Table 1: Hyperparameters used for Java code [6] compared to the ones for Scratch experiments.

	Java	RQ1	RQ2	RQ3
number of contexts	200	200	1000	200
embedding size	128	128	128	128
max path length	8	8	12	8
dropout keep rate	0.75	0.75	0.75	0.75
batch size	1024	16	512	1024

subtokens back together with a vertical bar “|” as separating character to support manual interpretation. Additionally, there can be sprites that have the default name (depending on the language settings, e.g., “sprite”) after this normalization step. These are sprites that were not named by the user, and therefore the name cannot be assumed to describe the code. We excluded these sprites from the dataset.

3.4 Neural Network Structure

For all experiments we used the network structure as described by Alon et al. [6] and their implementation⁵. Even after extensive hyperparameter tuning by rerunning the experiment while iteratively changing the parameters one at a time, most of the values as used by Alon et al. for their analysis on Java code [6] also perform best on SCRATCH code (see Table 1). Consequently, we mainly re-used the default or similar values for common hyperparameters. We adapted batch sizes for the different experiments based on the dataset sizes: For the small dataset for RQ1 we reduced the batch size to 16; for RQ2 we used a batch size of 512.

Of the additional hyperparameters specific to the domain of code embeddings, the maximum considered path length and the number of path contexts used for the representation require particular consideration: Increasing the maximum path length allows the model to learn about related elements that are further apart in the source code. However, this also increases the number of generated path contexts. Due to the limited amount of memory available to us during the training phase, a random sample of those has to be chosen. By generating too many path contexts, the chance of missing semantically important ones during sampling increases.

Generally, the maximum path length that should be considered in the case of SCRATCH is higher than for the original Java method name experiment: Even a single sprite encapsulates the full behavior of a figure in a game and can contain multiple scripts, each controlling different aspects of behavior. Therefore, a sprite can be seen as comparable to a class in Java with scripts corresponding to methods. This results in long paths especially for connections between AST leaves placed in different scripts or sprites. Figure 2 shows the average program sizes for the three different datasets, showing that the RQ2 and RQ3 datasets have substantially larger programs than the gender classification task (RQ1). As the project categorization task (RQ2) considers entire programs, only 2% of all paths would be retained when pruning at the maximum of eight, as used in the original Java study (Fig. 3). Consequently, for RQ2 we increased the length to 12, resulting in 18200 path contexts.

⁵<https://github.com/tech-srl/code2vec>

Figure 3: Cumulative distribution of path lengths.

Figure 4: Cumulative distribution of path context counts. Maximum path length hyperparameter in parentheses.

Figure 4 shows the trade-off between increasing the maximum path length and the number of programs for which sampling the path contexts is necessary. Limited by graphics card memory, the model was allowed to use up to 1000 path contexts which allows us to include all of them for nearly 60% of all programs. Lowering the number of considered path contexts showed worse results during hyperparameter tuning. For RQ1, the default value of 200 was sufficient due to the small size of the programs. For RQ3, the default value of a maximum path length of eight combined with a maximum count of 200 also yielded the best results; the average number of path contexts in this dataset (1319) is significantly smaller compared to the one for RQ2.

3.5 Threats to Validity

Although our experiments aim to improve external validity by investigating CODE2VEC on three different SCRATCH tasks, results may not generalize to other tasks and embeddings (e.g., [4, 28]). Although we applied methods to ensure data quality, additional filtering may further improve results. To decrease the influence of the random initialization of internal model parameters on the small RQ1 dataset, we re-ran the experiment for each hyperparameter setting multiple times with/without reshuffling of the training set. We performed incremental hyperparameter tuning using a validation set not used during training and are reporting the results on a separate test set. Nevertheless, on different datasets other hyperparameters might yield better results. To support independent validation, our code is open source⁶, and data is available on request.

⁶<https://github.com/se2p/litterbox>

Table 2: Top-1 and top-5 accuracy, precision, recall, and F1-Score for code2vec when replacing literal values with abstract tokens (AT) and when keeping them.

Task\Metric	Prec.	Recall	F1	Acc.	Top-5 Acc.
RQ1 (AT)	78.1	78.1	78.1	78.1	—
RQ1	90.6	90.6	90.6	90.6	—
RQ2 (AT)	63.3	59.2	61.2	57.9	93.4
RQ2	64.1	60.0	62.0	58.9	93.6
RQ3 (AT)	45.4	41.6	43.4	41.5	51.9
RQ3	57.4	53.5	55.3	53.8	61.2

4. RESULTS

To evaluate the CODE2VEC embeddings for SCRATCH, Table 2 shows the performance of the CODE2VEC model on three different classification tasks.

4.1 RQ1: Gender Classification

The gender classification task shows a very high accuracy of 90.6%, suggesting that the projects are quite homogenous within the two gender groups. Grassl et al. [13] observed structural differences between the projects of the two genders, which is reflected by the high accuracy. For example, boys tend to produce interactive projects using event handling blocks and loop control structures, while girls produce more sequential programs. We observe a sharp drop in accuracy when ignoring literals (Table 2); we conjecture that this is also related to the reported sequential nature of the girls’ projects: Girls tend to produce story-like projects where sprites speak more, thus using more string literals.

RQ1 Summary. CODE2VEC is able to predict the gender based on code with a high accuracy of 90.6%.

4.2 RQ2: Project Type Classification

Compared to the gender classification task, the project category classification task shows a substantially lower accuracy of 58.9% (Table 2). The lower accuracy is likely influenced by the more challenging multi-class classification task, more noise in the data compared to the small gender dataset, and the generally larger projects used in this dataset.

While the accuracy is lower, it is comparable to the performance of the original analysis by Alon et al. [6], which was applied to individual methods. The results on the project category task thus confirm that CODE2VEC can also be applied to whole SCRATCH programs. We initially assumed that the model requires more path contexts to be able to extract information from the larger scope of the whole program. However, changing the maximum number of contexts to values between 100 and 1000 did not impact the prediction quality. In all cases the accuracy remained between 56.7% and 58.9%. We assume that the model does not actually use the path contexts as such to categorize the programs but instead focuses on the presence or absence of certain block types within the path contexts. For example, the dataset contains the categories “animations”, “games”, and “music”. Games obviously contain many blocks based around the user’s interaction with the program, whereas animations rarely do. Similarly, musical programs can be iden-

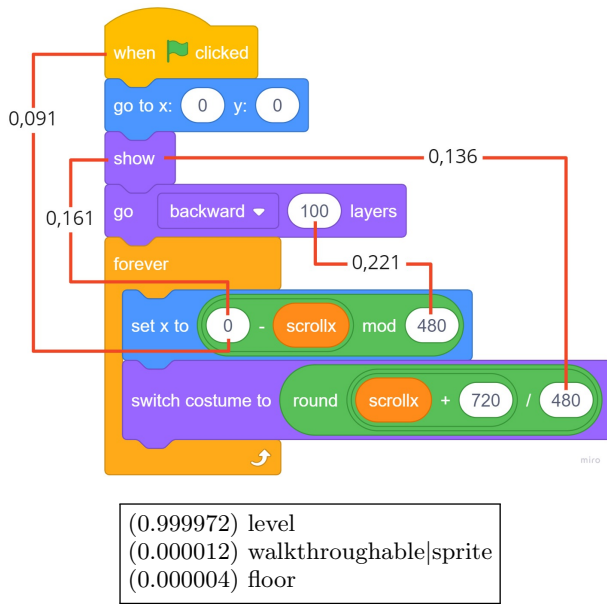

Figure 5: Example prediction with the top-4 paths with the highest attention weights, and the top-3 predictions.

tified by containing many sound-related blocks. As long as even the small path context samples contain some of those blocks distinctive to a program type, the model appears to have enough information to predict the correct category.

This conjecture is supported by the results without literals (Table 2), which even slightly increases the accuracy. This could be caused by two possible factors: The literal values might not be distinctive for project types; e.g., the movement of sprites in both animations and games relies on similar bounds checks on the visible stage area. Alternatively, some literal values are at least somewhat distinctive for the project type, but the attention mechanism focuses on other more significant differences. In both cases the model uses the attention mechanism to increase the weight for paths that contain project type specific blocks instead of relying on their start and end values. This coincides with our other hypothesis about the required number of path contexts.

RQ2 Summary. The model is able to extract semantic information from whole programs and is able to predict the project type with nearly 60% accuracy.

4.3 RQ3: Sprite Name Classification

The sprite naming task is most similar to the task used by Alon et al. [6] in the initial CODE2VEC evaluation, i.e., method name prediction. Alon et al. report F1 scores of slightly below 60%, and our results are quite close with an F1 score of 55.3% (Table 2). We conjecture that the slightly lower score is a result of the sprite naming task being slightly more challenging, as a sprite can consist of multiple scripts, and the name likely carries less semantic information than a descriptive method name.

To demonstrate that the embeddings actually represent semantic information, Table 3 shows example words and the

Table 3: Closest terms in the vector space for the example words “game”, “mario”, “easy” and “sound”.

game	mario	easy	sound
profile	luigi	hard	music
controls	link	medium	music player
text	sonic	insane	sounds
word	wario	extreme	audio
jimmy	yoshi	impossible	sfx

five closest words in the embedding space. All the terms close to “game” clearly have a connection to games themselves: Games tend to have player “profiles”, players interact using “controls”. Similarly, the terms close to “mario” mostly represent other characters from the Super Mario universe.

Unlike the project category task, the literals do contribute to some degree to the performance of the classification (Table 2). For example, Fig. 5 visualizes the most important paths in the “level” sprite from Fig. 1 as determined by the attention mechanism. In particular, the neural network gives the path between the tokens “100” and “480” the most attention; the number 480 represents the width of the stage, and thus is likely to be used in similar contexts.

RQ3 Summary. CODE2VEC can predict sprite names with a top-5 accuracy of more than 60%, suggesting that semantic information is successfully captured.

5. CONCLUSIONS AND FUTURE WORK

Code embeddings are a trending approach for program analysis, and the computer science education community has recently joined this trend and is exploring novel applications in learning analytics. An important prerequisite for applying machine learning methods is a better understanding of the capabilities and limitations of such approaches.

In order to contribute to such an improved understanding, we evaluated the popular code embedding method CODE2VEC. This is the first application of CODE2VEC to the SCRATCH programming language, and our work has identified a number of important differences between regular, text-based programming languages, and block-based languages like SCRATCH, such as differences in named entities (e.g., classes or methods) and the overall structure of the resulting AST.

Our experiments on three different classification tasks, predicting gender, project type, and sprite names, suggests that the adaption of CODE2VEC to the educational domain of SCRATCH is highly feasible, but there is room for improvement. This suggests that future work should investigate alternative code embedding methods, both those based on syntax (e.g., [28]) or graph neural networks [4].

