a diagonal line. The more recurrence points that align on a diagonal line in a recurrence plot, the higher the determinism. As seen in Figure 1, we have four diagonal lines (two diagonal lines of length 3, and two diagonal lines of length 2) we have a fully deterministic system with the determinism of 1. A system with a higher determinism is considered ordered and repetitious with periodic patterns over the time. A system with a lower determinism can be a sign of a more chaotic system. To compute determinism, l_{min} needs to be considered as a minimum length of which diagonal lines to consider. For instance, a $l_{min} = 3$ would eliminate the two diagonal lines of length 2 in Figure 1 and therefore lower the determinism compared to the default value ($l_{min} = 2$).

$$DET = \frac{\sum_{\ell=l_{min}}^N \ell P(\ell)}{\sum_{\ell=1}^N \ell P(\ell)} \quad (2)$$

- **Laminarity:** First introduced by [48], laminarity is designed to capture the percentage of recurrence points that align on a vertical line. A continuation of the same event in a system forms a vertical line. In our study, same skill codes appearing in consecutive messages results in a vertical line. For the computation, a minimum line length of v_{min} needs to be set to possibly restrict the length of vertical lines in the calculation of laminarity.

$$LAM = \frac{\sum_{v=v_{min}}^N v P(v)}{\sum_{v=1}^N v P(v)} \quad (3)$$

- **Entropy of diagonal lines:** Entropy reflects the complexity of the length of diagonal lines in a recurrence plot. It is calculated using the Shannon entropy [63] of $P(\ell)$ distribution, where $P(i)$ is the probability to find a diagonal line of length i in the recurrence plot. High entropy is an indication of high variation in length of recurrent sequences. In contrast, in a recurrence plot where all diagonal lines are the same length, the entropy would be zero.

$$p(\ell) = \frac{P(\ell)}{\sum_{\ell=l_{min}}^N P(\ell)}, \text{ENTR} = - \sum_{\ell=l_{min}}^N p(\ell) \ln p(\ell) \quad (4)$$

Table 2: Descriptive statistics of measures by cultural diversity

Measures	Cultural diversity degree				
	1	2	3	4	Full Sample
	$M(SD)$	$M(SD)$	$M(SD)$	$M(SD)$	$M(SD)$

Laminarity	0.71 (0.15)	0.67 (0.14)	0.66 (0.13)	0.72 (0.11)	0.67 (0.13)
Longest diagonal line	6.29 (4.07)	6.41 (4.28)	5.62 (2.93)	11.24 (6.06)	6.48 (4.21)
Recurrence rate	0.24 (0.06)	0.25 (0.05)	0.25 (0.06)	0.25 (0.06)	0.25 (0.06)
Discussion Time	715.15 (183.38)	727.34 (358.15)	885.42 (431.21)	1141.0 (285.84)	850.47 (404.31)
Average diagonal line	2.9 (1.23)	2.72 (0.73)	2.44 (0.37)	3.2 (1.25)	2.63 (0.74)
Number of messages	39.86 (11.02)	49.96 (31.14)	59.24(31.93)	77.47 (27.38)	57.0 (31.69)

notes: M = Mean, SD = Standard Deviation

- **Longest Diagonal Line and Divergence:** Another measure related to diagonal lines are (1) the longest diagonal line, L_{max} , excluding the line of identity, and (2) divergence which is the reverse of L_{max} . Along with determinism, these two measures are indicators of convergence, chaos, and stability in the system. The lower the L_{max} , the higher the divergence, chaos, and instability within the dynamical system.

$$DIV = \frac{1}{L_{max}} \quad (5)$$

4.5 Data Processing

4.5.1 RQA time series

To prepare the data for RQA, we created time series data using the skill codes associated with each chat within the same conversation. The utterances were grouped together based on the team identification code and therefore each group conversation is represented by a time series of messages and their associated skill codes. Categorical skill codes were mapped to a numeric code that represents that skill throughout the analysis. The mapping is one-to-one meaning that each skill is only mapped to one number and each number only represents one skill. RQA was then applied to the time series of numeric skill codes to explore structural patterns within the group conversation.

4.5.2 Cultural diversity

We quantified cultural diversity based on the heterogeneity of ethnic identities. To determine cultural diversity level, we calculated how many unique ethnicities existed in each group according to the students self-reported demographic information. Since groups consist of four members, there were four possible levels of group diversity ranging from fully homogeneous groups (coded as 1) to fully heterogeneous groups (coded as 4). Below is a breakdown of group compositions and their associated degrees of cultural diversity:

- 1: (4 White members), $N = 7$;
- 2: (3 White members, 1 Asian member) or (2 White members, 2 Asian members), $N = 42$;
- 3: (2 White members, 1 Asian member, 1 Hispanic member), $N = 67$;

- 4: (1 White member, 1 Asian member, 1 Hispanic member, 1 Black member), $N = 13$

4.5.3 Statistical Analysis

RQA was applied to a time series of CPS skill codes associated with each message in a conversation. As described in Section 4.4, RQA allowed us to study team dynamics, underlying behavioral patterns, and their complexity. In order to examine the influence of cultural diversity on CPS communication dynamics, we performed a Kruskal-Wallis test on each RQA measure to see whether structural components of dialogues were different across groups. In addition to seven RQA measures described, we also included the total amount of time (seconds) that students spent discussing their decision and the number of messages sent within that discussion time as conversational measures. We also conducted pairwise Wilcoxon rank tests as a post-hoc analysis with Benjamini-Hochberg p-value adjustment to further locate where the significant difference specifically resides. This analysis enabled us to detect significance of variations of conversational measures and their relation to the level of team diversity. The code and results of the RQA Analysis is available on Github at: github.com/The-Language-and-Learning-Analytics-Lab/cult-div-rqa

5. RESULTS

Descriptive statistics of conversational measures by cultural diversity is available in Table 2. Results for each Kruskal-Wallis tests on Table 3 suggest significant effect of cultural diversity on entropy at [$H(3) = 9.077, p = 0.029, \eta^2 = 0.049$], longest diagonal line at [$H(3) = 14.405, p < 0.01, \eta^2 = 0.091$], average diagonal line at [$H(3) = 10.858, p = 0.01, \eta^2 = 0.063$], longest diagonal line and divergence at [$H(3) = 14.405, p = 0.003, \eta^2 = 0.091$], number of messages sent at [$H(3) = 11.231, p = 0.01, \eta^2 = 0.066$], and the time spent in discussion at [$H(3) = 12.334, p = .007, \eta^2 = 0.075$]. Notably, due to the relationship of divergence and longest diagonal line in Equation 5, the same results for these two measures were expected. Combined, these suggest structural differences in conversations across the four groups, in terms of complexity of activity and patterns of behavior. We followed up this significant result with pairwise Wilcoxon rank tests reported in Table 4.

The post-hoc analysis suggests significant differences between the most diverse group and the rest of the diversity

Table 3: Results of Kruskal-Wallis test of conversational and recurrence measures by diversity

groups in most occasions, with the most difference apparent in time spent on discussions and longest diagonal line. The most culturally diverse groups spent more time (in seconds) discussing the problem ($M = 1141$, $SD = 285.84$) than all three other culturally demographic compositions (Level 1 diversity, $M = 715.15$, $SD = 183.38$; Level 2 diversity, $M = 727.34$, $SD = 358.15$; Level 3 diversity, $M = 885.42$, $SD = 431.21$). Descriptive statistics of the measures grouped by degrees of cultural diversity are available in Table 2. These findings further demonstrate the impact of cultural diversity on the group dynamics and key components of group discussions. Figure 3 visualizes the linear relationship between the RQA measures explored in the post-hoc analysis and the amount of cultural diversity in each group. Of the five RQA measures examined, we observed a steady increase in discussion time, number of messages, and longest diagonal line as degree of cultural diversity increased. In addition, both entropy and average diagonal line increased at a less consistent rate. Specifically, entropy and average diagonal line increased mostly between the second most culturally diverse groups and the most culturally diverse groups. We

discuss the implications of the results in the next section.

6. DISCUSSION

CPS has been increasingly recognized as an essential 21st century skill in both educational and workplace environments [22, 12], especially in settings where teams are becoming increasingly more diverse and international. As such, exploring ways to further our understanding of the communication behavior patterns in diverse teams and advance CPS skills has been at the forefront of educational research [12, 29]. In this study, we extended current literature that measures performance outcomes by using a dynamical systems lens to examine how the level of in-group diversity influences team communication behavior. Specifically, we quantified CPS skills exhibited in group discourse and characterized conversational structures through RQA measures.

In response to RQ1, we found that degrees of cultural diversity in teams are associated with systematic outcomes of group communication captured through RQA measures. Specifically, these outcomes include number of messages,

Figure 3: Normalized values of quantified measures of communication plotted by cultural diversity. Each dot represents individual values for the five measures, along with the fitted regression line. Shaded regions around the lines represents the confidence intervals for each regression.

time spent in chat, complexity and unpredictability of recurrent patterns (entropy), average length of recurrent pattern (average diagonal line in recurrence plot), and longest recurrent pattern (longest diagonal line in recurrence plot). Regarding RQ2, our post-hoc analysis further reveal that groups with the highest degree of cultural diversity had diagnostically different structural patterns of communication compared to more homogeneous teams. Specifically, groups with the highest level of heterogeneity spent more time and sent more messages in chat, had greater complexity in interpersonal exchange, and lower divergence in group discourse. Notably, there was no sign of significant difference among the moderately diverse groups and homogeneous groups. We discuss the implications of results in greater details as follow.

First, the finding that groups with greater cultural diversity spent more time and sent more messages during the discussion could indicate positive or negative group dynamics. On the positive side, higher number of messages signals more opportunities for information sharing and exchange of ideas, which may suggest that members in these teams are more actively engaged in the collaborative discourse and provided their diverse perspectives to the problem. On the other hand, it might also indicate teams getting stuck or struggle to reach consensus. Teams that struggle with internal conflicts also tend to spend more time on communication to resolve disagreements. This issue is more signified in the context of a CPS ranking task. Greater cultural differences in teams might result in different preferences and priorities over different job candidates, apartments, party venue, and professor qualities [14]. As such, increased cultural diversity in teams could bring challenges in team communication that are reflected through frequencies of messages and time spent on discussion. This finding is consistent with the notion that

cultural diversity in teams can be a “double-edged sword”. It has been widely suggested that cultural diversity is associated with both positive and negative team outcomes [66]. Previous studies demonstrate that compared to culturally homogeneous groups, culturally diverse teams are associated with higher levels of innovation and creativity but are also prone to more conflicts, less effective communication, and less cohesion [66]. It is worth noting that the interpretation of the results has to be situated in the context of tasks. For instance, in open-ended tasks like brainstorming, longer time spent and more messages are typically indications of more innovative perspectives and creativity. However, in decision making tasks, especially when groups were under time constraints to arrive at a decision, more time spent on the task and greater amount of discourse may suggest it takes more effort for heterogeneous groups to build shared understanding and reach a solution collectively.

Our RQA analysis further revealed more culturally diverse teams were associated with more complexity in the distribution of recurrent patterns (higher entropy), longer recurrent patterns of interactions (higher average length of diagonal lines, and higher longest diagonal line). The increased complexity in culturally diverse teams can signal less rigidity, more adaptability, and higher responsivity in team interactions. These attributes have been found to be key for innovation, creativity, and information sharing in team communication [61]. For instance, Fusaroli and Tylén found entropy and average diagonal line of recurrences in transcripts between the dyads to have a positive association with their performance [25]. In conjunction with our first finding, longer discussion time and higher number of messages may provide more opportunities for diverse groups to display recurrent patterns, which may explain why diverse

groups have higher longest recurrent patterns. Interestingly, we found that the most culturally diverse groups have noticeably higher longest recurrent patterns and lower divergence, suggesting higher convergence within group discussion over time. This is in contrast to previous research which has typically associated high cultural diversity with divergent communication behavior [66]. We consider two potential explanations for how higher convergence was reached in team interactions within the most diverse teams. First, the impact of diversity on performance can be mediated through goal-orientation and information elaboration [51]. We hypothesize that longer and more active discussions in more diverse groups allowed much more opportunities for information elaboration which may account for a longer recurrent pattern in diverse teams. Moreover, the goal-oriented nature of CPS decision making task may cultivate more convergent collaborative interaction patterns. Second, higher entropy in more diverse groups indicates the higher complexity in the recurrent patterns. Therefore, although the longest recurrent pattern shows convergence in discussions of more diverse teams, higher entropy suggests less rigidity in the patterns of behavior which allows for less habitual patterns and more flexibility in social and cognitive interaction sequences. These findings indicate a potential increased willingness within cultural diverse teams to engage in active information exchange and leverage different perspectives during collaborative discussions. Taken together, this finding suggests highly diverse groups' flexibility in communication structure and openness to new information. High convergence indicated their capacity in perspective-taking as well as the elaborated processing of new information. Moreover, higher longest diagonal line could possibly be a sign of lengthier discussion and argumentation to reach a conclusion which could be a result of less effective communication. This could be meaningful characteristics to look for as teams across educational and professional settings are increasingly diverse. Further research would be needed to examine whether such pattern is associated with productive performance and psychological outcomes for participating members.

Our work serves as a starting point for future studies to leverage RQA in establishing the possible positive and negative links between cultural diversity, communication dynamics, and other post-collaboration measures such as performance and team satisfaction. Moreover, we contribute a structural view of the recurrences of CPS skills through sociocognitive processes in discourse. By taking a look into how the temporal sociocognitive processes that occur during collaborative interactions are shaped by cultural diversity during CPS tasks, we can begin to take a step towards understanding factors in learning environments that make CPS communication more or less effective. In addition to leveraging CPS frameworks such as [2] to characterize group discourse, future research may also operationalize group dynamics by capturing linguistic features based on the content of messages through syntactic and semantic similarity, i.e., Conceptual Recurrence Plots [3]. This analysis would not only allow for more complexity and possibilities in the way recurrence appears in group communication, but also potentially reveal more nuanced linguistic patterns with respect to cultural diversity in teams. Finally, our current study mainly concerns with the degree of cultural diversity, how-

ever there is also a need to investigate the communication behavior of specific demographic subgroups (i.e. female, underrepresented minorities) in CPS. Further investigation on the differences within these demographic groups could examine how these factors independently and in combination play a role in shaping diverse groups. We call for more efforts towards promoting inclusivity and equity in teams. Future studies along this line should aim to provide further insights on identifying group patterns that promote effective problem solving and meaningful experiences among diverse teams.

7. CONCLUSION

We focused on the impact of cultural diversity on group communication in CPS. Our novel approach leveraged RQA to study the dynamics in group communication. Applying RQA to analyze CPS discourse provides a means to uncover how groups with different degrees of diversity exhibit different patterns of behavior during the collaborative process. Understanding these behaviors is essential given the dynamic and interdependent nature of CPS tasks. Specifically, insight on how group dynamics impact culturally diverse groups has important implications on monitoring and improving diverse group communications. In sum, our study emphasizes the need to further our understanding of the role of diversity in group communication behaviors as teams share information, negotiate, and navigate the problem-solving task. Exploring the intricacies of these group dynamics sets a first step towards future research on understanding how these behaviors relate to group outcomes such as performance, psychological experiences, and group satisfaction. Furthermore, this study aligns with the agenda of promoting diversity and inclusivity in AI systems. Our findings could be meaningful for the researchers in the greater EDM community for applying such methods to diagnose diverse team dynamics, as well as further inquiring positioning AI's critical role in structurally complex collaborative processes across diverse teams.

ABSTRACT

The need to identify student cognitive engagement in online-learning settings has increased with our use of online learning approaches because engagement plays an important role in ensuring student success in these environments. Engaged students are more likely to complete online courses successfully, but this setting makes it more difficult for instructors to identify engagement. In this study, we developed predictive models for automating the identification of cognitive engagement in online discussion posts. We adapted the Interactive, Constructive, Active, and Passive (ICAP) Engagement theory [15] by merging ICAP with Bloom's taxonomy. We then applied this adaptation of ICAP to label student posts ($N = 4,217$), thus capturing their level of cognitive engagement. To investigate the feasibility of automatically identifying cognitive engagement, the labelled data were used to train three machine learning classifiers (i.e., decision tree, random forest, and support vector machine). Model inputs included features extracted by applying Coh-Metrix to student posts and non-linguistic contextual features (e.g., number of replies). The support vector machine model outperformed the other classifiers. Our findings suggest it is feasible to automatically identify cognitive engagement in online learning environments. Subsequent analyses suggest that new language features (e.g., AWL use) should be included because they support the identification of cognitive engagement. Such detectors could be used to help identify students who are in need of support or help adapt teaching practices and learning materials.

Keywords

cognitive engagement, Coh-Metrix, discussion forums, natural language processing (NLP), online learning

Educational theories and empirical studies have emphasized the importance of learner engagement [34]. Engaged learners are active; they invest time and effort during the learning process [44, 56, 66]. Empirical studies have corroborated the importance of engagement for student learning and well-being [39, 57, 74]. Studies have consistently found a significant association between student engagement and the cognitive and non-cognitive skills of students. For example, engaged students are more likely to be academically successful [89], retain knowledge [9], and show higher levels of critical-thinking [13] and problem-solving [61, 97]. Furthermore, engaged learners are more likely to show higher levels of school belongingness and socio-emotional well-being [22, 36, 73]. They are also less likely to drop-out [2, 3, 41] or demonstrate negative behaviors in school [62, 93]. Consistent with these general educational outcomes, a positive association between active participation in online discussion forums and academic achievement has been found [23, 51, 85]. Learner engagement, therefore, is a vital and predictive aspect of student learning and well-being [30].

Given that student engagement is a strong correlate of student achievement, researchers have long been interested in identifying student engagement levels to improve student success and learning processes. Identifying student engagement levels could be used to generate actionable feedback for students [52]. This feedback can be provided by instructors or through automated feedback that is delivered via learning dashboards or system features that nudge students to engage with the task.

However, identifying student (dis)engagement is difficult for instructors in online settings. In recent years, researchers have been interested in automating engagement identification. Automatically identifying students' engagement levels may also help instructors identify potentially at-risk students. Instructors may intervene to minimize the negative impact of disengagement on student learning. Furthermore, engagement detection could generate real-time feedback that instructors could use themselves. This critical feedback may be used to inform and evaluate the effectiveness of instructional practices employed in the class. Additionally, engagement detection could be embedded in instructor-facing analytics dashboards to help them understand student engagement in their classes [67]. Detecting that many learners are disengaged with the task could help instructors change their instructional strategy and practice, adjusting to meet the

needs of learners in their class [1, 68]. Providing instructors with information about learner engagement could also enable them to intervene in a timely manner [31].

Instructors can harness information that is easily obtained in face-to-face learning environments to observe student behavior and make inferences about how they are engaging. However, certain types of engagement (e.g., cognitive, affective) are not directly observable. Students may also feign engagement. Even if the form of engagement the instructor is interested in monitoring is easy to observe in person, that may not be the case in online settings. With the recent challenges that the COVID-19 pandemic has brought and the associated widespread use of online learning environments [69], the automated detection of learner engagement has become more vital yet more complicated. With the use of log data and dashboards, instructors could evaluate learner time within the system or time on task as an indication of behavioral engagement [67]. Unfortunately, proxies, such as time spent within a system, will not help an instructor extract the type of cognitive engagement that students demonstrate in online learning environments.

Many have tried to define student engagement, which is latent and inherently multi-faceted. Along with this, they have tried to model different types of learner engagement (e.g., academic, behavioral, affective, cognitive) in various learning contexts (e.g., online education, in-person classes). Typically, engagement is defined as students' motivation, willingness, effort, and involvement in school or learning-related tasks [19, 87]. It is operationalized as students' investment of resources such as effort, time, and energy into learning [53, 60, 61, 62].

Behavioral, emotional, and cognitive engagement are frequently studied types of engagement. Behavioral engagement is generally defined as time on task [18, 42, 50, 64, 94], and focuses on overt student behaviors [7]. Emotional engagement typically refers to learners' feelings, affect, and emotional reactions [77, 81, 83]. Cognitive engagement is conceptualized as employing learning strategies and investing effort and persistence into the task at hand [18, 42, 86, 94]. Different types of engagement are not mutually exclusive. For example, some researchers have argued that cognitively engaged learners are also behaviorally engaged, but the reverse is not necessarily true [50].

Cognitive engagement is one of the most challenging types of engagement to detect. Although there are certain theories developed for characterizing and capturing cognitive engagement in physical classroom settings (e.g., ICAP; [15]), they can be difficult to directly apply in online discussion environments, particularly in discussion forum posts (see [90]).

In this study, we focused on developing predictive models for automating cognitive engagement detection in discussion posts using natural language processing (NLP) and machine learning (ML) methods. This will help us evaluate the feasibility of automating cognitive engagement identification in online discussion posts. We will also analyze the classification errors and feature importance when predicting cognitive engagement through these relatively transparent models. Understanding feature importance and classifica-

tion errors may help us develop better models for detecting cognitive engagement.

2. ENGAGEMENT IDENTIFICATION APPROACHES

Dewan and colleagues [30] proposed an engagement detection taxonomy and grouped engagement detection methods under three main categories: manual (e.g., self-report measures), semi-automatic (e.g., engagement tracing), and automatic (e.g., log file analysis).

Manual engagement detection methods include self-report measures, checklists, and rating scales. Using self-report measures, students are asked to indicate their own engagement levels (e.g., [5, 12, 43]). Although it is easier to administer and use self-report measures [82], one major limitation of these instruments is their susceptibility to reporter biases. When learners rate their own engagement level, they may not accurately reflect their engagement during learning processes [35] because they lack the capacity to do so, or students may not reflect their true engagement status to avoid getting in trouble in a class (e.g., [45]). Therefore, self-report measures may not provide an objective evaluation of engagement.

The checklists and rating scales that instructors use are less prone to self-report biases (e.g., self-serving bias) during the coding process. Yet, checklists and rating scales also have certain limitations. Using these methods requires a great deal of time and effort [30]. For example, instructors, especially in large-scale classrooms or online environments, may not track each learner accurately. Learners may also pretend to be on task when in fact they are not engaged with the task. Hence, teacher evaluations made through such means may not accurately present the engagement levels of learners in class. Additionally, both self-report measures and checklists may not accurately capture fluctuations in learner engagement [90].

Semi-automatic engagement detection methods include engagement tracing. Using log or trace data, the timing and accuracy of learner responses have been employed to identify engaged and disengaged learners [8, 54]. For example, an unrealistically short response time is considered an indication of student disengagement during a quiz attempt.

Finally, automatic engagement detection methods include sensor data, log data, and computer vision-based approaches that analyze eye movement, body posture, or facial expressions [30]. These detection methods may automatically extract features from learners' body movement or facial expressions using sensor data as input [91]. Additionally, learner activities have been traced in learning management systems to automatically extract features related to engagement detection [16, 17]. These approaches may provide useful real-time information about student engagement, but they introduce privacy concerns such as being recorded.

2.1 Cognitive Engagement Frameworks

Two frequently employed cognitive engagement frameworks include Community of Inquiry (CoI; [46]) and Interactive, Cognitive, Active, and Passive engagement (ICAP; [15]).

The CoI framework identifies three elements (i.e., social presence, teaching presence, and cognitive presence) that support successful learning. The cognitive presence element of the CoI framework has been widely used by researchers (e.g., [58, 70]) for analyzing student learning and developing predictive models in online courses. In those studies, cognitive presence encompasses five phases: triggering event, exploration, integration, resolution, and other.

The ICAP framework [15] conceptualizes hierarchical cognitive engagement levels. Higher levels are related to higher cognitive engagement and learning growth. From top to bottom, the order of cognitive engagement levels is interactive, constructive, active, and passive.

Although both frameworks have been used to model engagement, they approach the categorization of engagement differently and have distinct aims [38]. The CoI framework specifically targets online learning environments and tries to model how students develop ideas in online discussions. The ICAP framework has been used to characterize learning in both in-person and online learning environments. It focuses on students' *active learning* behaviors [15]. Both frameworks appear to be promising theoretical approaches for cognitive engagement modeling and prediction. CoI focuses on different phases whereas ICAP focuses on different levels of cognitive engagement.

In a recent study, Farrow and colleagues [38] compared these engagement frameworks to decipher their commonalities and differences. They found similarities between the predictors used for engagement detection (e.g., message length was correlated with higher levels of engagement in both frameworks) whereas there were differences in the interpretation of classes (e.g., ICAP rewarded interactivity more than CoI).

2.2 Identifying Engagement in Online Environments

Some studies of online learning have used qualitative content analysis methods [90, 98] to detect engaged and disengaged learners. These studies start with developing a coding scheme reflecting different levels of engagement (e.g., active or passive engagement). This coding scheme is then used by the trained coders to manually label learner activities. This labelling process requires that considerable time and manual labor be invested, which is why it is not surprising that automating engagement identification via machine learning methods has emerged as a viable approach.

There are several potential benefits of automating cognitive engagement detection that go beyond the reduction in human fallibility and manual labor. These potential benefits include reducing coding time, rapidly identifying at-risk students in terms of engagement, and the possibility of integrating learner engagement information into dashboards and learning management systems. Moreover, automation can build on the prior work that manually labelled student engagement and helped us to understand it at a smaller scale.

Automated engagement detection methods in online environments can be divided into two groups [56]. The first group of studies focuses on automatically extracting features

pertaining to learners' physical cues such as body movement, heart rate, head posture, or where learners are looking (e.g., [55, 65]). In a recent study, Li and colleagues [65] extracted students' facial features and trained a supervised model to classify student cognitive engagement type. Although facial features were found to be powerful predictors of cognitive engagement, these types of studies may require webcams to extract learners' facial features, body posture, or head postures. Additionally, the learners could be aware of the fact that they are being recorded, which can lead them to experience discomfort [29]. Furthermore, the implementation of such systems may be costly (e.g., integrating webcams) compared with extracting learner trace data from learning management systems.

The second group of studies focuses on using a less sensor-heavy approach. They extract linguistic features (e.g., coherence, number of words) and trace data (e.g., time on task, number of clicks) from online learning environments to detect engagement (e.g., [6, 58, 59, 70]). For example, Kovanović and colleagues [58] employed n-grams and part-of-speech features to train a predictive model of cognitive presence using the CoI framework [46]. Their model achieved 58.38% accuracy ($K = .41$). In a similar study, Kovanović and colleagues [59] extracted features using Coh-Metrix, Linguistic Inquiry and Word Count (LIWC), and latent semantic analysis (LSA) similarity to represent average sentence similarity. Their best model achieved 72% accuracy ($K = .65$). Moving from the COI lens to that of ICAP, Atapattu and colleagues [6] used word embeddings from Doc2Vec to detect only the active and constructive levels of cognitive engagement in a MOOC, where they ignored posts that were of a social nature. They argued that learners with active engagement posts paraphrased, repeated, or mapped resources whereas learners with constructive posts proposed new ideas or introduced external material going beyond what was covered in class [6]. Therefore, discussion posts similar to course content remained in close proximity to the vector space generated by Doc2Vec. These posts were classified as active engagement whereas discussion posts that were far away from the vector space were classified as constructive engagement.

Some linguistic and course-based contextual features might limit the generalizability of predictive models (e.g., n-gram based models are sensitive to vocabulary choices) of cognitive engagement across different courses and contexts. For example, in a recent study, Neto and colleagues [70] analyzed model generalizability across educational contexts by employing Coh-Metrix features and the CoI framework. In their study, the baseline model was trained with a biology course dataset and achieved 76% accuracy ($K = .55$). When applied to a dataset from a technology course, the model had an accuracy of 67% ($K = .20$), which indicates some limitations to the generalizability of the model to new courses.

3. PRESENT STUDY

The purpose of this study is to evaluate the feasibility of automating cognitive engagement identification in fully online graduate courses through the lens of the ICAP framework. Given that engagement is a latent trait, researchers typically start with creating labeled data so that they can train supervised ML models. Most studies have employed CoI for

labeling cognitive presence (e.g., [37, 58, 70]).

ICAP and CoI have different aims and operationalizations of cognitive engagement (see section 2.1). In this study, we defined cognitive engagement as investing effort and cognitive resources. ICAP is more congruent with our cognitive engagement definition since we want to identify different levels of engagement in posts. Therefore, we employed the ICAP framework as our theoretical background that informed labeling decisions.

There is a lack of consensus concerning the coding scheme of ICAP for online environments even though the available coding schemes partly overlap with one another. For example, while Atapattu et al. [6] employed a binary coding scheme (i.e., active vs constructive), Yogev et al. [95] employed a coding scheme with six categories.

We first adapted the available coding schemes for online discussion posts by aligning the engagement levels with Bloom’s taxonomy [4]. This was done to emphasize the increased nature of cognitive complexity in both the taxonomy and cognitive engagement. Then, we developed three supervised ML models to analyze the feasibility of cognitive engagement prediction in online discussion environments. We also analyzed feature importance to evaluate whether we identified the same order of features across the classifiers employed in this study.

Our research questions were as follows:

RQ1: To what extent can a model trained with Coh-Metrix and contextual features be used to automatically classify discussion posts based on cognitive engagement level?

RQ2: Which features are more important for cognitive engagement prediction?

RQ3: What types of misclassifications occur?

4. METHODS

The data for this study consists of discussion forums from fully-online, graduate-level courses. The course forums differed in terms of facilitation method (i.e., peer-facilitated vs instructor-facilitated) and course length, i.e., regular-term courses (long) and summer-term courses (short).

4.1 Participants and Study Context

The data used in this study were collected from an online discussion platform that is used to deliver courses in a highly ranked college of education in Canada. The data collection protocol was reviewed and approved by the university’s research ethics board prior to completion. Participant consent was obtained for supplementary data collection. The dataset included 4,217 posts that had been produced by 111 students. In Table 1, we present the number of students, term length, facilitation method, and percentage of cognitive engagement posts in each course.

The courses span departments within the college and cover topics from language learning to educational psychology, educational technology, and educational policy.

Table 1: Number of students, term length, facilitation method, and percentage (%) of cognitive engagement levels by course.

ID	<i>n</i>	Length	Method	S	A	C	I
1	31	Long	Instructor	57	24	17	2
2	18	Short	Instructor	10	30	41	19
3	17	Short	Peer	44	22	12	22
4	22	Long	Instructor	24	31	23	24
5	23	Long	Peer	11	29	17	43

Note. Social (S), Active (A), Constructive (C), Interactive (I)

Demographic data were not collected and the previous deidentification of the data means that it cannot be obtained retroactively. It is worth noting that students could have their data excluded at the post level by marking it as private.

4.2 Data Coding Procedure

Our coding scheme is largely informed by the coding framework developed by Wang et al. [90] and Yogev et al. [95]. We altered and simplified the coding scheme based on the challenges we observed during the coding process.

We informed the coding scheme with Bloom’s revised taxonomy [4] and adapted it to reflect the higher-order cognitive complexity in the ICAP framework. Specifically, we map Bloom’s taxonomy level indicators onto cognitive engagement indicators. Bloom’s taxonomy was chosen because it is widely used by K-12 and higher education instructors to develop measurable and observable instructional objectives, tapping different levels of cognitive complexity. Cognitive complexity refers to the amount of cognitive demand required to complete a task. Higher levels of cognitive engagement necessitate higher effort investment and align with higher levels of cognitive complexity in Bloom’s taxonomy. Hence, we emphasized the presence of higher-order skills when identifying higher levels of cognitive engagement in the coding scheme.

Figure 1 shows the cognitive engagement coding scheme we used for labelling the discussion forum posts.¹ It highlights how the hierarchical nature of cognitive engagement aligns with Bloom’s taxonomy levels. For example, in the lower levels of the taxonomy, we have *remembering* and *understanding*. Active engagement corresponds to these levels in the taxonomy since posts with active engagement include elements of paraphrasing, mapping resources, and retrieving the same or similar concepts that are covered in class. Constructive engagement aligns with the level of *applying* and *analyzing* in Bloom’s taxonomy since these posts compare, contrast, illustrate, and argue in a cause and effect fashion. Finally, Interactive engagement relates to the levels of *evaluating* and *creating* in the taxonomy because these discussion posts make judgments and evaluations about the topics covered.

Our coding scheme included four categories: social, active, constructive, and interactive. The engagement categories are hierarchical, and social engagement is the lowest cate-

¹We cannot share the post content due to learner privacy.

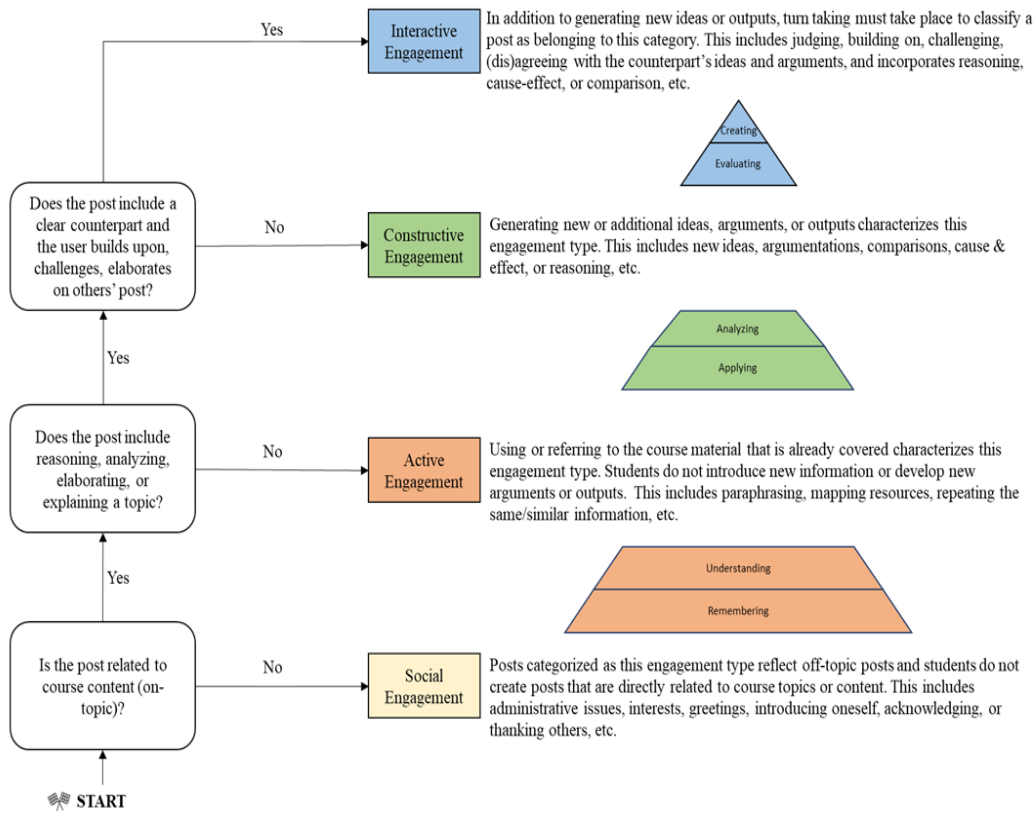

Figure 1: Cognitive engagement coding scheme.

gory followed by active, constructive, and interactive engagement. Note that we did not use *passive* engagement since our goal is not to categorize students’ engagement levels but rather to categorize the engagement observed in posts. Passive engagement entails that students read the posts but do not produce any posts, hence it cannot be employed for categorizing engagement in discussion posts. We also introduced a *social* engagement level corresponding to posts that are off-task and are meant to support relationship building (e.g., students introducing themselves).

Based on the coding scheme, we first identified whether the posts were on-task or off-task. Then, we asked whether the post exhibited reasoning, argumentation, or elaboration on a topic. Finally, we asked whether there was an evaluative argument and a clear counterpart in each post. While coding the posts, we assigned the highest engagement level observed in each post.

The coding was done by two content experts (Authors 1 and 2) who had previous experience with data coding and who were familiar with the cognitive engagement literature. First, we had a training session where we coded a sample of discussion posts, identified challenges, and reconciled discrepancies during the coding process. After the training session, we each coded a sample of discussion posts independently and we checked agreement between raters using the percent agreement method. We had an inter-rater reliability of .91.

Table 2: Distribution of cognitive engagement levels

ID	Label	Engagement Type	Number (%)
0		Social	1197 (28)
1		Active	1173 (28)
2		Constructive	930 (22)
3		Interactive	917 (22)

Table 2 shows the distribution of the four levels of cognitive engagement across all posts. The most frequently observed levels of cognitive engagement were social (28%) and active (28%). Given that constructive and interactive levels of engagement require higher cognitive effort and complexity, we expected to observe fewer constructive and interactive engagement level posts. Even though we expected to observe class imbalances based on previous studies (e.g., [38, 70]), we had a nearly balanced distribution of cognitive engagement levels. This might be due to the class structure where some instructors relied on peer facilitation as a management strategy for the course forums. Alternatively, having graduate-level courses could explain this balance.

4.3 Feature Extraction

This study used Coh-Metrix and non-linguistic contextual features to classify the cognitive engagement level seen in discussion posts.

Coh-Metrix is a tool used for discourse analysis. It estimates the cohesion, coherence, linguistic complexity, read-

Table 3: Hyperparameter search space used for model tuning

ML Classifier	Parameters	Values
Decision Tree	Max depth	3, 6, 9, 12, None
	Min samples leaf	A random integer between 1 and 10
	Max features	A random integer between 1 and 10
	Criterion	'Gini', 'Entropy'
Random Forest	Max depth	3, 6, 9, 12
	Min samples leaf	2, 4, 6, 10
	Max features	5, 10, 20, 30, 40, 50, 60, 70, 80, 90, 100, 107
	Number of estimators	500, 1000
	Min samples split	5, 10
	Criterion	'Gini', 'Entropy'
	Bootstrap	'True', 'False'
Support Vector Machine	Kernel	'linear', 'sigmoid', 'poly', 'rbf'
	C	50, 10, 1, 0.1

ability, and lexical category use in a text [32]. The English version of Coh-Metrix incorporates 108 features including referential cohesion, deep cohesion, and narrativity [33]. In previous studies on text classification, Coh-Metrix and contextual features were shown to be promising for cognitive presence identification (i.e., Community of Inquiry; [70]), suggesting their potential for supporting cognitive engagement detection in online discussion environments.

In addition to the Coh-Metrix features, we included three contextual features. These contextual features included information about whether a discussion post is a reply to another post, the number of replies that the post had received, and a count of the use of vocabulary from the academic word list (AWL) [20]. Whether a post is a reply was a binary variable, the number of replies a post received was an integer, and AWL count was an integer representing the total number of academic words in a post.

4.4 Data Pre-processing

To clean and prepare the corpus for training and classification, we ran several pre-processing steps. Our goal was to build a cognitive engagement classifier, thus we tried to create a corpus that was as clean and close to human readable form as possible [32]. We removed website links and “see attached” notations; stripped the html tags, eliminated new lines, white spaces, and tabs; expanded contractions; removed numbering and bullet points; and corrected misspelled words.

Because our unit of analysis was discussion posts, we created separate files for each post after applying the above data cleaning steps. We then ran Coh-Metrix 3.0 [47] to extract linguistic features for each post. All discussion posts have a single paragraph, so we removed the Coh-Metrix indicators of paragraph count (i.e., DESPC), standard deviation of the mean length of paragraphs (i.e., DESPLd), the mean of the LSA cosines between adjacent paragraphs (i.e., LSAPP1), and the standard deviation of LSA cosines between adjacent paragraphs (i.e., LSAPP1d). Finally, we created a data file containing all of the input features and the class labels. The input features included the 104 Coh-Metrix indicators and three other non-linguistic contextual features (e.g., whether a post is a reply). This data file was then used to train our

classifiers for cognitive engagement prediction.

4.5 Model Selection

To train and test models for predicting cognitive engagement, we split the dataset in two: 70% was used as a training set and the remaining 30% was used as a test set.

To answer our research questions, we trained three types of supervised classifiers:

- a **decision tree** (DT) [10] was selected because this approach is easier to interpret and the graphical representation of the tree can help us understand the relative importance of features;
- a **random forest classifier** (RF) [80] was chosen because it is an ensemble method that often exhibits superior performance on classification tasks in educational contexts (e.g., [59, 70]); and
- the **support vector machine** (SVM) [21] algorithm was chosen because it is designed to handle multidimensional data which may lead to superior performance when predicting cognitive engagement in discussion posts [40].

In addition to the above attributes, these types of models have previously performed well in other forum classification tasks [88] or they have supported educational data mining tasks with similarly sized or smaller data sets [25, 78]. Moreover, these classification algorithms are relatively transparent so they can aid us in understanding the contribution of each feature to cognitive engagement prediction.

4.6 Model Tuning

Model training, hyperparameter tuning, and analyses were conducted in Python (Version 3.8.8) using the sklearn [71] and mlxtend [75] packages.

We tuned the hyperparameters of each classifier using randomized search with 10-fold nested cross-validation. In Table 3, we summarize the hyperparameters and values used to tune the models for each classifier. For the decision tree,

Table 4: Model performance by model and cognitive engagement level (Cog. Engage.)

Cog. Engage.	Decision Tree				Random Forest				Support Vector Machine			
	P	R	F1	Acc. (%)	P	R	F1	Acc. (%)	P	R	F1	Acc. (%)
Social	.65	.70	.68	.71	.77	.74	.76	.73	.79	.83	.81	.83
Active	.50	.46	.48	.46	.56	.56	.56	.52	.60	.54	.57	.54
Constructive	.71	.58	.64	.62	.74	.69	.71	.68	.77	.73	.75	.73
Interactive	.55	.65	.59	.64	.60	.68	.64	.70	.64	.73	.68	.73
Full	.59	.58	.58	.60	.66	.66	.65	.66	.70	.71	.70	.71

the best model performance was obtained with max depth = 6, criterion = Gini, max features = 106, and min samples leaf = 7. For RF, the best model performance was obtained with max depth = 40, criterion = entropy, and number of estimators = 600. The best performing SVM model was obtained with kernel = linear and regularization (C) = 0.1.

The best model achieved 68% accuracy for the decision tree, 95% accuracy for random forest, and 85% for SVM on the training set.

4.7 Model Comparison and Analysis

We evaluated classifier performance with the test set using accuracy (Acc), Cohen’s Kappa (K), precision (P), recall (R), and F1 using 10-fold cross-validation. We use Landis and Koch’s guidelines to interpret Cohen’s Kappa, where values below .20 indicate slight agreement, values between .21 and .40 indicate fair agreement, values between .41 and .60 indicate moderate agreement, values between .61 and .80 indicate substantial agreement, and values greater than .81 indicate strong agreement [63].

We also statistically compared the model performance using Cochran’s *Q* test. Cochran’s *Q* test is a generalized version of McNemar’s test and it can be used to compare more than two classifiers [76]. The null hypothesis for Cochran’s *Q* test states that there is no difference between model classification accuracies. We also used McNemar’s test, a non-parametric statistical test, to perform the subsequent paired comparisons [76]. We report continuity corrected *p*-values for paired comparisons.

We analyzed feature importance across models to evaluate feature contribution towards cognitive engagement identification. For the decision tree, we evaluated feature importance with the Gini index. For random forest, we used the Mean Gini Decrease value to evaluate the features with the most explanatory power. For the support vector machine, after hyperparameter tuning with kernel and regularization parameter (C), we evaluated the feature importance by comparing the size of the support vector coefficients with one another.

4.8 Error Analysis Procedures

To better understand the classification errors, we analyzed the confusion matrix and the misclassified discussion posts. The confusion matrix allowed us to analyze the number of errors across models. We also compared the error rates (instead of the absolute number of errors) by dividing each value in the confusion matrix by the number of posts in the corresponding class and depicted the model performance in Figure 3. The rows represent the actual (human-assigned)

labels; the columns represent the predicted labels. This procedure allowed us to, first, identify which types of cognitive engagement tend to be misclassified as another type. Second, we compared the descriptive statistics of predictors of those misclassified posts to examine the reasons for misclassification.

5. RESULTS

5.1 RQ1: Model Performance

In Table 4, we provide the performance measures (i.e., precision, recall, F1 score, and accuracy) for all three models by cognitive engagement level. We also provide these measures for the full model (i.e., when all classes are being considered). Note that the accuracy of the zero-rule classifier for the full model would be 28.4%. As can be seen in Table 4, all of the models outperformed this simple baseline. Moreover, Cochran’s test revealed statistically significant differences between the classifiers we built, $Q = 55.68$, $p < .001$. We report the results of specific paired model comparisons below.