ABSTRACT

The challenge of learning programming in a MOOC is twofold: acquiring programming skills and learning online, independently. Automated testing and feedback systems, often offered in programming courses, may scaffold MOOC learners by providing immediate feedback and unlimited re-submissions of code assignments. However, research still lacks empirical evidence of their effect on learning behavior of MOOC learners, with diverse backgrounds and goals. Addressing this gap, we investigated the connections between the use of automated feedback system and learning behavior measures, relevant for MOOCs: engagement, persistence and performance. Further, two subjective measures of success are examined: sense of learning and intention fulfilment. In an experimental design, we analyzed data of active learners in a Python programming MOOC (N=4652), comparing an experimental group provided with automated feedback with a control group that did not. In examining the effect of automated feedback, prior knowledge of programming and Python was considered. Empirical evidence was found for the relation between automated feedback usage and a higher engagement and better performance, as well as higher attendance in "active watchers" and "high-performed completers" clusters, obtained by cluster analysis. Learners reports on their experience with the automated feedback system supported these findings. Regarding the subjective measures of success, however, no difference was found between groups. Our study and the offered future research may contribute to the considerations regarding the integration of automated feedback in MOOCs for programming.

automate feedback, MOOC for programming, learning behavior, prior knowledge, educational data mining, cluster analysis

1. INTRODUCTION

Massive Open Online Courses (MOOCs) for programming have the potential to teach programming to a broad and diverse audience [28]. The high demand for computer professionals and labor market needs have led to an abundance of courses, with large numbers of enrollees [25]. However, many learners struggle in these courses. Learning programming is challenging, but MOOC learners face additional difficulties, as they have to self-regulate their learning (SRL) and to cope with course content almost without the assistance of instructors [11]. The provision of feedback may assist

learners with these challenges. Feedback is considered essential in online learning, both as formative assessment, promoting learning and increasing learner engagement and as an acceleration of the SRL process [16].

In programming courses, the practice of writing and running code is the basis for acquiring software developing skills [5, 48]. An immediate, detailed and accurate feedback makes practice more effective and may significantly improve learning [38, 40]. But in large scale courses, and especially in MOOCs, instructors cannot provide feedback on each submission [15]. Automated testing and feedback (ATF) systems address the need, allowing an unlimited number of learners and submissions [22]. Upon uploading a solution to the system, the learner receives immediate feedback and is given the option to resubmit a revised code, to complete the learning process. Feedback may address syntax errors, the correctness of results, the efficiency of the code and whether it fulfils instructions accurately [13, 48]. It can consist of basic feedback, including only correct/incorrect information or presenting the correct answer, or a detailed feedback, suggesting possible causes of error and hints for the solution [22, 44].

ATF systems were developed decades ago, and today there is a variety of tools and systems employing diverse technologies and methods for testing and generating feedback [9, 22, 37]. Previous research suggested that incorporating an ATF system into a programming course improves affective measures, such as satisfaction and sense of learning [4, 6]. The automated feedback is perceived by learners as enhancing learning as well as contributing to motivation and engagement [2, 32, 37]. Results regarding the system's impact on performance, however, were not conclusive (e.g. [7, 13, 14]).

Yet, most studies in the field of ATF have only focused on frontal courses, or online courses offered as part of an academic curriculum. Students in these courses have extensive interaction with the faculty, which enhances their learning [36, 42] and might "overshadow" the impact of automated feedback on learning outcome [15]. In MOOCs, ATF system may have a different effect. Furthermore, the diverse goals and intentions of MOOC learners may affect their learning behavior and performance [24, 29], and consequently the impact of automated feedback [34].

To gain the full potential of ATF in MOOCs, empirical research needs to be conducted in order to better understand the impact of automated feedback on learning behavior and outcomes. Yet, empirical research in this field is still lacking [1]. With the aim of addressing the gap, this study set out to investigate the connections between automated feedback usage and learners' learning behavior and outcomes, in MOOCs for programming.

It is now well established from a variety of studies that the relevant measures for learning behavior in MOOCs are engagement (measured through learning activity), persistence and performance [18,

20, 24, 51]. Additional success measures refer to learners' perception of achieved knowledge levels and intention fulfilment [17, 39]. Hence, the research questions we posed are as follows:

RQ1: What are the differences, if any, in engagement, persistence, and performance between ATF users and not-users?

RQ2: Is there any difference in learners' perceptions of achieved knowledge levels and intention fulfilment between ATF users and not-users?

Previous studies suggested that prior knowledge, related to the course content, may influence learning behavior and the impact of automated feedback [28, 33, 46]. Therefore, the investigated learning behavior measures were analysed with prior knowledge as a covariate.

Using a quantitative method and learning analytics approach, we compared data of two groups of learners in a Python programming MOOC incorporating ATF system: An experimental group who was given feedback on the code assignments by using the system, and a control group who did not. Collecting data from the course and system logs, cluster analysis was applied to identify and compare learning behavior patterns. Subjective success measures were compared based on learners' self-report data.

2. RELATED WORK

2.1 Measures of learning behavior in MOOCs

Previous research has established that given the heterogeneity of learners in MOOC, the appropriate measures of learning outcomes differ from those of formal education context [10, 24]. The most commonly used indicator to measure learning outcomes in MOOCs is learning engagement, measured by the number of lecture videos watched, the number of posts to forums, the number of quizzes taken, and the number of tasks completed [20, 52]. Another common measure is persistence, as measured by the learner's determination to complete tasks and the achieved degree of progress. The relevant measures are therefore the number of attempts to solve course exercises, the number of learning units that were studied (watching video or attempt to solve an exercise) as well as the most advanced unit that was studied [10, 20]. Learner's performance in the course is often measured by the scores on the exercises and assignments [18, 47].

Several studies applied cluster analysis to identify learning behavioral patterns and classified learner' groups by similar learning characteristics. A key study, establishing the main characteristics of MOOC learners, suggested four identified groups: completers (students who completed most assignments), auditing (students who did few-to-no assignments but engaged in watching videos), disengaging (students who did assignments early in the course, but later stopped participating), and sampling (students who watched videos only in the beginning of the course) [24]. A similar research described 3 groups of MOOC learners as: (1) active engaged (those who submit assignments and were actively involved in forums); (2) passive engaged (those who watch video or show passive involvement in forums); and (3) disengaged (learners whose activity decreased throughout the course) [41]. Recently, a study investigated learners' interactions with video, exercises and discussion forums, identifying seven patterns of learners' behavior: tasters, downloaders, disengagers, offline engagers, online engagers, and two patterns characterized by moderate and high social engagement [21]. The variables used to derive these patterns were the number of videos watched, in-video questions answered, exercises and assignments submitted, thread views and activity in the discussion forums.

Considering the suggested measures of learning behavior in MOOCs, in the current study we first applied cluster analysis to identified groups of learners who behaved similarly and then investigated the connections between behavior patterns and ATF usage.

2.2 Subjective measures of success in MOOCs

A variety of reasons motivate learners to enroll in MOOCs [29], with a variety of learning outcomes to expect [39]. Thus, it has been proposed that the success of learning in MOOCs should be evaluated through learner-centered measures. One suggested criterion is fulfillment of learner intentions [17]. In research conducting self-reported surveys, learners' intention fulfillment was found to be correlated with their engagement in course activities [39]. "Sense of learning" or "sense of achievement", representing the perceived increase of knowledge, is another criterion for successive learning, being in use in previous studies to measure learning success and outcomes in MOOCs [30, 49, 51].

2.3 The effect of ATF in MOOCs on learning

In the context of MOOCs for programming, only a few studies have examined the impact of automated feedback, provided on code assignment, on learning behavior and outcomes. Regarding the aforementioned affective measures, several studies noted that automated feedback was perceived by learners as improving performance, increasing engagement and having a positive impact on learning strategies [8, 27]. An interesting study suggested that learners who "committed" by formal registration to use an ATF system in MOOC for programming were more engaged in solving code assignments, in compared with those who used it only partially, without registration [12]. Recent study came up with similar results [43]. No effect of using the system was found, however, regarding performance and course completion rates.

Most studies on automated feedback propose advanced algorithms and new approaches to improve error detection and feedback accuracy, but do not evaluate its effectiveness as a learning tool [31, 45, 50]. Several research reports on future intention to evaluate the impact of the examined ATF system on learning outcomes, yet to be done [5, 25]. Others suggest factors to consider while choosing or developing ATF systems for MOOCs, but no empirical results are provided [48].

Overall, there seems to be some evidence to indicate that automated feedback has the potential to support learners and enhance learning success in MOOCs for programming. The findings of the current study contribute to empirically based knowledge in this area.

3. METHOD

3.1 Course and ATF system

To answer research questions, we conducted an experiment in MOOC to learn the Python programming language, offered on Edx-based platform for MOOCs. The course consists of nine learning units, each of which includes content videos with comprehension questions, closed exercises (such as multiple-choice questions), and code-writing assignments. Answering the closed exercises is followed by feedback (correct/incorrect and an explanation).

The ATF system integrated in the course is INGINIOUS - an open-source software, suitable for online programming courses, providing grades and textual feedback for code assignments (for more details on INGINIOUS, see [19]). The system was incorporated into the course as an external tool, and registration was necessary for access. It was configured to allow unlimited submission of solutions. The textual messages provided as part of the feedback were adapted to the code assignments, containing different levels of

feedback according to error-type (e.g. correct / incorrect, expected correct answer or more elaborated feedback), as classified by [44].

3.2 Experimental design

Using the cohort-mechanism embedded in Edx platform, we randomly divided the learners enrolled for the course into control group (control-g) and experimental group (atf-g). Learners in the experimental group gained access to the ATF system. Those who chose to use it uploaded solutions for the code assignments, received feedback, and then were able to resubmit revised solutions. In the current experimental set, however, it was not possible to get information about how the learners in the control group solved the code assignments.

3.3 Data resources and definitions of measures

Research questions were answered by gathering data from different sources and harvesting measures to be compared. Definitions of research variables are provided in this section.

- 1) Demographics and prior knowledge (PK) in programming and Python obtained by pre-course questionnaire. To avoid subjective assessment, PK was defined in a Boolean manner (there is / there is no PK). From learners' responses we derived three PK categories: None, Programming (other language), Python [3].
- 2) Learning behavior data, consists of engagement, persistence and performance, obtained from course event logs (table 1). As we do not have information regarding the number of code assignments solved by learners who did not use the ATF system (control group and learners in atf-g who chose not to use the system), it was not defined as a measure of activity.
- 3) Log files of the ATF system, which contain information on submitted solutions, were analyzed to assess the use of automated feedback (relevant only to the experimental group).
- 4) Subjective measures were collected from the "learning experience" questionnaire, completed by learners at the end of learning. "Sense of learning" refers to the learner's evaluation of the level of knowledge achieved at the end of learning process. Learners were asked to choose one of four statements, representing four levels of knowledge. Intention fulfillment defined as one of three values (Yes / Partially / No).
- 5) Learners in the experimental group were asked to answer two additional questions regarding their perception of how the use of the system affected their engagement (Likert scale 1-5): "The system contributed to the motivation to complete more tasks in the course", "The option to correct my solution and resubmit prompted me to make an effort for a higher score". The obtained responses were used as supportive data to the results of the comparison between the two research groups.

The research was conducted under the rules of ethics, while protecting privacy and maintaining the security of information, and in accordance with the approval of the university ethics committee.

3.4 Research population

The study was conducted in the second half of 2021. Following the screening of non-active enrollees and learners who did not provide information about prior knowledge, N=4652 learners were included for our final study population, 15.6% (724) of which in the experimental group (hereinafter: atf-g) and 84.4% (3928) in the control group (hereinafter: control-g). The imbalance between the research groups was caused by technical reasons, as the system was integrated for the first time during the course cycle in which the study was conducted. To ensure that none of this affected the results, all

Table 1 : Learning behavior calculated measures

	variable	Description
Engagement (activity)	watched video	Number of watched videos (0-29)
	watched units	Number of units in which at least one video was watched (0-9)
	active-watched ratio	Ratio between the number of videos in which the learner solved a comprehension question and the total number of videos watched (0-1)
	solved exercises	Number of closed exercises (CE) learner attempted (0-39)
	solved units	Number of units in which at least one exercise was attempted (0-9)
	mean attempts	Mean attempts per exercise
persistence	units touched	Number of units in which the learner watched a video or attempted an exercise (0-9)
	max unit touched	The most advanced unit in which the learner watched a video or attempted an exercise (1-9)
performance	grade	The mean score in closed exercises (0-10)

the analyses were repeated several times, comparing the experimental group (atf-g) with random groups drawn from the control group, of the same size as atf-g. Upon completion of this study, which was also a technical pilot, all learners in the following course cycles were able to enjoy the benefits of using the ATF system.

Participants were all Hebrew speakers, which is the language in which the course is taught, and were interested in learning Python. In terms of gender identification, learners' distribution was 73.5% male, 25.9% female, and 0.6% unidentified. The learners ranged in age from less than 11 to over 75, with the majority in the age at the range of 12-34 (79.3%).

According to self-reported prior knowledge, 30.4% of learners had prior programming skills but not Python (PK=Programming), 15.1% reported of Python (and programming) knowledge (PK=Python) and 54.5% had no prior knowledge relevant to course content (PK=None). Chi-square test indicated no significant difference between the experimental and control groups regarding the distribution of prior knowledge.

4. FINDINGS

This section presents the results aimed to answer research questions. To control the impact of PK on the effect of automated feedback as a covariate, the comparison of the two research groups in all tests was conducted separately at each level of PK. The findings are presented without regard to this covariate unless it is found to affect the results in a significant manner.

In regard to the imbalanced research groups, five repeats of the analyses with random subgroups from control-g, equal to the size of atf-g, yielded identical answers to research questions. Therefore,

we have chosen to present the comparison between the experimental group ($N_{\text{atf-g}} = 724$) and the entire control group ($N_{\text{control-g}} = 3928$).

Table 2: Descriptive statistics of learning behavior measures (Natf-g = 724, Ncontrol-g = 3928 M=mean, MD=median, SD=standard deviation)

variable	atf-g			Control-g		
	M	MD	SD	M	MD	SD
watched video	12.7	11	9.0	8.8	5	8.6
watched units	4.3	4	2.9	3.1	2	2.7
active-watched ratio	0.4	0.4	0.2	0.3	0.3	0.3
solved exercises	15.2	12	12.9	8.3	1	11.8
solved units	4.3	4	3.1	2.4	1	2.9
mean attempts	2.4	2.1	2.0	1.7	1.6	2.0
units touched	4.7	4	3.0	3.4	2	2.8
max unit touched	4.8	4	3.0	3.7	2	3.0
grade	0.8	1	0.3	0.5	0.8	0.5

4.1 RQ1: The connection between ATF usage, learning behavior and performance

4.1.1 Comparing learning behavior variables

The operational variables of learning behavior and performance (table 1) were calculated from data and compared between research groups. Mann-Whitney test was applied, as the homogeneity assumption required for the t-test was not met. In the experimental group, the mean and median values of all behavioral variables were higher, as illustrated in table 2 and figure 1. This difference was found to be significant at the $p < .001$ level (Mann-Whitney U ranged between 1050975 – 954295.5), with small-medium effect size, given by the rank biserial correlation (0.228 - 0.402).

Figure 1: Mean values of learning behavior variables

Another way to measure persistence is to compare, per number of “touched” units, the percentage of learners from each group who reached this number. Chi-square test revealed significant difference between learners’ percentage of each group ($\chi^2(8) = 165.34$, $N = 4652$, $p < .001$). From three units above, the number of units “touched” by the experimental group is higher (see figure 2).

More specifically, it can be claimed that a higher percentage of learners from the experimental group completed the course, i.e. learned all the lessons. Further evidence of this fact comes from a finding that a higher percentage of learners from the experimental group studied units 7-9, the advanced units of the course. A significant difference was indicated between learners’ percentage from

Figure 2: Comparison of learners’ percentage per number of units “touched” (Natf-g = 724, Ncontrol-g = 3928)

each group who solved exercises in these units ($\chi^2_{\text{unit 7}}(2) = 100.00$, $\chi^2_{\text{unit 8}}(2) = 67.20$, $\chi^2_{\text{unit 9}}(2) = 34.42$, $p < .001$). Nevertheless, for learners with prior knowledge of Python, the difference between the groups regarding solving the exercises of the last unit (unit 9) was not statistically significant.

4.1.2 Cluster analysis of learning behavior variables

Among the variables representing learning behavior and performance, five “differentiating” variables were identified using PCA: active watched ratio, solved units, mean attempts, max unit touched and grade. k was assumed a priori to be between 4 and 6 so that the clusters would be distinct, but not too many. The elbow method plot and silhouette score were then used to identify the most fitting number of five clusters, explaining 72.7% of variance in data ($R^2 = 0.727$). Table 3 summarizes the clusters obtained and the mean values of the differentiating variables within each cluster. Following the behavior patterns characterizing each cluster, they were named as follows: (1) “Touched and left”: those who log in but showed almost no engagement with course content. This pattern, which represents learners who actually dropped out shortly after they started, was the most frequent. (2) “Completers, high performers”: learners with highest performance and completing rates, while only moderate consumption of content. This pattern was the second in number of learners (3) “Active-watchers”: those who watched video actively, answering in-video comprehension questions. (4) “Good starter, mean progress”: those who solved correctly few exercises, mainly of the first one or two units, but had no intention to complete the course. (5) “Trail-error solvers”: those who try to solve few exercises, with many attempts, low success and no progress. This was the least desirable behavior pattern.

Examining the presence of learners from each group within each of these clusters, presented in figure 3, revealed relatively high percentage of atf-g learners in clusters 2,3 (42.40%, 24.17%, respectively) and higher percentage of the control-g learners in cluster 1 (41.42%). Chi-square test indicated a statistically significant difference between atf-g and control-g ($\chi^2(4) = 277.208$, $N = 4652$, $p < .001$) over all levels of PK. Yet, cluster 2 was found to be significantly different from the other four clusters in terms of PK, as determined by one-way ANOVA ($F(4,4647) = 32.664$, $p < .001$)

and Tukey’s HSD test for multiple comparisons ($p < .001$ for all the comparisons of cluster 2 and other clusters).

Table 3: Cluster characteristics and mean value of learning behavior variables (In bold: characterizing attribute of each cluster)

Cluster	1	2	3	4	5
Size	1707	1161	897	756	131
percentage of N=4652	36.91%	25.10%	19.39%	16.35%	2.83%
Active-watched ratio	0.142	0.428	0.604	0.15	0.329
Solved units	0.164	7.205	2.557	1.655	1.473
Mean attempts	0.179	2.556	2.338	2.319	9.152
Max unit touched	2.17	7.999	3.198	2.298	2.183
Grade	< 1	95.1	87.4	95.1	67.4

4.1.3 Learners’ perception of ATF effects

Two questions about the effect of using the system were answered by 126 learners. In their responses, learners indicated they believed that using the ATF system affected their engagement and performance. The majority of respondents agreed with the statements that the option to correct and resubmit prompted them to make an effort for a higher score (87%) and using the ATF system motivated them to be more engaged in solving course exercises (81%). PK level had no impact on learners’ perceptions.

Figure 3: The percentage of learners from each group within each cluster

RQ2: Connections between automated feedback and success measures

Of the study population, 401 learners (9.87%) completed the “learning experience” questionnaire. Among the respondents, 32.27% (126) belong to the experimental group and 67.73% (275) to the control group. As can be seen in table 4, the majority of respondents described their achieved level of learning as “Can write basic code, needs more supported practice” (49.63%), followed by “Can write complex code and practice independently” (35.94%). Only 5.8% felt confident to start working in Python. To the question of intention fulfilments, however, the most frequent answer was “Yes” (81.91%).

Table 4: Subjective measures, learning experience questionnaire (N=401)

Sense of learning	
Understands the concepts, can't write code independently	8.56%
Can write basic code, needs more supported practice	49.63%
Can write complex code and practice independently	35.94%
Can work in Python	5.87%
Intention fulfilment	
No	0.98%
Partially	17.12%
Yes	81.91%

Applying the chi-square test to compare between research groups, no significant difference was found in all levels of PK. Notably, an expected significant dependency was found between PK and sense of learning ($X^2(6) = 67.73, N = 401, p < .001$), as prior knowledge led to higher assessment of the achieved level of knowledge.

5. DISCUSSION

With respect to the first research question, findings demonstrate connections between ATF system usage and learning behavior, as learners in the experimental group were more engaged with the course material and completed it at a higher rate. These results are in line with previous studies, suggesting that feedback (in general) enhances learners’ engagement and persistence in online courses (e.g. [16, 20]) as well as in programming courses, not necessarily be offered online (e.g. [12]). Notably, in the current study all learners received feedback on the closed exercises, and the difference between groups was due to the additional feedback provided to the experimental group for code assignments. Therefore, it should be assumed that feedback on code assignments in MOOCs for programming is of utmost importance. Our findings, however, are contrary to those of [43] who did not observe a connection between feedback and learners’ engagement. A possible explanation for this might be differences in feedback and course characteristics, which affect feedback effectiveness [33].

The current study indicates a connection between automated feedback and learners’ performance and suggests positive trend of higher grades of the ATF users. Previous studies have not conclusively established this connection (e.g. [13, 14]). Nevertheless, due to our experimental design, we defined performance by closed exercises score and not by programming abilities (e.g. grades of code

assignments). As such, the evidence of higher performance of atg in this case may indicate in fact a deeper understanding of programming principles [26].

Our clustering of learners based on learning behavior variables is similar to behavior patterns classified in previous studies [21, 24, 41], even though the number of clusters we selected is different. Learners of the experimental group were more “present” in the clusters described as “completers, high performers” and “Active-watchers” characterized by patterns identified as related to success in MOOCs [23]. The cluster analysis results support and expand the findings obtained for each variable as stand alone.

Interestingly, most of the analyses we conducted did not reveal any effect of prior knowledge on the connection between learning behavior and automated feedback. These findings do not support previous study, suggesting that prior knowledge affects the effectiveness of feedback in online learning environments [35]. Further research, with higher resolution determination of prior knowledge level, may shed light on this issue. One exceptional of our results is the case in Unit 9, where similar percentages of the Python experienced learners of two groups solved the closed exercises. It may be that the prior Python knowledge obscured the differences between groups, as experienced learners wanted to test their knowledge in this very specific unit, which is the most advanced one.