For the decision tree, we obtained 60% accuracy (K = .46) for the full model. If we consider the F1 scores for each level of cognitive engagement within the decision tree model, we can see that it did a relatively good job of predicting social and constructive engagement. Whereas, active engagement scored below .5 on all of precision, recall, and F1. While this is better than chance, these are the lowest performance measures observed across all three models.

The accuracy of the random forest classifier was higher than that of the decision tree (McNemar’s $\chi^2 = 21.70$, $p < .001$). However, this increased accuracy was not accompanied by a change in agreement-level (K was .55). Again, we consider the model’s relative performance across levels of cognitive engagement, which showed that it performed best when predicting social and constructive engagement. It also performed relatively well for interactive engagement.

The support vector machine classifier outperformed both the decision tree (McNemar’s $\chi^2 = 61.31$, $p < .001$) and the random forest (McNemar’s $\chi^2 = 19.04$, $p < .001$) models on the full prediction task. The SVM model’s Kappa value (.61) suggested substantial agreement between the predicted and human-assigned labels [63]. Similar to the models trained with the random forest and decision tree algorithms, we obtained the best model performance for social and constructive engagement followed by interactive and active engagement.

5.2 RQ2: Feature Importance

Figure 2: The feature importance scores for the 20 most important features for cognitive engagement prediction using random forest.

To evaluate feature importance for predicting cognitive engagement and answer our second research question, we first analyzed the decision tree classifier. The classification tree suggested that the most important predictor was the academic word list count (AWL Count), followed by whether a post is a reply, Flesch-Kincaid grade level (i.e., Coh-Metrix indicator of RDFKGL), and number of words (i.e., DESWC from Coh-Metrix).

To interpret the random forest classifier, we used the mean decrease in Gini coefficient because it supports the evaluation of the contribution of each feature to the model’s prediction [48]. Higher values of mean decrease in Gini score indicate that the feature contributed more when performing the prediction. Similar to the decision tree model, we found that the most important features were the number of words (i.e., DESWC), number of academic word list items (AWLCount), type-token ratio for all words (LDTTRa), and Flesch-Kincaid grade level (RDFKGL). Figure 2 shows this model’s most important twenty features and their relative weights.

For the support vector machine model, we evaluated the coefficient importance and found that the most important feature was second language readability (RDL2). This feature was followed by type-token ratio (LDTTRc), the standard deviation of the number of syllables in words (DESWLsyd), and LSA overlap between verbs (SMCAUSlsa).

We found that the decision tree and random forest models identified the same features as most important, yet their relative contribution to the prediction task changed across models. The support vector machine, on the other hand, identified a different set of features as most important.

5.3 RQ3: Error Analysis

All classifiers provided better prediction performance for social and constructive engagement (see Table 4). Table 5 presents the confusion matrix for the classifiers. The superior performance of the support vector machine model is evident in Table 5, where the misclassification of posts was the lowest across engagement categories.

We analyzed the performance measures and evaluated precision, recall, and F1 scores for each classifier and engagement category. This showed the jump between the precision and

Figure 3: Classification error rates for decision tree, random forest, and support vector machine.

recall measures for constructive and interactive levels for the decision tree. For decision tree, the true positive rate was 65% for the interactive posts; that is, the classifier missed 35% of the interactive posts that should have been labelled with interactive. On the other hand, 45% of the posts were incorrectly identified as interactive. Furthermore, the true positive rate was 71% for the constructive posts. That is, the decision tree missed 29% of the constructive posts that should have been labelled with constructive, and 58% of the posts with other engagement levels were incorrectly identified as constructive.

The length of the posts and the smaller AWL count seem to be the primary reasons why social and active engagement posts were confused with each other. For misclassified social engagement posts, the mean post length ($M_S = 134$), AWL count ($M_S = 19.25$), and Flesch-Kincaid grade level ($M_S = 12.4$) were similar to the mean post length ($M_A = 138$), AWL count ($M_A = 12.93$), and Flesch-Kincaid grade level ($M_A = 11$) of active engagement posts. For the misclassified interactive posts, we observed a similar pattern. The mean post length ($M_I = 129.5$), AWL count ($M_I = 17.9$), and Flesch-Kincaid grade level ($M_I = 12.65$) were similar to those extracted from the active posts.

Additionally, the confusion matrix (Table 5) suggested that all classifiers tend to misclassify social engagement with active engagement. Of those misclassified posts, approximately 70% of social posts were classified as active engagement across the predictive models. That is, social engagement was incorrectly grouped into the higher level. The active engagement level tended to be misclassified as social engagement, indicating model confusion between adjacent engagement categories. Of the misclassified active posts, approximately 55% of them were classified as social engagement across all predictive models. In contrast, constructive engagement tended to be misclassified as interactive engagement across all classifiers. Of the misclassified constructive posts, approximately 40% of them were classified as interactive engagement across all predictive models. Effectively, this means that it was incorrectly grouped into the higher level. Misclassifications of interactive engagement went in the opposite direction and were not for the neighbouring class. Rather, these errors were classified as active engagement instead of their being recognized as interactive posts. Of the misclassified interactive posts, approximately 60% of them were classified as active engagement across all predictive models. One possible explanation for this misclassification is as follows: Active and interactive discussion posts tended to be shorter in length compared with those at the

Table 5: Confusion Matrix for Decision Tree, Random Forest, and Support Vector Machine

		Decision Tree				Random Forest				Support Vector Machine			
		S	A	C	I	S	A	C	I	S	A	C	I
Predicted	Social (S)	244	72	11	22	258	66	12	13	289	44	6	10
	Active (A)	89	158	33	62	69	190	30	53	67	185	36	54
	Constructive (C)	22	38	175	65	1	33	206	60	5	30	218	47
	Interactive (I)	18	49	29	179	6	53	29	187	4	47	23	201

constructive engagement level. Although constructive posts, in general, had higher word counts ($M_C = 339$) and AWL counts ($M_C = 40.3$), some of the misclassified active posts were shorter. This conflicted with the fact that constructive posts expanded course content with reflections and argumentation and were thus expected to be longer with greater use of academic vocabulary. This expectation did not hold in all cases and may explain why constructive engagement posts were misclassified as interactive.

To further evaluate misclassification errors for each classifier, we plotted model error rates. Figure 3 shows the kinds of errors that the decision tree, random forest, and support vector machine made. Rows represent actual classes and columns represent predicted classes. Across all models, social, constructive, and interactive engagement were less likely to be misclassified with each other. For the model trained with SVM, active and constructive as well as the active and interactive engagement levels were less likely to be misclassified with one another.

6. DISCUSSION

The purpose of this study was to develop models that identify cognitive engagement in online discussion forums. Using the post features that were extracted with Coh-Metrix, we trained three classifiers. Employing transparent classifiers allowed us to more easily evaluate feature importance for cognitive engagement prediction. We also conducted an error analysis to better understand the classification errors across models. Below, we discuss the implications of our findings in the context of each research question.

6.1 Feasibility of Automating the Prediction of Cognitive Engagement

Of the three types of predictive models we trained (i.e., decision tree, random forest, and support vector machine), the support vector machine performed sufficiently well for it to be used to identify engagement levels in discussion posts.

Previous studies generally focused on cognitive engagement prediction using the random forest algorithm and the CoI framework. We used a different cognitive engagement framework (i.e., ICAP), and our best model (SVM) demonstrated similar accuracy (70.3%) and Cohen’s kappa values ($K = .63$) to those that used random forest under the CoI model of cognitive presence (e.g., [38, 59]).

The development of these models is the first step towards supporting instructors who want to be able to identify student engagement so that they can improve their teaching practices and intervene when student engagement levels are

low. These types of analytics fall into the category of those desired by instructors as they capture aspects of student post quality that are not currently available in most dashboards [1]. The models could be used to inform instructors about the engagement status of students in online course discussions. Given model performance, it would be important to effectively communicate uncertainty in its labelling of student posts [24]. Approaches, such as those suggested by Brooks and Greer [11], could be used to mitigate the risk of instructors relying on misclassified data so that they appropriately trust the output of the model and act in accordance with its limitations. For example, the system could identify the students who are disengaging to warn instructors so that they adjust their teaching and instructional practices. Additionally, such systems could be used to nudge students to better engage with tasks or to recommend posts that may enhance student engagement levels [14].

6.2 Feature Importance for the Prediction of Cognitive Engagement

By investigating how different features contribute to model performance, we can better understand the underlying phenomena which, in turn, will support the development of better predictive models for detecting cognitive engagement. Our study also provided further empirical evidence of feature importance, corroborating the findings of previous studies.

Both the decision tree and random forest feature importance analyses identified similar features (e.g., AWL count, Flesch-Kincaid grade level, word count). The features identified for the models in the present study were consistent with previous studies (e.g., [38, 59]). Similar to these previous studies, we found that higher levels of cognitive engagement were associated with longer messages. Our work builds on this by highlighting the importance of vocabulary use through the AWL count feature, which was not included in the other studies. Rather, those studies captured vocabulary through other means (e.g., Linguistic Inquiry and Word Count [84]). Our findings indicate that the use of academic vocabulary, like those in the AWL, that are not specific to a discipline (words such as hypothesis, conclude) support the identification of cognitive engagement. Moreover, their more general nature means that they should support generalization across courses at similar academic levels.

6.3 Interpreting Classification Errors

Classification errors occurred between the active and social engagement labels. Across all of the algorithms we used in our study, the worst performance was observed for active engagement. In a recent study, Farrow and colleagues [38] also found similar results for their prediction of active

engagement using random forest and the CoI framework. However, they did not perform an error analysis.

Our analysis of active and social engagement classes suggested that median word count, median AWL count, and Flesch-Kincaid grade level were similar for these two engagement levels. Furthermore, the dispersion of predictor values for active engagement was wide, overlapping with the range of predictors of other engagement levels. This helps explain what may have contributed to the poor performance of models for active engagement identification. Constructive engagement, on the other hand, had more distinct dispersion than other engagement levels, which could explain why the models were more successful when predicting constructive engagement. These results suggest the importance of having distinct engagement categories for successfully differentiating the vector space, thus achieving higher model performance and accuracy across engagement categories.

6.4 Limitations and Future Directions

Like all models, ours capture certain characteristics of student engagement and the decisions we made influence both their accuracy and the extent to which they are expected to generalize to other settings. We discuss these issues below and their potential for creating new opportunities for the development and use of models in online-learning settings.

The overall performance of the models suggests there is room for improvement. Nonetheless, these models can provide a snapshot of the engagement level in each post, providing an early signal of student engagement in online learning environments. This signal could help instructors to derive insight from this student-engagement data.

We labelled the data with the highest engagement level observed in a post. However, different cognitive engagement levels (e.g., social and constructive) may co-exist in a single post. While this type of coding approach is commonly employed [90], it may have limited the performance of our classifiers. It also prevents a more nuanced understanding of the types of cognitive engagement demonstrated by students. To support more nuanced representations of student engagement, future research can consider the co-existence of different engagement levels or how engagement relates to different areas of a course using something akin to aspect-based sentiment analysis [96].

Another limitation of our study is that we focused on identifying cognitive engagement in online discussion posts. That is, posts are classified rather than students. Because engagement may fluctuate based on course content or a weekly basis, we employed post-level analyses, which is a common practice in such research (e.g., [38, 70]). However, this may influence performance metrics. Future research can focus on how to derive an appropriate measure and representation of a student's cognitive engagement based on the varied levels of engagement that are exhibited across their posts. Perhaps more importantly, students who did not post to the discussion forums or those who only read posts and did not create messages (i.e., online listeners [92]) have not been included because there were no posts from these students. Alternative mechanisms need to be found to characterize their engagement through a listening lens. Since simply opening

a post is not enough to infer cognitive engagement, proxy measures may need to be developed. Behavioural patterns such as the ratio between the re-reading of posts and posts made [1, 72] or scan-rate [49] may provide reasonable signals of online listener engagement.

7. CONCLUSION

In this study, we gauged the feasibility of automating cognitive engagement prediction through NLP and ML methods. We first manually coded over 4,000 posts using the coding scheme we adapted from ICAP and Bloom's taxonomy. Then, we extracted linguistic and contextual features and trained three machine learning classifiers to predict the level of cognitive engagement demonstrated in a forum post. We obtained promising results with a support vector machine.

Now that we have models that can identify the highest level of cognitive engagement seen in a single post, we can start to consider how other factors might interact with student cognitive engagement. For example, we know that the course structure, length, and facilitation method influence student participation [72], language use [27], and social support [26, 72]. Additionally, the system used to deliver a course can influence student engagement [28, 79]. Future research could improve cognitive engagement identification by integrating such information.

This work makes several contributions, with some at the theoretical level and others at the empirical level. First, we mapped cognitive engagement levels onto Bloom's taxonomy. Bloom's taxonomy places cognitive complexity in hierarchical order, as does our ICAP-based cognitive engagement coding scheme. Second, this study illustrated the utility of different classifiers for cognitive engagement prediction in graduate-level online courses. Our analysis of the importance of model features and errors is consistent with previous studies; it confirmed the importance of word count for predicting cognitive engagement and revealed the importance of AWL count and Flesch-Kincaid grade level for predicting cognitive engagement. Future studies can include these features and use a support vector machine to develop a predictive model for cognitive engagement in online learning environments. Building on this work will enable the development of better models that can then be used to inform teaching and learning when online discussion forums are part of course delivery.

8. ACKNOWLEDGEMENTS

This work is supported in part by funding from the Social Sciences and Humanities Research Council of Canada and the Natural Sciences and Engineering Research Council of Canada (NSERC), [RGPIN-2018-03834].

ABSTRACT

In collaborative problem solving (CPS), people’s actions are interactive, interdependent, and temporal. However, it is unclear how actions temporally relate to each other and what are the temporal similarities and differences between successful vs. unsuccessful CPS processes. As such, we apply a temporal analysis approach, Multilevel Vector Autoregression (mIVAR) to investigate CPS processes. Our data were collected from college students who collaborated in triads via a video-conferencing tool (Zoom) to collaboratively engage a physics learning game. Video recordings of their verbal interactions were transcribed, coded using a validated CPS framework, and organized into sequences of 10-second windows. Then, mIVAR was applied to the successful vs. unsuccessful CPS sequences to build temporal models for each. A comparison of the models together with a qualitative analysis of the transcripts revealed six temporal relationships common to both, six unique to successful level attempts, and another eight unique to unsuccessful level attempts only. Generally, for successful outcomes, people were likely to answer clarification questions with reasons and to ask for suggestions according to the current game situation, while for unsuccessful CPS level attempts, people were more likely to struggle with unclear instructions and to respond to inappropriate ideas. Overall, our results suggest that mIVAR is an effective approach for temporal analyses of CPS processes by identifying relationships that go beyond a coding and counting approach.

1. INTRODUCTION

Collaborative problem solving (CPS) is a process where multiple people pool knowledge, skills, and efforts to solve complex problems [1, 26], and can be an effective approach compared to working individually [27, 28]. For example, in one study, pairs of people performed better than single individuals in discovering scientific laws [27]. In recent decades, CPS has appeared in more and more contexts such as schools [26, 36], online learning [34] and military tasks [41], and is recognized as an essential 21st century skill [1, 26].

But what exactly does CPS entail? Swiecki et al. argued that CPS is an interactive, interdependent, and temporal process [41]. Specifically, a typical CPS process involves two types of interactions: 1) people-task interactions where people interact with the environment or tools to solve problems [3] and 2) people-people interactions where team members interact with each other (e.g. exchanging information or coordinating behavior) to facilitate taskwork [23]. Interdependence refers to the fact that people rely on other people’s contributions to complete tasks, such as incorporating other people’s work/ideas into the solution and getting help from other people [25, 21]. Temporality refers to the fact that actions are produced as a series of inter-connected steps, and the strength of these connections relates to the temporal distance of the actions (the larger the distance, the weaker the connection) [8]. Thus, actions taken by the team at a certain time have an impact on the actions that the team will take in the near future, but this impact diminishes as time goes on. For example, when a question is asked, there is an immediate increase in the likelihood that the question will be answered, but this likelihood decreases as time progresses.

Since CPS is interactive, interdependent, and temporal, people’s behaviors ostensibly affect how tasks will be explored and whether tasks will be completed successfully or unsuccessfully. Emerging research has focused on discovering relationships between team behaviors and problem solving success [42, 1, 17, 6, 39]. However, as reviewed below, most existing work has investigated CPS behaviors independently, without effectively considering the interaction and interdependence between them [42, 1, 17]. This raises the following questions that motivate our work: how do teammates’ be-

haviors temporally relate to each other and what are the temporal similarities and differences between successful vs. unsuccessful CPS processes?

Further, with rapid development of remote collaboration tools and the high risk imposed by COVID-19 for holding face-to-face meetings, more and more collaborations are carried out remotely. Although remote collaboration has many advantages, it also narrows the communicative bandwidth [29]. For example, gesturing to physical objects is much more complex than in face-to-face communication [40] and certain patterns of social-visual attention (e.g., mutual gaze) are disrupted [43]. Given the necessity and challenges of remote collaboration, we focus on investigating the temporal dynamics of behaviors in remote CPS contexts.

2. RELATED WORK

Our literature review mainly focuses on two aspects of CPS processes related to our study: 1) successful vs. unsuccessful CPS and 2) temporal analysis of CPS behaviors.

2.1 Successful vs. Unsuccessful CPS Processes

Prior research has applied several methods to investigate CPS processes, such as qualitative analysis [2], coding-and-counting [1, 17, 6], and temporal analysis [6, 39]. For qualitative analysis, Barron studied face-to-face collaboration while solving math problems [2] using data from two three-person teams whose verbal interactions during collaboration were coded with three distinct functions: 1) articulation of solutions, 2) repetitions of proposals, and 3) responses to proposals. A qualitative analysis on the conversations revealed that successful CPS exhibited more effective mutual exchanges, better joint engagement, and shared goals.

Coding-and-counting analyses mainly count the occurrence of particular behaviors/actions and relate them to a desired outcome [42, 1, 17, 6, 39]. For example, Tausczik et al. analyzed data from an online mathematical problem solving community (MathOverflow) [42]. They first human-coded the discussion data with five distinct behavioral indicators and then built regression models to discover the association between indicator occurrences and solution quality [42]. Results showed that clarifying questions, critiquing answers, revising an answer and extending an answer significantly predicted solution quality. Similarly, Andrews-Todd et al. applied coding-and-counting to analyze college students' chat texts generated while collaboratively solving simulated electronics problems [1]. Based on the coded behaviors, they categorized students into four groups by a 2×2 median split - social (high vs. low) \times cognitive (high vs. low). Analysis results showed that the low social - low cognitive group performed worse than the other three groups. Additionally, having at least one high social - high cognitive student in the team could increase performance.

A few studies applied basic temporal analyses of CPS behaviors in addition to coding-and-counting methods. For example, Hao et al. analyzed CPS skills at the unigram and bigram levels [17]. They manually coded participants' collaboration chat texts generated while completing simulation-based tasks with four skills: sharing ideas (Share), negotiating ideas (Negotiation), regulating problem solving (Regulation), and maintaining communication (Maintain). Re-

sults indicated that at the unigram level (i.e., individual skills), effective CPS processes contained more negotiation than ineffective processes. At the bigram level (e.g., Share-Negotiation), effective processes had more share \rightarrow negotiate, negotiate \rightarrow share, regulate \rightarrow share, and negotiate \rightarrow negotiate patterns.

In another study, Chang et al. applied coding-and-counting and lag sequential analysis to examine students' interactions in simulated CPS scenarios [6]. Participants collaborated as triads (teams of three) via a chat box to solve physics problems. The chat texts were coded based on the Programme for International Student Assessment (PISA) CPS framework [26]. A counting based analysis indicated that successful groups had a high percentage (out of the total number of actions taken by the group) of two actions: 1) monitoring and reflecting on what they have done and 2) discussing the actions to take. Temporal lag sequential analysis showed that some students who engaged in trial-and-error failed to solve the problem in the end, while those demonstrating effective reasoning were more likely to solve the problem successfully. Similarly, Sun et al. applied coding-and-counting together with a pattern analysis approach to examine remote collaboration while students played a physics learning game [39]. Audio recordings of their verbal communications were transcribed and coded based on a validated CPS framework [38]. A coding-and-counting analysis showed that certain actions (e.g. discussing appropriate ideas, confirming understanding) were predictive of success in the game. Pattern analysis examining the co-occurrence of actions within short temporal windows revealed the importance of forming interactive communications among team members to establish common ground and support each other.

In sum, results from prior research suggested that CPS success is associated with both the occurrences of individual actions [2, 42, 1, 17] and connections between actions [17, 6, 39]. However these studies mainly utilized coding-and-counting to examine CPS success [42, 1, 17], and the temporal analyses were limited [17, 6, 39]. Next, we review studies that go beyond basic counts of individual behaviors by investigating temporal relationships of CPS behaviors.

2.2 Temporal Analysis of CPS

Prior work on temporal analyses of CPS has mainly focused on detecting the connections between individual actions from team interaction sequences [19, 7, 41, 9, 30, 22]. For example, Kapur applied lag sequential analysis to discover the most frequent communication patterns that emerged in CPS discussions [19]. Participants in the study coordinated in triads via online text chat to solve physics problems. Two experimental conditions (well-structured vs. ill-structured problems) were compared. The resultant chat texts were coded based on the Functional Category System framework [31]. Then, lag sequential analysis was separately applied to each condition to compute the transition frequency between indicators in consecutive utterance pairs. A comparison of the two resulting models showed that the ill-structured condition had several temporal between-action connections that occurred at least twice as frequently as those in the well-structured condition, whereas the well-structured condition had no such connections. This is a finding that coding-and-counting approaches did not reveal.

Csanadi et al. applied epistemic network analysis to investigate collaboration and thought processes of problem solving [7] and compared it with a coding-and-counting analysis. In that study, pre-service teachers were asked to reason about a pedagogical problem either in pairs or individually (following a think aloud protocol). Audio recordings of the discussions were segmented into propositional units, and coded with eight distinct indicators. Then epistemic network analysis was applied by sliding a window of two utterances on the coded sequences to discover co-occurrences of indicators. Based on the co-occurrence frequencies, a weighted, undirected graph was generated to represent the connections between indicators. A comparison of the networks for dyads and individuals showed that these two conditions had different indicator co-occurrence patterns. Again, the coding-and-counting analysis did not reveal such a finding.

Similarly, Swiecki et al. also applied epistemic network analysis to investigate the verbal interactions between team members in simulated military training scenarios [41]. In that study, 16 Navy air defense warfare teams performed the detect-to-engage sequence, which detects and identifies vessels or tracks, assesses whether tracks are threats, and decides what actions to take. Each team consisted of six roles and the analysis focused on the interactions between the tactical action officer and the other five members. Audio recordings of the verbal interactions were transcribed and coded via an automated coding scheme (nCodeR) [24]. Two conditions using a standard system (control) vs. a decision support system (experimental) were compared. In the epistemic network analysis, a sliding window of 5 utterances was applied to discover the temporal co-occurrence of indicators. Results showed that in the control condition, the tactical action officers frequently sought out information, while in the experimental condition, they mainly contributed information about the tactical situation. Again, the coding-and-counting analysis did not reveal such a finding.

Besides examining coded sequences, researchers have also investigated other types of sequences such as transcripts [9] and log traces [30, 22]. For transcripts, Dowell et al. applied group communication analysis to detect roles that emerged during group collaboration [9]. The analysis relied on computational linguistic techniques to map utterances into a latent semantic space (a n -dimension numerical space) upon which six measures were defined to describe the profile of each individuals' verbal contributions (e.g. social impact, overall responsivity, newness). Then, k -means clustering was applied to the profiles to detect emerging roles, resulting in six clusters with unique characteristics (e.g. "high social impact, responsiveness, and internal cohesion"). For log trace analysis, Perera et al. used sequential pattern mining to examine the process of competing a group course project for software development [30]. In that study, students collaborated in an online learning environment which logged events of group wiki editing, ticket management, and version changes. The event sequence of each group was then segmented into shorter sequences and sequential pattern mining was used to count the frequency of consecutive events (patterns) for each team. The analyses identified patterns (e.g., "1 version activity by 1 author" followed by "1 ticket activity by 1 author") that can distinguish the well-performing teams from the ill-performing ones.

2.3 Research Questions and Contributions

As reviewed above, researchers are beginning to uncover the specific behaviors - both individually as well as behavioral sequences - that predict CPS outcomes. Prior studies indicate that there are meaningful and detectable temporal connections between people's verbal actions (or problem solving actions) in CPS processes [19, 7, 41, 9]. Further, temporal analyses are sometimes more effective than coding-and-counting analyses for understanding collaborations [19, 7]. In the current study, we continue this line of research by utilizing multi-level vector autoregression (mlVAR) for a temporal analysis of CPS behaviors. mlVAR is a network analysis approach that examines temporal connections between actions in consecutive windows via linear mixed-effects models, thereby accounting for clustered/nested data. Specifically, for each variable in window t , mlVAR builds a linear model that uses all the variables in the $t - 1$ window to predict its value. mlVAR has been successfully applied in many domains, such as patient-physician interactions [16] and symptom-psychopathology interplays [10]. However, to our knowledge, it has yet to be utilized to investigate collaborative problem solving behaviors.

Towards this goal, we analyzed data from a study where students collaborated in triads via video conferencing to play a physics learning game. Next, we transcribed and segmented recordings of students' verbal communication into utterances, human-coded each utterance based on a validated CPS framework [39] and aggregated the occurrence of indicators with 10-second windows. We then applied mlVAR to the resultant multivariate time series to generate temporal graphs depicting relationships among indicators. Our primary research question is what are the temporal similarities and differences between successful vs. unsuccessful CPS interactions. We investigate this question by building separate mlVAR models for multivariate behavioral sequences associated with successful vs. unsuccessful CPS outcomes (i.e., solving a game level vs. failing to solve a level). Then, we compare the two resultant networks to discover the similarities and differences and conduct a qualitative analysis to further examine what interactions may facilitate CPS and what are the challenges people may face during CPS.

Our work extends existing CPS research in several ways. Whereas temporal approaches have been applied to analyze CPS data, some previous studies only focused on logged system actions rather than verbal communications [30, 22], which provides limited insights into how the collaboration unfolds (e.g. how students share information and negotiate). Of the studies that applied temporal analysis on coded sequences, some only considered the co-occurrence of indicators in a sliding window (e.g. epistemic network analysis), without specifying the direction of the relations [7, 41, 39]. Others only focused on the 1-to-1 temporal connections between variable pairs at time $t - 1$ and t (e.g. lag sequential analysis) [17, 6, 19], rather than n -to-1 connections as an action can be predicted by multiple prior actions [8, 9].

The approach we use in this work, mlVAR, has a number of desirable statistical properties over other approaches. First, unlike lag sequential analysis, which examines the 1-to-1 temporal connections between variables, mlVAR uses *a set of variables at time $t - 1$* to predict a variable at time t ,

resulting in n-to-1 temporal connections. This allows it to discover temporal connections fully in context. Second, as a statistical procedure, mlVAR allows for uncertainty quantification of findings through the use of p-values and standard errors. Finally, mlVAR analysis is inherently multi-level, thereby statistically accounting for the fact that CPS data is generally clustered within teams. Failure to take such clustering into account may yield untrustworthy results due to phenomena such as the Simpson’s Paradox [20]. The multilevel nature of mlVAR also allows for the estimation of both team-specific networks and general networks representing the dynamics of the average team. Another novelty is that we employed a quasi-experimental matching procedure to balance the number of successful vs. unsuccessful instances across multiple factors (e.g. school, experimental block, time duration) to factor out their possible impacts. Finally, rather than emphasizing short-term temporal relationships between actions (i.e., using the previous utterance to predict the next), we combined behaviors across short windows spanning an average of three utterances to better capture aspects of the unfolding dialogue (conversations involving three participants).

3. DATA SET

The data were collected as part of a larger study [11] involving collaborative problem solving. Only aspects germane to the present work are reported here.

3.1 Participants

A total of 303 Students (56% female, average age = 22 years) from two large public universities participated in the study. Self-reported race/ethnicity information indicated that 47% of participants were Caucasian, 28% Hispanic/Latino, 18% Asian, 2% Black or African American, 1% American Indian or Alaska Native, and 4% “other”. Students were assigned to 101 triads based on their scheduling availability. Thirty participants from 18 teams indicated they knew at least one person in their team prior to study. Participants were compensated with a \$50 Amazon gift card (96%) or course credit (4%) after completing the study.

Figure 1: A screenshot of the collaboration scenario

3.2 CPS Task

Participants were tasked with collaboratively solving levels in a learning game “Physics Playground” [37], which is designed for young adults to learn Newtonian physics (e.g., Newton’s laws of force and motion). The goal for each level is to create objects and use physics laws to move a ball to a

designated target (a red balloon) as shown in Figure 1. Everything in the game obeys basic physics laws (e.g., there is gravity, each object has its own mass). As such, to move the ball in a desired way, students need to use simple machines such as levers and springboards. These, along with other objects (e.g., weights) are drawn using the mouse, upon which the new object becomes “alive” in the game and interacts with other existing objects following basic physics laws. Students can restart (clearing objects) or quit a game level at any time. They receive a gold coin if they solve a level with an optimal solution (i.e., with minimal objects), and they receive a silver coin for a sub-optimal solution (i.e., with more objects). No coin is rewarded for unsolved levels.

The game includes 17 levels covering two physics concepts: “energy can transfer” (EcT, 9 levels) and “properties of torque” (PoT, 8 levels). Each concept contains several subconcepts. For example, kinetic energy and gravitational potential energy belongs to EcT. The 17 levels varied in difficulty (as rated by two physics experts) and the levels were organized into three “playgrounds”, one per block in the study (detailed below). In the navigation page, students can choose a level to enter from the “playground” they are in or view the tutorials that introduce the game mechanics.

3.3 Procedure

The study involved an individual “at-home” part and a collaborative “in-lab” part. Materials (Qualtrics surveys) for the “at-home” part were emailed to students at least 24 hours prior to the lab session. It included several individual difference measures (e.g., prior knowledge, personality), a short tutorial on how to use Physics Playground, a short (around 15-mins) individual practice with the game, and other aspects unrelated to this study.

Students completed the “in-lab” part of the study in triads, using computer-enabled workstations equipped with a webcam and headset microphone. All collaborations occurred via the Zoom video-conferencing tool (as shown in Figure 1), and participants in the same group sat away from each other to avoid in-person interactions. The study involved three 15-min CPS blocks. (There was a fourth block for a different task not analyzed here.) In each block, one person was randomly assigned the role of a controller and the other two were tasked with being contributors. Assignment of the controller role rotated across blocks, so each teammate served as the controller for one of the three blocks. The game was loaded on the controller’s computer, so only the controller could directly interact with the game. The controller’s screen was shared with the contributors using the screen sharing feature of Zoom. Contributors participated in the problem solving process through verbal communications (e.g., proposing ideas, giving instructions).

The first block included five easy-to-medium levels involving a mix of EcT and PoT concepts. After that, all teams completed two 15-min experimental blocks, on either EcT or PoT levels (counterbalanced across teams) and with a specific CPS goal (delivered via verbal and on-screen messages): “solve as many levels as possible” or “get as many gold coins as possible”. The CPS goal and physics concept for the two experimental blocks were within-subjects factors, counter-balanced across teams.

Table 1: Facets and Indicators

Facet	Indicator
Constructing Shared Knowledge	1) Talks about challenge situations (Situations)
	2) Suggests appropriate ideas (ApporIdeas)
	3) Suggests inappropriate ideas (InapporIdeas) [N]
Negotiation and Coordination	4) Confirms understanding (Confirms)
	5) Interrupts others (Interrupts) [N]
	6) Provides reasons to support a solution (Reasons)
	7) Questions/Corrects others' mistakes (Questions)
	8) Responds to other's questions/ideas (Responds)
Maintaining Team Function	9) Criticizes, makes fun of, or being rude to other (Criticizes) [N]
	10) Discusses the results (DiscuResults)
	11) Brings up giving up the challenge (GivingUp) [N]
	12) Strategizes to accomplish task goals (Strategizes)
	13) Tries to quickly save an almost successful attempt (Saves)
	14) Asks others for suggestions (AskSuggest)
	15) Compliments or encourages others (Compliments)
	16) Initiates off-topic conversation (InitOffTopic)
	17) Joins in off-topic conversation (JoinOffTopic) [N]
	18) Provides instructional support (Instructions)
19) Apologizes for one's mistakes (Apologizes)	

3.4 Coding Collaboration Behaviors

We adopted the validated coding scheme developed by Sun et al. [39] to code student's verbal communications, which includes three main CPS facets: constructing shared knowledge, negotiation/coordination, and maintaining team function. Within each facet, there are several indicators that specify the concrete function(s) of each utterance as shown in Table 1 (see coding examples in Section 5.2). Constructing shared knowledge contains two aspects: a) disseminating knowledge, ideas, and resources among team members and b) establishing common ground for understanding the task and solutions [1, 26, 32]. Negotiation and coordination pertains to reaching a consensus on a solution plan to be carried out, such as dividing labor, resolving conflicts, integrating different perspectives, and monitoring execution [1, 18, 35]. Maintaining team function reflects efforts to maintain a functional team via assuming individual responsibilities, taking initiative, and co-regulation [5, 18, 33]. Most of the indicators in Table 1 describe positive (beneficial) CPS behaviors, and the negative behaviors were marked with N.

Coding was done on machine generated transcripts of students' verbal communications using IBM Watson's automatic speech recognition software [14]. IBM Watson both segments the audio into individual utterances and provides transcriptions of the utterances along with word timings. Utterances spoken by the same person within two seconds were merged to address segmentation errors (a 2-sec threshold was selected after considering a range of thresholds). The coders also viewed the video recordings of gameplay during coding to understand the context of students' interactions, nonverbal behaviors of the group dynamics, and to address speech recognition errors. An utterance was coded with an indicator if it contained evidence of the function described by the indicator. The coders marked the number of occurrences of each indicator per utterance, and multiple

indicators could occur for a given utterance (see Table 7 in Section 5.2 for an example). Three trained human coders coded the data. Each received two rounds of training before performing individual coding. After the second round of training, they all reached a high percentage of agreement (89% – 100%) and a high Gwet's AC1 value (0.91 to 1.00), a measure of interrater reliability specifically designed for cases of high agreement where more traditional metrics like Cohen's kappa yield unexpected results (sometimes called the paradoxes of kappa [15]).

3.5 Level Matching

Considering that besides collaboration behaviors, other factors such as level difficulty, the physics concept involved, and the problem solving goal (originally designed for other studies and not involved in our analysis) could also affect the problem solving outcome, we used a quasi-experimental matching procedure to factor out their possible impacts on level attempt success in our analysis. Specifically, an initial processing of the game logs yielded 1,164 level attempts (27% gold, 29% silver, and 44% no coin). Then, level attempts shorter than 60s were excluded, resulting in 808 level attempts. We removed short attempts because they are likely to be cases that students were exploring a level to decide whether to attempt it or not.

A preliminary analysis indicated that Energy can Transfer (EcT) levels (18% attempts succeeded, 7% earned a gold coin) were more difficult than Properties of Torque (PoT) levels (63% attempts succeeded, 40% earned a goal coin). To ensure a sufficient number of matches, matches for EcT levels focused on a coin (gold or silver) vs. a no coin comparison, whereas matches for PoT levels focused on gold vs. silver vs. no coin outcomes (i.e., a triplet). Matching was based on the following covariates: 1) school, 2) level identifier, 3) manipulation (i.e., gold coins vs. solve many levels), 4) block number (first or second) for the experimental blocks, and 5) duration of the level attempt. Level attempt duration was constrained to be at most 0.25 standard deviations of the mean duration of all the level attempts. An initial matching (using the "bmatch" function in the R package "designmatch" [46]) yielded 131 level attempt matches (33 Warmup, 69 EcT, and 29 PoT). Given the labor intensive nature of coding, 81 matches were randomly selected from the 131 candidates for analyses. The resulting data set included 209 level attempts: 66 (22 × 3) Warmup attempts from 47 unique teams, 68 (34 × 2) EcT attempts from 49 unique teams, and 75 (25 × 3) PoT attempts from 54 unique teams. A preliminary analysis on the resulting matches revealed that the matching indeed balanced school, manipulation, and block across the outcome groups (coins in this case). These data were coded for the CPS indicators as noted above. In our analysis, the level attempts that resulted in a coin (either gold or silver) were considered as successful attempts, whereas those resulted in no coin were treated as unsuccessful ones.

4. ANALYTICAL METHODS

4.1 Data Organization

Since students collaborated in triads in our studies, we aggregated the utterances into windows spanning an average of three utterances to investigate how their CPS interactions

Table 2: Average speaker changes and utterances with different window sizes

Size (Seconds)	Speaker changes	Utterances
8	1.604 (1.531)	2.559 (1.721)
9	1.850 (1.672)	2.849 (1.853)
10	2.087 (1.793)	3.150 (1.979)
11	2.340 (1.940)	3.457 (2.112)
12	2.587 (2.064)	3.741 (2.240)

unfolds. We used windows instead of utterance batches for the aggregation because the utterances varied in length and the windows can better balance the amount of information across units in the sequences. To find an appropriate window size, we tested 11 different sizes from 5 seconds to 15 seconds (sample shown in Table 2). As expected, the number of speaker changes (i.e., when the speaker changes between utterance $t+1$ and t) and number of utterances in each window increased for larger window sizes. We selected the window size of 10 seconds because it has an average of two speaker changes and three utterances in each window, which would accommodate one utterance for each of the three speakers, though windows ranging from 9 to 11 seconds would also have been suitable.

The aggregation sums up the occurrences of each indicator in each window, resulting in sequences of integer vectors. An utterance was assigned to a window if: 1) the center (midpoint) of the utterance lies in the window or 2) it overlaps with the window for more than one second (since the mean utterance duration was 2.08 seconds). Of the 19 indicators, 9 were exceedingly rare, occurring in less than 1 percent of the utterances. Accordingly, we merged these into a miscellaneous other indicator category (OtherIndi). We also grouped the utterances that were not coded with any indicators into a no indicator category (NoIndi). Finally, to reflect changes in the game, we applied a validated motion tracker tool [45] to capture changes in the game area. We used screen motion instead of logs to reflect game state because the logs only recorded the addition/deletion of objects, but not their interactions, and are generally limited for open-ended games where players can draw objects of any shape. The use of screen motion is also more generalizable and has been used in other studies investigating CPS [44]. In sum, our models contained 13 variables (12 indicator-related variables as shown in Table 3 + Screen Motion).

We conducted a few additional data processing steps prior to constructing the models. First, sequences shorter than 150s were excluded to ensure that each sequence has at least 13 transitions for our 13-variable models (detailed below). Second, windows shorter than 5 seconds (50% of normal window length) at the end of the sequences were removed because they were too short to be considered as a complete window, and then the last window of each sequence was removed. The second step removed the last 5 - 15 seconds of each level attempt to alleviate the concern that the language/indicators might have focused on the success or failure of the outcome rather than the problem solving process.

The final data set contains 133 level attempts (82 successful [silver or gold coin] and 51 unsuccessful [no coin]) from 74

Table 3: Average number of each indicator per window

Facet	Variable	Successful	Unsuccessful
Constructing	Confirms	0.30 (0.60)	0.33 (0.60)
Shared	ApporIdeas	0.23 (0.51)	0.14 (0.41)
Knowledge	InapporIdeas	0.15 (0.43)	0.21 (0.49)
	Situation	0.17 (0.49)	0.16 (0.49)
Negotiation and	Responds	0.33 (0.63)	0.31 (0.60)
	Reasons	0.14 (0.38)	0.11 (0.34)
Coordination	DiscuResults	0.09 (0.33)	0.08 (0.30)
Maintaining	Instructions	0.27 (0.60)	0.33 (0.65)
Team	Compliments	0.20 (0.48)	0.16 (0.42)
Function	AskSuggest	0.03 (0.17)	0.04 (0.21)
Other	OtherIndi	0.21 (0.50)	0.24 (0.54)
Variables	NoIndi	1.22 (1.31)	1.31 (1.30)

matches (detailed in section 3.5). For successful attempts, sequence length ranges from 14 to 85, with an average of 30.82 (SD = 15.93). Each window has 2.03 (SD = 1.79) speaker changes on average, 3.03 (1.89) utterances, and 17.08 (11.78) words. For unsuccessful attempts, sequence length ranges from 15 to 87, with an average of 36.92 (SD = 21.00). Each window has 2.12 (SD = 1.73) speaker changes on average, 3.14 (1.80) utterances, and 18.02 (11.42) words. In both data sets, each sequence has at least 13 transitions (minimal sequence length (14) - 1) for our 13-variable models. Table 3 shows the average number of each indicator per window, showing mean (SD).

4.2 Multilevel Vector Autoregression

Multilevel vector autoregression (mlVAR) is a network analysis method for understanding temporal dynamics between multiple variables nested within multiple higher order clusters (e.g., individuals or teams) [4, 13]. It is multilevel in that linear mixed-effects models are built to examine temporal connections at the individual level while accounting for group differences. Vector autoregression is the process of predicting a vector of variables at time t using the same vector at time $t - n$ (n is known as the lag). We utilized the R package “mlVAR” (version 0.5) for all analyses [12].

mlVAR analyzes the relations between temporal vectors by building a series of linear mixed-effects models, each of which uses the vector at time $t - n$ [$y(t - n)_1^i, y(t - n)_2^i, \dots, y(t - n)_J^i$] to predict an element of the vector at time t , denoted as $y(t)_j^i$, where i is subject id (in our case, level attempt id), j is variable id, and J is the length of the vectors (in our case, $J = 13$ as we have 13 variables). The mixed-effects models can be described by the following equations:

$$\begin{aligned}
 y(t)_1^i &= \mathbf{y}^i(\mathbf{t} - \mathbf{n})\mathbf{b}_1 + \mathbf{y}^i(\mathbf{t} - \mathbf{n})\mathbf{u}_1^i + e_1, \\
 y(t)_2^i &= \mathbf{y}^i(\mathbf{t} - \mathbf{n})\mathbf{b}_2 + \mathbf{y}^i(\mathbf{t} - \mathbf{n})\mathbf{u}_2^i + e_2, \\
 &\vdots \\
 y(t)_J^i &= \mathbf{y}^i(\mathbf{t} - \mathbf{n})\mathbf{b}_J + \mathbf{y}^i(\mathbf{t} - \mathbf{n})\mathbf{u}_J^i + e_J,
 \end{aligned} \tag{1}$$

where $\mathbf{y}^i(\mathbf{t} - \mathbf{n})$ is the $1 \times J$ vector at time $t - n$ for subject i , ($y(t - n)_1^i, y(t - n)_2^i, \dots, y(t - n)_J^i$); each of $\mathbf{b}_1, \dots, \mathbf{b}_J$ is a $J \times 1$ coefficient vector for the fixed-effects, which associates $\mathbf{y}^i(\mathbf{t} - \mathbf{n})$ to $y(t)_j^i$; each of $\mathbf{u}_1^i, \dots, \mathbf{u}_J^i$ is a $J \times 1$ random-

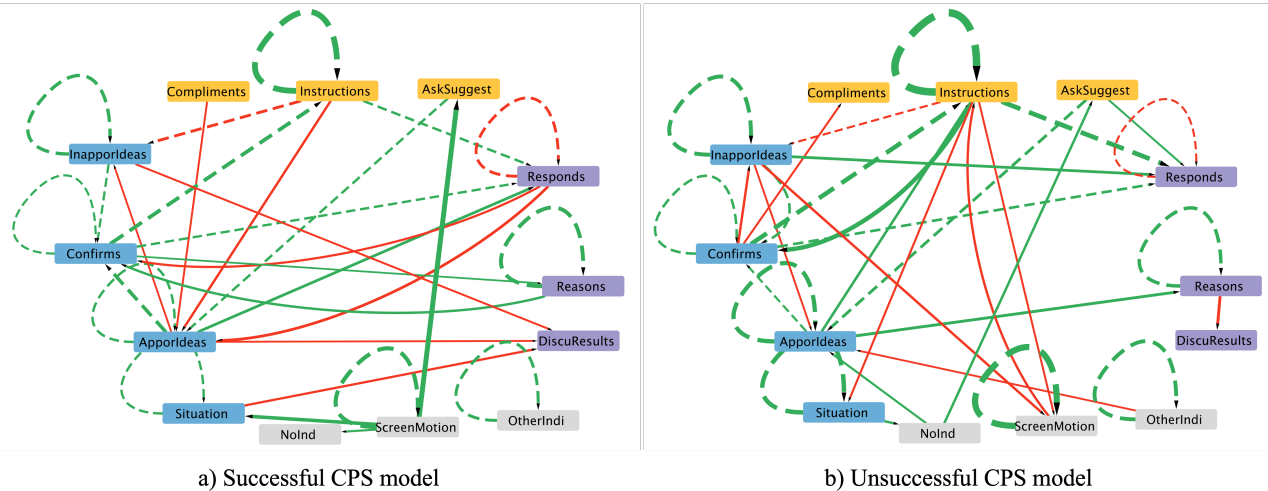

Figure 2: In the graphs, nodes were colored based on their facet, blue for constructing shared knowledge, orange for maintaining team function, purple for negotiation and coordination, and gray for other variables. Nodes with the same facet were grouped together to make within and between facet connections more obvious. Green lines in the graphs represent positive temporal relations and red lines represent negative relations. Dashed lines represent the relations that exist in both models, while solid lines represent the relations that exist only in one model. Arrows show the direction of the temporal relations and line thickness indicates the strength of the relationship (magnitude of the coefficient). Full names of the indicator labels are shown in Table 1.

effects vector, describing the deviation of individual i from the fixed-effects $\mathbf{b}_1, \dots, \mathbf{b}_J$; each of $\mathbf{e}_1, \dots, \mathbf{e}_J$ is a residual variable, describing the difference (error) between the model’s prediction and the actual value. Before estimating parameters for the linear mixed-effects models, all the variables are standardized using a z-transformation to ensure that the coefficient values are in the same range and comparable. We set the lag to be 1 as we were interested in fine-grained temporal effects (i.e., between 10-second consecutive windows). We also explored lag 2, but the resulting models had very few connections in them.