In support of the findings based on (objective) log files, the perceptions of the learners in the experimental group suggest that the automated feedback they provided heightened their motivation to be more engaged in solving exercises and encouraged them to score higher. This attitude is similar to learners’ perception towards automated feedback reported in previous studies, in the context of in-class programming courses (e.g. [2, 32]). With regards to affective measures, therefore, automated feedback is perceived beneficial in both frontal and online learning environments.

With respect to the second research question, however, finding of the current study do not indicate a connection between the use of the ATF system and the subjective measures of success - intention fulfillment and sense of learning. These results differ from previous studies which have suggested that intention fulfillment is correlated with engagement in solving exercises in MOOC [39]. A two-way effect may have been created here: On one hand, the automated feedback may have led learners in the experimental group to more comprehensive learning [38] and on the other, they were more aware of errors and incorrect solutions, leading to a lower assessment of their abilities in Python.

6. CONCLUSIONS AND FUTURE WORK

Overall, the results of this study indicate a connection between the use of the ATF system, providing automated feedback, and learning behavior. Furthermore, the findings suggest that the automated feedback enhances the learners’ engagement and persistence in the course as well as their performance. Nevertheless, we must be cautious in this context, and further research is needed to examine the effects of feedback on learning behavior (e.g. examining a “directional” connection). This is primarily due to the finding that the sense of learning and intention fulfilment were not affected by the use of ATF, suggesting the effect of feedback is likely to be complex and non-uniform within different facets of learning outcomes. However, the inability to obtain an objective assessment of the level of knowledge at the end of the learning is one of the current study limitations. The result of a final exam, for example, may reveal differences between research groups that are not apparent in self-reported evaluation. Nonetheless, there is no mandatory assessment in a MOOC due to its nature.

A further limitation is that the experimental design prevented a comparison of the research groups in regard to solving code assignments, which in fact is the subject of feedback. Future research be undertaken with a setup allowing the comparison of these data as well, might bring additional insight into the effect of automated feedback.

Lastly, the feedback provided by the ATF system was referred to in the current study as “black box”. In light of the concept proposed by Narciss [33], which links the characteristics of feedback to its effectiveness, further experimental research is needed to analyze the effects of feedback characteristics (e.g. the structure of textual message) on learning in MOOCs for programming. Expanding empirical research knowledge regarding the impact of automated feedback on learning may contribute to the effective integration of ATF systems and thus promoting learners’ acquisition of programming skills and achievement of learning goals.

7. ACKNOWLEDGMENTS

Our thanks to the Azrieli foundation for the award of a generous Azrieli Fellowship, which allowed this research. We are also indebted to our anonymous reviewers and the EDM program chairs for their valuable feedback.

Data-driven goal setting: Searching optimal badges in the decision forest

Julian Langenhagen

langenhagen@econ.uni-frankfurt.de

ABSTRACT

Although badges are among the most-used game elements in gamified education, studies about their optimal features to motivate learning are scarce. How should a badge be designed to represent an incentive for a specific goal like optimal exam preparation? This study examines usage data of a higher education learning app to determine whether the used badges have the intended motivational effect. The preliminary results suggest that the badges that were initially implemented in the app have the intended effect in most cases, but the stages of the multi-level badges could be optimized. The methodological framework used in this study can be transferred to usage data of other similar learning tools. With the help of easy-to-interpret outputs of decision trees, researchers and practitioners alike can work towards an optimal badge design.

Keywords

Gamification, Education, Badges, Decision Trees

1. INTRODUCTION

Badges are among the most used elements in game-based learning [1, 18, 14]. Yet, little is known about their optimal design in the educational domain. I define a design in this context as optimal if a badge can only be earned by following a learning strategy that leads to improved learning outcomes. The inspiration for the design of badges in game-based learning often comes from entertainment games [3, 22]. However, the goals of such games are usually different from those of learning tools used in school or higher education [20]. This difference also applies to commercial learning apps such as Duolingo. In Duolingo, for example, it is possible to earn a badge called “Weekend Warrior” if you use the app on a Saturday or Sunday and a badge called “Photogenic” if you upload a profile picture¹. These two badges are presumably intended to maximize usage time or identification with the app and are not necessarily aimed

at an optimal learning strategy. Since designers of game-based learning tools may use such commercial apps as a blueprint, they run the risk of copying badges that motivate non-optimal learning strategies. This study should help educators that use badges in their learning tools to evaluate whether their chosen design motivates learning strategies that lead to better learning outcomes.

Empirical studies that investigate optimal badge design in learning contexts are rare. Easley and Ghosh [9] analyzed optimal badge design with a game-theoretic approach from a general but not an educational point of view. Antonaci et al. [1] link the effects of different game elements on learning outcomes in their literature review to investigate the question of which game elements cause which effects. They find that some game elements can have either a positive or a negative effect depending on the context (e.g., specific setting, other game elements used and the personality of the students). This result is also confirmed by recently conducted meta-studies [2, 15, 24]. They all report an overall positive significant small to medium effect size of game-based learning on learning outcomes. However, it is still unclear which factors contribute most to the success or failure of game-based education. In addition, the meta-studies above shed light only on the overall effects of combinations of different game elements. A more in-depth analysis of different badge designs (or other single game elements) does not exist yet. Facey-Shaw et al. [12] provide an overview of different badge designs and their functions in various educational applications. Still, they do not link the different designs to the achieved effects on the learning outcomes. The present study will contribute to this research gap.

The data set used in this study consists of usage data from a gamified learning app that has been in use for four semesters in an accounting lecture at a large European university. Among other game elements, the app uses badges to motivate the students to learn. The required achievements to earn the badges include specific amounts of consecutive usage days or answered questions. The corresponding goals were developed based on learning theories and practical experiences from past lectures but without any empirical validation. The goal of this study is to answer the question of whether students who aligned their learning strategy to the given badge goals performed better on the exam. Based on the results, the basic features but also the levels of the badges can be discussed. For example, the badge awarded for the amount of answered questions in the data set has

three levels. The highest level is earned when a student answers 1,000 questions. Unless a large proportion of the top students answered that many questions in the app, you could conclude that the threshold might be too high. If the level is too high, earning that badge could even be a predictor for a bad performance in the exam, i.e., students who answer too many questions might overestimate the app as a learning tool and neglect other learning materials. The following two research questions will be answered in this study to contribute to the discussed research gap:

RQ1: Do the badges that were initially implemented in the gamified learning app incentivize a learning strategy that leads to good exam results?

RQ2: Are the levels of the multi-level badges optimally set?

2. RESEARCH SETTING

2.1 Lecture and App

The research subject of this study is data from a gamified learning app that was used in an undergraduate accounting course at a large public university in Europe. The course is usually taken by approximately 600 students per semester (see Table 1) and consists of a weekly lecture and bi-weekly tutorials and small group exercises. Attendance at the classes is voluntary. The learning materials consist of a script, a collection of exercises and a trial exam. In addition, a textbook and the corresponding exercise book are recommended for further study. Apart from the written exam at the end of the semester, there is no other formal assessment. In evaluations of past semesters, students often commented that there was no contemporary way to engage with the subject matter in addition the aforementioned traditional learning materials. As a result, the responsible chair applied for funding and planned to develop a smartphone app with gamification elements.

The launch of the app took place in the summer semester of 2019. Like attendance at the classes, the use of the app is voluntary and no formal advantages for the exam can be gained by using the app. The app is widely accessible, as in addition to an app version in Google Play Store and Apple App Store, it is also available as a web version that can be accessed via the browser. Over 550 questions were developed for the quiz app, covering all nine chapters of the course. There are four question types in the app: single and multiple-choice, as well as sorting and cloze text tasks. Students can use the app in three different modes: Chapter Mode, Random Mode, and Weekly Challenge. In Chapter Mode, students can choose to be shown only questions from a specific chapter. When they master a chapter, the next chapter is unlocked. The current status in a chapter is visualized by a progress bar. The corresponding progress is measured by the so-called Skill Level Indicator (SLI), which was designed based on Ebbinghaus's forgetting curve [10]. When a question is answered correctly, the SLI increases to 100%. The result is that the corresponding question is no longer displayed for the time being. However, over time, the SLI decreases again to indicate that the content of the question may have been forgotten. After a certain duration (which becomes increasingly longer after answering the same question several times), the question is displayed again to check whether it is still correctly answered. In the second

mode, Random Mode, questions are randomly drawn from the pool that have already been unlocked by the student. In the third mode, the Weekly Challenge, students can answer 25 randomly selected questions once a week from chapters that have already been covered in the lecture. They can then compare their performance with that of fellow students on a leaderboard. The more questions students answer, the more learning points they earn in the app and level up accordingly. Moreover students can earn the before mentioned badges for certain achievements (see Figure 2). A detailed description of the initial badge set is outlined in Section 2.4 and more information about the app in general and its usage can be found in [19].

2.2 Data Sources

The collected data in this study consists of three different sources over four semesters (see Table 1): the exam results of every enrolled student, the app usage data and responses from a survey conducted each semester.

Table 1: Data Sources and Sample Sizes

	SS19	WS19	SS20	WS20
App	559	595	447	546
Exam	575	648	616	644
Survey	127	108	114	167
App+Exam	230	243	190	190

The collected usage data from the app consists of various details, including the exact time a question was answered, the answer given, and whether it was correct or incorrect. The functions and design of the app did not change in any of the four semesters considered in this study. Since no laboratory conditions prevail in the present setting, it was important to keep as many parameters constant as possible [5, 11]. In addition to the app version, the instructors, the learning materials, and the type of exam were not changed over the entire observation period. In each semester, the exam consisted mainly of arithmetic problems and contained three major tasks, each worth 30 points, which were divided into smaller sub-tasks. Even though the style of the exam remained identical over the semesters, it cannot be guaranteed that the level of difficulty remains the same between semesters. This circumstance is considered in the evaluation and assignment of grades, i.e., a specific number of points can result in a different grade in different semesters. Therefore, the analysis in this study uses grades rather than points as the dependent variable to control for the effect of varying difficulty. Grades in this setting range from 1.0 (very good) to 5.0 (failed).

One limitation regarding the analysis of the data is that I need the students' matriculation numbers to be able to connect the data points from the app and the exam. Due to data protection rules, I was obliged to ask the students for their matriculation number in the app on a voluntary basis. As not every student provided his or her matriculation number, I am only able to connect the data of the two data sources for a limited number of students (see Table 1). Therefore, I cannot analyze the app's influence on every exam result because I do not know for every student in the exam score list to which extent they used the app. To address this issue, a later section of this paper will examine

whether students who gave consent for their data to be used for research purposes differ significantly from students who withheld consent.

The third data source is a survey that was conducted every semester. Although the average response rate of the survey (26%) is comparable with similar prior studies [25, 17, 26], I decided not to connect the survey answers to the other two data sources for the present study. To be able to connect the survey answers, the students also needed to submit their matriculation number with the survey answers. As only a small fraction followed this request, the sample size with information from all three data sources would be significantly smaller than the sample size with data only from the app and the exam (see Table 1). However, Table 2 shows with data from the survey that the four cohorts did not differ significantly in the major demographics and can therefore be considered comparable for this study.

Table 2: Demographics of the Four Cohorts

	SS19	WS19	SS20	WS20
Male	59.05%	53.70%	47.30%	49.18%
Female	40.95%	46.30%	52.70%	50.82%
∅ Age	21.82	21.10	21.81	21.24
∅ Semester	3.73	3.27	3.61	3.41

2.3 Methodology

To analyze the badges implemented initially, the badges and the corresponding learning metrics are discussed below in a first step. In a second step, to answer the first research question, I will analyze whether students who followed the learning strategy motivated by the badges performed better in the exam by comparing the average grades. To answer the second research question, a decision tree is built to illustrate the influence of certain limits of the previously mentioned learning metrics on the average grades. The decision tree method is used because its results are easy to interpret and explain. This advantage is significant if the results and the corresponding analysis framework are to be used in practice. For this, especially the graphical representation method is very suitable, especially in comparison to a traditional regression output. The disadvantages of the method are the lower predictive accuracy (e.g., compared to random forests) and the fact that they are less robust than other approaches [16]. However, from my point of view, the advantages outweigh the disadvantages for the chosen purpose. All analyses for this study were conducted in R (4.1.1) and to create the decision tree the packages `rpart` (4.1-15) and `rpart.plot` (3.1.0) were used. The resulting flow chart of a decision tree can be used to evaluate and adjust the limits of the multi-level badges to increase the motivational effect if necessary. In practice, the optimized badge set would then be used for another term and afterwards the resulting usage data would again be evaluated with regards to the target variable. This general iterative process can be summarized as outlined in Figure 1.

2.4 Initial Badge Design

The initial badge set included badges in six categories (see Figure 2). The badges can be divided into single-level badges (one learning metric results in one single badge) and multi-level badges (one learning metric results in multiple badges

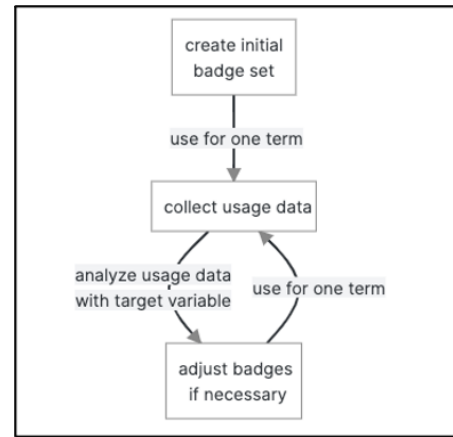

Figure 1: Iterative Optimization Process

divided into different stages). The first badge was awarded for students entering their matriculation number to share their usage data for research purposes. Since this is not a learning strategy or a measure of learning success, this badge will not be discussed further in this study. The remaining five badge categories and the corresponding learning metrics are discussed in the following sections.

2.4.1 Unique Questions

The second badge in Figure 2 is awarded if a student answered every question in the database correctly once. The influence of this badge is evaluated with the learning metric “Unique Questions”. This metric measures how many different questions a user has answered. As explained in Section 2.1, the SLI ensures that a question that has been answered correctly is only displayed again after a certain time. Nevertheless, each question can in principle be answered multiple times, which is why “Unique Questions” provides valuable information. The further a user has worked through the chapters, the higher this metric will be. If a student uses the app regularly, but only answers questions from the first chapter, this may result in a high number of total answers, but probably does not reflect a meaningful learning strategy. A user with the same number of total answered questions but more unique questions presumably has learned more and therefore a higher probability for a good exam performance.

2.4.2 Maximal Chapter

As described in Section 2.1 the rules of the app require a user to work through one chapter at a time. This means that each student starts in the first chapter and must master it to a certain degree to unlock the second chapter. This process continues until the final chapter nine. When a chapter is unlocked, the corresponding badge is awarded to the student. The learning metric “Maximal Chapter” measures the highest chapter a user has unlocked. As discussed in the previous section, a learning strategy that covers higher chapters is presumably more successful regarding exam preparation than an intensive usage only in lower chapters. A student with the same number of answers but a higher number of different chapters likely prepared better for the exam than a student with the same (or a higher) number of questions that only cover the topics of the first chapters.

No.	Achievement				Badge
<i>single-level</i>					
1	Entered matriculation number				
2	Answered each question correctly once				
3	Unlocked chapter (1-9)				
<i>multi-level</i>		<i>bronze</i>	<i>silver</i>	<i>gold</i>	
4	X consecutive usage days	3	5	15	
5	X total answered questions	50	500	1000	
6	X perfect weekly challenges	1	5	10	

Figure 2: Initial Badge Design

2.4.3 Highest Streak

According to prior research, the sequence of learning days can play a decisive role in determining learning success [21]. Continuous learning is considered to be better suited for knowledge retention than concentrating the same learning time on a few days. The goal of the badge in the fourth category in Figure 2 was to promote a continuous learning strategy. Using the app for several continuous days can manifest a habit, making it easier to learn for the days to come. The extent to which this learning strategy was used is measured by the learning metric “Highest Streak”. It states the highest number of consecutive usage days of a user in each semester. The intention of this badge was that a higher streak would lead to a better exam result. This badge is the first multi-level badge in Figure 2. The three stages are 3, 5, and 15 consecutive days.

2.4.4 Total Answers

The number of total answers given provides a basic estimate of the quantitative intensity of app usage. If a student has used the app frequently, this is necessarily indicated by a high number of answered questions. In comparable studies with data from learning management systems, such a conclusion is not so simple, since, for example, documents can also be read, but the actual reading time is not necessarily reflected in the log data [8, 13]. The click on a document in an LMS is captured, but usually there is no data about how long (and focused) the document was read. However, since there is no information to be passively consumed in the app other than feedback messages after a question, there is no reason to believe that a student remains studying at a single question for an extended time after answering it. If a student uses the app more, it presumably means that he or she learns more in general. On the one hand, it is proof of the fact that the student learns directly in the app. On the other hand, more intensive app use can also be a proxy for the fact that the student generally learns more and, for example, also engages more with the other learning materials. Nevertheless, this metric is a purely quantitative measurement without a qualitative assessment of the learning strategy. For example, a student with a certain number of answers that are all false has the same value of this learning metric as a student with exclusively right answers. However, as more learning time is considered to lead to better performance, this badge was designed to motivate a higher degree of usage time [4, 27]. This badge is the second multi-level badge in Figure 2 and is awarded for the stages of 50, 500, and 1000 answers.

2.4.5 Weekly Challenges

Competitive students are considered to be more motivated to achieve a better result in the final exam [6]. Therefore, the last badge in Figure 2 should motivate to participate in the Weekly Challenge. As the Weekly Challenge is entirely voluntary and no real rewards can be earned, an intensive use of this mode is considered a good proxy for a student to be highly competitive. The influence of this badge is analyzed with the learning metric “Weekly Challenges”, measuring the number of Weekly Challenges a student participated in. This multi-level badge is awarded for the stages 1, 5, and 10 Weekly Challenges.

3. RESULTS

3.1 Evaluating Initial Badges (RQ 1)

The following analyses examine whether the badges initially implemented in the app motivate successful learning strategies. For this purpose, I examine whether the students who earned the badges achieved a better grade on average than the students who did not.

Table 3: Unique Questions

Badge	Grade Average	n
No	2.84	799
Yes	1.95	53

Table 4: Maximal Chapter

Badge	Grade Average	n
0	3.37	137
1	3.34	87
2	3.21	88
3	3.22	79
4	2.74	54
5	2.54	43
6	2.61	27
7	2.92	25
8	2.56	45
9	2.13	267

Tables 4 and 5 show the average grades of the students who received the different badges based on the learning metrics “Unique Questions” and “Maximal Chapter”. In Table 4, it can be seen that the average grade of the students who answered all 551 questions is better than that of the comparison group. A similar picture emerges for the learning metric

Table 5: Highest Streak, Total Answers, Weekly Challenges

Badge	Highest Streak		Total Answers		Weekly Challenges	
	Grade Average	n	Grade Average	n	Grade Average	n
none	3.00	539	3.38	226	3.13	432
bronze	2.43	200	2.94	284	2.55	335
silver	2.41	108	2.36	134	1.93	56
gold	2.46	5	2.21	208	2.07	29

“Maximal Chapter”. The general trend shows that the more chapters have been unlocked, the better the average grade of the students. Although the trend is not ascending in every chapter step but has a small bump at chapters 3, 6, and 7, the result suggests that students who unlock more chapters perform better in the exam.

The following analyses examine the multi-level badges in the initial badge set (see Table 5). Students are divided into four groups: Those who did not achieve even the smallest stage, and those who achieved at least bronze, silver, or gold, respectively (see Figure 2). Here, too, the average grades in the final exam are compared group by group. Again, the trend for all three badges is that the higher a student climbs on the badge levels, the better the average grade on the exam. However, the effect size differs from badge to badge. For the badge “Highest Streak” the average grade improves by 0.54 to 0.59 depending on which stage was reached. Nevertheless, it should be noted that the gold stage was only achieved by 5 students. This already indicates that the highest stage may have been set too high. The average grade difference between the students who did not achieve any badge in the category “Total Answers” and those who achieved gold status is exceptionally high. Students who have not achieved any of the three levels obtained an average grade of 3.38 while students with a gold badge had an average grade of 2.21. The badge “Weekly Challenges” also shows that students at the higher levels tend to have better average grades. However, students with a gold badge have a slightly lower average grade (2.07) than students with a silver badge (1.93). The analysis of this badge also shows (although not quite as strongly as “Highest Streak”) that the higher levels were only achieved by comparatively few students suggesting that the thresholds were set too high. In summary, however, all initially created badges seem to motivate learning strategies that lead to better grades. The first research question (see Section 1) can therefore be answered affirmatively.

3.2 Evaluating Stages of Multi-Level Badges (RQ 2)

Still, as indicated in the previous analyses, the designs of initial badges should be further investigated to answer the second research question. Since the thresholds of the multi-level badges were based on common sense but not empirically validated due to a lack of data, I analyze in the next step, whether other stages are more appropriate to provide an optimal motivational effect. For this purpose, a decision tree will be generated with the app usage data as independent variables and the exam grades as dependent variable. The idea of such a decision tree is to determine the boundaries of the learning metrics that are best suited to divide the group into different subgroups. In other words,

at what level of the metrics is the difference between the group that exceeds the level to the group that does not exceed the level the greatest. For example, if all students who answered more than 3,000 questions have a 1.0 on the exam, it would seem to make little sense to include another stage at 4,000 answered questions. Since the discussed learning metrics are at least partially related (e.g., higher maximum chapter necessarily results in higher unique questions), all learning metrics are examined simultaneously. Moreover, all badges and not only the ones originally created as multi-level are considered in the calculations. This will allow to identify whether there are reasonable thresholds for single-level badges as well, and whether they should therefore be converted into multi-level badges. The result of the corresponding decision tree is shown in Figure 3.