In mIVAR, a temporal connection exists between two variables if the “earlier” one $y(t-n)_j^i$ is a significant predictor of the “later” one $y(t)_j^i$ in the corresponding linear mixed-effects model. We used a p-value of .05 to denote a significant effect as other studies did [16, 10]. The temporal connections between variables can be represented by a directed, weighted graph (network), as shown in Figure 2.

5. RESULTS

Our temporal analysis of CPS processes consists of a quantitative analysis comparing the mIVAR models built on successful vs. unsuccessful level attempts and a qualitative analysis to interpret the patterns in the data.

5.1 mIVAR Analysis

For the successful and unsuccessful outcomes, the linear mixed-effects sub-models in the mIVAR model reached an average root mean squared error of 0.887 (SD = 0.062) and 0.906 (0.045) respectively in our standardized data. Figure 2 shows a comparison of the network for the successful vs. unsuccessful model. Since we are interested in whether there exist temporal connections between indicators rather than how strong the connections are, we treated all the sig-

nificant connections equally (indicated by the lines in the networks) and did not account for their strength (indicated by line thickness). As we can see, the graphs contain several kinds of relations, including self-loops, positive relations and negative relations. A positive self-loop suggests that the appearance of an action in window $t-1$ informs the appearance of the same kind of actions in window t . Generally, positive self-loops indicate that the indicator occurs across multiple consecutive windows. By contrast, a negative self-loop indicates that if an action appears in a window, it is less likely that the same kind of actions will appear in the next window. Given that the self-loops are easy to understand, we do not discuss them further.

Regarding between-indicator relations, most of the negative relations only exist in one of the two models. This is not surprising because actions can be absent for many reasons, such as being replaced by other actions or simply not being appropriate with respect to collaborative discourse (e.g., discussing the challenge situation after receiving a complement) or the stage in the problem solving process. As such, we mainly focus on the positive between-action relations.

Table 4 shows a summary of the positive between-action relations, where they were grouped into three categories based on whether they occurred in 1) both models (Common), 2) the successful model only (Successful), and 3) the unsuccessful models only (Unsuccessful). The “Common” category had 6 relations, 4 of which involved “confirms understanding”. Among them, “proposes appropriate ideas” and “proposes inappropriate ideas” were likely to influence “confirms understanding” questions, while “provides instructional support” and “responds to others’ ideas/questions” were likely reactions to “confirms understanding” questions. The other two relations “asks others for suggestions” → “proposes appropriate ideas” and “provides instructional support” → “re-

Table 4: Positive between-action connections

Common
Proposes appropriate ideas → Confirms understanding
Proposes inappropriate ideas → Confirms understanding
Confirms understanding → Provides instructional support
Confirms understanding → Responds to other’s questions/ideas
Asks others for suggestions → Proposes appropriate ideas
Provides instructional support → Responds to other’s questions/ideas
Successful
Confirms understanding → Provides reasons to support a solution
Provides reasons to support a solution → Confirms understanding
Screen motion → Asks others for suggestions
Screen motion → Talks about challenge situations
Screen motion → No indicators
Proposes appropriate ideas → Responds to other’s questions/ideas
Unsuccessful
Provides instructional support → Confirms understanding
Proposes appropriate ideas → Provides instructional support
Proposes appropriate ideas → Provides reasons to support a solution
Proposes inappropriate ideas → Responds to other’s questions/ideas
No indicators → Proposes appropriate ideas
No indicators → Asks others for suggestions
Talks about challenge situations → No indicators
Asks others for suggestions → Responds to other’s questions/ideas

sponds to others’ ideas/ questions” are ordinary interactions. The common relations suggest that the process of establishing shared understanding via asking and reacting to “confirms understanding” (clarification) questions was common to both successful and unsuccessful level attempts and likely underlies basic collaborative discourse.

Successful model: For the successful level attempts, there was a bidirectional temporal relation between “confirms understanding” questions and “provides reasons to support a solution”. Both reflect efforts to enhance shared understanding and thus the interactions between them may facilitate successful CPS. Importantly, we found that the degree of screen activity (“screen motion”) was a significant temporal predictor for three variables: “asks others for suggestions”, “talks about challenge situations”, and “no indicator utterances”. This suggests that people in successful CPS processes reflected on the current game situation. Among the three relations, “screen motion” → “talks about challenge situations” reflects that successful teams were linking what occurred in the game with the underlying challenge situation, which can be considered a form of metacognitive processing. The “screen motion” → “no indicator utterances” indicates that people were likely to talk following screen change but the language was not captured by the coding scheme since it might not have been CPS-related discourse. The “screen motion” → “asks others for suggestions” suggests that people were likely to ask for suggestions according to the current game state. Ostensibly, this relation connects people to the game and thus may facilitate CPS. The “proposes appropriate ideas” → “responds to others’ ideas/questions” reflects that people were likely to express their thoughts towards appropriate ideas, suggesting a form of affirming dialogue.

Unsuccessful model: In the “unsuccessful” model, “confirm understanding” questions were likely to appear following “provides instructional support”. This relation together with the “confirms understanding” → “provides instructional support” in the “common” category forms a bidirectional relation, which indicates that people were looping between giving instructions and confirming understanding. This loop suggests that people had difficulty with conveying and understanding instructions accurately.

There were three relations involving proposing ideas, both appropriate and inappropriate. The “proposes inappropriate ideas” → “responds to others’ ideas/questions” suggests that people were likely to discuss inappropriate ideas, which is different from the “proposes appropriate ideas” → “responds to others’ ideas/questions” in the “successful” model. This contrast suggests that devoting efforts to appropriate ideas rather than inappropriate ideas may help solve the problem. Additionally, “proposes appropriate ideas” → “provides instructional support” and “provides reasons to support a solution”. Given that providing instructions and reasons both give details to support an idea, these two relations suggest that the proposed ideas, though appropriate, needed further illustration or justification. The “no indicator utterances” (NoInd) were involved in three relations. Since these relations involved communication functions that were not described by the CPS coding scheme, we do not discuss them further. Finally, “asks others for suggestions” was a significant predictor of “responds to others’ ideas/questions”. We noticed that there was a common relation “asks others for suggestions” → “proposes appropriate ideas” in both the “successful” and “unsuccessful” models. This suggests that the most common reaction to suggestion requests is directly proposing an idea. Thus, reacting to suggestion requests by simply responding to others, rather than proposing new and task appropriate ideas, reflects that people were unsure about what to say, or how to proceed with solving the problem.

a) Confirms → Reasons b) Confirms ↔ Instructions

Figure 3: Screenshot for qualitative analysis examples

5.2 Qualitative Analysis

To further interpret the temporal patterns revealed by ml-VAR analysis, we conducted a qualitative analysis to examine what actually happened behind the patterns. Given the page limit, we focused on two important CPS factors: 1) establishing shared understanding, and 2) linking people to the game. As discussed above, shared understanding was often established via asking and reacting to “confirms understanding” (clarification) questions. Thus, we exam-

Table 5: “Screen motion” → “Asks others for suggestions” examples from successful level attempts

Example 1: Asking for suggestions after starting a level		
Time	Window	Speech/Actions
40-50	1	[controller actions]: Entered the game and made a few objects, but did not figure out how to solve the level. [Screen motion] value: 0.117 (> 99.32% instances)
54-58	2	<u>Controller</u> : Do you guys have any suggestions? [AskSuggest]
Example 2: Asking for suggestions after an attempt		
490-500	46	[controller actions]: Created a heavy weight and deleted it to spring the ball up, but it did not go high enough. [Screen motion] value: 0.010 (> 78.62% instances)
502-504	47	<u>Controller</u> : Should I try it again with, like Bigger? [AskSuggest]

Table 6: “Confirms understanding” ↔ “Provides reasons to support a solution” examples from successful level attempts

Example 1: “Confirms understanding” → “Provides reasons to support a solution”		
Time	Window	Speech/Actions
[Scenario]: The ball is dropping repeatedly and the team is trying to figure out how to capture and move it, as shown in Figure 3.a. (The key to solve this level is to catch the right timing.)		
317-319	17	<u>Contributor1</u> : When you see the ball start to drop, let go. [Instructions]
319-323	17	<u>Controller</u> : To drop and let go? [Confirms]
323-325	18	<u>Contributor1</u> : So when the ball begins falling on the screen-
325-325	18	<u>Controller</u> : Uh-huh.
325-328	18	<u>Contributor1</u> : Then stop drawing, [Instructions] ‘cause that’s when it’ll start to fall. [Reasons]
328-329	18	<u>Controller</u> : Okay. (silence) [Responds] [in-game action: the controller then solved the level]
Example 2: “Provides reasons to support a solution” → “Confirms understanding”		
[Scenario]: The team is trying to rotate an object.		
392-410	18-19	<u>Contributor1</u> : Oh. I would maybe try to put... now, um, get rid of those dots and um, put a new dot where um, the tip is. [ApporIdeas] So it could like move more forward. [Reasons]
410-411	19	<u>Controller</u> : Like here? [Confirms] [in-game action: pointed to a position using mouse]
411-417	19	<u>Contributor1</u> : Um, yeah. Like how you connected them. Connect them again at like, the bottom of the thing. [Instructions]

Table 7: “Confirms understanding” ↔ “Provides instructional support” example from an unsuccessful level attempt

Time	Window	Speech/Actions
[Scenario]: One contributor is trying to convey the idea of using a springboard to bounce the ball up (see Figure 3.b).		
281-291	26-27	<u>Contributor1</u> : Like, put it like under. Actually no, I feel like that’s too...No like, you have to like connect and like, and like, put it underneath. [Instructions] Like you feel-
291-292	27	<u>Contributor2</u> : What? (laughs). [Confirms]
292-307	27-28	<u>Contributor1</u> : Like, connect the two dots, then like put it under the ball. [Instructions] Because like, you’re going to delete that black line [Instructions] and then it’s going to fall on the...it’s going to end up falling on the bouncy board and hopefully go up. [Reasons]
307-308	28	<u>Controller</u> : Oh, wait. So go like this? [Confirms] [in-game action: drew a short line that connected two dots, but still did not make a springboard]
308-312	29	<u>Contributor1</u> : Yeah, and then make it go under, don’t hit that...um black. [Instructions]
312-313	29	<u>Controller</u> : Huh? [Confirms]
313-313	29	<u>Contributor2</u> : What? [Confirms]
313-318	29	<u>Contributor1</u> : Yeah, make it just, make it go under, like the black and under the ball. [Instructions]
... ..		

ined the temporal differences that involved “confirms understanding”: 1) “confirms understanding” ↔ “provides reasons to support a solution” in the “successful” model and 2) “confirms understanding” ↔ “provides instructional support” in the “unsuccessful” model. The link between people and game was reflected by “screen motion” involved connections. Among the three such relations (all in the “successful” model), the “screen motion” → “talks about challenge situations” was easy to understand and “screen motion” → “no indicator utterances” involved language that was not captured by our coding scheme. Thus, we examined only the “screen motion” → “asks others for suggestions”.

Table 5 shows two typical scenarios for the “screen motion”

→ “asks others for suggestions”, showing the time in the block in seconds (Time), order of the window in the level attempt sequence (Window), and the speech/actions that occurred in the window. In example 1, the controller asked for suggestions right after a level started, where a screen refresh resulted in a large screen motion. In example 2, the controller asked for suggestions after a failed attempt that contains a series of large in-game motions. These examples revealed that in successful level attempts, controllers were likely to ask for suggestions according to the current game situation.

Next, we investigate the bidirectional relation “confirms understanding” ↔ “provides reasons to support a solution”.

An examination of the coded sequences showed that in most cases, these two relations exist independent of each other, rather than form a semantically connected loop. So, we investigate each of them independently as shown in Table 6. In the “confirms understanding” \rightarrow “provides reasons to support a solution” example, a contributor answered the controller’s clarification question with an instruction and a reason to clarify its purpose (to catch the right timing, which is the key to solve the level). This suggests that in successful CPS processes, people were likely to answer clarification questions with reasons. In the “provides reasons to support a solution” \rightarrow “confirms understanding” example, a contributor proposed an idea to move the object, and gave a reason to clarify the goal, but the controller did not fully understand the idea and asked a clarification question. This relation does not align with our intuition that providing reasons increases clarity and reduces confusion. A potential explanation is that reasons were used conditionally on unclear or complex ideas, rather than unconditionally or randomly on all ideas. However, more investigations are needed to understand how reasons were provided.

An examination of the coded sequences for the bidirectional relation “confirms understanding” \leftrightarrow “provides instructional support” showed that there exist many cases where these two relations were semantically connected, forming a loop. Table 7 shows an example of it, where we can clearly see that Contributor1’s unclear instructions repeatedly confused both the other two people and raised clarification questions. Note that the examples in Table 6 and Table 7 indicated that semantic connections do exist between utterances that are not in consecutive order. This suggests that aggregating utterances with windows is a valid way to examine the temporal relations between actions.

6. DISCUSSION

This work applied multilevel vector autoregression (mlVAR) to investigate the temporal similarities and differences in verbal behaviors between successful vs. unsuccessful collaborative problem solving (CPS) outcomes. The remainder of this section discusses the main findings, applications, limitations and future work.

Main findings Our comparison of the “successful” vs. “unsuccessful” model together with a qualitative analysis revealed six between-action temporal relationships common to both, six unique to successful level attempts, and another eight unique to unsuccessful level attempts. The common relations suggest that the process of establishing shared understanding via asking and reacting to “confirms understanding” (clarification) questions was common to both successful and unsuccessful level attempts. For successful level attempts, people were likely to answer “confirms understanding” questions with reasons and to ask for suggestions according to the current game situation, while for unsuccessful level attempts, teams were more likely to struggle with unclear instructions and to respond to inappropriate ideas. Next, we discuss why certain behaviors in successful level attempts may facilitate CPS processes and what makes it hard to convey instructions.

Our analysis revealed that controllers in successful level attempts were likely to ask for suggestions according to the

current game situation (typically when they got stuck). This behavior may facilitate productive CPS because asking for suggestions can increase other people’s participation. Further, other people’s contributions are more helpful when the controller has no idea about how to solve the level. Additionally, in successful level attempts, people were more likely to answer clarification questions with reasons. As discussed above, this behavior may facilitate CPS because providing reasons enhances the clarity of the ideas/instructions being conveyed.

For unsuccessful level attempts, people were likely to struggle with unclear instructions. From the example in Table 7, we noticed at least two potential reasons for that. First, the team does not have a shared concept of a springboard, and thus Contributor1 had to describe how to make it (“connect the two dots, then like put it under the ball”) and how it works (“it’s going to end up falling on the bouncy board and hopefully go up”). Second, Contributor1 had to describe everything via words, rather than point to the screen directly, which largely reduced the clarity of her descriptions.

Future applications: A potential application of this work is to support the provision of timely CPS feedback in computer supported collaboration environments. For example, when a “confirms understanding” \leftrightarrow “provides instructional support” loop is detected, the system could send an interactive message to the team asking whether people are struggling with conveying clear instructions. If so, the system can provide suggestions such as describing the high level idea rather than low level actions. Another potential application is to provide CPS analytics for people to inspect their collaboration behaviors and improve CPS skills.

Limitations and future work: A limitation of our work is that we aggregated the data with 10-second windows, and thus the mlVAR analysis only effectively captures the connections between two consecutive windows. Connections with a short or longer temporal distance cannot be effectively discovered. Future studies could aggregate the data with different window sizes and see what other temporal patterns can be found. The second limitation is our data were collected in a specific lab setting where triads collaborated via video conferencing to play a physics learning game. Thus, it is unclear whether our findings can be generalized to other collaboration scenarios (e.g. real-world activities, face-to-face coordination). Third, we did not account for people’s roles in our analysis (due to limited sample size). Roles can largely influence people’s actions (e.g. only contributors “provide instructional support”), and therefore taking roles into account may provide more insights into the CPS processes. Finally, we did not compare mlVAR with other temporal analysis approaches (e.g. lag sequential analysis) to see whether they would generate similar or different insights. This is a potential future research direction.

ABSTRACT

Automatic speech recognition (ASR) has considerable potential to model aspects of classroom discourse with the goals of automated assessment, feedback, and instructional support. However, modeling student talk is besieged by numerous challenges including a lack of data for child speech, low signal to noise ratio, speech disfluencies, and multiparty chatter. This raises the question as to whether contemporary ASR systems, which are benchmarked on adult speech in idealized conditions, can be used to transcribe child speech in classroom settings. To address this question, we collected a dataset of 32 audio recordings of 30 middle-school students engaged in small group work (dyads, triads and tetrads) in authentic classroom settings. The audio was sampled, segmented, and transcribed by humans as well as three ASR engines (Google, Rev.ai, IBM Watson). Whereas all three ASRs had high word error rates, these mainly consisted of deletion errors. Further, Google successfully transcribed a greater proportion of utterances than the other two, but with more word substitutions; insertions were low across the board. ASR accuracy was robust to different speakers and recording idiosyncrasies evidenced by <5% of variance in error rates attributable to the student and recording session. We found that ASR errors had a larger negative effect on downstream natural language processing tasks at the word, phrase, and semantic levels rather than at the discourse level. Our findings indicate that ASR can be used to extract meaningful information from noisy classroom speech and might be more suitable for applications that require higher precision but are tolerant of lower recall.

automatic speech recognition, collaborative problem solving, classroom speech, natural language understanding

1. INTRODUCTION

Students learn by telling and doing. Indeed, decades of educational research has converged on one (among several) perspectives of learning as a social and collaborative activity [8, 89, 97]. Effective collaborative learning (CL) activities give students the opportunity to work together towards a common goal, share their ideas and

build upon the ideas of others, negotiate strategies, monitor execution of plans, and reflect on outcomes [17, 28, 33, 39, 72, 75]. Thus, the benefits of CL are manifested not only in the acquisition of domain knowledge [86], but also in the development of essential 21st century skills such as collaborative problem solving and critical thinking [27, 29].

Despite a strong consensus on the value and merits of CL, its widespread implementation in contemporary classrooms is limited. A key factor limiting its adoption is that it is extremely challenging for teachers to effectively orchestrate rich CL activities in their classes. To support successful CL, teachers must monitor group progress on time-sensitive activities, provide guidance and help when students get stuck and risk disengagement, and ensure that students engage in productive knowledge-building conversations, all while ensuring that classroom norms for respectful discourse are maintained [71, 88]. To complicate things further, teachers must perform these demanding activities simultaneously across multiple (often 5-10) groups – a daunting assignment. Can intelligent systems, which unlike teachers, are able to be omnipresent across multiple student groups, enhance teachers’ ability to scaffold rich CL experiences for all their students?

One exciting possibility is to design systems capable of natural language understanding (NLU) to support CL in student groups. Indeed, the linguistic content of discourse during CL is considered the “gold mine of information” on how students acquire knowledge and skills [32, 73]. However, despite an extensive body of research demonstrating the utility of other modalities (e.g., body movement, gesture, eye-gaze, paralinguistics, see review [62] for automatically analyzing collaboration, an automated approach for capturing, transcribing, and analyzing student speech during face-to-face CL in the classroom has yet to be developed. Most language-based approaches to date thereby rely on typed transcripts from chats (or human-transcribed speech) to analyze and support collaborative discourse [21, 30, 52, 76].

At the heart of this challenge lies an extremely difficult technical hurdle: using automatic speech recognition (ASR) to obtain accurate (or even serviceable) transcriptions of student discourse in noisy, real-world classrooms. This endeavor is complicated by multiple compounding challenges. Namely, with upwards of 20-30 students in a typical US classroom [57] with multiple student groups simultaneously engaged in CL activities, speech signals are obfuscated by background chatter and ambient noise. In addition, ASR systems already have difficulty recognizing children’s speech (even in ideal, noise-free environments), as they tend to speak less clearly than adults [46]. In fact, even the basic acoustic

characteristics of children’s voices and language use [25, 46], differ from adults (on whose voices most ASR systems are trained), resulting in a degradation in performance when these systems are applied to children’s speech [70]. Multiparty speech recognition is another challenge for ASR [12, 65], where utterances - from an unknown number of unique speakers - may overlap, whereas ASR systems are generally trained on audio where speakers have already been separated.

Despite these challenges, pursuing technologies capable of automatically capturing and analyzing student speech during face-to-face CL in authentic school environments is an important avenue of research. These technologies have the potential to significantly improve orchestration and support of CL [73], whether by providing teachers with feedback on progress of student groups (e.g., via a teacher dashboard [87]), or enabling real-time interventions to guide groups of learners towards equitable and productive collaboration.

In this paper we take a first step towards understanding the feasibility and challenges of automatically analyzing student speech in classrooms. Specifically, we investigate: (1) patterns of errors in widely used commercial ASR systems for transcribing student discourse in authentic collaborative learning settings; and (2) the influence of ASR errors on downstream natural language understanding tasks at the word, phrase, semantic, and discourse levels. In doing so, we take an important step towards deploying speech-based collaborative learning technologies in classrooms.

1.1 Background and Related works

There is a large body of research on analyzing student- and teacher-classroom discourse [10, 54], so to keep scope manageable we focus on the automatic analysis of student speech and classroom speech.

1.1.1 Challenges with child speech recognition

Speech recognition in children is a well-documented challenge, with recognition accuracy substantially lower for children’s speech than adult’s [25, 61, 74]. Yet, both commercially-available and research ASR systems are generally trained with clean audio data from adult speakers, with one speaker per utterance, and often reading from a script, which perform substantially worse on realistic, spontaneous speech [83]. These systems do not easily generalize to child speech where vocal characteristics such as higher fundamental and formant frequency and greater variability in pitch, and linguistic factors such as disfluency rate, differ between children and adults, as well as changing as children mature [25, 46]. In an analysis of Google, Bing and Nuance ASR systems, [70] found that age significantly impacted performance for all ASRs except Google. Further, accented speech of non-native speakers impacts ASR performance, as articulation and pronunciation differ from the training data [19]. The classroom setting provides an additional challenge. Howard et al. [34] reported that the typical classroom signal-to-noise ratios range from -7 dB to +5 dB, further impeding ASR [95]. Finally, microphone placement impacts recognition - the further the speaker from the microphone, the greater the impact of reverberation and other signal degradation on ASR [23, 56].

1.1.2 Child speech recognition in controlled learning environments

Numerous educational applications which use ASR on children’s speech have been developed, albeit outside of the hustle and bustle of the classroom. One strand of research uses ASR as part of automatic reading tutors for young children learning to read aloud

from text. Here, the reference (ground-truth) transcript is available in the form of reading materials, and by comparing this to the ASR output, pronunciation errors can be identified and fed back to the student or their teacher [3, 51, 60, 66]. Generally, these systems are used in a quiet environment such as a library [66], and in all cases are designed with the expectation that only a single speaker is reading at a time. Another application of ASR is in conversational tutors, where both speech recognition and language generation are combined in a real-time system. One example is My Science Tutor (MyST [92]) which supports one-on-one and small-group science learning [13]. The MyST ASR system was trained using a dataset of elementary school students, and achieves a word error rate (WER) of 0.30 (about 70% accuracy) on a reduced vocabulary of ~6000 words. However tutoring sessions did not take place in the main classroom, and users wore a headset, both of which avoided some of the key challenges of classroom ASR. Online learning environments also simplify the collection of clean, speaker-separated speech recordings, and several examples exist of automated analysis of student-teacher dialog starting from ASR transcripts [47, 94].

1.1.3 Automated analysis of teacher speech in the classroom

Recent advances in ASR make the prospect of sufficiently accurate transcription of speech in the classroom a possibility. Most of the ASR literature focuses on adult speech, and this is mirrored in the availability of commercially available, cloud-based ASR APIs, (for examples, see [20] but see [15] for a child-tailored ASR service). As a result, most automated approaches have focused on analyzing teacher speech with varying degrees of automation including ASR-only [9, 37, 38, 42, 81, 96], human transcripts [82], or a combination of both [7]. There are also differences in the depth of the construct being modeled. For example, Zylich and Whitehill [96] recently aimed to automatically detect 21 key phrases (e.g., “good job”) in teacher talk from audio, but stopped short of measuring pertinent discourse constructs. In contrast, Kelly et al. [42] and Jensen et al. [37, 38] developed fully automated approaches to model five features of discourse: questions (vs. statements), authentic (open-ended), instructional utterances, elaborated evaluations, cognitive level, goal specificity, and presence of disciplinary terms.

One advantage of focusing on teachers is that it is easier to affix high-quality microphones on a single teacher than an entire classroom of students. For example, the Kelly and Jensen studies used a unidirectional, noise-canceling microphone with cardioid pickup pattern which is most sensitive to sounds from the front of the mic, thereby canceling background noise [37, 38, 42]. Despite a high-quality mic, classroom ASR is still challenging due to background noise, multidisciplinary chatter, dialectical variations, and so on. To this point, [5] and [18] compared several ASR engines for accuracy in transcribing teacher speech recorded in authentic classrooms. These two studies tested 7 ASRs yielding word error rates ranging from .31 to 1.00.

It is important that these studies are replicated due to the rapid advancement in ASR technologies each year. For example, using the same microphone and ASR engine on similar classroom data, Jensen et al. [37] obtained a major reduction in error (from 44% WER to 28%) in 2020 compared to Blanchard’s (2015) study [5].

1.1.4 Automated analysis of student speech in classrooms

Examples of automated analysis of classroom audio focused on student speech are rare, as justified by the many acoustic and

linguistic challenges inherent in the full pipeline from recording speech, to transcription in the context of overlapping, non-adult speakers in a noisy environment, to extracting meaning from language patterns of students still undergoing linguistic development. Nevertheless, several recent works have utilized non-specialized commercial ASR services for child speech with promising results - demonstrating that ASR transcriptions can be used to derive useful downstream measures despite very high WER [64, 84].

To our knowledge, the only example where ASR is used to transcribe conversations among students as input to an NLP model is in the context of a collaborative problem solving (CPS) study conducted in both the classroom and lab [64]. Here, students aged 12-15 participated in two CPS activities in math and physics. Participants wore headsets with microphones and completed the task (in dyads) over Zoom from a shared computer lab at the school, or for a subset of participants, in a laboratory. Captured speech was manually segmented into utterances, then transcribed using the IBM Watson speech-to-text service [36]. Performance degradation attributable to the classroom environment was evident, with a word error rate (WER) of 0.78 in the classroom, meaning only 22% of human-transcribed words were correctly transcribed, as compared to a WER of 0.54 for dyads recorded in the laboratory.

ASR has also been used to capture classroom conversation in preschool children. Lileikyte et al. [48] used LENA’s wearable audio recorders, which are designed for capturing speech in young children, to train an ASR with custom acoustic and language models using data augmentation, obtaining a WER of 0.64 on spontaneous conversation in 2–5-year-old children. Using the same wearable devices in preschoolers, Tao et al. [84] ran audio through Google Cloud ASR [26] and used the transcripts to derive network representations of groups in social interactions based on word count vector similarity between utterances, though ASR accuracy is not reported. Further, the use of LENA is cost-prohibitive, with pricing in the thousands of dollars, which is infeasible at scale.

Beyond these examples, speech analysis in the classroom is limited to extraction of non-linguistic (i.e., acoustic/prosodic) features, which nevertheless show promise for classification of discourse categories [6, 40, 91], speaker identification [84] and diarization to identify speaker turns [49, 53].

1.1.5 *Is perfect ASR needed?*

As reviewed above, ASR in the classroom is beset by many challenges, especially for analyzing student speech. However, the goal of many applications is not to obtain perfect transcripts of speech, but to use the transcripts for downstream NLU tasks relevant to education (e.g., assessment, feedback, intervention). Indeed previous research has indicated that useful information can be obtained from imperfect transcripts. Pugh et al. [64] found that using ASR instead of human transcripts led to only a 14% decrease in classifier performance (still significantly above chance) despite a WER of 0.78. Outside the classroom, Stewart et al. [78] reported a mere 4.2% decrease in accuracy for classifying collaborative skills using ASR versus human transcripts. Indeed, the question of robustness of models of team performance to simulated ASR errors was addressed by [22], with even a WER of 57% only decreasing classifier performance by 20% relative to perfect transcription. The authors suggest that the constrained, contextualized nature of conversation makes discourse-level NLP models robust to modifications of individual words.

Of course, there is likely an upper limit to errors beyond which the signal to noise ratio is too low to be useful, a likely possibility for

analyzing multiparty collaborative child speech in the classroom. This raises the questions of whether it is feasible to obtain meaningful information on student collaborative discourse despite noisy ASR and to what extent do ASR errors impact the meaning conveyed in an utterance and how does this impact downstream NLU tasks.

1.2 **Current Study, Contribution, & Novelty**

In this study, we take an important first step towards the automated analysis of student collaborative discourse in noisy, authentic classrooms. We compare a variety of commercially available ASR systems on both speech to text transcription, and we investigate the influence of ASR errors on downstream NLU tasks using a novel dataset of audio recordings from real-world middle-school classrooms where multiple student groups are engaged in CL.

Specifically, we quantify ASR performance in terms of traditional evaluation metrics (e.g., Word Error Rate [WER]), and investigate the types of speech recognition errors encountered (e.g., substitutions, deletions). Further, we seek an understanding of the sources of variability in ASR errors at the level of the utterance, student, and session by systematically sampling students across multiple recording contexts (i.e., across different lessons, student groups, and days). This information can provide insights into potential disparities of ASR systems, which may have unequal impacts on individual student outcomes when used as inputs to downstream applications. To this point, we also compare ASR errors and their influence on downstream NLU applications (e.g., semantic similarity of transcripts [43], recognition of task-relevant content words, assessing collaboration skills) to probe the feasibility of using automated transcripts for NLU-based CL analytics in the classroom.

To our knowledge, this is the first attempt to systematically analyze automated transcriptions of face-to-face student collaborative discourse in a real K-12 school environment. Although other studies use ASR as input to language-based models of classroom discourse, the majority of these focus on teacher speech [5, 9, 14, 37, 38] or collaborative problem solving in adult undergraduates [63, 78, 79]. We also use inexpensive, commercially available microphones placed on the tabletop, each capturing speech from 2-4 students, which allows us to expose the challenges of capturing real-world classroom audio where multiple speakers are intermixed in a single-channel recording with additional impacts of reverberation and background noise. This contrasts with prior studies analyzing classroom audio, which mostly employ individual microphones to isolate speech [5, 37, 47, 48, 64]. Also, we use data collected in the context of a live, face-to-face discourse rather than an online learning environment [47, 94]. The choice to use table-top mics rather than individual noise-canceling lapel microphones or headsets is motivated both by practicality and cost considerations, and by the concern that individually miking students would feel intrusive and even impede collaboration.

Finally, with respect to scope, we focus on widely available commercial ASR services in lieu of customized ASR systems with acoustic and language models trained on our target demographic and data. This may disadvantage speech recognition performance, however using publicly available ASR providers is desirable for practical reasons including the simplicity of integration due to a well-documented API, and the likely continuation of updates to the model in the future. We also don’t seek to improve or engineer better performance out of these systems in the current work because the goal is to establish baseline performance of out-the-box ASR

systems on the difficult task of analyzing child collaborative talk in noisy classrooms.

2. METHODS

2.1 Data Collection

The data was collected as part of a larger project involving a Research-Practice Partnership [41] focused on using co-design and professional learning to support the use of programmable sensor technology and computational thinking for authentic inquiry in middle school science and STEM classrooms [4]. We analyzed audio and video data from one participating U.S. public middle school teacher in this work.

2.1.1 Learning Context: Sensor Immersion

Participating teachers implemented a multi-day curriculum unit called Sensor Immersion that focuses on students working collaboratively to understand how to program and wire sensors to collect data about their local environments, empowering students to be data producers [31] and answer questions that they find personally meaningful and relevant. The Sensor Immersion curriculum uses an interactive data display called the Data Sensor Hub (DaSH [11]; Figure 1) as an anchoring phenomenon [24]. Students explore the system, create scientific models and learn to replicate its functionality in the context of their own investigations. Along the way, students develop a program that can control a variety of physical sensors including a sound sensor, moisture sensor, and an environmental sensor.

Sensor Immersion is broken down into five lessons, each of which can span multiple days. Lesson 1 focuses on question generation and modeling. Throughout the following lessons, students work to answer their questions about how the DaSH works. To do so they learn to program and wire the sensors, working in pairs doing a pair-programming task using MakeCode block programming (Figure 2). Students gradually build on their understanding of programming and sensors by working together to program and wire one sensor and eventually building and programming a sensor

system to answer questions about a personally meaningful phenomenon. Opportunities for small-group collaboration around these sensors and their programming are designed into each lesson.

Figure 1. Close-up of the DaSH system which links sensors to the computing interface. Various sensors can be wired to the system to measure local environmental conditions such as soil moisture levels (pictured), CO2, humidity, temperature and ambient room noise.

2.1.2 Participants

The data sample included 30 students from 4 cohorts taught by a single teacher in a suburban school district in the US. All procedures were approved by designated Institutional Research Boards and data were only collected from students who provided both personal assent and their parent’s signed consent forms. Most of the students were in the 6th-8th grades except for one class of 5th graders. Across the school district, the ethnicity of students enrolled (as of the 2021-2022 school year) was as follows: 62% White, 30% Hispanic, 3% Asian, 3% two or more races, 1% Black, 0.3% American Indian or Alaska Native, and 0.1% Hawaiian/Pacific Islander [77]. About half (49%) were female.

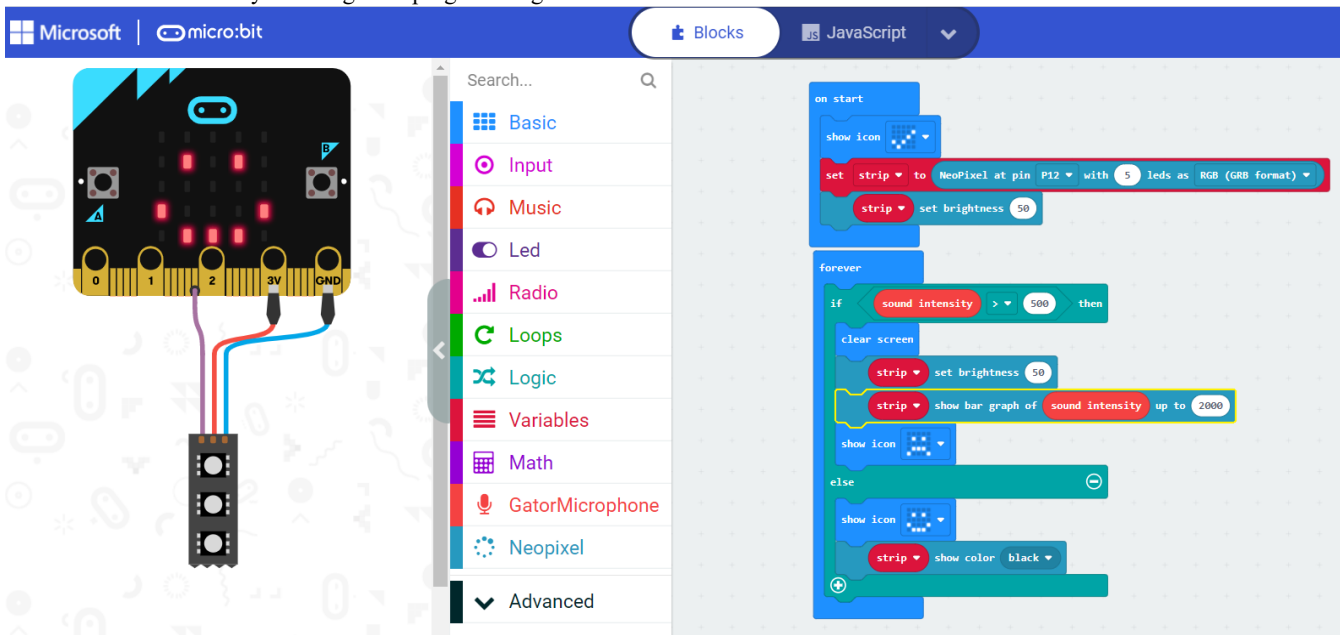

Figure 2. Screenshot of the MakeCode programming interface

2.1.3 Microphone

Our choice of microphone was influenced by several factors including audio quality, cost, power source, form-factor, and ease of use. We evaluated a range of candidates (e.g., MXL, Sony ICD PX370, ZOOM H1n, AudioTechnica-ATR, AudioTechnica-Omni, AudioTechnica-Cardioid, ProCon, Saramonic), we chose the Yeti Blue. This microphone has a user-configurable effective pickup pattern: omnidirectional, polar, XY stereo or cardioid, costing around \$100USD. It is USB-powered, enabling use with an iPad without the need for an external mixer or phantom power.

2.1.4 Procedure

During each class, researchers placed microphones (Yeti Blue) at tables around the classroom. Groups of 2-4 consenting students were seated at each table. Depending on the lesson the students either worked as a team or as multiple dyads (during pair programming). The microphone was placed on the table roughly equidistant from all students, using the omnidirectional setting when recording 3 or more students, or the stereo setting when two students were sitting at either side of the microphone. The microphone was connected to an iPad via USB that hosted the recording software recording at 48kHz sampling rate. We also collected iPad video from a subset of students. Microphones were set up by a researcher who recorded field notes on different events (e.g., start of lesson, start of small group work, technical failures).

2.2 Data Treatment

2.2.1 Sample Selection.

We opted to select recordings with both audio and video to aid in ground-truth speaker diarization efforts (i.e., who is speaking). Of a total of 118 recordings, 79 met this criterion, of which we selected 49 recordings which contained small-group work, where at least one student in each group appeared in a minimum of 4 recordings.

From each video, five 5-minute candidate samples were selected from within the small-group work segment of the lesson, constrained to the middle of the segment such that the random sample included the midpoint of the small-group interval as beginning and end of the task tended to include less on-topic speech. A researcher then listened to each of the five random samples in turn. If the sample met the 20-word criterion, then it was selected for the sample. If it did not meet the criteria ($n = 17$), the next segment was listened to and so forth. If none of the 5 segments met the criteria, then the recording was excluded entirely. Through this process, we ended with 32 samples totaling 160 minutes of speech from 30 students. A majority (70%) of the students were in at least two recordings (Table 1).

Table 1. Sample summary

	M (SD)	Range
No. students per recording	2.6 (0.7)	2-4
No. recordings per student	2.7 (1.6)	1-5
No. utterances per recording	61.6 (29.6)	21-139
No. utterances per student	65.7 (47.2)	10-188
Wordcount per utterance	4.55 (4.03)	1-47

2.2.2 Transcription and annotation

Samples were transcribed in ELAN annotation software by trained transcribers, who recorded millisecond-resolution timestamps (based on the audio waveform) for utterance start and end times along with speaker identity. Where speaker identity was clear, but speech was too indistinct to transcribe, some or all of the utterance content was coded as "[inaudible]". This resulted in 2207 student

utterances, of which 1970 contained at least 1 audible word (See Table 1).

Utterance-level audio segments were automatically transcribed by three cloud-based ASR services: Google Speech-to-text [26], Rev.ai [68], and IBM Watson [36]. We selected Google because it has been shown to work as well for children as adults [70] and in a recent review was shown to outperform similar services [20]. Watson has been used in multiple publications for ASR transcription of teacher talk [5, 37, 38] and as input to CPS linguistic models [63, 64]. Rev.ai was used as they claim equal or greater performance than Google [69]. We deemed these three ASRs sufficient for the present purposes of investigating patterns in and downstream influences of ASR errors and not to evaluate all available commercial ASR engines.

For Google, audio was first segmented using the human-segmented utterance-boundaries and individually submitted to the ASR. We used the video-optimized model as this was determined to outperform the default model in preliminary testing. For Rev.ai and Watson, all utterances from a given recording were concatenated before transcribing, as this theoretically allows the models to use prior language context to boost performance. The ASR result contains word-level timestamps which were used to split the full transcript back into the original utterances. We also tested using per-utterance transcripts for Watson and the Google streaming speech recognition API using the *single_utterance=True* option optimized for short utterances. Due to poorer performance than the main Watson and Google models, these were not analyzed further.

2.3 Measures

Before computing measures on the transcripts, all texts (human and ASR transcribed) were normalized to facilitate comparison. Non-word indicators used by the transcribers and ASR systems such as "[inaudible]", "[redacted]" and "%HESITATION" were stripped out. Numbers were spelled out if transcribed as digits. Leading and trailing punctuation was stripped from each word, and hyphens replaced by space. Finally, all words were transposed to lowercase.

2.3.1 Word Error Rate.

Using standard procedures [83], for each utterance, we used the Levenshtein algorithm at the word-level, which finds the minimum number of word substitution (S), insertion (I) and deletion (D) operations to align the reference (human transcript) to the hypothesis (ASR transcript). We used word error rate (WER) as a measure of transcription accuracy, which is given by: $WER = (S + D + I) / N_{reference}$ (number of words in the reference text). Proportion of insertion, substitution, and deletion errors were computed by dividing utterance-level error counts with the number of words in the human transcript. We also computed the number of words in the ASR transcripts along with a binary variable indicating whether the ASR returned any transcript at all.

2.3.2 Downstream NLP Measures

We focused on NLP tasks at the word, semantic, and discourse levels. In each case, we are interested in the error (distance) between the ASR (hypothesized) and human (reference) values.

2.3.2.1 BLEU Scores

The BLEU metric was developed to assess the performance of machine translation systems by comparing a gold standard translation to an output translation [59]. BLEU scores quantify sentence similarity based on modified n-gram precision, where scores vary from 0 (no match) to 1 (perfect match). This captures higher-order structure than WER: it is invariant to n-gram order,

and encapsulates longer subsequences than WER which is defined only at the individual word level. We computed the BLEU score for unigrams, bigrams, trigrams, and quad-grams and computed an unweighted average of the four, which was reversed (i.e., 1-BLEU) to get the BLEU distance (or error)

2.3.2.2 Topic Word Analysis.

At the word level, we quantified students’ uses of topic words that might be indicative of their cognitive engagement with the sensor immersion unit. The curriculum materials consist of storyboards, lesson plans, tutorials, etc., from which we generated a frequency dictionary of the named entities using the Named Entity Recognition algorithm from the Stanford CoreNLP toolkit [55]. Functional words were removed, resulting in 2,438 candidate words. Next, we used an existing Latent Dirichlet Allocation (LDA) topic model (created for an auxiliary purpose), which learns distinct topics from the document and returns the top 20 words that have the highest correlation with each of 20 topics. We computed the intersection of the 400 topic words and the 218 candidate named entities that occurred more than 20 times. This threshold ensured candidate words appeared at multiple points in the curriculum documents while keeping the list to a manageable size. This produced a set of 66 initial topic words. These topic words were then reviewed by curriculum experts who selected a subset of 33 topic words aligned to the following categories: science (e.g. *environmental*), coding (e.g. *function*), and wiring (e.g. *sensors*). For each utterance, we computed the number of topic words recognized by each ASR and the human transcript. To measure ASR fidelity specific to topic words, we compute *Topic Distance* as the absolute difference in utterance-level topic word counts between the human and ASR derived transcripts, with a lower bound of 0 and an undefined upper bound.

2.3.2.3 Semantic Distance

Beyond words themselves, we also evaluated the ASR transcripts using the semantic distance metric, which measures the similarity of a reference and a hypothesis transcript in a sentence-level

embedding space (using a pre-trained language model to obtain the embeddings), and has been shown to be a better predictor of performance on downstream NLP tasks than traditional metrics such as WER [43]. Following the procedure outlined in [43], we first extracted utterance-level embeddings using the *sentence-transformers* Python library [67] and the ‘*all-distilroberta-v1*’ model [50]. Then, we computed the cosine distances between the embeddings of each ASR (hypothesized) transcript and the reference human transcript. The cosine distance is defined as 1-cosine similarity (which ranges from -1 to 1), so it can take on values from 0 (identical) to 2 (dissimilar). To obtain a baseline value, we randomly shuffled the human transcripts within each 5-minute recording, then computed the semantic distance to each ASR transcript as described above. The average semantic distance over all ASRs was used as a baseline.

2.3.2.4 CPS Skill Classification

At the discourse level, we evaluated the utility of our ASR transcripts for a concrete NLP application: classifying collaborative problem solving (CPS) skills from student transcripts, which is one of the target applications noted in Section X. Specifically, we applied an existing classifier [63], which was trained to identify the following three CPS skills based on a validated CPS framework [80]: constructing shared knowledge; negotiation/coordination; maintaining team function, to our dataset. The classifier was a pre-trained BERT [16] model fine-tuned on a data set of 31,533 expert-coded student utterances (transcribed using the Watson ASR). Although the classifier was trained on a different dataset, it has been shown to be generalizable across domains [63], so we deemed it suitable for the present purposes. As such, we submitted both the human and ASR transcripts to the classifier, which outputs the predicted probabilities for the three CPS facets on each utterance. For each ASR, we computed the three-dimensional Euclidean distance between the ASR- and human- (reference) predicted probabilities as a measure of dissimilarity (CPS Distance). We also obtained a baseline shuffled value similar to the baseline Semantic Distance.

Table 2. Sample sentences and their corresponding ASR transcriptions. CPS codes: Const. = constructing shared knowledge; Neg. = negotiation/coordination; Maintain. = maintaining team function

Speaker	Human Transcript	Google	Watson	Rev	CPS Code
A	just start with the show number	start remove the show number	system started with the show numbers	start with the show number	Const.
B	oh	-	okay	okay	None
A	okay so you get rid of the show number	okc get rid of the sheriff	okay	okay so you get rid of the sharon remember	Maintain.
A	just drag it	stretch	dr don't	-	Maintain.
C	don't don't do that	don't don't do that	don't don't don't do that	don't do that	Maintain.
A	get rid of it	-	-	get rid of it	Maintain.
C	just okay	just	okay	it	Neg.
B	and now put this in this thing	i am for this and this thing	okay but this in this thing yeah	put this and this thing	Const.
A	yes	-	yeah	-	Neg.
C	no now you eat a taco	you know how you eat a taco	yeah are you talking	you need to talk	Maintain.
B	no do i put it in there	-	-	-	Const.
C	yeah	-	-	-	Neg.
A	yes	-	-	-	Neg.

2.4 Data Treatment

All measures (proportions of insertion, substitution and deletion errors; BLEU distance, Topic distance, semantic distance, CPS distance) were averaged per speaker per recording, resulting in 82 observations per ASR. This was done to obtain more reliable estimates due to the principle of aggregation. Because the distance metrics are only meaningful for utterances where the ASR returns a nonempty transcript, the averages for BLEU, Topic, Semantic and CPS distances were computed over nonempty transcripts only. To analyze the effects of ASR service and word errors on downstream measures, we used mixed effects linear regression models with speaker and recording identifier as random intercepts to account for the nested and repeated structure of the data with multiple speakers nested within recordings. Further, we used the *robustlmm* package in R [45], which provides estimates that are robust to outliers and other contaminants in the data. We used estimated marginal means (*emmeans* package in R) for pairwise comparisons using false-discovery rate adjustments for multiple comparisons and Satterthwaite’s degrees of freedom method. We used two-tailed tests with a $p < .05$ cutoff for significance.

3. RESULTS

3.1 ASR Errors

3.1.1 Patterns in Error Types

Table 3 provides descriptives on ASR performance measures averaged by student by recording. Immediately apparent is that the vast majority of ASR errors were deletion errors (67%) compared to substitution (17%) and insertion errors (6%; the sum of errors does not add up to 100% because of words correctly recognized). Indeed, when error rate was regressed on error type (three level categorical variable) and number of words in the human transcript (as a covariate), we found the following significant ($ps < .001$) pattern in the errors: Deletion > Substitution > Insertion (Table 3).

3.1.2 Comparing ASR Engines

We regressed each error type on ASR (a three-level categorical effect with Google as the reference group) and reference (human) transcript word count as a covariate. For deletion errors, we found Watson and Rev to be statistically equivalent and higher than Google suggesting the following significant ($ps < .0001$, FDR correction for 3 tests) pattern in the data: [Watson = Rev; $p = .61$] > Google. This pattern was largely flipped for substitution errors: Google > Watson > Rev; $p < .004$. For insertion errors, Google resulted in more insertion errors than Watson, but Rev was intermediate and not significantly different from either. Deletion errors ($p < .001$) were less likely as reference word count increased, but substitution ($p = .582$) and insertion ($p = .137$) errors were not.

Since insertion errors were rare, the tradeoff involved deletion and substitution errors (Figure 3) with Google providing fewest deletions but the most substitutions, the opposite for Rev, and Watson was intermediate. All things equal, the choice of ASR thus depends on obtaining as many transcriptions of speech as possible. Google provided a non-empty transcript for on average 61% of the cases, far exceeding the others (47% for Watson, 41% for Rev), and even among the utterances with nonempty ASR transcriptions, Google had a lower rate of deletions (0.29) than Rev (0.33) and Watson (0.44).

Table 3. Summary statistics of ASR results. M (SD) over utterances

	Google	Rev	Watson
N utterances	1970	1970	1970
N averaged	82	82	82
ASR metrics			
ASR wordcount	2.37 (1.36)	1.71 (1.46)	1.31 (0.95)
Nonempty ASR	0.61 (0.22)	0.41 (0.22)	0.47 (0.22)
Perfect ASR	0.05 (0.06)	0.04 (0.05)	0.02 (0.06)
Insertion rate	0.06 (0.09)	0.08 (0.16)	0.04 (0.08)
Substitution rate	0.21 (0.11)	0.12 (0.08)	0.19 (0.13)
Deletion rate	0.56 (0.18)	0.72 (0.17)	0.72 (0.17)
WER	0.84 (0.15)	0.91 (0.19)	0.95 (0.11)
Downstream NLP metrics			
Topic Distance	0.05 (0.10)	0.05 (0.09)	0.05 (0.07)
BLEU Distance	0.83 (0.11)	0.82 (0.15)	0.94 (0.06)
Semantic Distance	0.56 (0.14)	0.52 (0.15)	0.68 (0.09)
CPS Distance	0.29 (0.14)	0.29 (0.15)	0.33 (0.16)

Figure 3. Density plots of deletion and substitution errors by ASR

3.1.3 Sources of Variance

We carried out a multilevel decomposition of variance [35] on each type of ASR error, at three levels: utterance, speaker and recording. Utterances are nested within speakers, and speakers within recordings. We computed the proportion of variance attributable to speaker and recording by decomposing the data into a linear sum of cluster-level averages and within-cluster deviations. The variance between-cluster and within-cluster sums to the total variance, under the assumption that errors at utterance, speaker, and recording are independent. We found that the majority of variance (between 91 and 98%) was at the utterance level for all error types and ASRs, with just 1-3% attributable to individual students and 1-5% to the specific recording (Table 4). This suggests that each ASR system had stable performance across recording contexts and individual differences in vocal parameters.

Table 4. Multilevel variance decomposition. Proportion of variance attributable to each hierarchical level.

ASR	Error type	Utterance	Student	Recording
Google	Insertion rate	0.981	0.009	0.010
Google	Substitution rate	0.980	0.010	0.010
Google	Deletion rate	0.943	0.032	0.025
Rev	Insertion rate	0.980	0.004	0.016
Rev	Substitution rate	0.971	0.009	0.020
Rev	Deletion rate	0.914	0.032	0.053
Watson	Insertion rate	0.976	0.009	0.015
Watson	Substitution rate	0.972	0.011	0.017
Watson	Deletion rate	0.950	0.025	0.025

3.2 Downstream NLP measures

The Spearman correlations between distance metrics for the four downstream tasks are shown in Table 5. The most highly correlated metrics were semantic distance and BLEU distance ($r = .83$), whereas the CPS distance was only moderately correlated (r between .3 and .4) with these measures. Topic distance was not correlated with any other metric, which may be a result of topic words being so rare in the utterance (about 5% of words).

Table 5. Correlations between transcript distance metrics. * $p < 0.001$**

	BLEU Distance	Topic Distance	Semantic Distance
Topic Distance	-0.118		
Semantic Distance	0.830***	-0.040	
CPS Distance	0.321***	0.076	0.402***

Figure 4 shows the distributions of CPS and semantic distances. The peak of the distribution was lower than the baseline (derived by computing the average distances between ASR and human-transcribed utterances after shuffling; see Methods) for all three ASRs and for both CPS and Semantic distances. In fact, 97.5% of semantic distances were less than the shuffled baseline, and 79% for CPS, indicating that a degree of higher-order meaning was generally extracted from the ASR transcripts.

Figure 4. Density plots of CPS Distance and Semantic Distance by ASR. Dashed line shows the random baseline for shuffled utterances.

3.2.1 Comparing ASRs on Downstream NLP

We regressed each distance metric on ASR (a three-level categorical effect with Google as the reference group) and reference (human) transcript word count, with random intercept of student and recording. As indicated in Figure 5, the ASR services did not vary for Topic word distance ($p = .929$), but did for the other measures. Specifically, the pattern of significance ($ps < .001$) for BLEU and semantic distances was: Watson > Google > Rev. For CPS distance it was Watson > Rev, $p = 0.03$; Watson = Google, $p = 0.16$; Rev = Google, $p = 0.46$.

Figure 5. Estimated marginal means and 95% confidence intervals for NLP distance metrics for each of the ASR services

3.2.2 ASR errors on downstream NLP tasks

To test whether specific ASR errors impact downstream NLP metrics, we also fit a linear mixed-effects model to predict each distance metric from the rates of three ASR errors (Table 6). Whereas insertion errors did not significantly predict any of the outcomes, both substitution and deletion errors were negatively ($ps < .001$) associated with BLEU, semantic, and CPS distance measures, more so for the former. Specifically, a one standard deviation increase in each error type was associated with an approximately equivalent increase for BLEU and semantic distances, but only about a half a standard deviation increase for the CPS tasks. Error type was not associated with topic word distance, presumably due to a restriction of range with this measure.

Table 6. Mixed-effects model predicting distance metrics from ASR errors, showing standardized Beta values

Predictors	BLEU Distance		Topic Distance		Semantic Distance		CPS Distance	
	<i>std. Beta</i>	<i>p</i>	<i>std. Beta</i>	<i>p</i>	<i>std. Beta</i>	<i>p</i>	<i>std. Beta</i>	<i>p</i>
(Intercept)	0.07	<0.001	-0.27	0.020	0.05	<0.001	-0.05	0.189
Substitution rate	0.91	<0.001	-0.05	0.231	1.04	<0.001	0.46	<0.001
Deletion rate	1.08	<0.001	-0.05	0.256	1.12	<0.001	0.49	<0.001
Insertion rate	-0.03	0.345	0.01	0.676	0.03	0.446	-0.01	0.870

4. DISCUSSION

We investigated the feasibility of using commercially available ASRs to transcribe student discourse from a collaborative learning activity in a middle school classroom with an eye for downstream NLP tasks aimed to support student learning. In the remainder of this section, we discuss our main findings, applications, limitations, and areas for future work.

4.1 Main Findings

Overall, WER was very high (.84-.95) compared to performance on benchmark datasets, and even compared to WER from prior CL studies using classroom audio, such as in Pugh et al. 2021 who reported a WER of .78 using Watson, but with individual microphones in a more restricted in-class data collection setting compared to the current in-the-wild classroom context. At first blush, these high WERs suggest that it might be futile to expect meaningful ASR in noisy classroom environments without explicitly instrumenting the classroom for this purpose [1] or resorting to miking individual students with customized high-fidelity microphones [90]. However, an in-depth analysis of the pattern of errors suggests that there is hope: specifically, the ASRs had a large proportion of deletion errors and fewer substitution and almost no insertion error meaning that they tended towards high precision but low recall and are thereby feasible for applications that match this profile (as elaborated below).

Comparing the three ASR engines we examined, Google and Rev were biased towards more substitutions and deletions respectively, but also relevant is the proportion of utterances which did not get transcribed at all. Here, Google provided a clear advantage with nonempty results returned for 60% of utterances compared to less than 50% for the other two. Reassuringly, the variance in ASR errors was overwhelmingly from utterance-level differences, with very little attributable to recording or student. In addition, of 1970 utterances, only 477 (24%) returned no transcript from any ASR, raising the possibility of combining outputs from multiple ASRs.

We computed several distance metrics to capture ASR quality as reflected in downstream NLP measures, in each case computing the deviations between ASR-produced and human-transcript versions of each measure. With respect to the four measures, topic word usage was rare and there was very little variability in this measure so unsurprisingly there were no differences for it. Turning to the other measures, Watson was consistently outperformed by Google and Rev, which were equivalent on CPS distance. However, BLEU and semantic distance, which were strongly correlated, were best captured by Rev, despite Google having lower word-level error rates. Thus, Rev had a slight edge over Google for the downstream NLP tasks, but not sufficient to compensate for its higher deletion rate. Finally, as the NLP analyses got more abstract, ASR errors had less of an impact. The effect of substitutions and deletions on CPS distance (a discourse-based construct) was about half that of semantic and BLEU distances, (i.e. word- and semantic-level

measures). Whereas this pattern is intuitively plausible it awaits replication with additional downstream NLP measures.

4.2 Applications

The ability to automatically capture and transcribe student speech during CL activities in the classroom opens the door for numerous applications. Fair and accurate ASR transcripts are the first step for automated interventions that aim to support CL in classrooms. One promising strand of research involves designing teacher-facing applications, such as teacher dashboards, which convey information about student collaborative talk to the teacher. The design space for such technologies is broad and relatively unexplored. While there is potential for abuses such as increased monitoring and evaluation of student talk, responsible innovations can also leverage student transcripts to celebrate students' contributions, build communities within classrooms and foster authentic collaboration motivated by student interest, not desire for positive reinforcement. For example, information gathered from CL discourse could be presented to a teacher offline (i.e., after class), illustrating any number of relevant details about the CL activity (e.g., what students talked about when on-task versus off-task, balance of speaking time, quality of collaboration). To demonstrate, we created an example dashboard visualization of the model-estimated occurrence of three CPS facets in student utterances (Figure 4) using both human- and Google- generated transcripts. As evident in the figure, model estimations are notably impacted by ASR error (i.e., in this group, the model underestimates the use of constructing shared knowledge by students A and C). Although model estimations will be imperfect, they can still provide valuable insights, and the impact of errors can be diminished by aggregating over longer time scales. These after-action reviews could greatly benefit teachers, giving them insight into how they might better support CL in their classroom. This includes designing new activities to better engage students, understanding which student groups may need additional support in future classes and what CPS skills students need help developing.

Similarly, these insights could be conveyed to the teacher online (i.e., during class) via a real-time teacher dashboard. Real-time feedback on CL groups could also enhance a teacher's ability for more effective classroom orchestration by providing them with novel insights into how groups are working together and what kinds of feedback and encouragement will help increase productive collaboration for students. Ultimately, the specifics of these teacher-facing applications, such as what information to present, when to present it (e.g., real-time, offline), how to display it (e.g., graphic representations, transcripts of speech) and at what level of granularity (e.g., individual students, CL groups, whole class) will require co-design, testing, and refinement with teachers.

In addition to teacher-facing applications, ASR systems could be used to create student-facing CL supports in the classroom. These technologies could take many forms, from real-time or after-action

feedback that helps students develop CPS skills to a conversational agent which serves as a socio-collaborative ‘partner’, working together with student groups to enhance learning, equitable participation, and collaboration. Current approaches to support student collaboration (for example by prompting for the use of high-quality discourse called academically productive talk) have been shown to be successful in the context of text chat [85]. Further, after-action reviews to support CPS by providing feedback based on ASR/NLP models has demonstrated potential in the lab [64], but has yet to be tested in classrooms. Whether this is applied to student- or teacher-facing tools, fair and accurate ASR in classrooms has the potential to spotlight students’ verbally-expressed ideas and contributions. This offloads the demand that is normally placed on written work and provides more multimodal dimensions for classroom feedback and support.

Whereas perfect ASR should not be a prerequisite for several applications (as argued in the Introduction), the patterns in ASR errors should be carefully considered in that the ASRs have high precision (relatively low substitution and insertion errors) but low recall (high levels of deletion errors). This suggests that these data are best suited for applications for which transcription of a sampling of utterances is sufficient, for example, assessments of constructs with high-base rates (e.g., CPS skills) rather than those focused on rare events. This high precision could be helpful in avoiding unwarranted interventions triggered by CL supports, as there should be a low rate of false alarms of discourse features detected based on the ASR results. Nevertheless, our findings suggest that a real-time conversational partner will likely be off the table until ASR deletion errors can be reduced. Nevertheless, robustness of NLP models to ASR errors can be improved by data augmentation approaches where models are trained on ASR hypotheses as well as human transcripts [58].

Figure 5. Predicted probabilities of CPS skills over a sample 5-minute recording (using the student group shown in Table 2) based on human (left) and Google ASR (right) transcripts

4.3 Limitations and Future Work

There were several limitations to this study. First, although we investigated an automated approach to transcribe student utterances, we did not incorporate automatic utterance segmentation in our pipeline. Rather, utterances were manually identified and segmented by a human observer before being processed by the ASR systems, which is consistent with prior work on comparing ASRs [5, 18]. This was done because the present focus was on speech-to-text transcription and not utterance-segmentation, so we opted for a gold-standard baseline for the latter to compare the various ASRs for the former. Further, utterance-segmentation is technically not needed as a separate step in an automated pipeline in that the entire five-minute audio segment could be submitted to the ASR engines for combined utterance

segmentation and speech transcription, albeit less accurately than human segmentation. Indeed, longer context than single utterances are beneficial in modeling CL [64].

Another limitation is that we only tested out-of-the-box cloud-based ASR systems. One problem with this approach is that reliance on cloud-based services may be unrealistic in the near-term. In the US, nearly 28 million students did not have sufficient internet bandwidth for multimedia learning [97]. Similarly, we did not attempt to improve the performance of these out-of-the-box systems (e.g., by fine-tuning a custom ASR model on our data or providing a task-specific vocabulary) because the present goal was to compare these systems “as-is” since many researchers might not have the technical expertise needed to train customized models or fine-tune existing models. However, recent advances in deep-learning-based ASR mean pretrained models are widely available and a relatively small amount of data is needed for fine tuning [2, 74], which may provide better performance in this domain than standard cloud-based systems. To this point, we are currently developing a customized, locally hosted ASR system to improve upon the present results and address the limitations above.

One additional limitation is the lack of diversity in our sample. Whereas student-level demographic data was unavailable, district-level information suggests that 92% of the students were either White (62%) or Hispanic (30%). Racial disparities in ASR performance [44], as well as challenges with non-native English speakers [93] are well documented and may have disproportionately adverse effects on underrepresented groups when ASR is used for downstream applications. Thus, the lack of variability at the student level might be partly because our sample was non-representative. To create more fair ASR transcripts, non-native English speakers and students from non-dominant cultures should be oversampled to create representation, and thus accuracy, equal to students from dominant cultures. We also chose to include data from a single (although multi-lesson and multi-day) curriculum unit as implemented by one teacher with a small number of students. In sum, these factors reduce the generalizability of our findings to groups historically underrepresented in STEM. Our future work will aim to address these limitations by collecting classroom speech from racially and socioeconomically diverse populations, and examining ASR performance across different groups to identify sources of bias or nonequivalence.

4.4 Conclusion

Automated speech recognition in conjunction with natural language processing has the potential to unlock collaborative learning supports in the classroom. We recorded authentic small-group interactions in middle school STEM classrooms using inexpensive, commercially-available equipment, and analyzed the transcripts provided by several cloud providers. We show how different types of transcription errors influence downstream linguistic models, and find that the impact of ASR errors is smaller for the predictive accuracy of a CL model than for upstream measures capturing more literal aspects of speech content. Our results demonstrate the challenges of automating speech recognition in the classroom, but suggest the potential of using imperfect ASR to gain insights into collaborative discourse.

5. ACKNOWLEDGMENTS

This research was supported by the NSF National AI Institute for Student-AI Teaming (iSAT) (DRL 2019805). The opinions expressed are those of the authors and do not represent views of the funding agencies. We also thank Jon Cai (LDA topic models) and Robert Moulder (variance decomposition).

ABSTRACT

As outlined by Benjamin Bloom, students working within a mastery learning framework must demonstrate mastery of the core prerequisite material before learning any subsequent material. Since many learning systems in use today adhere to these principles, an important component of such systems is the set of rules or algorithms that determine when a student has demonstrated mastery. A relevant issue when discussing mastery learning is its durability—in particular, we are interested in the relationship between different mastery learning thresholds and the forgetting of the learned material. As such, in this study we investigate this question using a large data set from the ALEKS adaptive learning system. Applying a quasi-experimental design, we find evidence that, while a higher mastery threshold is initially associated with a higher rate of knowledge retention, after several weeks this difference has largely disappeared.

Keywords

Mastery learning, forgetting, adaptive learning

1. INTRODUCTION

Many adaptive learning and intelligent tutoring systems in use today employ the principles of *mastery learning*. As outlined by Benjamin Bloom [9], in such a framework students must demonstrate mastery of the core prerequisite material before working on any subsequent material. Thus, an important component of any system implementing mastery learning is the set of rules or algorithms used to determine when a student has mastered a skill or problem type. Over the years, important families of models have been developed for this purpose, with perhaps the most noteworthy being Bayesian knowledge tracing (BKT) and its derivatives [6, 17, 43, 68], and the factors analysis family of models, with examples of the latter including Learning Factors Analysis (LFA) [13] and Performance Factors Analysis (PFA) [45]. Additionally, other simpler rules and heuristics, such as re-

quiring students to correctly answer a certain number of questions in a row [32], are also utilized.¹

As there is a balance between ensuring students have sufficiently mastered a problem type, while not subjecting them to more practice than necessary—variously referred to as “over practice” [14] or “overlearning” [51]—previous works have looked in detail at mastery learning thresholds and how to optimize them for various factors such as student learning efficiency [7, 14] and classification performance [22, 32]. Additionally, it has been argued that the choice of data and the threshold used are more important than the specific type of model being applied [46].

A related subject is that of knowledge retention and forgetting. In particular, the Ebbinghaus forgetting curve [4, 21] models the decay of knowledge over time, with numerous studies having looked at the conditions affecting these curves in settings as varied as laboratory experiments [26, 40, 42, 56], classrooms [2, 8, 25], and adaptive learning and intelligent tutoring systems [37, 38, 62, 65, 66]. Other works have shown that learning systems benefit greatly by accounting for forgetting [16, 35, 47, 63] and having personalized interventions and review schedules [34, 44, 55, 58, 67].

In this work, we are interested in the relationship between different mastery thresholds and the retention of knowledge. Additionally, we compare and contrast the frequencies at which problem types are successfully learned under these mastery thresholds. To perform these analyses, we take advantage of a “natural” experiment that occurs within the ALEKS adaptive learning system where, depending upon the outcome of an assessment given at the beginning of a course, problem types are assigned to two different mastery thresholds. By comparing the outcomes from these different thresholds, we hope to understand more about the relationship between higher mastery, extra practice, and forgetting.

2. BACKGROUND

In this section we give a brief background of the ALEKS system. Within the system, a *topic* is a problem type that covers a discrete unit of an academic course. Each topic contains many examples called *instances*, with these examples being chosen so that they cover the same content and are

¹Interestingly, recent work has shown that some of these simpler models—including the one we consider in this study—can be viewed as special cases of BKT [19].

J. Matayoshi, E. Cosyn, and H. Uzun. Does practice make perfect? Analyzing the relationship between higher mastery and forgetting in an adaptive learning system. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 316–324, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

equal in difficulty. The topics in an ALEKS course contain many *prerequisite* relationships. That is, topic x is a prerequisite for topic y if x contains certain core concepts and material that must be learned before it's possible to learn the material in y .

At the start of an ALEKS course, the student's incoming knowledge is measured by an adaptive *initial assessment*. After each question of this assessment, a probability estimate is computed for each topic in the course, with this probability measuring how likely it is that the student knows the topic. At the end of the assessment, based on both these probability estimates and the prerequisite relationships between the topics, the ALEKS system partitions the topics in the course into the following three categories.²

- Topics that are most likely known
- Topics that are most likely unknown
- All remaining topics (uncertain)

Next, in the ALEKS learning mode a student is presented a topic the system believes they are ready to learn, and the student can access additional topics they are ready to learn from a graphical list. In all cases, the topics being learned are from the uncertain and unknown categories. To determine mastery, a *high mastery* threshold is used for the unknown topics, while a *low mastery* threshold is used for the uncertain topics (we give precise definitions of these thresholds shortly). As the system is not sure if the uncertain topics are actually known by the student, relaxing the threshold allows the student to more quickly demonstrate mastery.

When learning a topic, a student can take three possible actions: submitting a correct answer, submitting a wrong answer, or accessing an explanation page with a worked solution to the current instance. We define the *learning sequence* to be the sequence of actions taken by the student while working on a particular topic. A student begins their learning sequence with a score of 0, whereupon they are presented an example instance with a worked explanation. Following this, the student receives another instance for actual practice. Each time the student receives a new instance, they can try to answer it, or they can access the explanation page. Note that a student is always given a new instance after a correct answer, viewing an explanation, or submitting two consecutive wrong answers. Depending on the student's action, the score is updated based on the following rules.

- (1) A single correct answer increases the score by 1; however, if the correct answer immediately follows a previous correct answer, the score increases by 2 instead.
- (2) An incorrect answer decreases the score by 1 (unless the score is already at 0).
- (3) Viewing an explanation does not change the score. However, it does affect rule (1)—for example, if a student answers correctly immediately after viewing an explanation, the score increases by only 1 point, rather than 2, regardless of the student's previous responses.

²While beyond the scope of this study, the validity of both the probability estimates and the topic categorizations have been evaluated in works such as [18, 39].

For an unknown topic, the student must achieve a score of 5 before the topic is considered mastered—this is the aforementioned high mastery threshold. Alternatively, topics that are classified as uncertain only require a score of 3 to achieve mastery—this is the low mastery threshold. Finally, if a student gives five consecutive incorrect answers, this is considered to be a failed learning attempt—in such a case, the student is gently prompted to try another topic.

3. EXPERIMENTAL SETUP

Our study uses data from 13 different ALEKS mathematics products, ranging from elementary school mathematics to college-level algebra. From these products, we gathered data for a total of 2,235,061 students over a three-year period starting in January 2017. While we don't have access to detailed demographic information for our sample, we can say the majority of the K-12 students are from U.S. public schools, while the higher education products contain a mix of students from community colleges and four-year institutions, again mainly from the U.S.

To test the retention of the topics after they are mastered, we make use of the ALEKS *progress assessment*, an assessment given at regular intervals that is focused on the student's recent learning. The progress assessment plays a key role in the ALEKS system, as it enforces two learning strategies that have been shown to help with the retention of knowledge: spaced practice [30, 64] and retrieval practice [5, 31, 48, 49, 50]. To evaluate student knowledge retention, we define the *retention rate*—or, the *correct answer rate*—to be the proportion of the time that students answer topics correctly in the progress assessment after having mastered the topics in the ALEKS system.

Our analysis is complicated by a selection bias that exists with the assignment of the different mastery thresholds. That is, the topics using the low mastery threshold, being from the uncertain category, are the ones for which the ALEKS assessment was not confident enough to classify as either known or unknown by the student—as such, it stands to reason that some proportion of these topics are likely known by the students, or that, at the very least, these topics tend to be easier for the students to learn. In comparison, the topics that are classified as unknown by the ALEKS system are typically more difficult for the students.

Thus, to compensate for this issue, we apply the elements of a regression discontinuity design (RDD) [59] to our analysis. RDD is a popular quasi-experimental design that is commonly used in fields such as econometrics [3] and political science [23]. The idea is that, given an experimental condition assigned by an arbitrary cutoff, it's plausible the data points close to this cutoff are similar, regardless of which side of the cutoff they ultimately fall on. In this study, we leverage the fact that a probability cutoff determines the assignment of the mastery threshold in the ALEKS system, with topics below the cutoff being assigned the high mastery threshold, while topics above the cutoff are assigned the low mastery threshold. By comparing topics with probabilities close to the cutoff, we hope to get accurate estimates of the differences between the two mastery thresholds.

In order to apply these ideas, we must account for the fact

that the ALEKS system also uses the information from the prerequisite relationships to assign the mastery threshold to topics. For example, suppose topic x is a prerequisite for topic y . Because of this relationship, if x is answered incorrectly during an ALEKS assessment, topic y will most likely be classified as unknown and thus given the high mastery threshold. Since this decision does not depend directly on the probability cutoff, we exclude these examples from all of our subsequent analyses, so that the probability cutoff is the sole determining factor in assigning the mastery threshold.

4. ANALYZING LEARNING RATIOS

Our first analysis attempts to quantify the differences between the mastery thresholds by comparing the *learning ratios*—that is, the proportions of topics worked on by students that are eventually mastered. As just discussed, we want to only look at data points which have the mastery threshold determined exclusively by the probabilities. Additionally, we restrict our analysis to learning data prior to a student’s first progress assessment, as this assessment can alter the mastery threshold assigned to a topic, and we only select data points for which some work has taken place—for the latter, we minimally require that the student has at least looked at an example instance of the topic. Finally, out of the 2,154 total topics in our data set, we remove 7 that, due to technical issues, have systematic problems with their probability estimates. This leaves us with a total of 58,891,970 data points from 2,181,646 unique students.

Our next step is to select a reasonable *bandwidth* to conduct the RDD analysis, that is, a narrow interval around the probability cutoff to which the data points will be further restricted. While, all else equal, we want to have as much data as possible to work with, we also want our bandwidth to be narrow enough so that the included topics are expected to be similar in difficulty. We choose a bandwidth of 0.02 around the cutoff, which we believe works reasonably well at balancing these competing concerns. This leaves us with 1,949,102 data points from 984,138 unique students.

Table 1: Comparison of outcomes for the low mastery and high mastery groups.³

Mastery threshold	Learn	Fail	Inc.	No resp.
High (956,260)	0.847	0.057	0.062	0.034
Low (992,842)	0.865	0.052	0.050	0.033

For these data points, Table 1 shows the summary statistics after partitioning the learning outcomes into the following four categories.

- Learn: topic successfully mastered
- Fail: topic failed by submitting five consecutive incorrect answers
- Incomplete: at least one answer submitted, but topic is neither learned nor failed
- No response: an instance of the topic is viewed—and possibly an explanation page, as well—but no answers are submitted

³Based on 10,000 cluster bootstrap samples—with the data from each student representing a single “cluster”—the 95% confidence intervals for the point estimates in Table 1 are all less than 0.002 in width.

Based on this partitioning, the learning ratio is simply the proportion of the outcomes in the Learn category. From Table 1 we can see that the topics in the high mastery group have a lower learning ratio in comparison to the low mastery topics—0.847 vs. 0.865, respectively. Furthermore, the high mastery group has larger proportions of incomplete and failed topics. Note that all of these results make intuitive sense—that is, all else being equal, for a given topic we expect it to be harder to learn under the high mastery threshold in comparison to the low mastery threshold.

One concern we have is that students may be actively seeking out one mastery threshold or the other, with perhaps the most prominent worry being that students would try to find the topics with the low mastery threshold, as this information is available to them. While our previous experience working with the ALEKS system has shown us that students mostly work on the specific topic the system presents to them, this is still worth investigating. As a start, we can look at the proportions in the No resp. column of Table 1—here, it’s reassuring that these values are similar for the two different mastery thresholds.

Next, we can look at a *density* plot of the probabilities to see if there is an abrupt change as we move across the probability cutoff. Partitioning the interval $[-0.02, 0.02]$ into 100 bins of width 0.0004 each, in Figure 1 we plot the relative frequency (proportion) vs. the average distance from the threshold, based on the probabilities in each bin. While there’s an increasing trend in the density as the x -values increase—which is a reflection of the distribution of the probabilities, rather than any particular student behavior—we are specifically interested in what happens around the probability cutoff, which is at 0 on the x -axis. As there doesn’t appear to be clear evidence of a discontinuity—i.e., an abrupt increase or decrease—around the cutoff, we can use a *density test* to more precisely check for such a change [41]. Specifically, we apply the procedure outlined in [11], where the null hypothesis assumes there is no discontinuity in the density around the cutoff. Using the R implementation of this procedure in the `rddensity` package [12], the resulting p -value is 0.61—thus, the null hypothesis of no discontinuity is not rejected. Taking these results together, conservatively we can at least say there are no obvious signs of a bias from students electing to work on topics based on the mastery threshold.

5. FORGETTING AND RETENTION

In this next section, we attempt to estimate the differences in retention and forgetting between the topics that have been learned with the two mastery thresholds. While doing so, there are two important factors to consider. First, the students who learn with the high mastery threshold get more practice, as they tend to answer more questions in comparison to those who learn with the low mastery threshold. Second, as we saw previously the high mastery threshold is associated with a lower learning ratio in comparison to the low mastery threshold. This indicates there is a selection bias when we look at the students who learn a topic with the high threshold and compare them to students who learn with the low threshold—that is, the students who pass the high threshold tend to have a slightly better grasp of the material, or are perhaps slightly stronger students. Note that we’d expect both of these factors to benefit the knowledge

Figure 1: Density plot of the probability values, based on the distance from the probability cutoff. (More precisely, the x -axis reports the difference $\text{topic probability} - \text{cutoff probability}$.)

retention of the students who learn with the high threshold.

While it would be of interest to isolate these factors as much as possible, we won't be able to separate them in the analysis that follows, as they are directly connected to the specific mastery threshold used. On the one hand, from a purely scientific perspective this is unfortunate, as it would be of interest to, say, precisely compare the associations between the different amounts of practice. On the other hand, from a more practical viewpoint we can still analyze the overall differences between the mastery thresholds, which is arguably of more value for designing and improving adaptive learning and intelligent tutoring systems.

Table 2: Average number of actions per learning sequence—numbers in parentheses show the relative proportion of each action, based on the average total number of actions in the bottom row.

	High mastery (278,126)	Low mastery (302,191)
Correct answers	3.6 (0.66)	2.3 (0.61)
Wrong answers	1.3 (0.23)	1.0 (0.27)
Explanations	0.6 (0.10)	0.5 (0.12)
Total	5.4	3.8

Starting with the data set summarized in Table 1, we extract the subset of data points that (a) are successfully learned and (b) appear as questions in the student's first progress assessment—this leaves us with 580,317 data points from 436,735 unique students. In Table 2 we show the learning sequence statistics partitioned by the mastery threshold. The high mastery threshold topics have about 1.6 more learning events, with about 1.5 of these being either correct or wrong answers. Next, in Figure 2 we show a plot of the retention rates based on the distance from the probability cutoff, with the data points being divided into equal-width bins of 0.005, starting at -0.02 and ending at 0.02. For each bin the y -value represents the average correct answer rate when a topic appears in a student's first progress assessment, while the x -value is the average distance from the probability cut-

Figure 2: Retention (correct) rates based on the distance from the probability cutoff.

Figure 3: Mastery threshold forgetting curves.

off. Note there is a clear drop in retention as we move across the probability cutoff to the low mastery threshold topics. However, as we are studying the retention of knowledge, one factor we haven't taken into account is time. In particular, we next look at the forgetting curves for these data to see how these relationships might change at different time scales.

To generate these curves, for each data point we compute the time in days between the learning of the topic and its appearance on the progress assessment. Then, we group the data points into bins of width one day, compute the retention rate within each bin, and plot the results in Figure 3. The solid (blue) line shows the curve for the high mastery threshold topics, while the dashed (orange) line shows the curve for the low mastery threshold topics. For time values less than two weeks, the retention rate for the high mastery threshold group is higher—however, for larger time values it's not quite as clear how much of a difference, if any, exists between the retention curves.

We next use a linear regression model to more precisely estimate the differences in retention between the two mastery threshold groups—as our outcome variable is binary, this

model is known as a linear probability model. While the use of a generalized linear model—such as logistic regression—is typically recommended with binary outcome variables, we prefer to use a linear regression here to make it easier for us to interpret the coefficients. Although the use of a linear model with a binary outcome variable could theoretically lead to biased estimates, it’s been argued that this bias is typically low [3]. Additionally, a criticism of the linear probability model is that it could give invalid probability estimates less than zero or greater than one. However, based on previous works analyzing forgetting in the ALEKS system [18, 36, 37, 38], we expect the probability estimates of a correct answer to be bounded well away from zero and one.

As some students appear multiple times within our data, we treat data points associated to the same student as a “group” or “cluster”—this leaves us with 436,735 clusters, one for each unique student. To handle these clusters appropriately, in each of our analyses we fit a marginal model using the generalized estimating equation (GEE) class in the `statsmodels` [54] Python library. GEE models are commonly applied in epidemiological studies and analyses containing repeated measurements [27, 28, 33, 57], making them well-suited for our study.

Our regression models include the following predictors.

- x_1 : 1 for high mastery; 0 for low mastery
- x_2 : Initial assessment probability estimate
- x_3 : Initial assessment score = (number of topics classified as known) / (total number of topics in course)
- x_4 : Categorical variable encoding ALEKS product
- x_5 : Categorical variable encoding first event in learning sequence (correct, incorrect, or explanation)
- x_6 : Categorical variable encoding time (in weeks) since topic was learned (see Table 3)
- x_7 : Interaction between mastery and time ($x_1 \times x_6$)

The variables x_1 and x_7 are our main focus, as we want to estimate the average difference in retention between the two mastery groups—additionally, we want to see if these differences vary across the categories of the time variable. The remaining predictors are control variables, as they can help adjust for factors such as variation in starting knowledge (x_3), general differences between students using the various ALEKS products (x_4), and the amount of initial struggle experienced by the students while learning the topics (x_5). Finally, it’s generally considered good practice to include the assignment variable, represented here by the probability estimate x_2 , in the regression as well [23].

Regarding the time since the topic was learned, a complication with this variable is that it’s technically a *post-treatment* variable—that is, it’s measured after the “treatment” occurs, where in our case the treatment corresponds to the successful learning of the topic with the high mastery threshold. If a causal link is suspected between the post-treatment variable and the treatment, including the post-treatment variable in the regression could bias the estimate of the coefficient for the treatment variable [1, 53]. While we don’t have a compelling reason to think there is a causal link between the

Table 3: Categorical variable for time (x_6).

Category	Description
1	Less than 7 days after learning
2	Between 7 and 14 days after learning
⋮	
9	Between 56 and 63 days after learning
10	More than 63 days after learning

Figure 4: Coefficient estimates of the retention rate differences.

mastery threshold and the time variable, we use the following procedure in an attempt to address the possibility of post-treatment bias. First, we run our regression analysis including the categorical variable for time. Next, we re-run our analysis using the two-step regression procedure known as the *sequential g-estimator* [29, 60]. Using this procedure allows us to make an estimate of β , the coefficient of the treatment, that adjusts for possible bias from the inclusion of the post-treatment variable [1, 24, 29, 60, 61]. Comparing the results using the sequential g-estimator to our first regression, we do not see any substantial differences—for example, in the first model we fit, the estimates of the coefficients of interest differ by less than 0.0013 in absolute value. Thus, to simplify the exposition, in what follows we describe and report the results from the models fit without using the sequential g-estimator.

Figure 4 shows the results from fitting a model with variables x_1 through x_7 . For the given time category, each (blue) dot represents the estimated average difference in retention between the two mastery thresholds, with the dashed lines showing the 95% confidence interval for each estimate. For example, the first dot represents the data points with a retention time of less than seven days, where the high mastery group has an estimated average retention rate that’s higher by about 0.03, with a 95% confidence interval of (0.025, 0.036). The general trend suggests that larger time values are associated with smaller retention differences between the two groups. These results appear to be consistent with the plots shown in Figure 3, where the gap between the two forgetting curves is smaller for the larger time values.

Next, we take a different approach and use a type of matched

Figure 5: Matched data coefficient estimates, using bandwidths of 0.02 (top) and 0.04 (bottom).

design. Starting with the 580,317 data points from our previous analysis, we restrict the data to the 59,689 students who have learned topics using both mastery thresholds. This leaves us with 72,279 high mastery topics and 73,851 low mastery topics. The results from fitting a model using the variables x_1 through x_7 are shown in the top plot of Figure 5. Similar to the results from the unmatched data in Figure 4, the estimated average difference is about 0.03 for week 1, while then dropping below 0.02 for week 2. While the point estimates appear to have a negative trend—that is, the higher time values are associated with smaller estimated retention rate differences between the two mastery thresholds, on average—the trend is not nearly as pronounced as the one in Figure 4, and the estimates tend to be noisier.

In an attempt to get cleaner estimates of the average retention differences between the two mastery groups, we enlarge our data set by using a wider bandwidth of 0.04—this gives a total of 1,163,706 data points. Restricting our analysis to the 168,339 students who have examples of topics learned with both mastery thresholds, we have a new data set consisting of 476,105 data points. The results from the regression fit on this new data set are shown in the bottom plot of Figure 5, where it’s instructive to see that there is a clearer pattern than in the top plot—that is, using the enlarged data set, there appears to be a fairly strong negative association between the time values and the estimated differences in retention, similar to the results shown in Figure 4.

6. DISCUSSION

In this work we presented a detailed comparison of two mastery learning thresholds that are used in the ALEKS system. Attempting to adjust for selection effects and other possible confounding variables, we utilized elements of a regression discontinuity design by leveraging the fact that the assignment of the mastery threshold is determined by a probability cutoff value. Focusing on topics with probabilities close to this cutoff, we looked at the learning outcomes for the two different mastery threshold groups, with the results suggesting that, while differences do exist, they are not particularly large. For example, the average learning ratio difference between the two groups was less than 0.02. Additionally,

we used regression models to estimate the average difference in knowledge retention between the mastery threshold groups. The overall retention rates were more similar than we might have expected a priori and, furthermore, we saw evidence that the difference in retention rates between the two groups was negatively associated with time—that is, longer time gaps between the initial learning and the test of retention had smaller average differences in retention.

While performing our analyses, we investigated, and attempted to adjust for, several potential sources of bias and confounding. Nonetheless, being an observational study it’s possible that other sources of bias exist. Thus, in what follows we interpret our results within the larger literature on learning and retention, and also discuss potential implications for the ALEKS system, all while keeping this caveat in mind. To start, given that the difference in retention between the mastery threshold groups was smaller for larger time values, this might suggest that any possible gains from the high mastery threshold are not persistent. Notably, prior research on learning has shown that massed practice (i.e., grouping learning into a single session) and overlearning (i.e., continuing to practice after a skill has been mastered), while possibly beneficial in the short-term, do not lead to learning that is especially durable or long lasting [30, 51]. However, as most experiments studying these learning strategies involve simple verbal tasks in a laboratory setting [10, 15, 51], we found it informative to see similar results for students learning mathematics in an adaptive learning system.