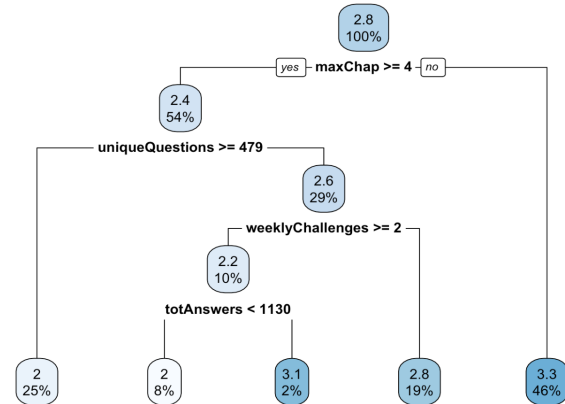

Figure 3: Decision Tree with Initial Badges

The decision tree can be interpreted as follows. “Maximum Chapter” is the most important learning metric for group classification in the data set. The average grade for all students is 2.8. For students who have only worked on chapters 1 to 3, the grade average is 3.3, and for students who have worked on at least chapter 4, the grade average is 2.4. The result can be interpreted in such a way that, for example, the badge for chapter 4 should be particularly highlighted, as it seems to mark an important threshold. In the next step, the learning metric “Unique Questions” is used for further subdivision. If students have answered at least 479 unique questions, the grade average improves to 2.0, if not, it declines to 2.6. The badge for “Unique Questions” has so far only been awarded if all questions, i.e. 551, have actually been answered. The data show that a change should be considered, and the badge should be changed from a single-level to a multi-level badge with one level at around 479. In the

next step, the group with less than 479 unique questions is subdivided according to the metric “Weekly Challenges”. If a student participated in less than 2 Weekly Challenges, the average grade worsens from 2.6 to 2.8. If the number of Weekly Challenges is at least 2, the average grade increases to 2.2. Since the smallest level of this multi-level badge was 1, the result not necessarily indicates a need for action at this point. In the last step, the group is subdivided based on the “Total Answers”. However, the subdivision goes in the opposite direction at this point. The average score improves to 2.0 if less (!) than 1,130 questions were answered. If more than 1,130 questions are answered, the average grade deteriorates to 3.1. Therefore, it does not seem to be a good strategy to simply answer as many questions as possible. However, it should be emphasized that this advice includes all the subdivisions made previously, so the limit of 1,130 answers should not be considered in isolation. In addition, it should be emphasized that “Highest Streak” was also included in the analysis but is apparently not suitable as a criterion for subdividing the groups.

3.3 Group Comparison

As discussed in Section 2.2, the data used in this study only comes from students who gave consent to sharing their usage data for research purposes. As all other usage data cannot be connected to exam results, it is omitted from the analyses in this study. This circumstance entails the risk that the corresponding results can only be interpreted considering a selection bias. Table 6 contains the result of the group comparison regarding the learning metrics of all active users that gave consent to share their usage data with the students who did not:

Table 6: Group Mean Comparison (Active Users)

Consent	Yes (n=838)	No (n=1,023)
Unique Questions	254.13	170.08
Maximal Chapter	5.42	4.04
Highest Streak	2.77	2.22
Total Answers	649.81	405.38
Weekly Challenges	1.79	0.95

The results show that there is a substantial difference between the two groups. An evaluation of every difference with a two-sided t-test showed a high significance in each comparison ($p < 0.01$). Users who have entered their matriculation number in the app and thus consented to the use of their data for research purposes are more active in the app than those who have withheld this consent. As the analyses in the preceding sections only contain the data from the subgroup who gave consent to the usage of their data, the effects of the learning metrics on exam score from the examined subsample cannot be unconditionally generalized to the whole sample due to a selection bias.

4. DISCUSSION

The objective of the present study was to develop an approach to test the design of badges in a gamified learning app with respect to the motivation of optimal learning strategies. In the first step, I examined whether the badges developed for the launch of the app motivate learning strategies that lead to better grades. This could be affirmed. In

the second step, I evaluated whether the levels of multi-level badges were optimally selected. A decision tree was developed for this purpose. The result of this analysis was that the originally selected levels could be optimized. However, as the decision tree output suggests a single threshold for each badge, a still open question is whether this threshold should be a replacement or if the future badge should only have two stages. This result could be considered in one of the next updates and in the following semester it could be checked if the newly chosen levels are optimal. This iterative process can also be applied to other learning applications. The major advantage of a decision tree here is that the results are very easy to interpret and transfer into practice. In my view, this advantage outweighs the disadvantages of this method (e.g., lower accuracy).

While the proposed process can be applied to other learning applications, the specific results for this project must be interpreted with caution. Due to the strict data protection rules at the university, I could not evaluate the data of all users, but only of those who gave us their permission to do so. This leads to a selection bias in the results. Thus, the effect of the badges cannot be confirmed for the entire cohort and therefore any adjustments to the badge architecture have to be made taking this issue into account. As previously described, one result of the study is that the levels of multi-level badges should be reconsidered. However, it could also be that certain learning strategies are not represented at all by the currently implemented badges. Therefore, in a future study, other learning strategies and the corresponding learning metrics will be developed and it will be examined whether these led to better exam results. If so, designing a corresponding badge to motivate the learning strategy would need to be considered. Until now, for example, the temporal aspect of the learning process has not been taken into account. Theoretically, the usage measured with most of the previously determined learning metrics could have taken place on one single day of the semester. More realistic are probably multiple days, but these could have been, e.g., shortly before the exam (indicating a cramming behavior) or directly at the beginning of the semester. A large body of research suggests that spaced repetition is best for optimal learning success [7]. If a student follows this strategy, he or she will have used the app on more days than a student who only started studying shortly before the exam and therefore followed a cramming strategy. This fact could be measured by a metric that states how many days in the semester a student has answered at least one question. In principle, it can be assumed that on average more learning days lead to a better performance in the exam. However, since there may also be an upper limit above which the marginal benefit decreases, a multi-level badge could be a suitable solution. Moreover, an early start could be decisive for successful course completion [23]. Therefore, the first use of the app in relation to the exam date could be measured in days. The extent of usage is measured by the metrics already discussed but this metric would measure whether a student started to use the app early in the semester. Therefore, students with an extreme cramming strategy, i.e., with the intention to start learning shortly before the exam would have a low expression of this figure. An implementation of this learning metric into the decision tree would show if there is a certain starting date that should be incentivized by a badge.

ABSTRACT

An online peer-assessment system typically allows students to give textual feedback to their peers, with the goal of helping the peers improve their work. The amount of help that students receive is highly dependent on the quality of the reviews. Previous studies have investigated using machine learning to detect characteristics of reviews (e.g., Do they mention a problem, make a suggestion, or tell the student where to make a change?). Machine-learning approaches to peer-assessment evaluation are heavily reliant on labeled data to learn how to identify review characteristics. However, attaining reliable labels for those characteristics is always time-consuming and labor-intensive. In this study, we propose to apply pseudo-labeling, a semi-supervised learning-based strategy, to improve the recognition of reviews that detect problems in the reviewed work. This is done by utilizing a small, reliably labeled dataset along with a large unlabeled dataset to train a text classifier. The ultimate goal of this research is to show that for peer assessment evaluation, we can utilize both unlabeled and labeled datasets to obtain a robust auto-labeling system and thereby save much effort in labeling the data.

Peer assessment, Problem detection, Natural language processing, Semi-supervised learning, Pseudo labeling

1. INTRODUCTION

Peer assessment has long been used as a pedagogical technique in project-based courses [10, 11, 13, 14]. An online system typically allows students to provide numerical scores and give textual feedback on other teams' work. It has been shown to be remarkably effective in improving students' learning and teaming skills [10]. Peer assessment can also help instructors evaluate student work and assign

grades to it. Double et al. [3] presented a meta-analysis suggests that peer assessment improves academic performance even more than teacher assessment. However, the reliability and validity of peer assessment are completely determined by peer-review quality [15]. High-quality reviews can help authors precisely identify issues with their work and make corresponding revisions. Low-quality reviews could be unhelpful or even detrimental to students' learning.

Hence, there is a growing interest in evaluating the review quality in peer assessment research [12]. However, having the instructors or TAs evaluate or grade all peer-review comments would be extremely time-consuming. Consequently, several studies have investigated machine-based automated review evaluation with the help of natural language processing techniques as well as machine learning, Nelson et al. [12] carried out a pioneering study on identifying high-quality reviews by investigating the features in the review text and determining what type of comments are most helpful and why. Xiao et al. proposed a machine-learning NLP-based approach for finding problem statements [18] (e.g., Do they mention any problems in the work that required revisions) and suggestions (e.g., Do they provide any suggested solutions on how to revise the work) [[23]] in the peer review comments.

As with most AI tasks, the biggest challenge for applying machine learning and deep learning algorithms to peer assessment is collecting labeled data [18]. Identifying whether review comments contain problem statements and suggestions is sometimes subjective, so the same review will be labeled differently by different students. This creates a major obstacle in collecting precise and reliable labels for the text analysis. Researchers have suggested approaches to tackle this problem of unreliable and insufficient labeling. Jia et al. [8] proposed an annotation process by two graduate students and measured the inter-annotator agreement between them to improve labeling validity. Xiao et al. [18] proposed to apply transfer learning and active learning to tackle the insufficient-labeling problem by using knowledge from a related task that has already been learned. All previous approaches required intervention from either human effort or out-of-domain knowledge; there is not a single study on peer assessment evaluation that has examined how to train a robust classifier on the data alone, and in particular how to

make good use of unlabeled dataset, which is much easier to collect. Semi-supervised learning has proven to be an effective approach to address these issues [6].

Semi-supervised learning is a learning paradigm that stands between unsupervised and supervised learning [6]. The goal of semi-supervised classification is to train a classifier that uses both a small labeled dataset and a large unlabeled dataset to outperform the traditional supervised classifier trained only on the labeled data. Basic approaches to semi-supervised learning involve a well-known technique called pseudo-labeling [9], in which method a classification model is first trained on the labeled dataset and then used to infer pseudo-labels on the unlabeled dataset. Then the unlabeled dataset with pseudo-labels is combined with the labeled dataset, so that the predicted labels are used as ground truth. This allows us to essentially scale up the labeled dataset in order to train a more robust model.

Xie et al. [19] conducted an extensive study on pseudo-labeling and presented a self-training method with “student” and “teacher” models on image classification tasks (note that “student” and “teacher” here are not referring to the user of the model), which achieved an outstanding result. The idea is almost the same as the pseudo-labeling approach. Initially a “teacher” model is trained on the labeled dataset and used to predict pseudo-labels on the unlabeled dataset, then a “student” model will be trained on the combination of the labeled and the pseudo-labeled dataset, these steps will be run iteratively. In each iteration, once the “student” model is trained, it will be used as the “teacher” model to generate predictions in the next iteration. This has proven to be a promising approach by creating more labeled data to address the data-insufficiency issue. Pseudo-labeling and self-training strategies have been widely applied in computer vision tasks [5, 19]. However, very few studies have attempted this approach in natural language processing tasks. This paper aims to apply natural language processing techniques and text-classification models to investigate the validity of applying pseudo-labeling to improve the performance of detecting characteristics in the peer review comments.

The main pedagogical contribution of this study to the peer assessment evaluation is to show how to deploy our student taggers (people who labeling the review data) more effectively and eventually build an auto-labeling system. More specifically, in our peer assessment system, the labels can only be collected from student taggers, and, if they are requested to label numerous comments, they may potentially become careless, resulting in the poor labeling quality. We could deploy them more successfully by applying the pseudo-labeling approach to build a text classifier for evaluating peer reviews with considerably less labeled data.