Furthermore, while only a limited number of experiments investigate these issues for learning mathematics, two particular studies seem relevant and informative for our current work. First, the results in [51] indicated that the gains from massed practice of mathematics problems did not appear to be as durable as those from using distributed practice—specifically, while the benefits from these techniques appeared similar after a week, with a longer gap of four weeks distributed practice was superior. Second, in [52] two massed practice conditions for learning mathematics problems—with these conditions being somewhat analogous to our high mastery and low mastery conditions—were compared, with no clear difference in performance observed between the conditions. Thus, the outcomes of these two studies are seemingly consistent with the results from our current work.

If the results of this study prove to be valid, a possible adjustment to the ALEKS system is to reduce the usage of the higher mastery threshold for topics close to the probability cutoff. The benefit of this approach is that it would allow students to more efficiently learn additional topics. Taking a slightly different view, it’s well-documented that distributed practice is more effective as an overall learning strategy in comparison to massed practice [10, 15, 20, 30, 64]. Thus, rather than removing the high mastery threshold completely, perhaps the extra practice enforced by the high mastery threshold could be distributed over multiple learning sessions. Additionally, as previous work found evidence that retrieval practice within the ALEKS system is associated with better retention [38], it would be of interest to find the most effective way of combining the principles of both retrieval and distributed practice in the system. This is a line of research we are currently exploring in more detail.

ABSTRACT

Peer assessment systems are emerging in many settings, such as peer grading in large (online) classes, peer review in conferences, peer art evaluation, etc. However, peer assessments might not be as accurate as expert evaluations, thus rendering these systems unreliable. The reliability of peer assessment systems is influenced by various factors such as assessment ability of peers, their strategic assessment behaviors, and the peer assessment setup (e.g., peer evaluating group work or individual work of others). In this work, we first model peer assessment as multi-relational weighted networks that can express a variety of peer assessment setups, and can also capture conflicts of interest and strategic behaviors. Leveraging our peer assessment network model, we introduce a graph neural network which can learn assessment patterns and user behaviors to more accurately predict expert evaluations. Our extensive experiments on real and synthetic datasets demonstrate the efficacy of our approach, which outperforms a variety of peer assessment methods.

Keywords

Peer Assessment, Graph Neural Network.

1. INTRODUCTION

Peer assessment systems have emerged as a cost-effective and scalable evaluation mechanism in many settings such as peer grading in large (online) classes and peer review in conferences. In these systems, peers assess each others' work (e.g., assignments, papers, etc.) in lieu of a set of pre-appointed experts responsible for evaluation (e.g., instructors, teaching assistants, program committee members, etc.). These peer assessment systems not only make the evaluation of thousands of contributions plausible, but also help to deepen peers' understanding [22], and facilitate peers providing feedback to each other [20]. However, the reliability of peer assessment systems is directly impacted by the accuracy of peers in their assessments. Peers might lack knowledge or motivation to accurately evaluate others, or

they might be strategic in their assessments for their own gain [1, 12, 11, 2, 15, 34, 25, 21].

Related work. Two classes of approaches are taken to address reliability challenges. One primarily focuses on designing strategy-proof peer assessment mechanisms, which incentivize peers to accurately assess each other [6, 24, 9, 16, 11, 35, 32]. The other class of approaches—most relevant to our work—emphasizes learning peer aggregation mechanisms, which aggregate noisy peer assessments for an item (e.g., assignment or paper) as an estimate of its ground-truth valuation (or expert evaluation) [19, 27, 7, 30, 4]. The learning methods for peer assessment aggregation fall into unsupervised [27, 19, 5] and semi-supervised [7, 30] approaches based on whether or not a subset of ground-truth labels are used for training in addition to peer assessment data. These models usually possess particular inductive biases such as peer's assessment accuracy being correlated with his/her item's ground-truth valuations (e.g., the grade of his/her assignment) [19, 27, 7]; or peer's accuracy in an assessment depending on the extent of its agreement with others' assessments or ground-truth valuations [30]. However, these machine learning methods are empirically shown to be only as effective as simple aggregation mechanisms such as averaging [23]. Moreover, these approaches are not flexible and general enough to accommodate a wide variety of peer assessment modes (e.g., when an individual assesses the group contribution of others or self assessments). Our focus in this paper is to develop a semi-supervised aggregation mechanism without any specific or restrictive inductive bias, accommodating various modes of peer assessments.

Contribution. We first introduce our graph representation model of peer assessment, which we call *social-ownership-assessment network (SOAN)*.¹ Our SOAN model can express a wide variety of peer assessment setups (e.g., self-assessment and peer assessment for both individual or group contributions) and represent conflict-of-interest relations between peers using auxiliary information, such as social networks. Leveraging our SOAN model, we then introduce a semi-supervised graph convolutional network (GCN) approach, called *GCN-SOAN*, which can learn assessment patterns and behaviors of peers, without any restrictive inductive bias, to predict ground-truth valuations. We run extensive experiments on real-world and synthetic datasets to evaluate the efficacy of GCN-SOAN. Our GCN-SOAN outperforms a wide variety of baseline methods (including sim-

¹SOAN can read as “swan.”

ple heuristics, semi-supervised, and unsupervised approaches) on the same real-world dataset [23], which was shown to be challenging for machine learning approaches. Our GCN-SOAN also outperforms others on a wide range of synthetic data, which captures strategic assessment behavior between users, follows the assumptions of competitor baselines, or considers strict and generous graders. GCN-SOAN can be a stand-alone approach or possibly be integrated with some incentivizing mechanisms (e.g., [32, 5, 35]).

2. PROPOSED APPROACH

Our goal is to predict the ground-truth assessments (e.g., expert evaluations of educational or professional work) from noisy peer assessments. We first discuss our proposed graph representation model, *social-ownership-assessment network (SOAN)*, for capturing the peer grading behavior. We then present a modified graph convolutional network (GCN), which leverages our SOAN model, to predict the ground-truth assessments. We call this approach *GCN-SOAN*.

2.1 Social-Ownership-Assessment Model

We assume that a set of n users \mathcal{U} (e.g., students or scholars) can assess a set of m items \mathcal{I} (e.g., a set of educational, professional, or intellectual work). The examples cover various applications ranging from peer grading in classrooms to peer reviewing scientific papers, professional work, or research grant applications. We also consider each item $i \in \mathcal{I}$ possesses a (possibly unknown, but verifiable) ground-truth value $v_i \in \mathbb{R}^+$ (e.g., staff grade for a course work, or expert evaluation of intellectual or professional work).

The user-item assessments can be represented by *assessment matrix* $\mathbf{A} = [A_{ui}]$, where A_{ui} is the assessment (e.g., grade or rating) of user $u \in \mathcal{U}$ for item $i \in \mathcal{I}$. We let $A_{ui} = 0$ when the user u 's assessment for item i is missing; otherwise $A_{ui} \in \mathbb{R}^+$. As the assessment matrix \mathbf{A} is sparse, we equivalently represent it by an undirected weighted bipartite graph, consisting of two different node types of users \mathcal{U} and items \mathcal{I} , and weighted assessment edges between them (see Figure 1a as an example).

We introduce a *social-ownership-assessment network (SOAN)*, an undirected weighted multigraph, consisting of three types of social, ownership, and assessment relationships on two node types of users and items. In addition to the assessment matrix \mathbf{A} , this network consists of two other adjacency matrices: *social matrix* $\mathbf{S} = [S_{uv}] \in \mathbb{R}^{n \times n}$ and *ownership matrix* $\mathbf{O} = [O_{ui}] \in \mathbb{R}^{n \times m}$. The social matrix \mathbf{S} , by capturing the friendship and foe relationships between users \mathcal{U} , can accommodate "conflict of interest" information. The ownership matrix \mathbf{O} , by capturing which users to what extent own or contributed to an item, not only completes conflict of interest information but also provides flexibility of modeling group contributions, self-evaluation, etc. We let $G = (\mathbf{S}, \mathbf{O}, \mathbf{A})$ denote the tuple of all three networks of SOAN. Figure 1 demonstrates some instantiations of our models for various settings. SOAN offers various advantages over the existing peer assessment models (e.g., [27, 19, 7, 4]):

Expressiveness. Our model is more *expressive* as it facilitates the representation of many various peer assessment settings that could not be accommodated in the existing models. Its expressive power can be realized in the settings such as self

assessments (Figure 1b), peer assessments for both solo and group work (Figures 1e and 1f), and the mixtures of peer and self assessments for solo and group work (Figures 1c and 1d). For all of these settings, our SOAN model can also express conflict of interest (which is neglected in other models) through a social network (see Figure 1g).

Less Assumptions. Dissimilar to some existing models (e.g., [27, 19, 7, 30]), our model avoids making explicit or implicit assumptions about the relationships between ground-truth values (or grades) and the quality of peer assessments. It is still flexible enough to learn such correlations from assessment data if it exists. Our experiments below have shown that our model outperforms other models with restrictive assumptions regardless of whether their assumptions are present in the data or not.

2.2 Graph Convolutional Networks

Our learning task is semi-supervised. Given a social-ownership-assessment network $G = (\mathbf{S}, \mathbf{O}, \mathbf{A})$ and a set of ground-truth valuations $V_{\mathcal{D}} = \{v_j | j \in \mathcal{D}\}$ for a subset of items $\mathcal{D} \subset \mathcal{I}$, we aim to predict v_i for $i \notin \mathcal{D}$. More specifically, we aim to learn the function $f(i|\boldsymbol{\theta}, G)$ for predicting the ground-truth valuation v_i by $\hat{v}_i = f(i|\boldsymbol{\theta}, G)$. The model parameters $\boldsymbol{\theta}$ are learned from both the observed ground-truth valuations $V_{\mathcal{D}} = \{v_j | j \in \mathcal{D}\}$ and social-ownership-assessment network G . We formulate the function f by a modified graph convolution network (GCN) with a logistic head:

$$f(i|\boldsymbol{\theta}, G) = \sigma(\mathbf{w}^{(o)} \mathbf{z}_i + b^{(o)}), \quad (1)$$

where $\sigma(\cdot)$ is the sigmoid function for converting the linear transformation of the node i 's embedding \mathbf{z}_i into its predicted valuations. Here, \mathbf{w}_o and b_o are the weight vector and the bias parameter for the output layer. The node (i.e., item) embedding \mathbf{z}_i is computed with K layers of graph convolution network. Let $\mathbf{H}^{(l)}$ be the $(n+m) \times d$ matrix of d -dimensional node embeddings at layer l for all users \mathcal{U} and items \mathcal{I} such that user u and item i 's vector embeddings are located at the u -th and $(m+i)$ -th rows, respectively. In Eq. 1, the item i 's embedding \mathbf{z}_i is the $(m+i)$ -th row of $\mathbf{H}^{(K)}$ with the updating rule of

$$\mathbf{H}^{(l+1)} = g^{(l)}(\mathbf{D}^{-1} \mathbf{M} \mathbf{H}^{(l)} \mathbf{W}^{(l)}). \quad (2)$$

The matrix \mathbf{M} is constructed from the graph $G = (\mathbf{S}, \mathbf{O}, \mathbf{A})$ by $\mathbf{M} = \begin{pmatrix} \mathbf{S} & \mathbf{P} \\ \mathbf{P}^\top & \mathbf{0}_m \end{pmatrix} + \mathbf{I}$, where $\mathbf{P} = \mathbf{O} + \mathbf{A}$, \top is the transpose operator, $\mathbf{0}_m$ is $m \times m$ zero matrix, and \mathbf{I} is the identity matrix. In Eq. 2, \mathbf{D} is the diagonal matrix with $D_{ii} = \sum_j \mathbb{1}[M_{ij} \neq 0]$ with $\mathbb{1}[\cdot]$ as the indicator function. The core idea in Eq. 2 is to update the node embeddings at layer $l+1$, denoted by $\mathbf{H}^{(l+1)}$, from layer l 's node embeddings $\mathbf{H}^{(l)}$. This update includes the multiplication of the layer l 's embeddings $\mathbf{H}^{(l)}$ by the normalized matrix $\mathbf{D}^{-1} \mathbf{M}$, then linear transformation by learned weight matrix $\mathbf{W}^{(l)}$ at layer l , and finally passing through a non-linear activation function $g^{(l)}$. The initial embedding matrix $\mathbf{H}^{(0)}$ can be node-level features (e.g., textual features for items, user profiles for users, etc.). When the node-level features are absent, the common practice is to initialize the embeddings with one-hot indicators [14, 28, 10]. As our GCN is built upon SOAN, we refer to this combination as *GCN-SOAN*.

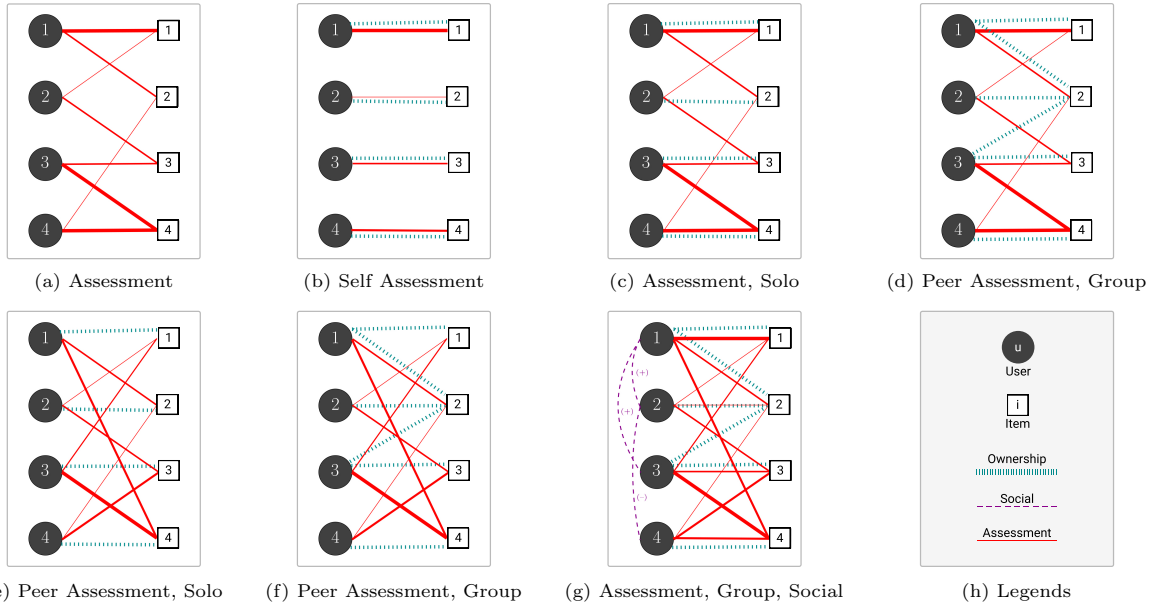

Figure 1: Different instantiations of social-ownership-assessment network (SOAN): (a) assessments provided by users to items as weighted edges; thicker lines for higher weights; (b) self assessments of users for their own items; (c) combination of self and peer assessments of solo contributions; (d) self and peer assessments of both solo and group contributions; (e) peer assessments of solo contributions; and (g) self and peer assessments of group contributions with the social networks between users for capturing conflict of interest.

The updating rule in GCN-SOAN (see Eq. 2) benefits from row normalization of the adjacency matrix similar to many other graph neural networks [31, 26, 28, 29]. As the choice of an effective normalization technique is an application-specific question [10, 3], we have decided to normalize our weighted SOAN model by taking an unweighted average, which has been suggested as a solution to address the sensitivity to node degrees for neighborhood normalization [10].

Our GCN-SOAN differentiates from vanilla GCN in various ways: (i) GCN-SOAN supports weighted graphs as opposed to GCN which solely is designed for unweighted graphs; (ii) it has asymmetric normalization as opposed symmetric normalization. These properties well-equip our GCN-SOAN to aggregate the information from multi-hop neighborhoods (e.g., neighbors, neighbors of neighbors, and so on) of SOAN, thus successfully capturing various assessment behaviors and patterns as evidenced in our experiments below.

Richer data as node-level features. To incorporate richer data for users (e.g., grader’s profile, reviewer’s expertise level, reviewer’s interest, etc.) and items (e.g., textual or visual information) in peer assessment systems, our GCN-SOAN can readily accommodate those information in the form of their node-level features. For example, the expertise level of peers can be represented as the one-hot encoding for initial embeddings. These initial embeddings can be extended with any other type of peers’ auxiliary information (e.g., education, age, sex, etc.). Similarly, initial embeddings of items can accommodate item features (e.g., the keywords for papers, textual features extracted from a paper, etc.).

Learning. Given the SOAN of G and a small training set of ground-truth valuations $V_{\mathcal{D}}$, we learn GCN-SOAN parameters by minimizing the *mean square error* of its predictions:

$$L(\theta|G, \mathcal{D}) = \frac{1}{|\mathcal{D}|} \sum_{i=1}^{|\mathcal{D}|} (v_i - f(i|\theta, G))^2, \text{ where } |\mathcal{D}| \text{ is the number of items in the training dataset, and } f(i|\theta, G) \text{ is the estimated valuation of GCN-SOAN for item } i. \text{ This loss function can be minimized by gradient-based optimization techniques (e.g., stochastic gradient descent, Adam, etc.).}$$

As opposed to many existing peer assessment systems with unsupervised learning approaches (e.g., [19, 4, 27]), we deliberately have adopted a semi-supervised learning approach for predicting ground-truth assessment. This choice offers many advantages at some cost of access to a small training dataset. By learning from the training data, GCN-SOAN is well-equipped to mitigate the influence of strategic behaviors, assessment biases, and unreliable assessments in peer assessment systems. Of course, the extent of this mitigation depends on the size of training data.

3. EXPERIMENTS

We run extensive experiments on real-world and synthetic datasets to compare our GCN-SOAN model against other peer assessment methods. While the real-world datasets allow us to assess the practical efficacy of our approach, we generate various synthetic data to assess its robustness in various settings (e.g., strategic and biased assessments).²

Real-world dataset. The peer grading datasets of Sajjadi et al. [23] includes peer and self grades of 219 students for exercises (i.e., questions) of four assignments and their ground-truth grades.³ For each specific assignment, the sub-

²See the longer version for additional experiments [17].

³The datasets can be found at http://www.tml.cs.uni-tuebingen.de/team/luxburg/code_and_data/peer_grading_data_request_new.php. The original datasets are for six assignments. However, two of the datasets have ordinal peer gradings, not applicable to our experiments.

Table 1: The summary statistics of real-world peer grading datasets.

Asst. ID	Average Grades			Number of					
	Ground-truth	Peer	Self	Exercises	Groups	Students	Items	Peer grades	Self grades
1	0.62 ± 0.27	0.70 ± 0.26	0.74 ± 0.22	3	75	183	225	965	469
2	0.71 ± 0.24	0.76 ± 0.23	0.80 ± 0.22	4	77	206	308	1620	755
3	0.69 ± 0.33	0.75 ± 0.31	0.82 ± 0.26	5	76	193	380	1889	890
4	0.59 ± 0.27	0.68 ± 0.29	0.76 ± 0.24	3	79	191	237	1133	531

missions are group work of 1–3 students, but each student individually has self and peer graded all exercises of two other submissions (in a double-blind setup). We treat all data associated with each assignment as a separate dataset, where all the submitted solutions to its exercises form the item set \mathcal{A} and the user set \mathcal{U} includes all students who have been part of a submission. We also have scaled peer, self, and ground-truth grades to be in the range of $[0, 1]$. Table 1 shows the statistics summary of our datasets.⁴

Synthetic datasets. We discuss different models used for the generation of our synthetic data.

Ground-truth valuation/grade generation. For all $i \in \mathcal{A}$, we sample the true valuation v_i from a mixture of two normal distributions $v_i \sim P(x; \boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma}) = \sum_{c=1}^2 \pi_c \mathcal{N}(x; \mu_c, \sigma_c)$, where $\boldsymbol{\pi} = (\pi_1, \pi_2)$, $\boldsymbol{\mu} = (\mu_1, \mu_2)$, and $\boldsymbol{\sigma} = (\sigma_1, \sigma_2)$, with π_k , μ_k , and σ_k being the mixing probability, mean, and standard deviation of the component k .

Social network generation. We create social networks between users by *Erdős-Rényi (ER)* random graph $G(n, p)$ model: each pair of n users are connected to each other with the connection probability of p .

Ownership network generation. For all synthetic datasets, we randomly connect each user to just one item (i.e., one-to-one correspondence between users and items). This setup is in favor of existing peer assessment methods (e.g., [19, 27, 7]), which does not support group ownerships of items.

Assessment network (or peer grades) generation. To generate peer assessment for each item $i \in \mathcal{A}$, we first randomly select a set of k users $N(i) \subset \mathcal{U}$ such that $|N(i)| = k$. Then, for each $u \in N(i)$, we set u 's assessment for item i , denoted by A_{ui} , using one of these two models. The *strategic* model sets $A_{ui} = 1$, if the grader u is a friend of the user j who owns the item i (i.e., $s_{uj} \cdot o_{ji} = 1$); otherwise A_{ui} comes from a normal distribution with the mean of v_i and standard deviation of σ_H . This implies that friends collude to peer grade each others with the highest grade, but would be relatively fair and reliable in assessing a “stranger.” The *bias-reliability* model draws A_{ui} from the normal distribution $\mathcal{N}(x; \hat{\mu}, \hat{\sigma})$ with the mean $\hat{\mu} = v_i + \alpha$ and $\hat{\sigma} = \sigma_{max}(1 - \beta v_l)$, where v_l is the true valuation of item l owned by user u , and σ_{max} is the maximum possible standard deviation (i.e., unreliability) for peer graders. Here, the *bias* parameter $\alpha \in [-1, 1]$ controls the degree of generosity (for $\alpha > 0$) or strictness (for $\alpha < 0$) of the peer grader. The *reliability* parameter β

⁴While GCN-SOAN can easily accommodate user/item features, we were not able to explore its full potential due to a lack of access to datasets with such features.

controls the extent that the reliability of the grader is correlated with his/her item’s grade (i.e., the peer graders with higher grades are more reliable graders). The inductive bias of many peer assessment models (e.g., [27, 7, 19]) include the assumption that the grader’s reliability is a function of his/her item’s grade. Our bias-reliability model allows us to generate synthetic datasets with the presence of this assumption. So we can compare our less-restrictive GCN-SOAN with those models tailored to this specific assumption in such datasets.

Baselines. We compare the performance of our GCN-SOAN model with PeerRank [27], PG1 [19], RankwithTA [7], Vancouver [4], Average, and Median. Average and Median (resp.) outputs the average and median (resp.) of each item’s peer grades as its predicted evaluation. As PeerRank, PG1, and RankwithTA treat users and items interchangeably, they can’t be directly applied to our real-world data with individual assessments on group submissions. For these methods, we preprocess our real-world dataset by taking the average of the grades provided by a group’s members for a particular submission as the group assessment for the submission. For the PeerRank and PG1, we have used the same parameter settings reported by the original papers. The parameters for RankwithTA and Vancouver are selected by grid search with multiple runs, since the optimal parameters either were not reported or result in non-competitive performance.⁵

Experimental setup. We implement GCN-SOAN based on PyTorch [18] and PyTorch Geometric [8].⁶ For all experiments, we use two GCN-SOAN convolutional layers with an embedding dimension of 64 and ELU as activation functions of all hidden layers. We train the model for 800 epochs with Adam optimizer [13] and a learning rate of 0.02. We initialize the node embeddings with vectors of ones. We use Monte Carlo cross-validation [33] with the training-testing splitting ratio of 1:9 (in synthetic data) or 1:4 (in real-world data), implying that just 10% or 20% data is used for training and the rest for testing. To make our results even more robust, we run all tested methods (our model and baselines) on four random splits and report the average error over those splits. For each random split, we compute the root mean square error (RMSE) over testing data as the prediction error.

Results: Real-World Datasets. To assess the effectiveness of GCN-SOAN in predicting ground-truth valuations, we compare it against the baseline methods on eight real-world

⁵We set the Vancouver’s precision parameter to 0.1. For RankwithTA, we set 0.8 and 0.1 (respectively) for the parameters controlling the impact of working ability on grading ability and grading ability on the grade (respectively).

⁶The implementation of GCN-SOAN can be obtained from: <https://github.com/naman-ali/GCN-SOAN/>

Table 2: Root mean square error of various methods over two classes of real-world datasets. The first and second best are shown with dark and light gray backgrounds, respectively. \uparrow and \downarrow denote better and worse than Average. GCN-SOAN (ours) is the only method that consistently has outperformed Average for all datasets. Results are averaged over three runs.

Model	Peer evaluation				Peer and self evaluation			
	Asst. 1	Asst. 2	Asst. 3	Asst. 4	Asst. 1	Asst. 2	Asst. 3	Asst. 4
Average	0.1917	0.1712	0.1902	0.1989	0.1944	0.1681	0.2023	0.2117

datasets. These datasets differentiate on (i) which assignment dataset is used and (ii) whether both peer and self-grades are used or only peer grades. For GCN-SOAN, we just create an assessment network, thus allowing us to measure how the assessment network alone can improve the predication accuracy. As shown in Table 2, our GCN-SOAN model outperforms others in five datasets and ranked second in remaining ones with a small margin. RankwithTA and PG1 are the only models that slightly outperform GCN-SOAN for those three datasets. Notably, GCN-SOAN is the only model which consistently outperformed the simple Average benchmark. This observation is consistent with Sajjadi et al.’s findings [23] on the same dataset that the existing machine learning methods (not including ours) could not improve results over simple baselines. However, the conclusion does not hold anymore as our machine learning GCN-SOAN approach could consistently improve over simple baselines. This improvement mainly arises from the expressive power and generalizability of GCN-SOAN (discussed in Section 2).

Results: Synthetic Data with Bias-Reliability. We run an extensive set of experiments with the bias-reliability peer grade generation model to assess our GCN-SOAN under various peer assessment settings. For these experiments, we define a *default* setting for all parameter of synthetic generation methods (e.g., bias parameter α , reliability parameter β , etc.). For each experiment, we fix all parameters except one; then, by varying that parameter, we aim to understand its impact on the performance of GCN-SOAN and other baselines. Our default setting includes a number of users $n = 500$ and number of items $m = 500$; random one-to-one ownership network; $\mu = (0.3, 0.7)$, $\sigma = (0.1, 0.1)$, and $\pi = (0.2, 0.8)$ for the ground-truth generation method;⁷ the number of peer grades $k = 3$,⁸ $\sigma_{max} = 0.25$, bias parameter $\alpha = 0$, and reliability parameter $\beta = 0$ for assessment network generation; and no social network generation.⁹

Figure 2a shows how the prediction error changes with the number of peer graders k while the other parameters are fixed to the default setting. Unsurprisingly, the performance

⁷This setting for ground-truth distribution is motivated by two-humped grade distribution in academic classes.

⁸This choice of 3 is motivated by the fact that most practical applications (e.g., conference review or peer grading in classrooms) do not require more than 3 peer assessment per item due to time-consuming nature of assessment processes.

⁹We have run some other experiments with different default settings. The results were qualitatively similar.

of all methods improves with k . GCN-SOAN not only outperforms others for any k , but also exhibits significant improvement over others for a relatively small k (e.g., $k \leq 4$). This superiority of GCN-SOAN with minimal number of peer graders is its strength to make peer assessment suitable and practical for different applications, as so many peer assessment requests will put unnecessary stress and burden on users, thus impeding the practicality of the system.

Figure 2b illustrates the errors for each model while changing the bias parameter α (and keeping other parameters fixed to default). GCN-SOAN performs significantly better than other models for any bias values, including generous ($\alpha > 0$) and strict graders ($\alpha < 0$). GCN-SOAN owes this success to its ability to learn students’ grading behavior by leveraging a small portion of ground truth grades and assessment network structure. These experiments show that our model could be a great choice for those peer assessment settings where the peer grades are intentionally or unintentionally overestimated/underestimated.

Figure 2c reports the errors for various values of reliability parameters β . Recall that the β controls the extent that the accuracy of each peer in his/her assessments is correlated with his/her item’s grade. Our results show that GCN-SOAN is very competitive to other models, even those built based on this correlation assumption (e.g., [27, 19]). We observe that only when $\beta > 0.8$, PeerRank outperform GCN-SOAN. One might argue that $\beta > 0.8$ is implausible scenario in practice. However, this result suggests that our model is still competitive choice for settings in which peer assessment accuracy is correlated with peer success.

To study how various ground-truth generation distribution impacts the prediction error of various method, we first change the default bimodal mixture of normal distributions (for ground truth generation) to a normal distribution by setting $\mu_1 = \mu_2$ and $\sigma_1 = \sigma_2 = 0.15$. Then, we only vary the mean of distribution while other parameters are fixed to default. As shown in Figure 2d, GCN-SOAN consistently outperforms others regardless of the underlying ground-truth distribution. Notably, PeerRank and RankwithTA do not perform well when most users own items with low grades.

Results: Synthetic Data with Strategic Assessment. We study the performance of all peer assessment methods under the strategic model discussed above. For this set of experiments, we define this default setting: number of users $n = 500$ and

Figure 2: Root mean square errors of various methods, synthetic data with bias-reliability peer generation model, default setting for all parameters but varying (a) number of peer graders k , (b) grading bias α , (c) reliability parameter β , or (d) ground-truth mean μ . Average over four runs.

Figure 3: Average of root mean square errors, synthetic data with strategic peer grade generation model and random graph model.

number items $m = 500$; random one-to-one ownership network; $\mu = (0.3, 0.7)$, $\sigma = (0.1, 0.1)$, and $\pi = (0.2, 0.8)$ for the ground-truth generation method; the number of peer grades $k = 3$ and $\sigma_{max} = 0.25$ for assessment network generation by the strategic model; and ER random graph model with $n = 500$ and $p = 0.05$ for social network generation. We only vary the connection probability p while keeping other parameters fixed to study how the connection density of colluding social networks impact the accuracy of peer assessment methods. Figure 3 show the outstanding performance of our model compare to other benchmarks and illustrate how our model is more resilient to colluding behaviors. This result suggest that GCN-SOAN is well-equipped to detect conflict-of-interest behaviors and mitigate the possible impact of any strategic behaviors.

Discussion. Our experiments show that GCN-SOAN learns very well various grading behaviors, even when graders have intentional or unintentional biases in their evaluations. We also observe that our GCN-SOAN can outperform other benchmarks even when their main inductive biases are strongly present in the dataset (e.g., when the grading ability of users are strongly correlated to the quality of their own work).

Our set of benchmarks, in spite of being very competitive, does not cover all ML-based peer assessment methods. We make a few remarks about this. PG3 [19] is missing in our experiments as its implementation was not publicly available and we could not properly implement it to gets its competitive performance. However, we expect that GCN-SOAN outperforms PG3 since the relative improvements of GCN-

SOAN over PG1 is 10.27% (on average) compared to the average relative improvement of 1.76% for PG3 over PG1 (as reported in their original paper [19]). We also speculate that the other traditional ML-based methods might not outperform our GCN-SOAN for at least one reason: except graph neural networks, most ML methods assume that the data points (e.g., peer grades, ground-truth valuation, etc.) are identically and independently distributed (i.i.d.). However, as argued earlier, the peers’ grading behaviors, ownerships, social connections, and valuations of their owned items are all dependent on each other. Ignoring these dependencies in machine learning methods with i.i.d. assumptions make them less competitive to our GCN-SOAN in which these dependencies are well-expressed by our proposed SOAN and well-exploited by our proposed graph neural network algorithm. This might explain why the literature has even been thin in successfully exploring other advanced machine learning models and Sajjadi et al. [23] concluded that machine learning methods cannot improve over simple heuristics (e.g., average).

4. CONCLUSION AND FUTURE WORK

We represent peer assessment data as a weighted multi-relational graph, which we call social-ownership-assessment network (SOAN). Our SOAN can easily express many different peer assessment setups (e.g., self assessment, peer assessment of group or individual work, etc.). Leveraging SOAN, we introduce a modified graph convolutional network approach, which learns peer assessment behaviors, to more accurately predict ground-truth valuations. Our extensive experiments demonstrate that GCN-SOAN outperforms state-of-the-art baselines in a variety of settings, including strategic behavior, grading biases, etc.

Our SOAN model provides a solid foundation for the broader investigation of graph neural network approaches for peer assessments. Our GCN-SOAN can be extended to mitigate the over-smoothing effect observed in our experiments, or to include a different set of network weights for each relation type of social, assessment, and ownership. Another promising direction is to assess the effectiveness of GCN-SOAN or its extensions on real-world assessment data, with the presence of social network data. Finally, it would be interesting to collect data with richer node features in order to evaluate how node features can further improve our GCN-SOAN.

ABSTRACT

Considerable amount of research in educational data mining has focused on developing efficient algorithms for Knowledge Tracing (KT). However, in practice, many real-world learning systems used at scale struggle to implement KT capabilities, especially if they weren't originally designed for it. One key challenge is to accurately label existing items with skills, which often turns out to be a herculean task. In this paper, we investigate whether an increasingly popular approach to knowledge tracing, the use of neural network models, can be a partial solution to this problem. We conducted a case study within a commercial math blended learning system. Using the data collected from middle school students' use of the system over two years, we compare the performance of a neural network-based KT model (DKVMN) in three scenarios: 1) with the original (possibly unreliable) system-provided skill tags, 2) with coarser-grained domain tags based on state standards, and 3) without inputting any mappings between content and skills. Our results suggest that including the system-provided skills in the training of the model leads to the worst performance. The best performance is observed when the skills are entirely disregarded. This supports the possibility of bypassing the laborious step of item-skill tagging in real-world learning systems which were not originally designed to work with KT models, especially if the goal is only to predict the performance of a student on future items. We discuss the implications of our findings for practice and future research.

Keywords

Knowledge Tracing, Skill Tagging, Deep Learning, DKVMN, Adaptive Learning

1. INTRODUCTION

Knowledge tracing has become an essential part of modern adaptive learning systems and even many non-adaptive learning

systems. The ability to infer a students' latent knowledge of a skill -- or at least predict their performance on future items within the skill -- has several applications. One of the key applications of knowledge tracing is mastery learning [7]. A system using knowledge tracing for mastery learning divides content into skills (sometimes also called concepts or knowledge components), and once a student starts a skill they cannot advance beyond it without demonstrating that they have mastered the skill. Knowledge tracing is also often used for creating reports for teachers [31] or open learner models for students [4]. A third use of knowledge tracing is as a component in automated detectors that recognize a range of student behaviors or states, including help-seeking strategies [1], and disengaged behaviors such as gaming the system [18].

While the first learning systems to use knowledge tracing were designed with that function in mind [2], many real-world learning systems used at scale today were not designed with knowledge tracing or adaptive learning originally in mind. Increasingly, these systems are being retrofit to use some form of these types of functionality [16]. One of the key ways that these systems often differ from learning systems originally designed for use with knowledge tracing is in how content is mapped to skills (often referred to as skill-item mappings or as KC mappings -- KC stands for knowledge component -- [13]). Systems designed from the start to use KT first select what skills are to be included, and then develop items tailored to those skills [2]. Afterwards, there may even be a process of using data to refine the KC mapping, attempting to improve the correlation of items to each other while maintaining human comprehensibility of the overall mapping [12, 14, 15]. By contrast, when content is retrofit for use with knowledge tracing, items are created first, and then the items are labeled with skills.

Labeling an existing item with a skill is much harder than creating a new item for a skill. Often, items have been developed by multiple authors over time, or have come from different original sources such as different textbooks. Mapping this disparate content -- sometimes tens of thousands of items -- to a set of skills can be a herculean task. In many cases, items have been tagged in terms of governmental curricular standards, but these standards are typically much coarser-grained than the types of skills used within knowledge tracing models [6]. Therefore, there is a challenge to using many of the classic approaches to knowledge tracing, used at

scale in past real-world systems, with content not initially designed with this use in mind.

In this paper, we investigate whether an increasingly popular approach to knowledge tracing, the use of neural network models [12, 17, 33], can be a partial solution to this problem. Unlike earlier approaches to knowledge tracing (i.e. [8, 19]), neural network models do not require a KC model in order to predict student performance on future items. As such, it may be possible to bypass the step of developing a KC model entirely, at least for goals such as choosing what problem to give the student next. In investigating this, we select the DKVMN (Dynamic Key-Value Memory Network – [33]) algorithm, a generally successful early approach to neural network-based knowledge tracing, as it has the ability to both use an existing KC model *and* to fit a new KC model, giving us the ability to compare between using a KC model known to have considerable limitations and using no KC model at all.

Towards this goal, we conduct a case study within a commercial math blended learning system. Using the data collected from middle school students’ use of the system over two years, we compare the performance of KT models in three scenarios: 1) with the original (possibly unreliable) system-provided skill tags, 2) with coarser-grained domain tags based on state standards, and 3) without inputting any mappings between content and skills. Our results suggest that including the system-provided skills in the training of the model leads to the worst performance. The best performance is observed when the skills are entirely disregarded. This supports the possibility of bypassing KC modelling in real-world learning systems which were not originally designed to work with KT models, especially if the goal is only to predict the performance of a student on future items.

2. MOTIVATION

2.1 Knowledge Tracing

There have been a range of algorithms used for knowledge tracing over the last three decades. The first widely-used knowledge tracing algorithms relied on a KC model, as mentioned in the introduction. Perhaps the first widely-used algorithm for knowledge tracing was Bayesian Knowledge Tracing [8], based on a simple Markov Model (and also mathematically equivalent to a simple Bayesian Network – [27]). More recently, models based on logistic regression have become popular in the literature [5, 20] although they remain rare within real-world use (but see [16]). Algorithms related to item response theory (IRT) such as Elo [21] and temporal IRT [30] have also become more widely seen in the literature recently, and are used at scale in several learning systems [3, 22, 30]. While Elo and temporal IRT can be used without a KC model, typically a separate Elo model is used for each of several skills.

A contrasting set of approaches uses neural networks to avoid the need for a KC model. The first member of this family of algorithms, deep knowledge tracing [24], discovered complex item-to-item mappings as part of predicting future performance on items. Later approaches such as DKVMN introduced the ability to use or fit skill-item mappings (KC models) as well [33]. The last five years have seen a proliferation of knowledge models based on neural networks [11, 17, 29, 33], gaining increasing ability to predict future performance. However, due to concerns about unpredictable behavior [9, 32], and the challenge of using this type of models for mastery learning and reporting on student skill (as discussed above, the main applications of knowledge tracing in contemporary learning systems), neural networks have been much more popular in the published literature on knowledge tracing than in actual real-world

use. One of the key limitations to neural network models in this regard has been that they predict correctness on specific problems but do not map that back to inferring proficiency on human-interpretable skills. Recent extensions have taken this step, suggesting the potential for broader real-world use and uptake of neural network knowledge tracing models. In particular, an extension in [28] can be applied to any neural network knowledge tracing model for which there is a KC model available (even at the coarse level of state standards).

2.2 Case Study: A Commercial Learning System with Imperfect Skill Tags

This study uses data from a commercial math blended learning platform used in schools across the United States by students from kindergarten through Algebra II. This platform allows teachers to assign problem sets to students by standards and topics, and assignments can be personalized based on the teacher’s assessment of a student’s progress. The system measures a student’s mastery of underlying mathematical concepts through Bayesian Knowledge Tracing (BKT), and may suggest more foundational or advanced assignments based on a student’s performance. In this way, the system contains several elements frequently seen in intelligent tutoring systems. Assignments may be worked on at home or at school, and guidance provided by the creators of the platform suggest that students should work in the platform for approximately 30 minutes per week.

The learning platform has two classes of problems, authored in different ways. In the “classic” problems, students answer multiple-choice, multi-step word problems, with a series of scaffolded, smaller word problems triggered when the student answers the initial problem incorrectly. The second “new” class of problems tends to be more interactive: for example, students plot points and lines on a graph, rotate shapes, and sort statements or numbers using drag-and-drop functionality. These problems tend to be open-response and typically lack the kind of scaffolding seen in the classic problems.

The difference in the content within this system can be attributed to the development of the content in two phases. In a first phase of development, a team of math content specialists created multiple-choice items with scaffolding for incorrect answers (based on the model in [26]). In this model, students that answer an item correctly will move onto the next problem, but if a problem is answered incorrectly initially, the problem will be broken into a series of additional, smaller questions that scaffold an effective set of problem-solving steps. The math content specialists tagged each item with a set of skills based on mathematics standards. After the acquisition of the system by a different company, and the subsequent departure of the original development team, a different approach was adopted to build out additional content for the same courses. In this new approach, existing content created by an outside company was added to the system. This additional content had more item types, as discussed above. However, this new content did not use the same scaffolding model as the original content. Items had been tagged by the outside company according to the same overall mathematics standards, but there were considerable inconsistencies and incompatibilities between the two tagging approaches. The result was an overall set of skill tags that were of uncertain usability.

While the case of a system being acquired by a different company and adopting a new process for content is perhaps somewhat unusual, the overall problem of content and skill tags being developed by different teams over time is not unusual. Many contemporary online learning systems integrate data from different textbooks,

shift the membership of content authoring teams over the span of many years, and tag content according to multiple state standards and internal content schemas. While many of the systems which are most heavily published on at this conference (and related conferences) do not have these issues, it is likely that the majority of learning systems used at large scale suffer from these issues to at least some degree.

3. METHODS

3.1 Data Collection

The analyses presented here are based on data collected as part of a larger, exploratory study on the implementation of the blended learning platform discussed in section 2.2. Though the focus of the study was on 6th-8th grade students, we also collected data from sections of Algebra I and Geometry students when a teacher taught across several grade levels and wanted to use the platform across their classes. These data were collected in the 2018-19 and 2019-20 school years from students located in 19 schools across Texas. These schools tended to be located in less populated areas, with 11% of schools in the sample in cities (according to Federal classification), 5% of schools in the sample in suburbs, 26% in towns, and 58% in rural areas. 41% of the students in our sample schools identified as white, 9% as African-American/Black, 46% as Hispanic, and 1% as Asian. 60% of students in sample schools qualified for free/reduced price lunches.

Data collected occurred across two years, with 38 teachers and 2069 students participating in the first year, and 14 teachers and 743 students participating in the second year. Teachers were instructed to have students engage with the blended learning software for approximately 30 minutes each week, though use of the system diminished over the course of the school year (cf. [23]). The primary goal of the larger study was to examine the naturalistic relationships between learning, engagement, and classroom implementation, so researchers interfered very little in how teachers and students decided to use the platform. Teachers used the software differently: some teachers sat their students in front of the system, offering little help, while others used the system while teaching to the class, talking about the problems presented. Some teachers disliked the scaffolding problems and checked students' answers to top-level problems to avoid their students receiving scaffolding problems. In some classes, students asked each other for help, while in others they were expected to work alone.

3.2 Descriptive Statistics

This analysis involves data from 2564 students. Table 1 presents the number of problems, skills, and first attempts for classic and new content. The overall correctness of students' first attempts on problems is 32% across all the problems. However, when the content is categorized based on the new and classic content (see description in Section 2.2), we see that the percentage correctness is higher for classic content (59%) with the new content having a much lower correctness (15%). There are several possible explanations for this finding. Students may be more likely to get scaffolding problems correct than initial problems, as scaffolding problems are designed to have lower difficulty. In addition, the more interactive problems often require the student to take several actions or input multiple steps in order to arrive at the correct final answer, which creates more opportunities for mistakes. Due to the clear differences in these two types of learning content, we will look at these separately in our final experiment.

Table 1. Total number of problems, skills, first attempts, and percentage correctness for all content, classic content, and new content in the data used in this analysis

Content Type	#problems	#skills	#first attempts	%correct
All content	7252	2,237	110,214	32%
Classic content only	1764	532	42,353	59%
New content only	5488	1,705	67,861	15%

3.3 DKVMN

In this analysis, we use Dynamic Key-Value Memory Networks (DKVMN; [33]) for knowledge tracing. DKVMN is a KT model developed based on neural networks and has demonstrated improved performance compared to traditional KT models, such as Bayesian Knowledge Tracing or Performance Factors Analysis [25, 28, 33]. In DKVMN, the model employs two matrices to predict student performance on items and estimate mastery on a set of automatically-derived skills. By learning from the relationships between the two matrices (i.e. a static matrix that stores skill relationships and a dynamic matrix that stores and updates mastery level), the algorithm generates underlying skills associated with items and identifies connections between them, creating a skill map. DKVMN utilizes the map to make predictions on student performance and estimates mastery learning, as opposed to the human-generated skill-item mapping that the traditional KT models rely on. Given DKVMN's capability of automatically generating underlying skills and exploiting the relationships between them, we are interested in investigating how the algorithm can be applied to handle data with unreliable skill tagging.

4. ANALYSIS

The goal of our analysis in this paper is to investigate the use of a neural network-based KT model (DKVMN) that doesn't require skill tags, for a system where the skill tags may be unreliable or inconsistent. Accordingly, we compare the performance of KT models with and without mappings between content and skills. Since we don't have out-of-system performance data on students to validate knowledge estimates, we infer performance within the system rather than outside the system (note that DKVMN can also be used to predict out-of-system performance – [28]). Thus, we validate the model based on its ability to predict a student's correctness on the next problem. We use [33]'s implementation of the DKVMN model with a set of hyperparameters that have been reported to produce optimal outcome for a previously collected dataset (the ASSISTments2009 data set in [33]), including a state dimension of 50 and a memory size of 20. We use this previously established set of hyperparameters instead of tuning them, to avoid overfitting. In addition, since the goal of the paper is to study whether the skill tags are useful and whether DKVMN can compensate for a lack of good skill tags in a data set of this nature, tuning the hyperparameters to find the best performing KT model is not related to the goals of the analysis. We evaluate our model using AUC ROC. We perform a student-level 10-fold cross validation, and the reported results are the average across the CV folds.

Using this approach, we conduct the following three kinds of analysis:

- 1) Experiment #1 (Default-Skills): In this experiment, we chose to include the initial skill mapping provided by the

learning system during the training of the DKVMN model. The system provides a total of 2237 skills.

- 2) Experiment #2 (**Domains**): In this experiment, instead of using the default skills, we group the skill tags provided by the learning system into coarser-grained domains defined by the Common Core Standards [6]. We derive domain information from the nomenclature used within the standards (e.g., exponential functions, quadratic equations, and two-dimensional shapes). This reduced the 2237 skills to 24 domains.
- 3) Experiment #3 (**No-Skill**): In this experiment, we disregard the skill tags entirely and instead treat all problems as a single skill. As discussed above, DKVMN will then find a latent mapping of skills to the problems on its own.

We repeat these three experiments for three data setups: 1) with all content, 2) classic content only, and 3) new content only. In the last two settings, we separate the training and testing data to only include new content or classic content since we have some evidence that data for these two types of content is qualitatively different (see discussion in Section 2.2).

5. RESULTS

Table 2 presents the results of our experiments. Here we summarize our observations:

- 1) Experiment #1 (**Default-Skills**): We observe that including the system-provided skills in the training of the DKVMN model leads to the worst performance in all three cases (all content, classic content, new content). For all content and classic content models, the model performance as measured by cross-validated AUC ROC is between 0.5 and 0.6 (0.564 and 0.532), relatively modest improvements on chance and much lower than is typically seen for DKVMN (e.g. [25, 33]).
- 2) Experiment #2 (**Domains**): When the system-provided skills are grouped into coarser-grained domain mappings, we observe a big improvement in DKVMN’s performance. For example, there is a 0.206 increase in AUC when the model trained on all content uses the domain tags instead of skill tags (0.770 vs. 0.564). Similarly, there is a big increase in AUC of 0.233 for the model trained on new content (0.900 vs. 667). However, there is a relatively smaller increase in AUC of 0.084 for the model trained on classic content (0.616 vs. 0.532).
- 3) Experiment #3 (**No-Skill**): Finally, disregarding the skills entirely leads to the best performance in all three cases: 0.821 for all content, a still relatively unimpressive 0.634 for classic content, and 0.920 for new content.
- 4) If we compare the results of the DKVMN models separately for the new and classic content, we observe that the model trained only on new content perform much better than models trained only on classic content (e.g. 0.667 vs. 0.532 with default skills and 0.920 vs. 0.634 with no skills)

Table 2. Average AUC of DKVMN models across 10-fold cross-validation for the four experiments conducted using default skills (#1), domains (#2), no skills (#3), and for new and classic content separately.

Content Type	Default-Skills (exp #1)	Domains (exp #2)	No-Skill (exp #3)
All content	0.564	0.770	0.821
Classic content only	0.532	0.616	0.634
New content only	0.667	0.900	0.920

Overall, we also see that the DKVMN model trained without the skill information on all content (0.821) or new content (0.920) has a comparable or better performance than the best-performing models reported on some benchmark datasets (0.827 for Synthetic-5, 0.816 for ASSISTments2009, 0.727 for ASSISTments2015, 0.828 for Statics2011; [33]). With the exception of ASSISTments2015 dataset, the best performing models for the other three datasets have achieved AUCs between 0.80 and 0.83. Our best-performing model for all content combined (0.821) is comparable to the performance of the best models on these benchmark datasets. The best model trained only on new content has higher performance (0.920) than the best models on benchmark datasets. However, the best model for the classic content has much lower performance (0.634) than previous uses of DKVMN.

6. DISCUSSION

Knowledge tracing models are often used in learning systems to estimate students’ knowledge of a skill. In some cases, this is operationally defined as simply predicting whether or not a student will get the next problem (or a specific problem) right. Accordingly, considerable amount of research has focused on developing efficient algorithms for knowledge tracing. However, in practice, many real-world learning systems used at scale are difficult to implement knowledge tracing for, especially if the system or content was not originally designed for use with a skill model. The key challenge is to accurately label existing items with skills, which often turns out to be a herculean task (Section 1). Little research has explored ways to address this practical constraint limiting the use of knowledge tracing models at scale. In this paper, we investigate whether an increasingly popular approach to knowledge tracing, the use of neural network models, can be a partial solution to this problem.

Our analysis investigates the use of a neural network-based KT model (DKVMN) that doesn’t require skill tags (and can even automatically assign its own skill tags) to bypass the step of retrofitting content with skills. We conduct a case study of a commercial math blended learning system which has a potentially unreliable and/or inconsistent skill tagging, due to the content and skill tags being developed by different teams over time (Section 2.2). We collected data from 6th-8th grade students’ system usage over two years within 19 schools across Texas. We compare the performance of DKVMN in three scenarios: 1) with the potentially unreliable default system-provided skill tags, 2) with coarser-grained domain tags based on state standards, and 3) without inputting any mappings between content and skills. We also investigate differences in predictive performance for two disparate content types in the system: classic content (multiple choice, with scaffolds) and new content (more interactive, open-response, with no scaffolds).

Our results suggest that including the system-provided default skills in the training of the DKVMN model leads to the worst performance at predicting future student performance within the learning system. The AUC ROC for this case is much lower than what is typically seen for DKVMN. Big improvements in performance are observed when the system-provided skills are grouped

into coarser-grained domain mappings. However, the best performance is obtained when the skills are entirely disregarded. To our surprise, there is a noticeable difference in the improvement between the classic and new content, with relatively smaller increase in AUC for the model trained on classic content.

6.1 Implications

The objective of our investigations was to explore the possibility of bypassing the herculean task of item-skill tagging (KC model) for real-world learning systems which were not originally designed to work with KT models. Our results provide some support to this possibility, especially if the goal is only to predict the performance of a student on future items. For example, if a KT model is being developed for a system for optimal next problem selection, using a neural network-based model like DKVMN and ignoring the skill tags may be more effective than using unreliable system-provided skills.

However, our results were not consistent across all content, suggesting that this approach may not be sufficient for all legacy content. Despite using DKVMN, the best model for classic content still achieves an AUC that is much lower than is typically seen for neural network-based KT models. Therefore, careful consideration is needed before making the decision on deploying such a model to make real-time decisions on what content the student will see next. In comparison, the DKVMN model trained on new content without any skill information is at par with the best models on benchmark KT datasets. It is difficult at this point to explain why DKVMN was so much more successful for new content than for classic content. There is no obvious reason why either of the two clear attributes of the older content – scaffolding problems and the use of multiple-choice – would lead to poorer prediction by DKVMN, given the past successful use of DKVMN and related algorithms on content with these attributes.

Though these findings suggest that DKVMN may be useful for legacy systems with unreliable or inconsistent skill tags, it is important to keep a few things in mind before assuming that these findings will apply to other contexts. First, this is a case study of one commercial learning system. These results need to be replicated in other content types, system design, subject matters, student demographics, etc. We have made the code public at (redacted for review) to aid replication. Second, a better performing model may still not necessarily serve all student subgroups equitably. Before actually applying an algorithm, it is necessary to investigate it for potential biases that could lead to discriminatory behaviors. In this case, a biased KT model could deliver content below a student's actual skill level more often for students from certain subgroups, leading to missed learning opportunities. Since neural network models are prone to overfitting due to their complex decision boundaries, it is particularly important to investigate whether a model like DKVMN generalizes less well for students who are unrepresented in the training data. For instance, it may be that a neural network model captures complex interrelationships between skills that only occur in students with specific past curricular experiences.

6.2 Limitations and Future Work

There are a few limitations to the analysis conducted in this paper. First, since the learning system itself made pedagogical decisions based on a knowledge tracing model using unreliable skill tags, the problems it gave students were probably not always appropriately chosen. As such, the data may not represent students participating in mastery learning (although this is also true of the data sets used to initially train KT for mastery learning in other commercial systems). Second, we chose to explore DKVMN because it has

generally been reported to be successful, and generates its own skill mapping. A more comprehensive comparison between other neural network-based models could be helpful in understanding whether other algorithms can perform better for the old content. Lastly, before disregarding non-neural network-based KT models for the case discussed in this paper, it may be worth comparing these results with newer extensions proposed for classic KT models. For example, future work could explore BKT variants that include skill refitting (cf. [12]).

Future work also may be able to shed more light on the contexts where this approach does and does not work. For instance, why is there a noticeable difference in the improvement between the classic and new content with relatively smaller increase in AUC for the model trained on classic content? Exploring answers to this question may help identify cases where this approach may be more efficient than others and identify ways to improve it.

Finally, like most neural network models, DKVMN lacks easy interpretation. This could make it harder for instructors to trust its recommendations and hard to troubleshoot. A potential solution is to interpret the output of the DKVMN model. Considering that DKVMN creates its own internal tag-concept mapping, this study's results suggest that it may be worth studying those mappings in greater detail. Since the no-skill model outperformed the default-skill model to such a degree in this dataset, it is likely that DKVMN's distilled concepts represent accurate relationships between the problems in the data. Zhang and colleagues [33] mention the possibility of using DKVMN for concept discovery, but most subsequent work on the algorithm has instead focused on its predictive accuracy (but see [10], who discuss interpretability). Additional research on DKVMN's process of concept discovery could not only improve its interpretability but potentially also allow for better automated skill tagging and more accurate student skill level estimation.

ABSTRACT

Emoji are commonly used in social media to convey attitudes and emotions. While popular, their use in educational contexts has been sparsely studied. This paper reports on the students' use of emoji in an online course forum in which students annotate and discuss course material in the margins of the online textbook. For this study, instructors created 11 custom emoji-hashtag pairs that enabled students to quickly communicate affects and reactions in the forum that they experienced while interacting with the course material. Example reporting includes, inviting discussion about a topic, declaring a topic as interesting, or requesting assistance about a topic. We analyze emoji usage by over 1,800 students enrolled in multiple offerings of the same course across multiple academic terms. The data show that some emoji frequently appear together in posts associated with the same paragraphs, suggesting that students use the emoji in this way to communicating complex affective states. We explore the use of computational models for predicting emoji at the post level, even when posts are lacking emoji. This capability can allow instructors to infer information about students' affective states during their "at home" interactions with course readings. Finally, we show that partitioning the emoji into distinct groups, rather than trying to predict individual emoji, can be both of pedagogical value to instructors and improve the predictive performance of our approach using the BERT language model. Our procedure can be generalized to other courses and for the benefit of other instructors.

Keywords

Affect recognition, Course Forums

1. INTRODUCTION

Students typically experience a range of affective responses to learning materials, taking the form of emotions, beliefs

A. Blobstein, K. Gal, D. Karger, M. Facciotti, H. Kim, J. Almahmoud, and K. Sripathi. #lets-discuss: Analyzing student affect in course forums using emoji. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 339–345, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

and attitudes that have a profound effect on their learning (and vice versa) [7]. Understanding what students are feeling when they learn can, therefore, be useful for teachers who may wish to adapt course content and/or delivery in response to student affect [26, 18, 1].

Emoji are conventionally used in social media to enhance the meaning of text or to be used as substitute for words [17]. When conversing through text, such as with written posts in course forums, emoji can be a natural way for students to express what they are feeling about the learning material. A body of work in the social and computational sciences has studied people's use of emoji, and used them to facilitate computational tasks such as sentiment analysis and emotion recognition [19, 13]. However, the use of emoji by students in educational forums has been much less studied. Our contribution is a computational analysis of students' use of emoji in a course forum with over 1,800 of students.

Students in this course use the Nota Bene (NB) collaborative annotation-based forum, which allows them to anchor messages directly to reading material in their online course textbook. Course instructors designed a set of 11 emoji that allow students to communicate affective responses in their posts, such as expressing curiosity or confusion about topics in the course, or inviting discussion about a topic. Students were incentivized to use these emoji by receiving course points on their reading assignment for using at least one emoji in their forum posts.

We provide a detailed analysis of emoji usage in the course at the post level as well as the paragraph level in the reading material that the post refers to. We find that the most commonly used emoji request discussion and assistance from instructors or peers, and that in some cases students combine several emoji in the same post to create complex affects. Some emoji frequently appear together in posts that are anchored in the same paragraph, suggesting that students may simultaneously experience a combination of responses to the course readings or that they choose to use multiple emoji to express more complex affects that are not sufficiently well represented by a single emoji.

We explore the use of computational models for classifying emoji use at the individual and group level. We use a

pre-trained deep-learning language model (BERT) to predict emoji at the post level. This model significantly outperforms a Long-Short-Term-Memory (LSTM) architecture that was used by others to predict emoji in social media model, but was trained on the same task. [13, 3].

In agreement with course instructors, we cluster the emoji into categories, based on the relationship between the predicted emoji probabilities that are outputted by the BERT model. We partition the emoji into eight distinct groups (3 groups containing an emoji pair, and 5 groups containing a single emoji). Partitioning the emoji into these distinct groups makes pedagogical sense to the course instructors while also improving performance when predicting emoji-groups rather than individual emoji.

The contribution of this work is in a new computational model for predicting student affect that was trained on students' self-reported emoji without requiring hand-labeling of the data by experts. The model can directly be applied to any discussion forum, even where emoji information is not readily available, potentially increasing its impact. Our work can help instructors, particularly in high-enrollment courses, decide where and how to intervene in discussions, and to assess where content or course revisions might be made to improve student learning.

2. RELATED WORK

Our work relates to past studies for inferring student affect from their online text conversations, as well as computational work that analyzes the use of emoji in social media. We mention relevant prior works below and refer the reader to the review of the field by Kastrati et al. [16] for additional details.

Basic approaches to infer students' sentiments in online conversations used classic NLP methods (parsing, lexical dictionaries) [8, 6]. Studies showing the correlation between affects and dropout [28] and the correlation between affects and exams scores exist [23]. Jena [15] used classical machine learning methods (SVMs, Naive Bayes) to learn the sentiment polarity (positive, negative, and neutral) from students' posts, as well as predicting basic students' emotions from text (e.g., anxiety, bored, confused, excited). Estrada et al. [12] used deep neural networks, such as convolutional neural network and LSTMs, as well as evolutionary generative models, in order to classify sentiment polarity and emotions.

As noted by Kastrati et al. there are relatively few works on recognizing students' emotions from text, despite the pedagogical importance of this task, and the growing prevalence of online learning [26, 18]. One possible reason for this scarcity of works is the reliance on hand-labeled data sets which are costly and time-consuming to obtain. We directly address this gap in our work by using students' self-reported affect in the form of emoji as proxies for their emotional state.

There is growing research studying the use of emoji as tools in computer-mediated communication [25, 17]. Emoji can be used in two different ways. They can appear alongside text to include an affect or to enhance the meaning of a

text. They can also be used as a substitute for words, or to conform a new notion.

Zhang et al. [29] investigated the use of emoji among students in the Nota Bene framework and showed the potential of detecting students' affects by training a classifier in order to distinguish between confusion and curiosity. Geller et al. [14] defined rules for confusion detection that are based on students' use of two types of emoji. They showed that the resulting rules closely align with the ground truth judgement of educational experts. We generalize both works to the more challenging task of recognizing multiple affects, and explore ways to facilitate this task by combining clustering methods with input from the course staff.

Felbo et al. [13] trained an LSTM architecture to predict emoji use in Twitter as proxies for users' emotional states. They show the model was able to generalize to other datasets containing self-reported emotional states. They employed clustering methods to learn relationships between 64 different emoji. We go beyond this work in several ways. First, we study the relationship between emoji use on the topic level. Second, we use the clusters to build better predictive models. Third, we involve course instructors in the analysis and use them to determine the best partition.

Çöltekin and Rama [10] used SVMs to predict emojis with a bag-of-b-grams feature set, combining both character n-grams and word n-grams and weighted by the TF-IDF score. This model achieved top performance in a recent competition for predicting 20 emoji on Twitter (SemEval 2018 task 2) [2]. Zhang et al. [30] used a BERT model for the emoji prediction task that outperformed Çöltekin and Rama [10] approach. We directly extend Zhang et al. model in adapting BERT to a biology course setting with an additional pre-training over the course's previous data.

3. THE NB SETTING

The Nota Bene (NB) web application is an open source social annotation tool that was developed at MIT [31]. NB is used in hundreds of university courses and includes more than 40,000 registered student users. The main feature of Nota Bene gives users the ability to directly annotate course content. Course content (PDF, HTML, or video file) is uploaded to the NB website by instructors. Students can annotate the content by highlighting a passage in the document (called "the marked text") and then add a post by typing into a text field that appears in the margin. These annotations may be used to create a post or to ask questions about the content. Classmates are encouraged to reply to other students' comments and to answer any posted questions.

NB posts are organized into threads, which consist of a starting comment or question followed by all the replies made by other students or instructional team to the initial annotation or to the subsequent replies. The in-place structure of the NB tool allows students to interact in the forum while they are reading the course material and provides context to the discussion. This structure has been shown to be beneficial for learning [22]. The NB interface allows students to express emotions and other affects in their comments via hashtags (which are translated to graphical representations of emoji), thus allowing students and instructors to filter

students' comments based on the type of affect in which they are interested.

3.1 The FYBIO course and emoji

FYBIO (First Year BIOlogy) is a general biology course required for all life sciences majors at a large, public university and is typically taken by students during their first year of study. Depending on the academic term it is offered, the course consists of 25 or 26 lectures. During this study, the course staff posted reading materials before each lecture and the students were assigned to read these materials and to provide three substantial posts in NB before each class. This encouraged active participation in forum discussions. Students received additional credit for including at least one emoji in at least one of their posts per lecture. The NB interface displays the hashtags graphically using relevant emoji symbols in students' posts. The emoji were designed by the course instructors to allow students the option to express emotions and opinions about course material, as well as invite assistance or participation from their peers or instructors. For the remainder of this paper, we will use the term "affects" to refer to all of the above expressions.

A full list of the emoji and their intended uses is shown in Table 1. Some examples of emoji and their intended uses are as follows: The #i-think emoji expresses an idea to share; the #lets-discuss emoji invites students and instructors to contribute to a discussion; the #learning-goal emoji identifies a topic or idea related to the course objectives; the #question emoji requests help from the course staff regarding a topic.

Emoji	Associated hashtag	Intended use	Percentage of use
?	#question	...you would like the professor to address a specific question in class.	18.7%
💭	#i-think	...you have an idea to share about something but are not sure if it is accurate.	18%
🤔	#just-curious	...you would like to learn more about a certain topic that you are curious about or intrigued by.	13.4%
!!	#important	...if you found a topic or idea to be important.	11.7%
❤️	#interesting-topic	...you found a topic or idea to be interesting.	10.7%
💡	#lightbulb-moment	...something (e.g., course material, a peer's post) led you to a new understanding (an "ah-ha" moment).	8.3%
🗣️	#lets-discuss	...you would like to invite your fellow classmates and instructors to weigh in, in a NB discussion.	5.6%
🌍	#real-life-application	...a topic or idea has any implications in the real world.	4.2%
😮	#surprised	...you found a topic or idea to be surprising.	3.9%
😞	#lost	...you are totally confused or overwhelmed about a topic and have no idea what question to even ask.	2.9%
🗨️	#learning-goal	...you identify a topic or idea related to the course objectives or reading-specific learning goals	2.5%

Table 1: Hashtags in NB, their associated emoji, intended uses and percentage of usage

Nota Bene provides instructors with a heatmap showcasing students' use of the different emoji (See Figure 1). Each emoji is displayed using a different color, and the brightness varies with respect to the density of the emoji in the posts.

Instructors can filter which emoji to display.

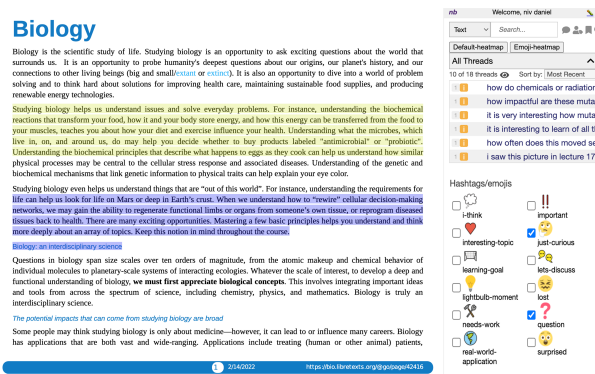

Figure 1: Emoji heat map in Nota Bene

Table 2: Statistics of our data set (different course instances of FYBIO)

Statistics (Num.)	Winter 2021	Summer 2021	Winter 2022	Total
Lectures	14	26	14	54
students	758	182	905	1,845
posts	28,072	15,072	36,165	79,309
emoji	23,867	10,635	28,674	62,906

Our dataset contained 79,309 unique student posts from three instances of the FYBIO course, as shown in Table 2. In total, 55,437 posts contained at least one emoji.

All students who participated in FYBIO courses filled a consent form allowing their data to be anonymized and analyzed for the sake of this study. The study was reviewed by the IRB (1456274-1) and deemed exempt. All students whose data was included in the study filled out a consent form and opted into the study. The high fraction of posts containing emoji (over 70%) shows that students' use of this tool went beyond the requirement in the course and echos past work demonstrating the educational benefits of affect [1, 18, 27].

4. METHODOLOGY AND RESULTS

Our goal is to provide teachers with better tools for making sense of students' affect in the course. To this end, we explore two main research questions. First, how do students use emoji in their posts? Second, can we use machine learning to infer how students would have tagged posts using the available emoji?

Our methodology addresses the first research question with a detailed analysis of emoji usage at the post and paragraph level, and addresses the second research question with the design of language models for emoji classification from text.

4.1 Analysis at the post level

Table 1 shows the percentage of emoji use in FYBIO. The table shows that the #question and #i-think emoji were used most often. Both of these emoji reflect uncertainty about the material and invite participation by instructors and students. The emoji expressing more direct requests for participation (e.g., #lets-discuss, #lost) were used much less frequently. This may reflect a resistance towards revealing

information about understanding that may have an adverse affect for students (e.g., peer pressure or getting a lower grade). Future editions of FYBIO will allow anonymous posting, which may change the way students use these posts.

By analyzing students’ comments we have found that about 70% of posts included at least one emoji. The majority (about 89%) of these posts include a single emoji, showing that students express a single affect in each post. The use of multiple emojis in the same post creates a complex affect. 10% of the posts contained two emoji and less than 1% of the posts contained 3 or 4 emoji.

4.2 Classifying individual emoji

In this section we describe how we use language models to classify students’ use of emoji at the post level. A good classification model can potentially aid instructors in making sense of students’ affective states in situations where emoji are not used, which is the case for most forums.

The model provides a mapping from a post to the most relevant emoji for the post according to the family. To this end we define a multiclass prediction task where the target class is the set of emoji shown in Table 1.

An instance was created for each post in the FYBIO dataset, and labeled with the relevant emoji for the post. For posts with multiple emoji, duplicate instances of the post were created for each emoji. The instances were split into training (85%) and test sets (15%), such that 15% randomly sampled instances of the training set are used as a validation set. We stratified the training and test sets such that each set contains approximately the same percentage of samples of each target class. In no case did the training and test sets include an instance with the same post. We compare two types of language models for the classification task. BERT is a pre-trained, transformer based language model that is commonly used in state-of-the-art natural language tasks [11]. We used an open-source BERT configuration (“bert-base-uncased”) that was trained on broad domain corpora (English Wikipedia and BooksCorpus).¹ The architecture contains 12 layers, 768 hidden units and 12 attention heads. We use this architecture in all of our experiments. Augmenting BERT with a pre-training procedure has demonstrated promising results in downstream NLP tasks [5, 20].

Our proposed model architecture (See Figure 2) consists of two components: 1) A language representation model (pre-training step) and 2) a fully connected neural network (fine tuning step). The language representation model was pre-trained using two sources: The FYBIO text book (150K words), as well as students’ posts from past instances of the course in 2020 (6.4M words). “bert-base-uncased” comes with a predefined vocabulary which consist of the approximately 30K most frequent words and sub-words from its pre-training corpus. We initiated the BERT model previously described, with its pre-trained weights, and afterwards trained the model for 50 additional epochs with a learning rate of $2e - 5$, which gave us the best results. Note that BERT allows the user to add special words or sub-words

¹<https://huggingface.co/transformers/modeldoc/bert.html>

that are unique to our domain. Since we pretrained using the Biology text book, we did not encounter words that are out of vocabulary, and so did not change the vocabulary.

The neural network was trained for the emoji classification task using 768 nodes with a softmax activation function above the additional pre-trained model. The input to this network was the embedded student’s post using the language representation model. The output of the network is a probability distribution over the 11 emoji in the target class. We fine-tuned the model with an addition of three epochs with a learning rate of $2e - 5$, using a maximal sentence length of 250, which gave us the best results.

We compared BERT to a bi-directional LSTM architecture, similar to the one used by Felbo et al. and Baziotis et al. [13, 4] to classify emoji in social media. The model included five layers. One layer was used to embed words in students’ posts as high-dimensional vectors; three layers for classification consisting of 64 LSTM units (32 units in each direction); the final layer was an attention mechanism layer that connects words in posts with preceding and succeeding words while computing the importance of each word with the corresponding label. The model was implemented using Python’s keras package [9]. We used a separate pre-training process using word2vec [21] to construct a high dimensional 200-sized vector representation of words in students’ posts. The pre-training used the FYBIO textbook, as well as students’ posts from 2020 and implemented using Python’s Gensim package [24].

Table 3 compares the BERT and LSTM models when classifying emoji according to precision, recall, and weighted F-1 scores. We can see that the BERT model outperforms the Bi-LSTM model in all three metrics by a significant margin (McNemar’s test, $p < 1.16 \cdot e^{-35}$). We attribute this difference to the pre-trained language model in BERT which allows it to generalize to domains with low amounts of training data [11].

Table 3: Model output comparison

Model	Precision	Recall	F-1 Score
BERT	40.2%	43.3%	40.7%
LSTM	26.6%	32.8%	29.3%

We note that prior work using BERT to classify emoji report a macro F-1 score of 38.5% [30], while our Macro-F1 score is lower (32.2%). However, we do not compare directly with these models for several reasons. First, they used an order of magnitude more data (550K tweets vs. 50K posts). Second, their target set was larger (20 vs. 11 emoji). Third, the emoji setting is different (e.g., smiley-faces, hearts, etc.) and is used in different ways (e.g., use the same emoji in different parts of the sentence).

Table 4 breaks down the performance of the model according to individual emoji. The table shows a positive relationship between the amount of training data for a given emoji and the prediction performance of the model for the emoji. An interesting exception is the #lets-discuss emoji, which is pedagogically important and represents more than 6% of the dataset, but achieves very low performance. The reason

Figure 2: Model architecture used for Emoji prediction

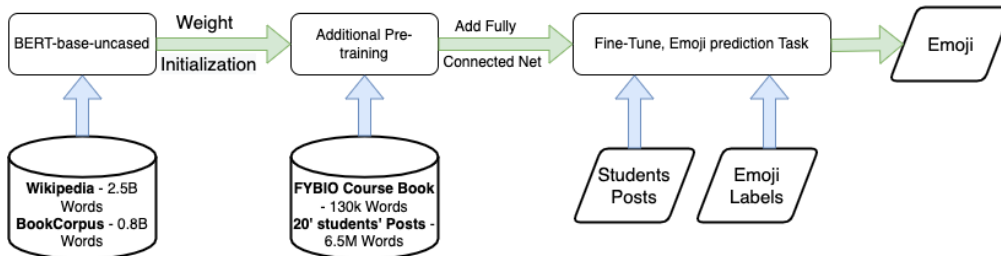

Table 4: BERT prediction score, divided by prediction output score for each emoji

Metric	?	☁️	😬	!!	❤️	💡	💬	🌍	😮	😞	🗨️
Precision	0.55	0.49	0.37	0.4	0.33	0.33	0.18	0.31	0.33	0.39	0.19
Recall	0.72	0.62	0.28	0.52	0.34	0.26	0.05	0.23	0.28	0.2	0.05
F-1 Score	0.62	0.55	0.32	0.45	0.34	0.29	0.08	0.26	0.3	0.26	0.07

is that the model misclassified over 50% of #lets-discuss as #i-think, suggesting that students may use these two emoji interchangeably to convey the same affect. We study this question in the next section.

Another possible reason for the low performance for some of the emoji may be that they were used by students to convey different affects than those intended for the emoji. For example, the following post shows a student has reached a conclusion but does not understand why it is true. This reflects a question rather than total confusion which was the originally intended purpose of this emoji: *I also get the impression that not having similar proof-reading mechanisms in transcription means that they are less severe. However. I'm not sure why this would be the case #lost.*

4.3 Classifying groups of emoji

In this section, we exploit the fact that emoji are often used together in paragraphs to cluster the emoji into pedagogically meaningful categories and predict the categories, rather than individual emoji. Felbo et al [13] clustered emoji based on the relationships between predicted probabilities of a computational model. We follow their approach and apply a hierarchical clustering algorithm with average linkage on the correlation matrix on the predicted probabilities of the BERT model shown in Table 4. Each emoji is represented as a vector of predicted probabilities for each post in the test set. To illustrate this approach, consider the following post from the test set: *is there an operon for every single metabolite? [trp] operon applies to tryptophan while lac operon applies to lactose. how many different types of operons are there and how they function differently?* The BERT model, applied to this post, outputted the highest probability for the #question and #just-curious emoji (0.467 and 0.45 probability, respectively) and low probability for the rest of the emoji (e.g., 0.008 probability for the #interesting-topic emoji, and 0.003 probability for the #lightbulb-moment emoji). Note that because we are using the softmax function, these probabilities add up to 1, although the two emoji have a combined probability of approximately 0.92. The fact that the model is likely to assign a high or low probability to both #question and #just-

curious emoji for a given post suggests that they should form a single category.

Figure 3 shows the dendrogram that is outputted by applying hierarchical clustering. The height of each node in the y -axis is proportional to the value of the intergroup dissimilarity between its child nodes. The distance threshold of the clustering is used to determine which nodes to put in the same cluster.

In concurrence with the FYBIO instructions, we determined a threshold of 1. This threshold grouped the 11 emoji into three emoji pair clusters and 5 singleton emoji clusters: (#question, #just-curious), (#lets-discuss, #i-think), (#important, #learning-goal), (#surprised), (#lightbulb-moment), (#lost), (#interesting-topic), and (#realworld-application).

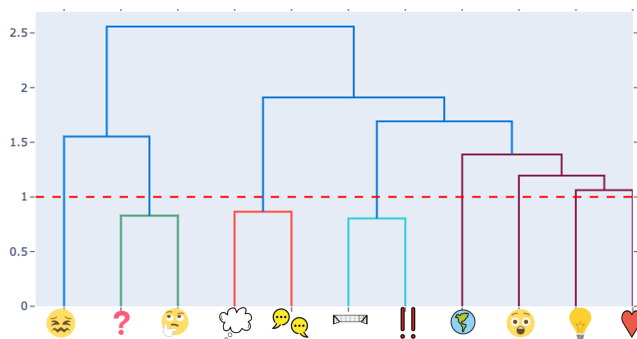

Figure 3: Hierarchical clustering of the emoji based on the model's prediction. The dashed red line represents the confidence threshold.

The justification provided by the course instructors for this division are as follows: With respect to the cluster containing the emoji (#question, #just-curious), instructors claimed that they invite a response from peers or the instructors, remarking that *“They are both requesting responses but with different urgency.”* The individual emoji were also highly correlated on the paragraph level. Both of these aspects led instructors to agree to put them in the same category.

Table 5: Model score of each cluster and the weighted average score of all labels

Cluster	Precision	Recall	F-1 Score
#question, #just-curious	77.8%	83.9%	80.7%
#lets-discuss, #i-think	58.4%	60.5%	59.5%
#important, #learning-goal	47.3%	51.4%	49.3%
Total Score (8 Categories)	55.2%	56.8%	55.8%

With respect to the cluster containing the emoji (#lets-discuss, #i-think), instructors claimed that *“both of these emoji indicate enthusiasm to continue around a topic, either for curiosity or sometimes to clarify [...] they are expressing how they understand it and want clarification or alternate views from peers.”* The individual emojis were also highly correlated on the paragraph level.

With respect to the cluster with the emoji (#important, #learning-goal), instructors claimed that both emoji depict students’ perspectives on exam-related content. They claimed that *“these emojis are used when students identify parts of the text that they believe are important for them to perform well in the course - that may be linked to assessment or the development of knowledge that build towards good performance on assessments.”*

Interestingly, the emoji-pair (#surprised, #interesting-topic) exhibited a high correlation on the paragraph level but was deemed sufficiently distinct by instructors to warrant a separate affect category for each emoji. Instructors claimed that *“Both emoji are expressions of ”enjoyment” of the text - though as noted slightly different.”*

The last part of our methodology was to study whether predicting the 8 categories, rather than the 11 original emojis, would improve prediction performance. To this end we trained the BERT model with the same architecture as described in Section 4.2, using the 8 categories as the target set. Table 5 shows the performance for the three emoji-pair clusters as well as total performance over all 8 of the categories. As shown by the Table, there was an improvement of 15% in prediction performance (from 40% to 55.8%) when compared to using a target set containing the original 11 emoji. We note that an improvement in prediction performance was to be expected, given the reduction in the size of the target set. What is interesting is that the two emoji #lets-discuss and #learning-goal, which achieved very low performance when predicted as individual emoji (see Table 4), exhibited significant improvement when clustered together with another emoji (F-Score of 59.5% and 49.3% respectively). The cluster with the emoji pair (#question, #just-curious) received the greatest score across all metrics. In terms of predicting the clusters with a single emoji, we saw a slight reduction in performance (less than one percent).

5. DISCUSSION AND CONCLUSIONS

This paper studied students’ use of emoji in a large scale course forums used by hundreds of students. We found that when made available to them, students tend to use emoji in their posts to enhance their meaning or to express affect (an emotion, belief and opinion), rather than as a substitute

for words. The most popular use of emoji was to invite further explanation or to express an interest in a given topic. Emoji expressing confusion or misunderstandings were less popular, and may reflect students’ hesitation to expose these affects in public. Students’ use of emoji is complex. In some cases, students use multiple emojis in the same post to convey a joint affect, while in other cases students use different emoji interchangeably to mean the same affect. Some students may use emoji in a different way than their intended use, and instructors may wish to present their meaning to students in the beginning of the course.

We began to explore the use of emoji as a pedagogical tool by instructors to aid course design or guide students. To this end, we analyzed how topics in the course material generate different emoji reactions from students. This led us to partition emoji into groups using hierarchical clustering. We identified the most pedagogically meaningful emoji clusters with the help of the course instructors, and designed a language model based on BERT that was able to classify students’ posts to the right cluster with good performance.

The language model allows to classify students’ posts with affects even when emoji are absent from the post, which can naturally extend our contributions to other courses and forums. By adding more data to the learning process, we hope to improve our language model. Following the improvement, we want to apply the model in two separate scenarios. (1) non-bio NB course (with same emojis) (2) course forum with different labels in hope that the model is able to learn affects signals from students writes.

We also intend to use our insights and computational tools to help teachers make sense of student affect in an active class. We envision a dashboard that would alert instructors to affects they care about, like confusion, or insights conveyed by students about learning goals. We wish to study how teachers use this tool to inform their course design, or to actively intervene in a forum to guide discussion.

University of Wisconsin-Madison

ABSTRACT

Instruction in many STEM domains heavily relies on visual representations, such as graphs, figures, and diagrams. However, students who lack representational competencies do not benefit from these visual representations. Therefore, students must learn not only content knowledge but also representational competencies. Further, as learning progresses, knowledge likely becomes more abstract, so that content knowledge may no longer be tied to a specific representation. This raises the question of whether students integrate representational competencies with content knowledge as learning progresses. The present study addresses this question by building knowledge-component models using log data collected from two studies in an introductory electrical engineering course. We compared knowledge-component models that separate representational competencies from content knowledge to knowledge-component models that integrate representational competencies with content knowledge. Our results show that as learning progressed, integrated knowledge-component models had better model fit. This finding indicates that over time, students' representational competencies become gradually integrated into content knowledge. Further, this suggests that different knowledge-component models might be needed at different times during a learning progression.

Keywords

Representational competencies, content knowledge, knowledge-component model, intelligent tutoring system

1. INTRODUCTION

The success of adaptive educational technologies depends on analyses of students' knowledge growth during their interaction with problem-solving activities. These analyses equip the educational technology with information about the students' current learning progress to mastery of the targeted knowledge [32] and enables it to provide adaptive feedback or to select appropriate interventions [16] based on the individual student's learning progress [7]. This capability has contributed to the success of adaptive educational technologies [30].

Therefore, much research has investigated how to analyze students' knowledge growth based on log data generated by students' problem-solving interactions in educational technologies. The first step in analyzing knowledge growth is to capture students' knowledge in a way that can then be used to trace their knowledge acquisition over time [4, 7]. Knowledge-component models are a common way of capturing students' knowledge [15]. The basic assumption of

knowledge-component models is that knowledge consists of fine-grained "atom-like" components [15]. Hence, knowledge-component modeling seeks to identify all knowledge components required for mastering the targeted knowledge [13].

Traditional knowledge-component models have focused on capturing content knowledge. However, focusing on only content knowledge may not adequately enable educational technologies to support students' learning, especially in STEM fields. Previous research showed that, students often have difficulties understanding visual representations, while most STEM instruction heavily relies on multiple visual representations [2, 17]. Such struggles can impede their content learning [24]. For example, electrical engineering courses on signal processing frequently use visual representations as shown in Fig. 1 to explain concepts related to sinusoids. While visual representations are often thought to support learning [1], they can impede learning for students who do not know how to interpret the visual representations. For instance, if the students are unfamiliar with time-domain graphs (Fig. 1a) or phasor graphs (Fig. 1b), they may struggle to understand the concept of the sinusoid. This example typifies that many instructional scenarios expect students to have *representational competencies*. Representational competencies are defined as the knowledge and skills that enable students to understand and use visual representations to reason and solve tasks [9].

While most research on knowledge-component models has focused on content knowledge, only a few studies show that capturing representational competencies in addition to content knowledge improves the fit of knowledge-component models [25]. A limitation of these studies is that they have assumed a static structure of knowledge-component models; that is, representational competencies and content knowledge were captured as separate knowledge components, and this did not change over time. However, as learning progresses, students' content knowledge likely becomes more abstract and their use of representational competencies becomes more automated. Thus, the goal of this paper is to address this limitation by comparing knowledge-component models that separate or integrate representational competencies and content knowledge in various ways.

2. LITERATURE REVIEW

In the following, we first review research on representational competencies. Then, we briefly review the few prior studies that have captured representational competencies in knowledge-component models.

2.1 Representational Competencies

The educational psychology has identified several types of representational competencies that enable students to learn content knowledge from visual representations [24].

First, students need *visual-understanding competencies*: the ability to map visual features to relevant to-be-learned content [28]. In the

J. Rho, M. Rau, and B. Vanveen. Investigating growth of representational competencies by knowledge-component model. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 346–352, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

<https://doi.org/10.5281/zenodo.6853077>

previously mentioned example of a student learning about sinusoids, visual-understanding competencies allow the student to map a visual feature (e.g., the peak in the time-domain graph) to the concept it depicts (e.g., the amplitude of a sinusoid).

Second, students need *conceptual connection-making competencies*: the ability to conceptually understand similarities and differences between multiple visual representations [1]. This allows students to explain how domain-relevant concepts are depicted in different visual representations [29]. For example, the red arrow in Fig. 1 illustrates how a student should connect the amplitude in the time-domain graph (Fig. 1a) to the phasor's magnitude in the phasor graph (Fig. 1b). Conceptual connection-making competencies also involve identifying visual features that have surface similarities among visual representations but are conceptually irrelevant [11]. For example, a student may notice that both the time-domain graph (Fig. 1a) and the phasor graph (Fig. 1b) have two axes. Yet, the axes represent different concepts: time and amplitude in the time-domain graph, the imaginary and real parts of the phasor in the phasor graph.

Third, students need *perceptual connection-making competencies*: the ability to effortlessly and efficiently translate between multiple visual representations [12]. Students with perceptual connection-making competencies can intuitively translate between two visual representations and quickly judge whether they depict the same concept, without experiencing mental effort when executing this task [12]. For example, a perceptually proficient student would see "at a glance" the phasor graph in Fig. 1b represents the amplitude of the sinusoid in Fig. 1a.

Figure 1. Mapping time-domain graph amplitude (a) to phasor graph magnitude (b).

2.2 Knowledge-Component Model

Adaptive educational technologies require information about the students' learning progress in order to provide individualized support. [30]. They must describe the knowledge students have already learned and what knowledge they still have to learn [6]. Furthermore, adaptive educational technologies rely on algorithms that predict which types of support (e.g., contextual feedback, choice of problem-solving activities) would help the student acquire the knowledge s/he has not yet learned [21].

Educational technologies rely on knowledge-component models to trace students' knowledge acquisition and to predict the growth of students' knowledge. Knowledge-component models represent "acquired units of cognitive function that can be inferred from performance on a set of related tasks" [15]. Here, knowledge components refer to a unit of distinct skills or concepts, which together compose the knowledge students learn in problem-solving activities. Therefore, the accuracy of a knowledge-component model depends on identifying all relevant knowledge components that describe the targeted knowledge [13, 16].

Cognitive Task Analysis (CTA) is one prominent method to describe the requisite knowledge components to perform a task [33]. However, since CTA relies on a thorough analysis of how experts solve tasks, it is time consuming. To increase the efficiency of knowledge-component modeling, educational data mining techniques can be used to automate the process of building models, including learning factors analysis (LFA) [4], Knowledge Spaces [31], and matrix factorization [8]. Typically, multiple potential models are compared using Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC) scores [14]. However, since this research has focused mostly on modeling content knowledge, the interplay between representational competencies and content-focused knowledge components remains unexamined.

One study compared knowledge-component models that captured (1) only content knowledge and (2) content knowledge and representational competencies. Capturing both content knowledge and representational competencies resulted in better model fit [25]. A follow-up study tested whether adapting instructional support to students' representational competencies in addition to content knowledge resulted in higher learning outcomes than adapting only to content knowledge [23]. Results showed that adapting to students' representational competencies in addition to content knowledge enhanced students' learning of content knowledge.

However, this prior research is limited in two ways. First, while most prior research focuses on modeling content knowledge [18, 20], the few studies that have also modeled representational competencies [23, 25] have focused on a particular domain; namely chemistry. Therefore, we seek to replicate these findings in another domain. A second limitation is that the prior studies assumed that the structure of the knowledge-component model remains static over time. Yet, according to expert-novice research, students gradually acquire highly abstract schemas about the content knowledge relevant to a given domain [5, 10]. This yields the hypothesis that capturing representational competencies separately from content knowledge is most important early in a learning progression whereas later in a learning progression, representational competencies likely become integrated with content knowledge.