2. METHODOLOGY

2.1 Automated peer-review quality evaluation

Although peer review is a widely accepted approach in the educational setting, the effectiveness of peer review in promoting students’ learning can vary significantly. Most research has investigated the overall pedagogical contribution of peer review of writing. However, research on evaluating review quality is particularly lacking.

Nelson et al. [12] demonstrated that high-quality review has proven to be a great benefit in improving students’ learning. Their paper proposed an approach to determining what type of feedback is most helpful and why it is helpful to students’ writing performance. They also listed the features for identifying high-quality peer reviews. This study laid an excellent foundation for later research projects on automatically detecting characteristics of peer review comments.

The earliest study on automated peer-review quality evaluation was conducted by Cho et al. [1]. This study proposed a machine-learning algorithm to evaluate peer reviews collected from SWORD—a web-based reciprocal peer-review system. The review data was encoded for multiple characteristics such as problem detection, solution suggestion, etc., and then several traditional machine learning algorithms (Naive Bayes, SVM, and Decision Tree) were applied on the text-classification task to evaluate quality.

Subsequently, automated evaluation became increasingly fashionable in peer assessment. Xiong et al. applied supervised machine learning to automatically identify problem localization (pinpoint the location of where the problem is) [20, 22] and helpfulness [21] in peer review comments using NLP techniques. Zingle et al. [23] describe a method for automatically detecting suggestions in the review text, Xiao et al. [17] proposed to auto-detect problem statement in review comments.

Our study introduces an intriguing approach for automatically assessing review quality by detecting problem statements in the comments and applying a semi-supervised learning approach to address the problem of labeled-data insufficiency. Our goal is to help students get instant and accurate feedback on the reviews they write and enable them to improve their reviewing. This approach can also significantly reduce the workload of student taggers who label those characteristics in peer-review comments.

2.2 Semi-supervised Learning & Pseudo-labeling

Deep learning has achieved great success in the area of artificial intelligence; however, most of the state-of-the-art (SotA) models were trained using supervision, which required a large labeled dataset to attain excellent performance [6]. In most cases, labeling was a difficult and time-consuming task; even if we devote the time to do this, we would still be ignoring potential insights from the unlabeled dataset, which is far easier to collect in the real world. Semi-supervised learning has shown promise from using both labeled unlabeled data. The objective of semi-supervised learning is to improve learning behavior by combining labeled and unlabeled data, or equivalently, to achieve the same model performance with a relatively small labeled dataset.

Pseudo-labeling is one of the most effective and efficient methods in semi-supervised learning [9]. With pseudo-labeling, the initial model is trained on the labeled dataset:

$$D_L = \left\{ (x^i, y^i) \right\}_{i=1}^{N_L} \quad (1)$$

, where x^i represents each input, $y^i \subseteq \{0, 1\}$ is the corresponding labels where 0 represents “does not include prob-

Figure 1: Self-training workflow

lem statement” and 1 represents “does include problem statement”, N_L is the size of the labeled dataset. There is also an unlabeled dataset:

$$D_U = \left\{ (x^i) \right\}_{i=1}^{N_U} \quad (2)$$

where x^i represents each input without labels, and N_U is the size of the unlabeled dataset. In most cases $N_U \gg N_L$, so we believe that the unlabeled dataset may potentially contain more valuable features than the labeled set. Next, the model trained in the initial step generates predictions \tilde{y}^i as pseudo-labels on the unlabeled set D_U ; hence we can construct a pseudo-labeled set:

$$D_U = \left\{ (x^i, \tilde{y}^i) \right\}_{i=1}^{N_U} \quad (3)$$

where \tilde{y}^i will be used as the ground-truth label y^i to compute the loss in back-propagation in the next training phase, after this, another model is trained on the combination dataset:

$$D_C = D_L + D_U \quad (4)$$

and we believe that with more training data, the model will become still better.

Pseudo-labeling is often performed through an iterative process rather than one-step label generation. Self-training [19, 5] can be interpreted as an iterative pseudo-labeling approach. Defining the model used to generate labels as “teachers” and the model trained on both pseudo-labeled and labeled dataset as “students”, the two roles will be swapped in each iteration after incorporating more pseudo-labeled data into the labeled dataset (as shown in Figure 1). In this way, we can achieve our initial goal of improving model performance with the help of the valuable unlabeled dataset without human intervention or external knowledge.

3. EXPERIMENT

3.1 Datasource

The dataset we used in this paper comes from [Redacted] [4], a web-based peer review system that allows students to provide both numerical ratings and textual feedback to

other groups’ assignments. Each student must review multiple assignments and provide appropriate peer assessments to earn credits. The scores assigned by peer reviewers help the instructor or TAs to give a final grade to the assignments. The textual feedback also helps the authors to make revisions. Students have the chance to earn extra credit by labeling the review comments they received from the peer reviewers, and these labels support the construction of text classifiers for peer-review evaluation as ground-truth labels.

Student taggers label the review comments for whether or not they contain characteristics such as: problem statements, suggestions, and explanations. In this study, we only use the problem statement label. The quality of these labels cannot be fully guaranteed, but the success of training a robust model depends heavily on the quality of the ground-truth labels. We propose a data-filtering approach to select the review comments with the most reliable labels. When students use the [Redacted] system, up to four students on a team will label the same review comments they received on their team’s work. We will not select a review comment for the dataset if any team members disagree on the label (this will be defined as “taggers agreement rule” in the following section). Initially, 48,412 review comments with the corresponding labels were pulled from [Redacted] from the Fall 2017 to Fall 2020 semesters of a masters-level object oriented design class. After the raw data was filtered by the taggers agreement rule, 3100 pieces of “high-quality” labeled data were collected. Since our goal is to investigate the effectiveness of the unlabeled set, only a small labeled subset is required to train the initial model. Because of that, we extract 1600 review comments as the training set and 1500 as the validation set. The remaining 45,312 review comments that do not follow the taggers agreement rule will have their labels stripped and used as the unlabeled dataset.

Another motivation for pseudo-labeling is to compare the effectiveness of this strategy on different sizes of labeled datasets. If the amount of labeled data required can be reduced without harming the model performance, our approach can have a great impact on peer-assessment evaluation. For this paper, we conducted multiple experiments with different sizes of labeled sets. We will report only which size brings the most improvement after applying our strategy, rather than comparing model performance between different-sized datasets, as it is an indisputable fact that more labeled data will produce a better result.

3.2 Model implementation

Comparing the performance of different deep-learning models was not a goal of this study; hence we will only select one language-classification model to train both the teacher and student models. We use the transformer-based language model known as Bidirectional Encoder Representations from Transformers (BERT), which was first introduced by Google in 2019 [2]. Transformers apply a specific self-attention mechanism, which is designed for language understanding [16]. Self-attention emphasizes which part in an input sentence is crucial to the understanding. The transformer is an encoder-decoder-based architecture consisting of a standard feed-forward layer and a special attention layer, as shown in Figure 2 [16].

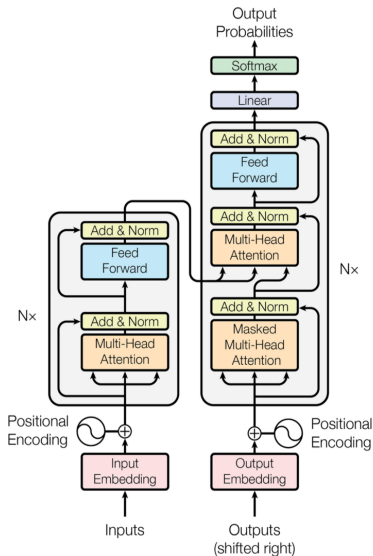

Figure 2: The Transformer - model architecture [16]

The traditional language model reads the input sentence in a single direction, either left to right, or right to left, which is enough for the task of next-word prediction. However, for a deep understanding of the sentence, the context is necessary. For a given word, considering both the previous and next token is valuable in learning the text representations, which is why the BERT model can achieve such superior performance on language-understanding tasks.

The BERT model consists of several layers of transformer blocks; the base model has 12 layers with 110 million parameters. By comparison, the large model has 24 layers with 340 million parameters [16]. Note that the BERT model only uses the encoder part of the transformer, which is responsible for reading the input text and processing it. In this study, we will only apply the BERT base model, considering the training efficiency.

The BERT model is trained in two phases, pre-training and fine-tuning. Pre-training includes two NLP tasks: Masked Language Modeling (MLM) and Next Sentence Prediction (NSP), using 3.3 billion words from Wikipedia and BooksCorpus; note that all data is unlabeled. Then the pre-trained model is used for the downstream NLP tasks in the fine-tuning phase, like text classification. In our study, we simply used the pre-trained BERT base model, then fine-tuned the model by feeding our peer-review data to carry out the text-classification task.

3.3 Pseudo-labeling setting

As mentioned in Section 2.2, we initially trained a teacher model only on the labeled dataset. We aimed to assess the improvement achieved by our strategy with three different sizes of the labeled set. Accordingly, 400, 800, and 1600 labeled reviews were randomly selected from the training set. These samples were used to train the initial teacher model and later combined with pseudo-labeling data to train the student model in the self-training loop.

After the pseudo-labels are generated on the unlabeled dataset, another attractive experiment is to investigate whether we should use the entire pseudo-labeled dataset, or just a part of it, to train the student model. There are three common approaches for selecting the pseudo-labeled subset. We define them as—

- **Full selection:** Combine the entire pseudo-labeled set with the labeled set to train the student model.
- **Random selection:** Randomly select a subset from the pseudo-labeled set and combine it with the labeled set; the labels of the remaining samples will be stripped, and those samples will be considered as the unlabeled dataset in the next iteration.
- **Top- $k\%$ selection:** Follow almost the same steps as random selection, except for the sampling method, as shown in Figure 3, the teacher model will retain the prediction score while generating the pseudo-labels, and then only the samples with the $k\%$ highest prediction scores will be selected.

For this paper, we use the Top- $k\%$ selection method to create the subset of the pseudo-labeled dataset in each iteration. This proved to be an effective way to address the confirmation-bias issue (Section 3.4), below. In our study, $k = 100\%$ (same as full selection) was chosen as a baseline, and the $k = 10, 20, 40\%$ were selected for the experiment.

As previously mentioned, pseudo-labeling is implemented as an iterative process so top- $k\%$ selection will be applied in each iteration. Once a pseudo-labeled subset has been selected, the remaining pseudo-labeled data is used as the unlabeled set and new predictions are generated from the teacher model in the next iteration. We ran this process 10 times (epochs = 10) and for consistency, the entire pseudo-labeled dataset will be fed into the model in the last iteration.

3.4 Handling confirmation bias

Machine-learning models predict incorrect labels when they are unable to learn enough patterns from the data. In pseudo-labeling, overfitting the student model to these incorrect labels predicted by the naïve teacher model is defined as confirmation bias. This leads to a significant impairment of the pseudo-labeling strategy. Initially, the teacher model could well be affected by noise, especially with very little labeled data being trained. Although this cannot be avoided fundamentally, there are still some approaches that can help reduce the effects of confirmation bias.