3. HYPOTHESES

To address the limitations of prior research just described, we test:

Hypothesis 1: A knowledge-component model that captures representational competencies and content knowledge is more accurate than a knowledge-component model that captures only content knowledge or a knowledge-component model that captures only representational competencies.

Hypothesis 2: As students' learning progresses, a knowledge-component model that integrates content knowledge and representational competencies is more accurate than a knowledge-component model that captures content knowledge separately from representational competencies.

4. DATASETS

To test these hypotheses, we use log data generated from students' problem-solving interactions in Signals Tutor, an intelligent tutoring system (ITS) for undergraduate electrical engineering. In the following, we first describe the problem-solving activities in Signals Tutor, and then the log data we used to test our hypotheses.

Figure 2 Example of a problem in Signals Tutor and steps that labelled with different knowledge components for hypothesis 1

4.1 Signals Tutor

Signals Tutor supports learning through problem solving [22, 27, 30]. As is typical for ITSs, Signals Tutor provides step-by-step guidance for complex problem-solving tasks [30], detects multiple possible solution paths, provides personalized feedback that addresses diagnosed misconceptions, and on-demand hints for each step. As illustrated in Fig. 2, students work with interactive visual representations to visually depict concepts related to sinusoids.

Because Signals Tutor incorporates multiple visual representations, it offers opportunities for students to practice representational competencies. Specifically, students practice *visual-understanding* competencies when they interact with one visual to make sense of sinusoid concepts. Students practice *conceptual connection-making* competencies when they have to integrate information from multiple visual representations to understand sinusoid concepts. They practice *perceptual connection-making* competencies when a task requires translating quickly among multiple visual representations to extract relevant information about sinusoids.

4.2 Log Data

We collected log data from two studies that were conducted as part of an introductory electrical engineering course on signal processing at a university in the Midwestern U.S. Study 1 was conducted in Fall 2020; Study 2 was conducted in Spring 2021. The course was taught online during both semesters. Students used Signals Tutor as part of the course for a study described elsewhere [26]. The present paper focuses on log data generated from students' interactions with two units of Signals Tutor that provided opportunities to practice the representational competencies described above. Specifically, we extracted 84,960 transactions generated by 136 students from Study 1 log data and 76,786 transactions generated by 145 students from Study 2. These transactions involved problem-solving steps where students constructed visual representations and equations and answered conceptual questions by selecting answers from drop-down menus or via text input.

5. ANALYSIS

To test hypothesis 1, we created knowledge-component models with and without representational competencies. To test hypothesis 2, we created several knowledge-component models that captures

the integration of content knowledge and representational competencies. We compared the fit of each model in the earlier vs. the later unit of Signals Tutor.

5.1 Knowledge-Component Models with and without Representational Competencies

To test hypothesis 1, we created three knowledge-component models: (1) the *only-content-KC model* captures only content knowledge, (2) the *only-RC-KC model* captures only representational competencies, and (3) the *both-content-and-RC-KC model* captures both content knowledge and representational competencies. The knowledge components captured by each model were derived from manual cognitive task analysis relying on expert content knowledge provided by an engineering professor who taught the course for more than 30 years/decades.

First, the *only-content-KC model* contains 9 *only-content knowledge components* that describe concepts and skills irrespective of the representational competencies, listed in Table 1. For example, the knowledge component 'Inference' in Table 1 refers students' ability to make an inference about changing a value of the given sinusoid's frequency into the angular frequency.

Second, the *only-RC-KC model* captures only representational competencies but not content knowledge. It contains 11 knowledge components, listed in Table 1. As mentioned above, Signals Tutor offers opportunities to practice three types of representational competencies. The *only-RC-KC model* describes the competencies students need to understand the visual representations used in the problems; for example, conceptual connection-making competencies (e.g., 'Conceptual_time-phasor') and perceptual connection-making competencies (e.g., 'Perceptual_time-phasor') related to translating a time-domain graph to a phasor graph.

Finally, the *both-content-and-RC-KC model* captures both content knowledge and representational competencies. It contains 42 knowledge components, listed in Table 1. To develop content knowledge of translating a time-domain to a phasor graph, students practice competencies for making both conceptual and perceptual connections among visuals. For example, consider the following steps that provided practice opportunities for conceptual connection-making competencies. Students first built a time-domain graph

Table 1 Examples of knowledge components in Signals Tutor (For the value in [], students type in their answer).

Knowledge Components	Examples of knowledge components	Description	Example
<i>only-content KC</i>	Inference	Make inferences about changing the value of frequency to angular frequency or vice versa.	$x(t)$ is has an angular frequency ω of $\frac{\pi}{2}$ in radians/sec. The frequency in cycles/sec is [.25].
	Planning	Plan how to represent the sinusoid using different type of visual representation.	The complex amplitude can be represented visually by a [phasor].
	Build phasor graph	Construct a phasor graph of a given sinusoid	Plot the phasor corresponds to $x(t)$.
	Build time-domain graph	Construct a time-domain graph of a given sinusoid	Plot this sinusoid on the given time-domain graph.
<i>only-RC KC</i>	Conceptual_time-phasor	Make sense of how a time-domain visual correspond to a given phase-domain visual	The given graph shows a sinusoid $x(t)$. Plot the phasor corresponding to $x(t)$.
	Perceptual_phasor-time	Translate a phase-domain visual to a time-domain visual	Here's a phasor. Which cosine function represents that phasor?
<i>both-content-and-RC KC</i>	Conceptual_step1_equ_time	Given a cosine function, build a time-domain graph representing the given time-domain equation	For the equation $x(t) = 3\cos(\pi t)$, plot $x(t)$.
	Conceptual_step2_phaseshift	After building a time-domain graph in step 1, identify its value of phase shift	The phase shift ϕ of $x(t)$ is [0].
	Conceptual_step3_time-phasor	Based on identified information in step 2, translate a time-domain graph to a phasor graph	Draw the phasor associated with $x(t)$, $c = Ae^{j\phi}$.
	Conceptual_step4_phasor-exp	After building a phasor graph in step 3, write corresponding complex exponential notation.	We may express $x(t)$ in complex exponential notation as $Re\{[3]\exp(j[0])\exp(j[3.14]t)\}$
	Perceptual_time-phasor (clockwise)	Translate a time-domain graph to a phasor graph (rotated in the clockwise direction)	Here's a sinusoid (cosine function). Which phasor represents that sinusoid?
	Perceptual_time-phasor (counter-clock)	Translate a time-domain graph to a phasor graph (rotated in the counter-clockwise direction)	Here's a sinusoid (cosine function). Which phasor represents that sinusoid?

representing a given sinusoid represented in the equation form (e.g., 'Conceptual_step1_equ-time' KC in Table 1). The next step is to find the value of phase shift (e.g., 'Conceptual_step2_phaseshift'), which is basis for building a corresponding phasor graph in the next step. In the third step, students translate the time-domain graph to a phasor graph (e.g., 'Conceptual_step3_time-phasor').

Hypothesis 1 predicts that the *both-content-and-RC-KC model* has better model fit than the other knowledge-component models.

5.2 Knowledge-Component Models with and without abstracted Knowledge Components

To test hypothesis 2, we created two knowledge-component models: (1) the *separate-RC-KC model* describes the knowledge structure of students starting at the novice-level (2) the *integrated-RC-KC model* describes the knowledge structure of students reaching to the expert-level through working on Signals Tutor, detailed in the following.

First, based on learning gains we observed between units [26], we assumed that structural changes in knowledge components would occur between units 1 and 2. Therefore, we chose to investigate knowledge components that were common to units 1 and 2 and examined how these knowledge components changed after finishing each unit. Thus, starting with the list of knowledge components in the *both-content-and-RC-KC model* described in 5.1, we identified 33 knowledge components that unit 1 and unit 2 had in common.

This yielded the *separate-RC-KC model*. Given that this knowledge-component model separately captures content knowledge and representational competencies, we anticipate that this might capture the knowledge structure of novice students in the first unit.

Second, based on previous studies' finding that sufficient training makes students' knowledge become abstracted [5, 10] or abstracted away from the type of representational competencies [25], we assumed that students' knowledge components started to be integrated into content knowledge after finishing unit 1. Thus, we identified lists of knowledge components from the *both-content-and-RC-KC model* that describe similar content knowledge. For example, in Signals Tutor, students learn about concepts related to the phase shift of sinusoids, which we classify as content knowledge. Depending on how students interact with the visual representations that depict these concepts, they practice different representational competencies. The *both-content-and-RC-KC model* contains six knowledge components related to phase shift, illustrated in Table 1: three knowledge components describe students' ability to conceptually connect a sinusoid's shifted amount and direction shown in a time-domain graph to a phasor's rotational direction and amount shown in a phasor graph (e.g., 'Conceptual_step1_equ_time', 'Conceptual_step2_phaseshift', 'Conceptual_step3_time-phasor'), and two knowledge components describe students' ability to make perceptual connections between a time-domain graph and a phasor graph by treating the representations holistically (e.g., 'Perceptual_time-phasor (0)',

‘Perceptual_time-phasor (clockwise)’, ‘Perceptual_time-phasor (counter-clock)’).

If these six representational competencies become more integrated with content knowledge about phase shift after practice (hypothesis 2), separating these representational competencies from content knowledge may no longer adequately describe students’ abstracted knowledge structure. To capture this more abstracted understanding, we built new knowledge-component models that contained merged knowledge components. Starting with the knowledge components from the *separate-RC-KC model*, we first merged knowledge components that covered similar content knowledge. For example, ‘Conceptual_step1_equ_time’, ‘Conceptual_step2_phaseshift’, ‘Conceptual_step3_time-phasor’ and ‘Perceptual_time-phasor (clockwise)’ were merged into the ‘Build phasor graph’ knowledge component, which is one of the knowledge components from the *only-content KC model*. We then tested whether merging these knowledge components improved model fit using AIC and BIC scores. If it did, we kept the merged knowledge component; if it did not, we kept the separated knowledge components. We repeated these steps until there were no more opportunities to merge knowledge components. We carried out these steps separately for the data from Studies 1 and 2, yielding *integrated-RC-KC model-1* and *integrated-RC-KC model-2* as shown in shown in Table 2.

Hypothesis 2 predicts that the *integrated-RC-KC model-1* and the *integrated-RC-KC model-2* have a better model fit compared to the *separate-RC-KC model* in unit 2. Similarly, since students are novice at the beginning stage, hypothesis 2 predicts that the *separate-RC-KC model* shows better model fit compared to the *integrated-RC-KC model-1* and the *integrated-RC-KC model-2* in unit 1.

Table 2. Separate and integrated knowledge components.

Separate KCs in unit 1	Integrated KCs in unit 2
Conceptual_step3_time-phasor	Build phasor graph (<i>integrated-RC-KC model-1</i>)
Perceptual_time-phasor (0)	
Perceptual_time-phasor (clockwise)	
Perceptual_time-phasor (counter-clockwise)	
Perceptual_phasor-exp	Write complex exponential notation (<i>integrated-RC-KC model-1</i>)
Conceptual_step4_phasor-exp	
Perceptual_phasor-cartesian	Write cartesian form (<i>integrated-RC-KC model-2</i>)
Individual_phasor-cartesian (real part)	
Individual_phasor-cartesian (imaginary part)	

6. RESULTS

To test hypothesis 1, we compared the model fit of the *only-content-KC model*, *only-RC-KC model*, and *both-content-and-RC-KC model* using data from Studies 1 and 2. Table 3 shows that the *both-content-and-RC-KC model* has a better model fit than the *only-content-KC model* and the *only-RC-KC model* in Study 1 and Study 2. For AIC scores, the lower AIC indicate a better-fit-model, and more than -2 is considered significantly better than model it is being compared [3]. Similarly, a decrement greater than 10 indicates very

strong evidence in terms of BIC [19]. Lower values of RMSE also indicate better fit. These results support hypothesis 1.

To address hypothesis 2, we compared the model fit of the *separate-RC-KC model*, the *integrated-RC-KC model-1*, and the *integrated-RC-KC model-2* as shown in Table 4. For Study 1, results show that in unit 1, the *separate-RC-KC model* shows the better fit than the *integrated-RC-KC models*. By contrast, in unit 2, the *integrated-RC-KC model-1* shows better model fit than the *separate-RC-KC model* in terms of AIC and RMSE (but based on BIC the *integrated-RC-KC model-2* shows the best model fit). This supports hypothesis 2.

For Study 2, we found that in unit 1, the *separate-RC-KC model* shows a better model fit than the *integrated-RC-KC models* in terms of AIC as shown in Table 5. However, the BIC and RMSE scores indicated that the *integrated-RC-KC model-1* had the best model fit. By contrast, in unit 2, the *integrated-RC-KC model-2* shows the best model fit. This result supports hypothesis 2 in terms of AIC scores. For BIC and RMSE scores, the results partially support hypothesis 2, because the *integrated-RC-KC model-1* shows the better model fit than the *integrated-RC-KC model-2*.

Table 3. Test of hypothesis 1: Model accuracy for study 1 and study 2. Bold stands for the best fit.

Study	KC Model	# of KC	AIC	BIC	RMSE
1	<i>both-content-and-RC</i>	42	22,123	24,221	0.4422
	<i>only-RC</i>	34	22,736	24,709	0.4456
	<i>only-content</i>	9	23,853	25,446	0.4537
2	<i>both-content-and-RC</i>	42	18,559	20,358	0.4370
	<i>only-RC</i>	34	19,120	20,796	0.4421
	<i>only-content</i>	9	20,133	21,418	0.4544

Table 4. Test of hypothesis 2: Model fit by unit (Study1). Bold stands for the best fit.

Unit	RC-KC Model	# of KC	AIC	BIC	RMSE
1	<i>separate-RC-KC model</i>	33	9,733	11,488	0.4367
	<i>integrated-RC-KC model-1</i>	30	9,779	11,491	0.4368
	<i>integrated-RC-KC model-2</i>	27	9,803	11,492	0.4374
2	<i>separate-RC-KC model</i>	33	10,387	12,133	0.4414
	<i>integrated-RC-KC model-1</i>	30	10,372	12,075	0.4387
	<i>integrated-RC-KC model-2</i>	27	10,396	12,054	0.4399

Table 5. Test of hypothesis 2: Model fit by unit (Study 2). Bold stands for the best fit.

Unit	RC-KC Model	# of KC	AIC	BIC	RMSE
1	<i>separate-RC-KC model</i>	33	8,134	9,587	0.4445
	<i>integrated-RC-KC model-1</i>	30	8,156	9,567	0.4431
	<i>integrated-RC-KC model-2</i>	27	8,201	9,570	0.4461
2	<i>separate-RC-KC model</i>	33	9,095	10,598	0.4278
	<i>integrated-RC-KC model-1</i>	30	9,085	10,546	0.4263
	<i>integrated-RC-KC model-2</i>	27	9,080	10,498	0.4264

7. DISCUSSION

Our results show that the knowledge-component model incorporating both representational competencies and content knowledge had the best model fit (hypothesis 1). This result aligns with findings from a previous study that investigated whether a knowledge-component model should incorporate representational competencies using chemistry students' learning data. Our results replicate this finding in the electrical engineering domain.

Further, we found that students' representational competencies become abstracted and integrated with content knowledge as students practice representational competencies (hypothesis 2). This shows that as students' learning progress, their representational competencies are gradually merged with content knowledge. We note that the time at which each representational competency is integrated into the content knowledge may not be uniform. For instance, while students' representational competency of translating a time-domain graph to a phasor graph were merged with content knowledge in unit 2, the representational competency of translating a phasor graph to a time-domain graph remained separate from content knowledge. It is possible that after more practice, the latter representational competency would also merge with content knowledge.

Additionally, our results indirectly suggest that students' timelines may differ depending on their learning rates. Specifically, we found differences between the Study 1 and Study 2 cohorts. The fact that BIC, AIC, RMSE disagreed as to whether the *integrated-RC-KC model-1* or the *separate-RC-KC model* had a better model fit for unit 1 suggests that students in Study 2 started with somewhat more integrated knowledge and ended with more integrated knowledge compared to students in Study 1. We do not want to speculate what might have caused these cohort effects because there are numerous possible reasons, but it suggests that students may start and end at different points on a separate-to-integrated knowledge trajectory.

Our study makes novel contributions to the field of educational data mining because it is, to our knowledge, the first study capturing dynamic development of students' representational competencies using knowledge-component models. Knowledge-component modeling allowed us to identify dynamic, developmental patterns of representational competencies and to show that they are not static. Further, our finding that knowledge-component models should incorporate representational competencies in addition to

content knowledge expands the search space for knowledge-component models in future work.

Our findings also have important implications for the design of adaptive educational technologies. First, technologies that use visual representations should trace students' acquisition of representational competencies in addition to content knowledge. Doing so is particularly important at the beginning of a learning sequence. When students first learn a new concept with visual materials, instructional supports should be designed with consideration of students' representational competencies and content knowledge. Second, as students' representational competencies change dynamically through practice, the educational technology may no longer need to monitor representational competencies separately from content knowledge. This, however, may need to be adapted to the rate at which students learn specific representational competencies and content knowledge.

8. LIMITATIONS & FUTURE WORK

Our results should be interpreted considering the following limitations. First, we collected log data from students working on Signals Tutor in the context of online learning. Online learning differs from in-person learning in multiple ways. Therefore, future studies should replicate our results in the context of in-person learning. Second, our experiment was constructed in a specific electrical engineering course. Even though visual representations are commonly used in many STEM instructions, representational competencies are domain-specific and highly dependent on the particular content knowledge covered. Thus, future research needs to test whether our results generalize to other STEM domains and topics. Finally, open questions remain about the suitable length of a learning intervention to ensure that all representational competencies become integrated with content knowledge. Although this study found that the students' representational competencies are gradually integrated with content knowledge, it did not examine when each representational competency becomes fully integrated into the content knowledge. To address this limitation, a longer intervention is needed. Such research could help establish the length of learning trajectories that relate to representational competencies.

9. CONCLUSION

The present paper shows that the structure of students' knowledge changes over time. Consequently, different knowledge-component models are best suited at different times during a learning trajectory. While modeling representational competencies is important, representational competencies become integrated with content knowledge with practice. Thus, educational technologies should employ dynamic knowledge-component models that capture representational competencies separately from content knowledge at the beginning of a learning trajectory while merging them with content knowledge later in a learning sequence. The way in which these knowledge components are merged may depend on the student's learning rate. Given that prior research shows that adapting instructional support to students' representational competencies can significantly enhance their learning of content knowledge and given the prevalence of visual representations in STEM instruction, our study may have considerable impact on the effectiveness of educational technologies.

ABSTRACT

Online educational technologies facilitate pedagogical experimentation, but typical experimental designs assign a fixed proportion of students to each condition, even if early results suggest some are ineffective. Experimental designs using multi-armed bandit (MAB) algorithms vary the probability of condition assignment for a new student based on prior results, placing more students in more effective conditions. While stochastic MAB algorithms have been used for educational experiments, they collect data that decreases power and increases false positive rates [22]. Instead, we propose using adversarial MAB algorithms, which are less exploitative and thus may exhibit more robustness. Through simulations involving data from 20+ educational experiments [29], we show data collected using adversarial MAB algorithms does not have the statistical downsides of that from stochastic MAB algorithms. Further, we explore how differences in condition variability (e.g., performance gaps between students being narrowed by an intervention) impact MAB versus uniform experimental design. Data from stochastic MAB algorithms systematically reduce power when the better arm is less variable, while increasing it when the better arm is more variable; data from the adversarial MAB algorithms results in the same statistical power as uniform assignment. Overall, these results demonstrate that adversarial MAB algorithms are a viable “off-the-shelf” solution for researchers who want to preserve the statistical power of standard experimental designs while also benefiting student participants.

MAB, bandits, experimental design, hypothesis testing

1. INTRODUCTION

Digital educational technologies offer unique opportunities to conduct pedagogical experiments and learn how to improve student outcomes. For example, experimenters can compare worked examples versus tutoring [19] or vary an avatar’s dialect [9]. When an intervention’s impact is mea-

sured soon after the intervention (e.g., via response times as in [32] or later problem correctness as in [18]), real-time data could be used to direct more students to more effective conditions. Multi-armed bandit (MAB) algorithms have been proposed as a way to conduct such adaptive experiments [15] and used for optimizing A/B comparisons (e.g. [16, 25, 26]).

While MAB assignment tends to improve outcomes for participants, it poses problems for drawing conclusions from the data. Prior research has shown systematic measurement errors, increases in false positive rate (FPR), and decreases in power when stochastic MAB algorithms are used for A/B comparisons (e.g., [22]). Potential benefits to student participants could thus be outweighed by harm to the research: lower power decreases the probability that effective interventions will be detected and deployed outside the trial, and higher FPR may lead to deploying unhelpful interventions at significant cost. While developing new algorithms and analysis approaches for these challenges is an active area of research (e.g., [5, 8]), these approaches are not yet an “off-the-shelf” solution for MAB-based experimental design.

In this paper, we consider the impact of using MAB algorithms that make performance guarantees in the adversarial case. These algorithms make weaker assumptions about their environment [4], decreasing the degree to which they can assign more students to a perceived better condition. Yet, we hypothesize that these relaxed assumptions may also decrease the *negative* consequences for drawing conclusions from the data, resulting in collected data that is more robust to the realities of educational experiments. Adversarial MAB algorithms could thus be used by researchers who want some of the benefits of condition-assignment via MAB algorithms but where their primary focus remains on drawing generalizable conclusions. These algorithms could also be *more* effective than uniform random assignment in some cases, as they can be sensitive to condition variability, and allocating more participants to an extremely variable condition can result in a better measurement of its effectiveness.

Using simulations, we first explore how 22 previously conducted experiments [29] might have been impacted if conditions had been assigned with a stochastic bandit algorithm (Thompson sampling [30]) or with one of three adversarial MAB algorithms in the Exp family [4], rather than with uniform random assignment.¹ These experiments were all conducted in ASSISTments homework assignments [11],

leading to a thorough investigation of how these algorithms might perform in real-world settings. We go beyond prior work that has often focused on binary outcomes for students (e.g. [35]) to examine real-valued outcomes that may follow idiosyncratic distribution patterns. We show that the Exp family of adversarial bandit algorithms largely avoids the measurement and hypothesis testing inaccuracies incurred by stochastic bandits, while still providing a small but reliable improvement in average student outcomes.

We then turn to exploring MAB algorithms in the context of experiments where conditions differ in variance, which occurs when interventions narrow (or widen) gaps among students. We find that the potential power advantage for adversarial MAB algorithms is not realized in practice, although there are some scenarios in which the more exploitative stochastic MAB algorithm does increase power.

Overall, we make the following contributions: (a) introducing the idea of adversarial and stochastic-adversarial MAB algorithms as an off-the-shelf solution for allocating students to conditions; (b) demonstrating that these MAB algorithms have minimal detrimental impacts on the performance of statistical hypothesis testing in a range of real-world educational experiments; and (c) illustrating that differences in variance across two conditions are not sufficient for condition assignment with adversarial MAB algorithms to increase power over uniform assignment. These results suggest that adversarial and stochastic-adversarial MAB algorithms offer a good solution for researchers who want to improve student participant’s experiences without negatively impacting their own ability to learn from the experiment and improve experiences for the many students who are not participants.

2. RELATED WORK

Assigning participants to experimental conditions using MAB algorithms has been proposed as an alternative to uniform assignment (e.g., [12, 31, 34]). In clinical trials, a variety of methods that adapt based on previous results have been presented (e.g., [3, 5, 7], often to more quickly use data to benefit patients (e.g., [36]). More closely related to our work, applications of MAB algorithms to educational settings can help to more quickly identify pedagogically effective conditions (e.g., [15, 16, 33]) and lower barriers to teachers conducting experiments in their classrooms [35]. While MAB algorithms have also been used in education to assign students to educational interventions with the sole goal of producing the best outcomes for that particular student (e.g., [6, 13]), we focus here specifically on cases where there is a desire to extrapolate beyond individual students and draw generalizable conclusions, as in traditional scientific experiments.

While MAB algorithms are a natural choice for assigning participants to conditions to limit how many students are assigned to less effective conditions, these algorithms have consequences for researchers’ ability to use the collected data to draw conclusions about the relative effectiveness of conditions. Traditional stochastic MAB algorithms minimize regret, but this can lead to systematically biased estimates of arm means (e.g., [5, 20, 37]). They also impact traditional statistical hypothesis testing: false positive rates, where there is no actual effect in the population but the test points to there being an effect, can be increased, and

power, which measures how often a test will detect a difference when there is one, can be decreased (see e.g., [22], for specific documentation of these phenomena with Thompson sampling [1, 30], which we compare to in this paper). A variety of approaches have been taken to addressing these issues, including both statistical approaches to create unbiased estimators from the collected data (e.g., [5]) and algorithmic approaches that incorporate measurement into the algorithms’ objective (e.g., by including estimation accuracy in the objective [8] or incorporating lower bounds on power [38]). Using such approaches off-the-shelf can be challenging: the power-constrained bandits algorithm [38] makes multiple decisions about one participant, rather than learning across participants, and researchers may wish to use their standard statistical estimators and tests rather than switching to a different paradigm. In this paper, we take a slightly different approach by exploring an alternative class of MAB algorithms and examining their performance in real-world scenarios.

3. BANDIT-DRIVEN EXPERIMENTS

MAB problems are a kind of reinforcement learning problem focused on maximizing immediate rewards. A classic example is allocating limited pulls to a set of slot machines. In these problems, agents must balance collecting new information about little explored arms and exploiting information from received rewards. Here, we model selecting better educational interventions as a MAB problem: Each intervention is an arm (action) the system can choose, and initially, rewards are unknown. After a student experiences an intervention, the system receives a stochastic reward (e.g., a measure of the student’s understanding/efficiency) that influences the arm choice for the next student.

Stochastic bandit algorithms. These algorithms assume there is some stationary reward distribution underlying each arm. Here, we focus on Thompson sampling (TS; [2, 30]), which maintains an estimate of the reward distribution of each arm. From the reward that it gets from each choice, it updates this distribution. At each time step, the algorithm samples from the posterior reward distribution of each arm and chooses the arm that has the highest sampled value.

Adversarial bandit algorithms. Adversarial bandits make no statistical assumptions about the reward distribution of each arm, making them appropriate for reward distributions that are non-stationary or of unknown form. Because of the lack of assumptions, they are designed to explore more strongly and adapt more quickly to perceived changes in reward distributions. If the rewards in fact follow stationary distributions, this can lead to lower expected reward than stochastic bandit algorithms, but when reward distributions deviate from these assumptions, adversarial bandit algorithms have stronger performance guarantees than stochastic bandit algorithms. From the perspective of using MAB algorithms for experimental design, the extra exploration in adversarial algorithms could collect better data for drawing conclusions about differences between arms, albeit while lowering benefits for participants in the experiment.

In this work, we focus on the popular Exp3 family of adversarial bandit algorithms [4]. Exp3 balances exploration and exploitation via an exploration hyperparameter that influ-

ences both the probability of picking an arm uniformly at random and the strength of response to high rewards from low-probability arms. This hyperparameter allows an experimenter to adjust the amount of exploration, potentially increasing reward at the cost of collecting more biased data. Because this choice is difficult to optimize ahead of time, we also examine the performance of Exp3.1, which eliminates the hyperparameter and provides worst case performance guarantees regardless of the true reward distributions [4].

One algorithm that has performance guarantees in both stochastic and adversarial environments is Exp3++ [28]. While this algorithm achieves lower expected rewards than TS, it often improves upon the obtained reward of Exp3 while still employing enough exploration to perform well in adversarial environments. It also can be used off-the-shelf, with fixed values for the hyperparameters that probabilistically guarantee asymptotic performance [27].

We want to explore how well adversarial and stochastic MAB algorithms meet the needs of researchers for data collection in educational experiments and how they impact student experiences compared to traditional uniform assignment. We hypothesize that the adversarial bandit algorithms (Exp3 with a fixed value of 0.05 for the hyperparameter, Exp3.1, Exp3++) will have comparable performance for collecting research data to uniform random allocation, with benefits to students that are greater than uniform random allocation but less than those from a representative stochastic bandit algorithm (TS). Further, Exp3++ is likely to improve on the purely adversarial algorithms’ performances in assigning more students to better arms.

4. EVALUATING ADVERSARIAL BANDITS: ASSISTMENTS EXPERIMENTS

The probabilistic asymptotic performance guarantees of MAB algorithms, both in stochastic and adversarial environments, suggest that student participants would benefit if these algorithms were used for experimental design. However, these guarantees do not speak to how biased the collected data will be, nor whether standard statistical hypothesis testing will be able to draw accurate conclusions from that data. Further, real educational experiments may have non-normally distributed outcome measures, impacting the collected data and performance of each algorithm. To explore how well the Exp3 variants meet the needs of researchers to draw accurate conclusions and the desire to place more students in a better condition, we conduct simulations that leverage previously collected datasets from educational experiments, conducted on the ASSISTMENTS platform [11]. We use these datasets as a case study for how to apply MAB algorithms to scenarios with varying, real-valued reward distributions, where some students reach mastery quickly and others never do so, and by repeatedly simulating the potential impact of each of the four bandit algorithms (TS, Exp3, Exp3.1, Exp3++), we can measure statistical power, false positive rate (FPR), and accuracy of arm measurement across algorithms.

4.1 Methods

4.1.1 Modeling real-world datasets

We focus on datasets from 22 randomized controlled experiments run inside the *SkillBuilder* interface of the ASSIST-

ments online learning platform [29], which focuses primarily on 4th-12th grade math. These datasets included a total of 14,947 students in grades 5-12 (25% of students lacked a reported grade). Students had 200 different teachers and were drawn from 19 states (states deidentified in the data), and included a “guessed” gender based on name for 68% of students (of these, 53% were female; see [10] for information on gender methodology). No information on student race/ethnicity or SES was available, and experiments were IRB approved; see [29] for more dataset details.

In each experiment, students were placed into one of two conditions when completing homework. Each student must answer several *consecutive* problems correctly to complete the homework (typically three), and the number of problems P the student attempted before completion was recorded. Both completing homework and doing so in fewer problems are desirable, and we translate these measures into a reward signal for the MAB algorithms. To eliminate scaling issues, rewards are scaled to a fixed range as follows. Based on examination of the range of problems to completion across experiments, we cap the maximum number of problems at 30. If $P \geq 30$ or the student did not complete the homework, then we set P to 30. Because lower values of P are better, reward is then $r = 30 - P$. This reward is guaranteed to be in $[0, 30]$ and is then linearly interpolated into $[0, 1]$ for the MAB algorithms. We refer to the better condition as arm 1 and the worse condition as arm 2 on all datasets.

To conduct repeated trials with data from previously conducted experiments, our framework *resamples* an outcome associated with the chosen condition in the dataset when that condition is assigned to an incoming student. Within each trial, we fix the number of students n to the number in the original experiment ($n \in [129, 1797]$).

4.1.2 Simulation setup

To assess the ability of traditional hypothesis tests to draw accurate conclusions from the collected data, we measure (1) power – the proportion of the time an effect is detected when one exists – using scenarios where two conditions are *different* and (2) false positive rate (FPR) – the proportion of the time an effect is falsely detected when one does not exist – using scenarios where two conditions are the *same* in terms of expected reward. For (1), we focus on the seven ASSISTMENTS datasets with the largest effect sizes measured in terms of Cohen’s d ($0.16 \sim 0.51$), as larger effect sizes are more likely to reflect educationally relevant differences and may lead to larger differences across algorithms; we refer to these as ASSISTMENTS-GES (greater effect size). We examine how the allocation methods impact average reward, which measures student outcomes, and statistical power and measured arm means, which are of large importance to researchers. For (2), we create modified datasets in which each condition’s reward list contains all rewards from *both* arms. This creates two conditions with the same expected outcome while keeping their realistic reward distributions. We refer to these 22 modified datasets as ASSISTMENTS-RC (reward combined). Because no allocation method could increase benefits to students given that the conditions do not differ, we focus here on examining FPR and measured arm means. For both (1) and (2), we follow Section 4.1.1 and run 1000 trials for each dataset-algorithm combination.

Figure 1: In terms of benefiting students as measured by mean average reward (a), all Exp allocations under-performed TS but out-performed uniform (except on dataset 293151). This was possible even when Exp3.1 and Exp3++ allocation achieved comparable power to uniform allocation, as indicated by overlapping error bars on all seven datasets (b). Error bars show $\pm 1.96 \times \text{SE}$.

4.1.3 Data collection and analysis

For each trial, we record all condition assignments and unscaled rewards. We then compute: the average reward per student, the average reward $\hat{\mu}$ for each condition (true expected reward denoted by μ^*), and the conclusion of a two-sided hypothesis test of whether the two conditions differ at a population level. Because capping P as discussed in Section 4.1.1 can lead to strong bimodality in reward distributions, which dissatisfies the assumptions of a standard t -test, we use the non-parametric Brunner-Munzel test for testing for a difference between conditions in the collected data. This test assumes neither normality nor equivariance of the distributions from which the samples are drawn. We consider the test to detect an effect if and only if $p < .05$.

To determine if a statistic differed reliably based on condition allocation method, we use generalized linear regression, with factors for algorithm (with uniform as reference group) and ASSISTments dataset. We report two decimal places except for small or similar values.

4.2 Results

4.2.1 Datasets with effects: ASSISTments-GES

Mean average reward: All MAB allocations were associated with significantly higher benefits to students, as measured by mean average reward, than uniform allocation (coefficient for TS: 0.80; Exp3: 0.19; Exp3.1: 0.10; Exp3++: 0.15; all $p < .001$). TS collected data with highest mean average reward (16.34), followed by Exp3 (15.74; 24% of the reward gain of TS over uniform), Exp3++ (15.69; 19% of TS over uniform), Exp3.1 (15.64; 12% of TS over uniform), and Uniform (15.54). For a breakdown by dataset, see Figure 1a.

Power: TS and Exp3 allocations had significantly lower power than uniform (coefficient for TS: -1.42 ; Exp3: -0.18 ; both $p < .001$), while allocation with the other two algorithms did not (Exp3.1: -0.05 , $p = .22$; Exp3++: -0.07 , $p = .11$). On average, TS collected data with lowest power (0.40), followed by Exp3 (0.59), Exp3++ (0.61), Exp3.1 (0.61) and

Figure 2: TS allocation led to a clear, systematic underestimation of arm 2 [worse arm] on all seven datasets (a), while Exp allocations resulted in arm mean estimates similar to those of Uniform (a). Error bars are not shown for clarity and are delegated to hypothesis testing. Also, the worst-case $\hat{\mu}$'s are much worse for TS allocation than for Exp (b).

Uniform (0.62). Figure 1b shows a breakdown by dataset.

Measured arm means: Our work replicates prior work showing that TS underestimates the worse arm in binary trials [22] and further finds a small underestimation of the better arm (arm 1 [better arm] coefficient: -0.05 ; arm 2 [worse arm] coefficient: -0.76 ; all $p < .001$). The Exp algorithms resulted in more accurate measurement of arm means: while Exp3 and Exp3++ also underestimate both arms, the extent to which they underestimate the worse arm is much less than TS (for Exp3: arm 1 coefficient: -0.02 , $p < .05$; arm 2 coefficient: -0.04 , $p < .05$; for Exp3++: arm 1 coefficient: -0.02 , $p < .01$; arm 2 coefficient: -0.04 , $p < .05$). Arm mean estimates using data from Exp3.1 did not differ significantly from those derived from uniform allocation (arm 1 coefficient: 0.004 , $p = .71$; arm 2 coefficient: -0.007 , $p = .69$). See Figure 2a for a qualitative comparison by dataset and Figure 2b for a worst-case analysis showing results for the trial with the most inaccurate $\hat{\mu}$.

4.2.2 Datasets without effects: ASSISTments-RC

FPR: TS allocation was associated with significantly higher FPR than uniform allocation (coefficient for TS: 0.56 , $p < .001$), while allocation with the other three algorithms was not (coefficient for Exp3: 0.0065 , $p = .88$; for Exp3.1: -0.0019 , $p = .97$; for Exp3++: -0.0047 , $p = .91$). On average, TS collected data with the highest FPR (0.0867) and is followed by Exp3 (0.0517), Uniform (0.0514), Exp3.1 (0.0513) and Exp3++ (0.0512). As shown in Figure 3a, TS inflates FPR for almost all datasets, while the other algorithms have FPR $< .06$ for the vast majority of datasets.

Measured arm means: Since the two arms are identical and within a trial, their average values are not independent, we arbitrarily examine one of the two arms for each trial. Allocation using TS, Exp3, and Exp3++ was associated with significantly lower estimates of arm means compared to uniform allocation (coefficient for TS: -0.42 ; Exp3: -0.0320 ; Exp3++: -0.0274 ; all $p < .001$); note that the bias for TS is much larger than for Exp3 and Exp3++. Similar results

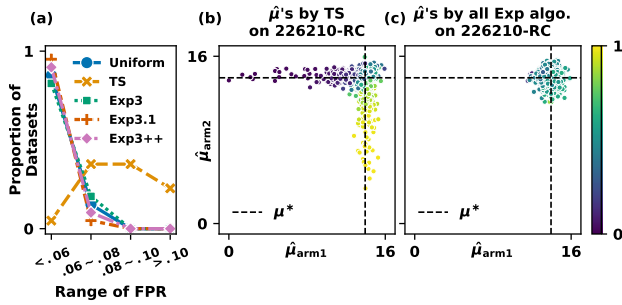

Figure 3: (a) TS allocation results in more datasets with inflated FPR than uniform and adversarial allocations. Remaining figures show the distribution of $(\hat{\mu}_{\text{arm1}}, \hat{\mu}_{\text{arm2}})$ pairs of TS (b) and of all Exp algorithms (c) on dataset 226210-RC, with hue showing $N_{\text{arm1}}/N_{\text{total}}$. Clearly, TS has trials where one arm is very badly estimated while Exp algorithms don't. Hue offers an explanation: for TS (b), $\hat{\mu}_{\text{arm1}}$ is roughly unbiased when arm 1 is pulled more often (a proxy of appearing to be better) and negatively biased when it is pulled less often (a proxy of appearing to be worse early-on); Exp algorithms (c) allocate more evenly, indicating that it explored both arms beyond initial under/over-estimation.

hold if we arbitrarily analyze the other arm instead. Exp3.1 did not have a significant negative bias with one choice of arm for analysis (coefficient: -0.0092 , $p = .23$), but did for the other (coefficient: -0.0173 , $p < .05$), suggesting a weak negative bias in estimated mean. This replicates results for TS from prior work [22] and shows the same underestimation can occur for adversarial bandits, albeit with much smaller magnitude of underestimation: in all cases, the MAB algorithm underestimates the mean of the arm that appears, due to random sampling, to be worse, and then samples the arm that appears to be better more often, leading the estimate of the other arm to be below its true mean. See Figure 3b and c for a comparison between TS and Exp algorithms.

Overall, these results show that experimental design using the Exp family of algorithms can collect data that meets researchers' needs better than a purely stochastic bandit algorithm, with higher power, lower FPRs, and more accurate condition measurement. These algorithms do not benefit students as much as the purely stochastic TS, but all Exp algorithms do improve on uniform allocation. Exp3++ provides a balance between Exp3.1 and Exp3, achieving 19% of the reward gain of TS, requiring no hyper-parameters, and demonstrating only a slight underestimation of arm means.

5. POWER AND UNEQUAL VARIANCE

The ASSISTments simulations demonstrate that across a range of educational experiments, the Exp algorithms performed better when measured in terms of researchers' concerns, like power and arm mean estimates, while TS attained greater benefits for students. More generally, both TS and Exp aim to optimize reward, but they do so with different assumptions about the environment, meaning that the specific characteristics of an experiment will influence how well each performs on both student- and researcher-centric measures. However, because the ASSISTments experiments do

not vary systematically from one another, they are not an ideal platform for exploring the impact of *specific* experimental characteristics on the MAB algorithms' performance compared to one another and compared to uniform allocation. We thus turn to simulations with constructed datasets to explore the impact of one experimental characteristic: the relative variability of the two conditions.

Ideally, pedagogical interventions increase equity and narrow achievement gaps between students, indicated by lower variability among students who experience the intervention, but in the non-ideal case they also could widen these gaps. Interestingly, differences in condition variability affect what allocation of students is best for power: uneven allocation that places more students in the more variable condition will result in higher power than uniform allocation, at the potential cost of reward. In the simulations that follow, we examine how allocation using TS and Exp algorithms juggles power with reward differently, as well as whether Exp algorithms' adversarial assumptions and sensitivity to condition variability make them improve upon uniform allocation for measures like power that are researchers' primary concern.

5.1 Methods

5.1.1 Two-arm scenarios

To systematically investigate the impact of having conditions that differ in variability, we construct artificial scenarios with two arms that have normally distributed rewards. We fix the expected reward of arm 1 as 1 and that of arm 2 as 0, and vary whether the better or worse arm has a higher variance and the magnitude of the differences in variance; specifically we consider the following 19 scenarios:

$$\{(1, 1)\} \cup \underbrace{\{\{1\} \times \{2 : 10\}\}}_{\text{Worse arm has higher SD}} \cup \underbrace{\{\{2 : 10\} \times \{1\}\}}_{\text{Better arm has higher SD}}$$

where each tuple gives the standard deviation (SD) of arm 1 followed by arm 2.

As in Section 4, rewards are interpolated into $[0, 1]$ for the MAB algorithms. Rewards are first clipped to $[-30, 31]$, where -30 is the mean of the worse arm (0) minus three times the maximum possible SD (10) and 31 is the mean of the better one (1) plus three times the maximum possible SD. We run 10000 trials for each scenario-algorithm combination, and each trial includes 250 simulated students.

5.1.2 Data collection and analysis

Data collection is described in Section 4.1.3. For analysis, we use Welch's test (t -test that does not assume equal variances) instead of the Brunner-Munzel test, as raw rewards are normally distributed and the clipping range is wide.

To determine if a statistic for data collected using the MAB algorithms differed reliably from that for data collected using uniform allocation, we use generalized linear regression, with factors for algorithm (with uniform as reference group), standard deviation of the arm with variable variance, and the interaction between the two.

5.2 Results

As shown in Figure 4, the impact of allocation method on power differed systematically based on whether the better

Figure 4: TS has higher power than uniform when the better arm is more variable (a), but lower power when the worse arm is more variable (b); Exp algorithms and uniform perform similarly. In all cases, MABs outperform uniform, with TS attaining the highest reward (c-d). Error bands: ± 1.96 SE.

or worse arm had higher variance. TS allocation was associated with significantly higher power than uniform allocation when the better arm was more variable (coefficient: 0.20; $p < .001$; Figure 4a), but significantly lower power when the worse arm was more variable (coefficient: -1.94 , $p < .001$; Figure 4b). In contrast, the three Exp algorithms performed qualitatively similarly to uniform allocation in both scenarios, with a small but reliable decrease in power for Exp3 and Exp3.1 when the worse arm was more variable (coefficient for Exp3: -0.13 , $p < .001$; Exp3.1: -0.09 , $p < .01$). No other power differences were detected. While the potential of TS to increase power in some situations seems promising, researchers will not know in advance whether to expect TS to increase or decrease power, and the decreases in power from TS when the worse arm has higher variance are larger than the increases in the opposite case. Further, designing an intervention where the better arm is more variable is generally undesirable: it corresponds to a scenario in which an intervention that helps students on average also widens gaps among individual students.

As expected and shown in Figure 4c-d, TS had larger reward compared than the Exp algorithms, but all MAB algorithms resulted in reliably higher reward – i.e., benefits to students – than uniform allocation (better arm more variable: coefficient for TS: 0.47; Exp3: 0.07; Exp3.1: 0.03; Exp3++: 0.07; worse arm more variable: TS: 0.45; Exp3: 0.08; Exp3.1: 0.04; Exp3++: 0.07; all $p < .001$).

6. DISCUSSION

Pedagogical experiments are a useful tool for improving education, but allocating students to conditions uniformly at random can pose challenges, with larger subject pools lead-

ing to more students experiencing an inferior educational condition but smaller subject pools potentially decreasing the ability of researchers to differentiate conditions with certainty. Our results suggest that adversarial bandit algorithms offer a way to increase the proportion of students assigned to a better condition with limited compromises to the conclusions that can be drawn from the experimental results. Hyper-parameter free adversarial bandit algorithms like Exp3++ thus offer a researcher-friendly option for experimental design that performs well even with non-standard outcome distributions, as we saw in the ASSISTments simulations. While TS improved power when the better condition had higher variance, it also decreased power when the worse arm had higher variance. Researchers are unlikely to know which of these scenarios applies before collecting results, and this unpredictability of the impact of TS, coupled with the higher FPR and lower power on average in the real educational datasets, may make stochastic bandits less attractive to researchers.

One limitation of this work is its use of simulations rather than new experiments. Importantly, simulations are needed to measure power and FPR, but field testing with adversarial algorithms is also needed to assess their real-time feasibility as well as the existence and impact of temporal trends in outcomes. All studied algorithms run in real-time on a single CPU, but students may complete homework contemporaneously, with some assigned a condition prior to another student finishing and thus without incorporating the outcome of that student. This could be handled by batch updating [17,21], but there has been limited exploration of the impact of batching on analyzing the collected data. Temporal trends may occur in experiments if, say, higher prior knowledge students complete homework first, or multiple schools participate in an experiment at different times. Adversarial bandit algorithms should outperform stochastic ones in these situations, but empirical study is necessary.

A second limitation is our assumption that one arm is better for all students, without regard for personalization. While personalization is an exciting area for future work, incorporating personalization in bandit algorithms for education poses its own ethical conundrums, including potentially lesser outcomes for less well-represented groups (see [14]).

Future work should also examine other scenarios where bandit algorithms might increase power. Here, we focused only on conditions with differing variance, but other interesting scenarios include experiments with more conditions, with predicted outcome distributions that exhibit particular non-standard characteristics (e.g., bimodality), or with different analysis goals than detecting if two conditions differ in mean. One or more types of bandit algorithms (e.g., stochastic, adversarial, or best-arm identification [23]) may be best for each scenario; based on their weak environmental assumptions, we believe adversarial bandits may be reasonable in all of these scenarios. Work in optimal experiment design (OED; see, e.g., [24]) shows the potential of non-uniform allocation to increase the information gained from an experiment. Bandit algorithms often require less setup and a priori knowledge than OED, and thus identifying information gain benefits of these algorithms in particular settings could benefit both researchers and student participants.

Towards Real Interpretability of Student Success Prediction Combining Methods of XAI and Social Science

Lea Cohausz
University of Mannheim
lea@informatik.uni-mannheim.de

ABSTRACT

Despite calls to increase the focus on explainability and interpretability in EDM and, in particular, student success prediction, so that it becomes useful for personalized intervention systems, only few efforts have been undertaken in that direction so far. In this paper, we argue that this is mainly due to the limitations of current Explainable Artificial Intelligence (XAI) approaches regarding interpretability. We further argue that the issue, thus, calls for a combination of AI and social science methods utilizing the strengths of both. For this, we introduce a step-wise model of interpretability where the first step constitutes of knowing important features, the second step of understanding counterfactuals regarding a particular person's prediction, and the third step of uncovering causal relations relevant for a set of similar students. We show that LIME, a current XAI method, reaches the first but not subsequent steps. To reach step two, we propose an extension to LIME, Minimal Counterfactual-LIME, finding the smallest number of changes necessary to change a prediction. Reaching step three, however, is more involved and additionally requires theoretical and causal reasoning - to this end, we construct an easily applicable framework. Using artificial data, we showcase that our methods can recover connections among features; additionally, we demonstrate its applicability on real-life data. Limitations of our methods are discussed and collaborations with social scientists encouraged.

Keywords

Educational Data Mining, Student Drop-Out Prediction, XAI, Explainability

1. INTRODUCTION

Educational Data Mining (EDM) and in particular its sub-field of student success and dropout prediction has gained prominence in recent years due to the increased digital education data availability and because the prediction of students' successes and struggles poses an important real-life

problem. Accordingly, a multitude of studies exist testing various Machine and Deep Learning techniques on different data with some achieving remarkable accuracy and F1-values of more than 80 or even 90% regarding drop-out or success prediction [19, 13, 14, 6, 11]. This seems impressive and Xing & Du [17] write that individual drop-out probabilities can be used to "provide stronger and prioritized intervention to these students as a way of personalization" (p. 558). However, simply using the predictions will not enable one to do that. These only allow us to know *who* is likely to drop out; but in order to do anything with this prediction, we ought to know *why* the prediction has been made. Understanding why a prediction is made, is the topic of another timely topic in computer science, Explainable Artificial Intelligence (XAI). There, the *why* is split up further in *global* and *local* feature importance. With global, we mean what features are generally considered important by the model for predictions. This is valuable information so that we can control that features which would lead to a biased system discriminating against certain populations or features mistakenly included do not have an impact. A local explainability of a prediction, in contrast, relates to the importance of features regarding a specific person's prediction. This is important when we aim to use our predictions to help and advice a student predicted to be at risk as it allows us to understand what features contribute to their prediction specifically. Providing a basis to construct a personalized intervention system is the aim of this paper - thus, we work with local explainability.

The importance of XAI in EDM seems obvious and we are not the first to think so. Chitti et al. [5] heavily advocate a use of XAI techniques in future studies lamenting a lack thereof in current research. Alhamri & Alharbi [2] investigated the use of XAI and explainability techniques in performance prediction and came to the conclusion that few studies focus on it, and that those doing so merely focus on global explainability and do not employ techniques offered by XAI, instead simply using standard techniques as Decision Trees and looking at the generated rules. Indeed, it seems that with one notable exception [3], hardly any current research includes local explainability.

At first, it seems surprising that XAI techniques have not been employed more frequently as comparatively easy to use and model agnostic methods to extract important features exist¹. However, we will see in this paper, that employing

¹SHAP for global, and LIME for local explainability [10,

XAI techniques off-the-shelf still leads to rather empty explanations. While knowing the important features explains why a prediction has been made, we also need to be able to interpret why and how these features matter at all. To better distinguish between those concepts, we argue for a distinction between *explainability* - which in this paper will relate to explaining the decision of the model, i.e. knowing the important features - and *interpretability* - which in this paper will relate to being able to interpret why and how features are important. Current XAI methods, as we will demonstrate later on, do not allow for interpretability.

Upon showing this, the objective of this paper is to provide a way of reaching interpretability as a basis for constructing personalized interventions. To this end, we will turn to another discipline, social science, that is traditionally well-equipped to deal with causal mechanisms and combine the predictive abilities of Machine Learning with the theory and causal analysis tools of social science. More precisely, we will:

- after a brief introduction to LIME, introduce a step-wise model of interpretability that will be illustrated with an example showing that XAI alone only achieves explainability but not interpretability.
- argue for a combination of XAI with social science, allowing us to gain full interpretability to construct a personalized intervention system. To this end, we will introduce a pipeline employing techniques from both disciplines.
- evaluate the approach on artificial data, so that we can test whether causal relationships are recovered; and show the applicability of the approach on real-life data.
- discuss the limitations of the approach and call for more collaborations among social scientists and computer scientists.

2. LIME

The aim of a personalized intervention system is both to provide a student with an idea of why they are predicted to struggle and what can be done to change this; and to provide pointers to those concerned with tailoring programs to help students. The requirements are, thus, to know what exact features contribute to a specific student's prediction (local explainability), which features' values would need to change in what way to change the prediction, and what underlying causal mechanisms are at work.² Note that when we consider causal mechanisms, we stray away from what

15].

²Note that while with global XAI, we often strive to exclude features that could be discriminating (e.g. age, gender, ...), local interpretability and the task of providing personalized intervention systems allows us to use those features as (a) people are not selected into programs because of it and more importantly (b) because we can try to mitigate difficulties certain populations have. If we identify, e.g., that some older students struggle, we could think about the mechanisms behind this, (e.g. older students generally have other responsibilities such as jobs and family competing for time), and and try to find solutions (e.g. provide flexible timetables, childcare on campus, ...).

XAI and purely data-driven approaches can provide. XAI techniques are concerned with explaining a model's decision but when we are interested in the causal mechanisms behind the important features we a) can no longer use XAI off-the-shelf and b) simultaneously make the assumption that the features important for the model also carry importance in real-life. The latter assumption should be kept in mind as it is not necessarily a given. Nonetheless, XAI can serve as a valuable basis for interpretability. Due to our focus on local interpretability, we choose to employ LIME. LIME is an acronym for Local Interpretable Model Agnostic Explanations which - as the name says - works for every model and finds local explanations for each instance. The basic idea is to randomly sample n feature vectors around the instance we want to explain given the normal distribution and to then weigh these new instances according to the distance to the instance we want to explain. Furthermore, the predicted label for each sample is obtained by feeding the feature vector into the model (note, that this works regardless of the specific method making it model agnostic). Based on this, Lasso regression is employed on the generated data with the predicted labels being the dependent (or target) variable. This allows us to extract the k most important features for the prediction [15].

3. A MODEL OF INTERPRETABILITY

One of the reasons why XAI techniques have not been used much may relate to their limitations regarding actual interpretability [9, 8, 1]. To illustrate our argument, consider Figure 1. It shows a Directed Acyclical Graph (DAG) of factors influencing whether a course, C1, is completed. We can observe whether courses C2, C3, and C4 are taken in parallel or not. These are our observable variables that could be used as features in a ML model. Taking these classes in parallel does not influence the completion of C1 directly. However, they do so indirectly through latent factors we cannot observe. Courses C2 and C3 compliment the contents of C1 well and taking them in parallel increases the competences required to complete C1 which then increases the probability of finishing the course. C4 is not related to C1 regarding content and thus does not contribute to competence important to complete C1. All three classes C2, C3, and C4 contribute to the workload, though. Having a high workload decreases the probability of finishing C1. Imagine now that for a student, Alice, the drop-out probability for C1 is predicted to be high. In order to fully leverage on this prediction, we should walk through each of the three steps of interpretability.

1. *Understand which features matter.* This means that we know which features matter for a person's prediction (local explainability). In our example, this means that the most important features regarding Alice's prediction are revealed to be the parallel taking of C2, C3, and C4. Furthermore, we know at this step that all three have a negative impact on completing C1. This is good to know but knowing the direction and impact of features is not equal to knowing what has to change in order to change the prediction. Should Alice not take any of these classes in parallel?
2. *Understand what would need to change to change the prediction.* In other words, we are looking for coun-

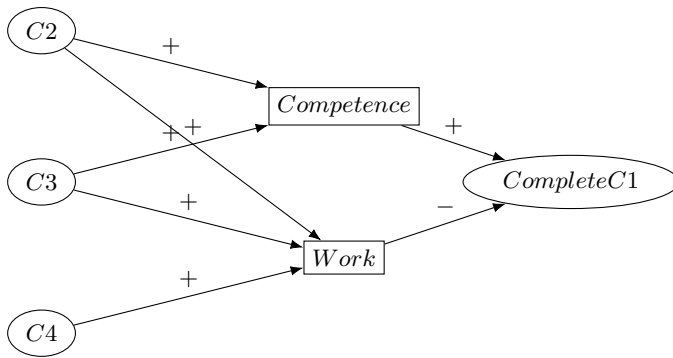

Figure 1: An example of causal modelling explaining factors influencing whether Course 1 (C1) is dropped or not.

terfactual explanations. In our case, we want to know whether not taking one or a combination of the classes will lead to a different prediction of our model. This can provide sensible advice.

3. *Understand the causal relationships among features and latent factors.* This refers to a causal understanding of features and latent factors. In this last step, we try to uncover the DAG (as shown in Figure 1) by theorizing about latent factors and testing whether the observations support this. We aim to understand that the courses influence latent factors competence and workload and which course influences which factor in which way. Not only does this lead to the best intervention for Alice; moreover, we can use this knowledge to construct better programs for all students.

If we use LIME off-the-shelf, we can extract the k most important features per person but counterfactual explanations are not provided. Thereby, we reach the first but not subsequent steps of interpretability. This limitation of XAI particularly regarding counterfactual explanations has been addressed and sometimes dealt with by other scholars as well [9, 8, 1]. Given these limitations, it is, therefore, maybe not surprising that few scholars saw it worth to employ XAI. How can we reach the other steps of interpretability and find a basis for personalized intervention? We argue that in particular reaching the third step calls for turning towards and employing techniques of social science. Firstly, we need an understanding of the concept of counterfactuals and aim to extend LIME in that way. Secondly, we need a theory-, instead of data-driven approach to explore causal mechanisms. Social science is well equipped for this task.

3.1 Reaching Step 2: MC-LIME

Reaching step 2 is easily possible as it rather naturally extends the idea of LIME, but requires an understanding of the concept of counterfactuals common in social science. In short, we attempt to answer the question of what would have happened regarding the outcome (the prediction) if the treatment (the features' values) had been different. In our case, we consider the k features extracted by LIME that have a *positive* impact on the drop-out probability (i.e. make it more likely that someone drops out). Then, we check for the smallest subset of these features that - when changing

their values - changes the prediction and return the features and changed values³. We achieve this by iteratively changing one feature's value; if this never leads to a prediction change, we check for all combinations of two features etc. Because we look for the smallest necessary change, we call this approach Minimally Counterfactual LIME (MC-LIME). If multiple subsets of the same size exist, but we only want a certain number, we can select to receive the c changes that lead to the largest difference in the output probability. This procedure is straightforward for binary variables where we can simply use the complementary value. For categorical and ordinal features, we propose iterating through all possible values; all values, for which a change is reported, are stored - the highest change counts towards the selection of the top c features. For count features, we propose shifting the value a standard deviation towards the mean, so that the change is large enough to make a substantial difference. The resulting subset tells us what would minimally need to change in order to change the prediction and how this change would need to look like.

3.2 Reaching Step 3: A Causal Analysis

While this information is already very important, it is not enough to provide good interventions and to potentially construct programs, though. In order to know why features matter - for the model but hopefully also overall - we propose to use *all* features LIME returns (positive and negative impact) as a basis for a deeper analysis. For this theory-driven approach, we propose to follow the steps:

1. Extract all features and their impacts and use it to cluster people into groups. Therefore, we only work with a subset of all extracted variables that are known to be relevant for a set of students thereby simplifying the model while at the same time assuring that we use relevant features.
2. For the demographic (and if available social and psychological) features, e.g., age, having a student job, living closer or further away from university, look for social science studies that investigate their effect on drop-out and let it inform you on causal mechanisms. If you find that other features could also be important, add them.
3. For features specific to your domain, e.g. the courses offered, try to understand what they are about and how this could influence the outcome variable, i.e. the drop-out.
4. Begin drawing a DAG and consider the following questions: (a) Is a connection between two variables direct or does it go through a latent variable we cannot observe? Does the latent variable mediate the effect? (b) Is there an actual relationship between two variables or are they confounders meaning that a third variable effects both? (c) Does a third variable moderate the effect between two variables? (d) Is the effect linear or quadratic?

³Note that this is very similar to LIME's understanding of feature importance.

5. Model a regression formula according to your DAG and run the regression on the training data with success or drop-out being the dependent (or target) variable.
6. Check the effects of the terms of your formula. What is significant? Does the direction conform to your theoretical considerations?
7. Construct personalized interventions according to social science theory and in combination with the insights of step 2.

4. EVALUATION

In order to demonstrate the pipeline and its applicability, we test our approach on an artificial and a real-life set of data.

4.1 Data

Artificial Data. As, typically, we do not know the real causal mechanisms and can only make informed guesses considering the existing literature and our own reasoning, we test MC-LIME and our causal framework on artificial data. Regarding MC-LIME we can test whether it returns the feature subset that is intended to make a difference. It is, of course, not very telling to use this data on our causal framework as we know the causal mechanisms we decided on. However, it is still valuable to see whether we can recover the intended effects and their directions as specified in data generation. Our data consists of the target variable drop-out and 26 other binary features. Of these 26 features, when they are set to 1, eight have no effect, three have no direct effect but do have one when combined with other variables, two have a negative impact on drop-out that reverses when combined with other variables, three have a positive impact that reverses when combined with other variables, five have a negative effect and five have a positive effect. The first row of Table 1 summarizes this; a plus indicates a positive effect on drop-out, a minus a negative effect. The number of symbols represents the strength of the effect, as each causal relationship was given a weight by which the probability of a drop-out changes. We created 10,000 instances by randomly sampling features. The drop-out value was determined by the sum of the weights of the non-zero variables. If the sum was 0.5 or higher, we assigned a 1, else we assigned a 0. This resulted in 30% of instances having assigned a 1.

Real-Life Data. In order to demonstrate the process on real-life data, we gathered information on a mandatory first-year theoretical computer science course - that we will call C1 - part of a three-year Bachelor degree at the University of Mannheim, Germany.⁴ We have information on all students that registered for this course between 2010-2020 and try to predict who will drop out. Note that students who failed or dropped out once and then registered in subsequent years may appear in the data twice. Our data contains 1,738 instances. Furthermore, even though the course is meant to be taken in the first year, many students take it later. The data contains seven demographic features, and 160 features on high school results, previous courses taken, previous results and drop-out behavior, and classes taken in parallel.

⁴The data was k-anonymized prior to analysis to ensure privacy.

To understand our data structure, consider a course A. This course has four features assigned to it: whether it is taken in parallel to C1, whether the student failed it, whether the student dropped out, or whether the student passed. Note that a student can have 1 assigned to several of these features, if, e.g., a person first dropped and then passed course A. Again, remember that this only encompasses the information we have at the time when the student registers for the course we are predicting on. In total, we consider 30 courses. Table 2 provides summary statistics of the data.

4.2 Step 1: LIME

For both sets of data, we predicted the drop-out using several methods: Support Vector Machine (SVM), a simple Deep Neural Network (DNN), Naive Bayes, Decision Tree, and Random Forest. Then, we selected the model leading to the highest F1-value and accuracy in the test data. For the artificial data, this was the DNN with an accuracy of 99.5% and a F1-value of 0.99. For the real data, it was the SVM with an accuracy of 87.12% and an F1-value of 0.9. Having selected the best model, we extracted the ten most important features and their directions for each instance of the test data. We only considered those instances for which drop-out was predicted, as these are the ones we are most interested in.

Artificial Data. 318 of the 1,000 test instances were predicted to drop out. Table 1 shows which features were extracted at least for one instance. We can see that feature V8 was not considered important at all, even though it is supposed to have a negative effect on drop-out. In contrast, V20 was extracted once, even though it should not have an effect. Furthermore, V17 and V18 were not extracted; these features do not have an effect on their own, but do when combined. The most extracted features were V2, V11, V12, and V13 which were extracted for each instance, followed by V5 (316), V1 (312), V6 (284), and V3 (213). Note that this does not mean that for all those predicted to drop out, each of these variables was set to 1 or had a positive impact as the table also includes features that have a negative impact on drop-out. As a matter of fact, the extracted directions of the effects are correct for all extracted features that upon being set to 1 are supposed to have a positive or negative effect on drop-out. For those features for which the direction of the effect changes upon combination with others, we can see that the reverse effect is extracted. This shows the limitations of LIME and, therefore, the importance of our remaining steps.

Real Data. For 26 instances the label drop-out was predicted. In total, 25 important features were extracted; of these, six only appeared once. The most frequently extracted features were whether a person planned to take the exam on the first date or in the resit (26)⁵, the study year (26), the age (26), whether two other first year classes were taken in parallel (24 each), whether one of these first-year courses had been dropped before (20), and whether a second year course had been passed (12).

⁵Students have the opportunity to decide between taking the exam right after the lecture period or two months later; the latter is known as the resit date.

Table 1: Artificial Data - variables, their effects, and what could be recovered using LIME and regression on extracted features.

Effects	Pos. Effect	Neg. Effect	Effect in Combination	No Effect
Variables	V1(++), V2(++), V3(++), V4(++), V5(++)	V6(--), V7(-), V8(-), V9(-), V10(-)	V11(--)+V12(--)+V13(No): +++; V14(+)+V15(+)+V16(+): ---; V17(None) + V18(None): ++	V19-V26(No)
Recovered (LIME)	V1(+), V2(+), V3(+), V4(+), V5(+)	V6(-), V7(-), V9(-), V10(-)	V11(+), V12(+), V13(+), V14(-), V15(-), V16(-)	V20(-)
Changed Prediction (MC-LIME)	V1, V2, V3, V4	V6, V9	V11, V12, V13	V20
Recovered (Regression)	V1(+), V2(+), V3(+), V4(+), V5(+)	V6 (-), V7 (-), V9(-), V10(-)	V11(-)+V12(-)+V13(None): +; V14(+)+V15(+)+V16(None): -; V17(None)+V18(None): +	V20(-)

Table 2: Summary statistics of real-life data regarding the first year course C1.

Variable	Key Statistics
Age	20.49 (min: 16, max: 36)
Year	1.7 (min: 1, max: 5)
N of Attempts	1.3 (min: 1; max: 3)
Gender	female: 18.35%, male: 81.65%
Nationality	domestic: 83.77%
Domestic HS Degree	91.48%
Drop-Out of C1	41.49%

4.3 Step 2: MC-Lime

Artificial Data. We now selected those important features that have a positive effect on drop-out for each instance and iteratively changed the values. For 302 instances, it was enough to change a single value to change the prediction; for 14 of these, there was only one feature which managed to change the prediction on its own. Table 1 displays what features changed the prediction on their own for at least one instance. 14 instances needed two changes, the remaining three changes. The feature most often leading to a change when assigned a different value was V11 (291), followed by V13 (288), 12 (287), and V2 (112). Interestingly, V20 also changed the prediction on its own once. Several variables could not change the prediction on their own. Apart from V5, though, these are only variables that have a small impact on the drop-out rate in comparison.

Real Data. Proceeding in the same fashion, we found that 14 instances only needed a change in one feature to change. This rose to 19 when we considered changes in features referring to the same course as just one. There were 10 instances for which only one specific feature changed the prediction. Two instances needed two changes, the remaining instances three or more. 16 features changed the prediction on their own for at least one instance. The instances most often leading to changes were relating to two of the three classes extracted as important before (16, 13), the variable indicating the date (16), the age (8), and semester (6). Of course, a person cannot change their age upon learning that this contributes to the prediction. However, universities can identify causal mechanisms explaining the importance of age and then construct specialized offers. In order to be able to this, we of course need to continue with step 3.

4.4 Step 3: Regression and Modelling

Artificial Data. For the artificial data, we simply used all the extracted features and our knowledge⁶ about the data generation to construct the logistic regression formula. Then, we entered this together with the training data in a logistic regression. The last row of Table 1 shows the recovered effects. All variables entered into the regression were significant (then they were given the sign of the direction of their effect in the table) apart from V16 and V11 - even V20 (albeit only on the 5%-level) which means that by chance in data generation, more instances got the label drop-out assigned which also received a 1 in this variable. V16 was positive but not significant, even though it should be. V11 was correctly identified as no longer being significant once combined with the other two variables. All effects now also had the correct directions. Interaction terms of V11, V12, and V13 and V14, V15, and V16 were also significant and had the correct direction. We can see that reasoning about and investigating causal mechanisms made it possible to recover most effects and their directions.

Real-Life Data. For the real-life data, as explained above, we first clustered our test instances using k-Nearest Neighbor based on the features extracted so that we only focus on features relevant for this set of students. We chose $k = 3$ upon visual inspection. For illustrative and space reasons, we will focus on the largest of the clusters containing twelve instances. We used all features that were extracted for more than one instance in the cluster (Table 3). The only two features that are not specific to our setting are the variables age and nationality. Therefore, we consult the literature on these variables. For age, scholars are divided. While some studies stress that older students are generally more successful and achieve higher grades, others find that advances in age can also be seen as a positive predictor for drop-out [16, 18, 4]. The former is generally attributed to older students being more certain of their goals and having an increased focus; the latter is often attributed to having other important parts of life such as a family or a job. Based on this, we theorize that those being a little older are influenced by the former, and those who are much older by the latter; thus, for the regression, we include *age* and *age*². Of course, that age has been selected in the first place, could also be due to the fact that those students taking the class later in their studies are older and may regularly struggle with courses. To account for this, and because it is also extracted as a feature, the number of years one has studied is also included. For domestic nationality, the likely reason

⁶Therefore also entering V17 and V18 again.

for the negative effect LIME implies is that the degree is in German which creates a language barrier to non-German speaking students [12, 7]. This might be mitigated when a student already received their high school diploma in Germany; thus, we enter this variable in an interaction term, even though, it is not extracted as an important feature. The other features are specific to our setting. We argue that having failed the course before leads to a decreased probability of dropping out because students have already completed the course before. Writing the exam on the resit date leads to an increased probability of dropping out because the exam is written almost two months after the end of lectures meaning that a) students may have not paid enough attention on this course during the lecture period and b) students may have forgotten important information in the meantime. We argue that having passed courses C2, C3, and C4 leads to a decreased drop-out probability, because these courses have connected contents and require a similar skill-set. Those who did not struggle much with these courses can then also complete this one. Likewise, having struggled in these courses leads to a higher drop-out probability. Furthermore, we argue that taking C2 and C3 together with our queried course C1 - as intended by the study program - may lead to a very high workload; thus, we also include an interaction term of these. Table 3 shows our results, the middle column summarizes the results of the logistic regression without interaction or quadratic terms, the right-hand column the results including these terms. The symbol “+” indicates a positive effect on the drop-out probability, symbol “-” a negative one. One “+” indicates an effect on the 10%, two on the 5%, and three on the 1% level; a “No” indicates no significant effect. We can see that the effect for age - which is at first positive - reverses when age^2 is added with higher age now leading to a decreased drop-out probability on average, though age^2 is not itself significant most likely due to the small sample size. Similarly, the non-significant effect for domestic students and high school diploma may be due to that. The study year does not matter, but the date greatly matters with taking the exam at a later date leading to a higher probability on average. Having failed the course before, leads to a smaller drop-out probability, but having dropped it to a larger one. Only taking C3 in parallel seems to have an effect on its own. C2 has no effect. For C3 we see that those who dropped this also have a higher probability of dropping C1; having passed C3 also means that C1 will likely be completed. For C4, even not having passed already leads to a smaller probability of drop-out. Having passed all three courses also leads to a smaller drop-out probability. What do we take away from this? Generally, we should investigate whether the age effect that comparatively old and young students struggle persists across the overall program. If so, we should think about how to help these age groups. Furthermore, considering this course in particular, we should encourage the students to not choose the resit date. We should also identify students who have struggled with the courses of similar content before and offer increased assistance and attention to them. How to best do this, is something social science may also help us with. Finally, we combine our insights of step 2 and 3 for each student to tailor the best intervention.

5. CONCLUSIONS, LIMITATIONS, & FUTURE WORK

Table 3: Regression results of real-life data.

Variable	Without Interaction	With Interaction
Age, Age^2	+	-, No
$Year, Year * Age$	No	No, No
$Date$	+++	+++
$Domestic, Domestic * HS$	No	No, No
$failC1, dropC1$	No, +	-, +
$parC2, parC3, parC4, parC2 * parC3$	No (all)	No, -, No, No
$failC2, dropC2, pasC2$	No(all)	No(all)
$failC3, dropC3, passC3$	No, +, No	No, +, -
$failC4, dropC4, passC4$	-, No, --	-, No, --
$passC2 * passC3 * passC4$		-

In this paper, we addressed the issue of a lack of XAI in EDM. More specifically, we attempted to provide a framework enabling us to use the information extractable from predictions as a basis for a personalized intervention system. To highlight the challenges and requirements, we came up with a step-wise model of interpretability where step 1 means identifying important features, step 2 identifying the minimal set of value changes to change the prediction, and step 3 identifying causal mechanisms. We described methods to reach each of the steps and evaluated them on an artificial and real-life dataset showing the applicability. Our results on artificial data showed that the method works well when we correctly theorize about causal mechanisms. Of course, we may not always be able to do that. This is a limitation of our work which, in general, provides no “one size fits all”-formula, but needs to be adjusted for different settings. Furthermore, our methods can certainly be further refined but we hope that our step-wise model of interpretability provides a good orientation. A third limitation is that we do not show an actual application of our method in a real-life setting meaning that we cannot evaluate whether the conclusions derived from our analysis benefit the students in practice. This is a future endeavour. When using predictive systems in practice, we would like to once again stress that this should be made clear to students and should be very transparent. Finally, we would like to argue for an increased collaboration among social and computer scientists. Whereas computer scientists are typically experienced with predictions and deriving knowledge from data, they lack experience when it comes to theory-driven approaches and causal analysis. Social scientists, in contrast, typically do not work on predictions but are knowledgeable regarding statistical tools to uncover causal mechanisms and deriving models from theory. While these differences in approaches are prone to hinder collaboration, for this task it will greatly benefit both disciplines. Furthermore, while social science informs our models, it can also gain new insights through large-scale predictions and deriving information from data.

An Evaluation of code2vec Embeddings for Scratch

Benedikt Fein, Isabella Graßl, Florian Beck, Gordon Fraser
University of Passau
Passau, Germany

ABSTRACT

The recent trend of embedding source code for machine learning applications also enables new opportunities in learning analytics in programming education, but which code embedding approach is most suitable for learning analytics remains an open question. A common approach to embedding source code lies in extracting syntactic information from a program's syntax tree and learning to merge these into continuous distributed vectors (e.g., CODE2VEC). CODE2VEC has been predominantly investigated in the context of professional programming languages, but learning analytics are particularly important in the context of educational programming languages such as SCRATCH. In this paper, we therefore instantiate the popular embedding approach CODE2VEC for SCRATCH programs, create three different classification tasks with corresponding datasets, and empirically evaluate CODE2VEC on them. Our experiments demonstrate that a transfer of CODE2VEC to the educational environment of SCRATCH is feasible. Our findings serve as a basis to apply code embeddings to further educational tasks such as automated detection of misconceptions of programming concepts in SCRATCH programs.

Keywords

code2vec, Scratch, programming education.

1. INTRODUCTION

The application of natural language processing (NLP) and machine learning (ML) methods in the field of software engineering (SE) is gaining popularity in research and industry [27]. A central prerequisite for such machine learning applications on source code is to represent semantically similar code as similar continuously distributed vectors, the *code embeddings*, in a vector space. Popular code embeddings such as CODE2VEC [6] have been successfully used for program analysis tasks such as predicting method and variable names, or identifying bugs and misconceptions [3, 5, 17].

Programming education research frequently relies on analysis of learners' programs, for example to automatically detect incorrectly used programming concepts and bugs [2, 11, 25, 26]. Code embeddings bring the promise of novel applications also in the educational domain [9, 10, 24]; e.g., continuously distributed vectors make it possible to monitor learner trajectories or to detect outliers and anomalous behavior. However, code embeddings are predominantly generated from syntactic features of the source code. For example, CODE2VEC considers the relation of pairs of textual tokens in the context of the syntax tree that results from parsing the source code. Most code embedding approaches are designed for textual programming languages such as Java or Python. Programming education, however, is frequently based on simplified block-based programming languages such as SCRATCH [22]. These programming languages are intentionally designed to reduce the syntactic overhead for learners, and may thus affect the same syntactic properties of programming languages that make them amenable to code embedding models. This may in turn affect the applicability of these models in an education context.

The aim of this paper is to adapt and investigate the popular CODE2VEC code embeddings for the educational programming language SCRATCH. We implement an analysis for SCRATCH programs that extracts the path context information on which CODE2VEC is built. We then create three different classification tasks with corresponding datasets to study the suitability of the resulting embeddings:

- Girls and boys are known to implement different project types and programming concepts [13, 16]; we explore whether code embeddings can capture these nuances.
- A major characteristic of SCRATCH programs with educational implications [1] is their type (e.g., game, animation, etc.). We explore whether code embeddings enable the prediction of project types from code.
- The original evaluation of CODE2VEC explored the ability of embeddings to capture semantic content by predicting names of methods. We adapt this task to SCRATCH by predicting names of sprites.

Although SCRATCH code differs from text-based code in important ways affecting code embeddings, such as the structure or size of syntax trees, or the organisation into sprites and scripts rather than classes and methods, we find that CODE2VEC nevertheless performs well at these tasks.

2. BACKGROUND AND RELATED WORK

To understand the application of CODE2VEC to the introductory programming language SCRATCH, this section outlines the concepts and their use cases.

2.1 The Scratch Programming Language

SCRATCH is a block-based programming environment that is particularly designed for learners due to its ease of use through the arrangement of visual blocks [22]. In SCRATCH, the behavior of graphical objects, the sprites, is controlled by means of code blocks, which are assembled to scripts. The code blocks have particular shapes so that they can only be assembled in syntactically valid ways, without the need for the syntactic overhead of text-based programming languages (such as indentation, braces, semicolons, etc.) Code blocks control the appearance and behavior of sprites, as well as interactions with the user.

Besides the intuitive programming user interface, the popularity of SCRATCH is also supported by a rich ecosystem of users sharing their programs publicly and interacting around them. In addition to accessing this information through the user interface, it is also possible to use a REST-API to programmatically access all publicly available data conveniently, which is helpful to enable data mining applications.

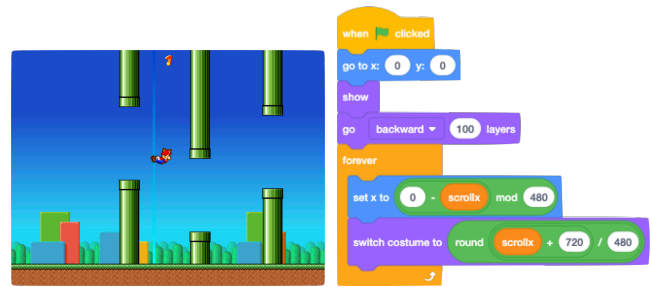

SCRATCH programs are categorized into one or more project types: *games*, *stories*, *animations*, *music*, *art*, and *tutorials*. It has been established that some project types require certain programming concepts more than others [1,18]. Furthermore, it has been repeatedly observed [13,16] that there are gender-dependent preferences regarding the project type and thus in the programming concepts: While girls mainly prefer programs with storytelling elements, boys implement more programs with game structures [1,13,16].

2.2 Analyzing Scratch Programs

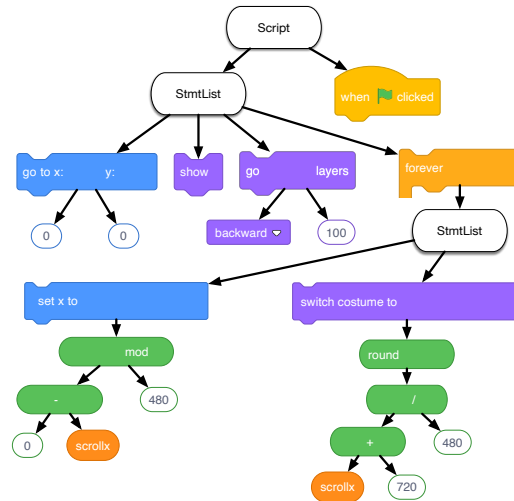

The source code of programs in text-based programming languages is represented using plain text files. In contrast, block-based programs require an intermediate format to describe the program blocks. In particular, SCRATCH programs are represented using JavaScript Object Notation (JSON) format. These JSON files organize programs in terms of their “targets” (stage and sprites), and for each target the JSON file lists its name, its procedures (i.e., custom blocks), scripts, variables, lists, messages, sounds, costumes, and blocks. The blocks are organized as lists, where each element contains a unique identifier as well as the identifiers of the parent and successor blocks, we well as any parameter blocks. Whereas text-based programs are often used directly as input for machine learning approaches, this JSON format is intuitively less suitable for NLP-based approaches.

Static program analysis is usually not conducted on the raw text representation, but the abstract syntax tree (ASTs) intermediate representation, which results from parsing the source code. An AST-like representation is used by the SCRATCH virtual machine in order to interpret SCRATCH programs. The LITTERBOX [12] analysis framework provides a Java API to parse SCRATCH programs and apply static analysis. Figure 1 shows a publicly shared example project¹

¹<https://scratch.mit.edu/projects/18024798>

(a) The game in action. (b) Code of the level sprite.

(c) Abstract syntax tree of the script in Fig. 1b.

Figure 1: Example project (ID: 18024798): Flappy mario.

implementing a flappy bird game (Fig. 1a). Figure 1b shows the code of one of its 24 sprites: This sprite represents the ground and the script implements the scrolling motion to simulate movement of the “flappy Mario” character. Figure 1c shows the AST representing the same script: Although this AST is slightly simplified for space reasons, it is noteworthy that this AST is less “abstract” than an AST for other languages would be. For example, while a text-based programming language would likely define an abstract token type for binary operators, with the actual operator as one of its leaf children², in SCRATCH none of the operators are leaves, while only variables, literals, menu-options (e.g., `backward ▾`), and blocks without parameters (e.g., `show`) appear as leaves in the AST. The AST can be used for analysis tasks such as identifying bugs [11], code smells [15], evidence of misconceptions [2], or progress and understanding [19].

2.3 Code2vec Code Embeddings

CODE2VEC [6] learns code embeddings from the syntactical representation of programs through a neural network, where semantically similar code snippets, which are implemented differently but serve the same purpose, represent vectors with a small distance to each other in the vector space. As a basis, CODE2VEC extracts *path contexts* from the AST: A path context consists of two leaves together with the path

²For example, <https://javaparser.org/>

that connects them. For example, consider the two `scrollx` variable tokens in Fig. 1c, which are connected by a path that ascends from the leaf node up to the abstract `StmntList` node, which is the least common ancestor of the two leaves, and then descends to the other leaf:

CODE2VEC extracts the path contexts for all pairs of leaves in the AST [17]. Then, a neural attention model is used to combine the path contexts to a single vector representation, i.e., the code embedding [6]. The attention mechanism learns to assign weights to path contexts depending on their importance to the semantics of the code snippet, which is assumed to be captured by method names. Consequently, CODE2VEC is applied to individual functions; note that, except for custom blocks, SCRATCH scripts are not named. The final single vector that represents the code is calculated as a weighted sum over the learned individual vectors for the path contexts [6]. When given an unseen code snippet, the network can then use the learned weights of the paths to calculate such a weighted sum again and therefore assigns a similar vector to semantically similar program code.

2.4 Code Embeddings in CS Education

Various approaches to create code embeddings have recently been considered in an education context. Piech et al. [21] created embeddings for programs written in a text-based educational language by executing unit tests; these embeddings were shown to be useful for predicting which students would benefit from instructor feedback. Azcona et al. [7] demonstrated that CODE2VEC embeddings on Python code are particularly promising on learner’s code when compared to word embeddings applied directly to tokens. Cleuziou et al. [9] proposed a two-step embedding approach where first the AST paths executed by predefined test cases are extracted, and embeddings are created using document embedding techniques. This approach was applied to Python code for the task of propagating teacher feedback. Shi et al. [23] evaluated the two code embedding techniques CODE2VEC and ASTNN [28] for the supervised learning task of bug prediction on Java programs. Paassen et al. [20] introduced the AST2VEC approach for embedding Python programs, with the aim to also support transformations back from embeddings to source code. Finally, Bazzocchi et al. [8] proposed to bypass the embedding problem by using an encoder-decoder architecture directly on Python source code. All of these approaches have in common that they are applied to text-based programming languages.

To the best of our knowledge, there is only one prior investigation of CODE2VEC on block-based programs: Shi et al. [24] applied CODE2VEC to SNAP [14] and clustered the embedded programs to identify clusters representing common misconceptions. Shi et al. demonstrated that for this application CODE2VEC embeddings are superior to other models of the code, such as Bags of Words. In this paper we aim to shed more light on how CODE2VEC generalizes to other tasks. Although SNAP represents programs using XML files that are closer in their structure to regular programs, the resulting ASTs are similar to those of SCRATCH, and so we expect our findings to generalize also to SNAP.

3. METHOD

To evaluate the CODE2VEC code embeddings for SCRATCH programs, we investigate the following research questions:

- RQ 1** Gender: How accurately can CODE2VEC assess a binary classification task on SCRATCH programs?
- RQ 2** Category: How accurately can CODE2VEC assess a multi-class classification task on SCRATCH programs?
- RQ 3** Sprite naming: How accurately can CODE2VEC assess a classification task on SCRATCH programs?

3.1 Datasets

The RQs require different datasets for their classification tasks: predicting gender, project type, and sprite names.

RQ1. To answer RQ1, we use a dataset of 317 SCRATCH programs [13], of which 171 were created by 64 (self-identified) girls and 146 by 68 boys in the range of 8–10 years. The programs are the result of the final task of a multi-day introductory programming course; the children were tasked to implement a SCRATCH program based on a topic of their own choice. The resulting programs were then manually labelled with the students’ genders. The programs of both genders are comparable in block size (on average: boys 27, girls 22) and number of sprites (on average: girls 6.10, boys 4.78) although the types of blocks and sprites differ [13].

RQ2. To answer RQ2, we sampled 216 000 SCRATCH programs publicly shared between March 2021 and June 2021. Since the REST API of the SCRATCH website³ does not provide information about project types, we downloaded programs from each category individually by using GET requests containing certain category names⁴. To create a balanced dataset we subsampled these programs to create a uniform distribution of labels; each program can belong to one or more categories. Since users often use hashtags with all category keywords to gain more visibility, the dataset contains a high percentage of misclassifications. To mitigate these misclassifications, we applied several filtering steps: First, we excluded duplicates and remixed programs. We then also excluded programs tagged as games from the music and tutorial categories, as users often incorrectly add the hashtag music to their game programs simply because they contain background music. In addition, we removed programs in the tutorial, art, music categories that contain their category keyword in the notes and credits section, as users would state credits to the music they included. We evaluated the effectiveness of these filtering steps by manually classifying 10 randomly selected programs from each category, which confirms a decrease of the misclassification rate to 20 % or less in every category. The final dataset consists of 50 560 multi-labelled SCRATCH programs in 40 categories representing various combinations of the six base-categories.

RQ3. To answer RQ3, we created a randomized sample of 530 696 SCRATCH programs publicly shared between April 2007 and April 2020. The data mining was realized by retrieving the 10 000 most recently publicly shared SCRATCH programs each day using the REST API of the SCRATCH website in the mentioned period.

³<https://github.com/LLK/scratch-rest-api/wiki>

⁴<https://scratch.mit.edu/explore/programs/all/>

Figure 2: Cumulative distribution of block counts.

3.2 Data Analysis

Each dataset is divided into training, validation and test dataset with a ratio of 80:10:10. For RQ1, the training set contains 253 programs, the test and validation set 32 programs each; for RQ2 the training set contains 34639 programs, the test and validation set 4335 programs each. To answer RQ3, we use a classification task to identify the names of sprites based on their code, thus resembling the method name prediction task [6]. In contrast to RQ1/RQ2, this task considers the ASTs of individual sprites, rather than entire programs. The training set contains 504503 programs with 4487940 sprites, the test set 15000 programs with 137429 sprites and the validation set 15000 programs with 132875 sprites. The training dataset contains 247317 different names with 90802 of them appearing more than once. The 100 most frequent names are used for 580544 sprites. We use accuracy, precision, recall and F1-score to quantify the performance of the generated models. To better understand the contribution of the code structure versus the literals used in programs, we conduct a small ablation study with a model for each task where literal values are replaced with abstract tokens for their type (string or number).

3.3 Data Preprocessing

The SCRATCH programs must first be processed to extract the path contexts in an appropriate format for the CODE2VEC model. SCRATCH programs are saved as .sb3 files, containing image and audio files as well as the JSON program code. We use LITTERBOX [12] to parse these JSON files into their AST representation. We extended LITTERBOX with the extraction and cleanup of the path contexts, such that no additional intermediate representations of the graph structure are needed. The extraction of path contexts ignores non-code related aspects of the AST, such as the positions of blocks in the code editor or post-it style comments.

For RQ1 and RQ2, the entire AST of the program, starting with the Program root node, is considered when extracting path contexts, and the labels are included in the dataset. For RQ3, we extract the path contexts per sprite from their sub-trees (ActorDefinition nodes in LITTERBOX), as well as the sprite name as the label for the classification task. Similar to how CODE2VEC treats method names, sprite names are split on special characters into subtokens, and the subtokens are normalized to only contain lowercase letters. The final sprite name is then obtained by joining the non-empty