3.4.1 Top- $k\%$ selection

As mentioned in section 3.3, random selection would potentially perform better than full selection as it can alleviate the negative impact of bias, since only a subset of the pseudo-labeled data will be fed into the model in each iteration. In this way, relatively less bias will be introduced into the model.

Instead of randomly selecting the subset, the top- $k\%$ selection method is based on the prediction scores generated

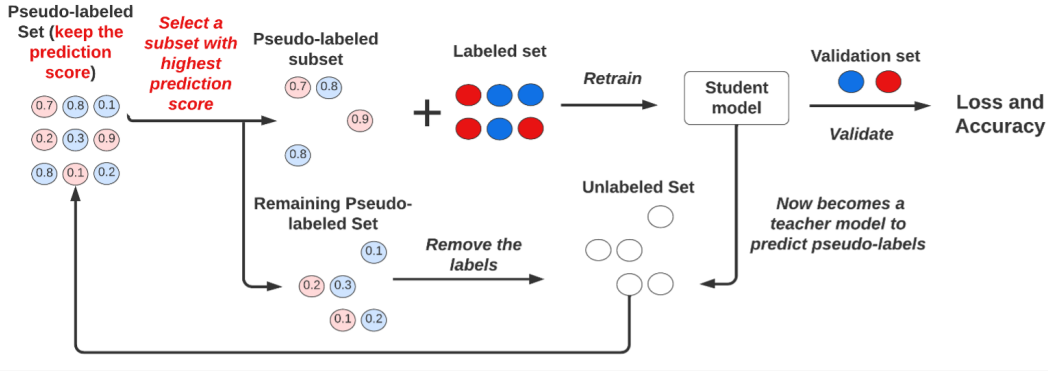

Figure 3: Top- k % selection workflow

by teacher models. Only the data points with the highest predicted probability score will be selected and included into the labeled set. The theoretical justification for this is similar to entropy regularization [7], which is another semi-supervised learning technique that encourages the classifier to infer confident predictions on the unlabeled dataset. For example, we would prefer to assign the unlabeled data a high probability of belonging to a particular class, rather than diffuse probabilities across different classes. However, this confidence-based approach must assume that the data are clustered according to class, which means that neighboring data points should have the same class, while the points in different classes should be widely separated.

3.4.2 Weighted loss

Another approach to handling confirmation bias is to re-define the cross-entropy loss as a weighted summation between the labeled and pseudo-labeled set. Initially, the naive teacher model is incapable of generating reliable pseudo-labels. If we simply add the unlabeled loss to the labeled loss, especially when the size of unlabeled dataset is much larger, the model tends to overfit on the unreliable pseudo-labeled data and consequently generate wrong predictions.

Therefore Lee et al. [9] proposed to use weight in the loss function. The overall loss function looks like this:

$$L = \frac{1}{n} \sum_{m=1}^n \sum_{i=1}^C L(y_i^m, f_i^m) + \alpha(t) \frac{1}{n'} \sum_{m=1}^{n'} \sum_{i=1}^C L(y_i^m, f_i^m) \quad (5)$$

In simple terms, the equation can be interpreted as follows: Loss per Batch = Labeled Loss + Weight \times Unlabeled Loss. In this equation, the weight (alpha value) is used to control the contribution of the unlabeled loss to the total loss. The value is initialized small and slowly increases during the model training. Since few training epochs are needed to fine-tune the BERT model for text-classification tasks, it does not seem necessary to define the alpha as a function of time. Therefore, in this study, we simply initialize the alpha value to be 0.1 and increase it by 0.1 in each epoch.

Considering the obstacle of calculating the loss after combining the labeled and pseudo-labeled sets, we designed the experiment as training on the pseudo-labeled set for each epoch and calibrating on the labeled set every three epochs. The

	Accuracy			F1 score		
	Initial	Final	Imp	Initial	Final	Imp
<i>Training with 400 labeled data</i>						
Baseline	85.3%	84.7%	-0.6%	83.4%	82.1%	-1.3%
k=10%	85.3%	91.8%	6.5%	83.4%	90.6%	7.2%
k=20%	85.3%	90.5%	5.2%	83.4%	87.7%	4.3%
k=40%	85.3%	90.2%	4.9%	83.4%	88.1%	4.7%
<i>Training with 800 labeled data</i>

k=40%	89.8%	91.7%	1.9%	87.2%	88.8%	1.6%

Table 1: The improvement of accuracy and F1 score

alpha value is multiplied by the pseudo-labeled loss in each epoch and increases during the training iterations, while the labeled loss will remain the same.

4. RESULTS

Figure 4(a) displays the learning curve of validation accuracy and Figure 4(b) displays the F1 score, with different sizes of labeled data over 10 epochs. The performance of different values for k are compared in each plot. Table 1 demonstrates the measurement before and after applying the pseudo-labeling method. Our goal is to compare the improvement in each experiment setting to assess the effectiveness of the Top- k % selection approach and the impact of the labeled data size.

RQ1: Does the pseudo-labeling improve the model performance?

We can see from Figure 4 that in general the learning curve is continuously rising with each experiment setting, and all settings achieved a significant improvement in the last epoch, except where $k = 100\%$; we will analyze this in the following section. These results undoubtedly show that by applying the pseudo-labeling approach, we can obtain a robust classifier using a large unlabeled dataset.

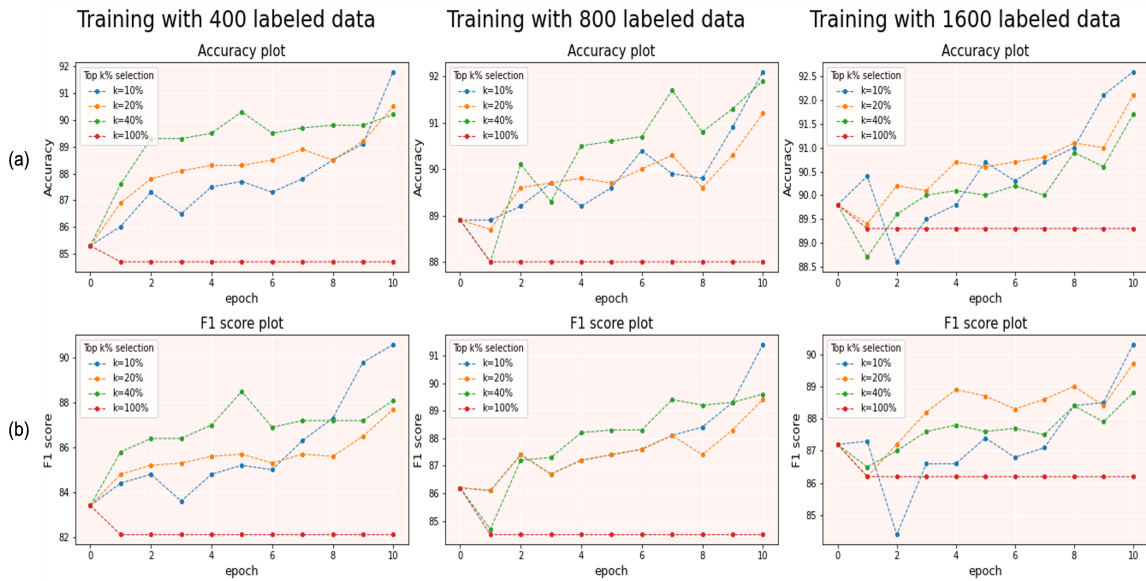

Figure 4: Validation accuracy and F1 score for different size of labeled subset

RQ2: Does the top- $k\%$ selection approach help reduce confirmation bias?

We use $k=100\%$, with the entire pseudo-labeled dataset selected as the baseline, to assess the effectiveness of the top- $k\%$ selection approach. As shown in Figure 4, the learning curve of $k=100\%$ for each setting does not change over epochs and there is a notable drop in the early epochs, indicating that the pseudo-labeling does introduce bias into the model training in the absence of top- $k\%$ selection.

Both Figure 4 and Table 1 illustrate that the improvements are slightly different with a different k value; $k = 10\%$ yields the best result regardless of the size of the labeled dataset. Table 1 shows that on an average we are able to achieve 4.4% improvement in accuracy and 5.4% improvement in F1 score with $k = 10\%$, which is higher than with the other k values. This result clarifies that by selecting the pseudo-labeled subset based on the prediction score, we can obtain high-confidence predictions as reliable labels. The result also supports the cluster assumption in our case, which means that the review comments containing the problem statement are distinguishable from the comments not containing it.

RQ3: Does the pseudo-labeling work better on a small labeled set or large labeled set?

From Table 1 we can clearly see that regardless of the k value, the overall improvement on the small labeled set is comparatively higher than on the large labeled set, which indicates that the pseudo-labeling strategy works better on the small labeled set. This also implies that the unlabeled dataset can be more valuable than labeled set in certain practical problems, and using the unlabeled set can significantly improve the learning accuracy.

5. CONCLUSIONS

This paper presents a semi-supervised learning approach based on pseudo-labeling for evaluating peer-assessment quality. We investigated the effectiveness of the pseudo-labeling

technique for different sizes of the labeled set. The results indicate that our approach can achieve an outstanding result with a small labeled dataset by augmenting it with an unlabeled set. The main contribution of this study to the peer-review process is the fact that not much labeled data is required to detect problem statements in peer-assessment comments; our student taggers do not have to label so much data. With less labeled data required, student taggers can be more careful to assign correct labels. In addition, we can find some better filtering approach to extract the smaller “high-quality” labeled data, which can greatly facilitate building our automatic labeling system.

Although we achieved a good result by using the top- $k\%$ selection approach as well as the weighted loss function to handle confirmation bias, the same success is not guaranteed on other tasks: confidence-based selection approaches are not always applicable; they will not work well without the cluster assumption.

The results of this study point the way to more efficiently analyzing review comments. Our pseudo-labeling approach can easily calculate how much labeled data for each characteristic is required for training a robust text classifier. For example, given a 91.8% classification accuracy in problem detection achieved with only 400 labeled data (a 6.5% improvement from supervised training alone), we can save a lot of labeling effort—effort that can then be devoted to identifying other salient review characteristics. Further research can explore better filtering approaches (similar to the tagger-agreement rule) for extracting small quantities of higher-quality labeled data in order to build a more reliable auto-labeling system.

ABSTRACT

Research into "gaming the system" behavior in intelligent tutoring systems (ITS) has been around for almost two decades, and detection has been developed for many ITSs. Machine learning models can detect this behavior in both real-time and in historical data. However, intelligent tutoring system designs often change over time, in terms of the design of the student interface, assessment models, and data collection log schemas. Can gaming detectors still be trusted, a decade or more after they are developed? In this research, we evaluate the robustness/degradation of gaming detectors when trained on older data logs and evaluated on current data logs. We demonstrate that some machine learning models developed using past data are still able to predict gaming behavior from student data collected 16 years later, but that there is considerable variance in how well different algorithms perform over time. We demonstrate that a classic decision tree algorithm maintained its performance while more contemporary algorithms struggled to transfer to new data, even though they exhibited better performance on unseen students in both New and Old data sets by themselves. Examining the feature importance values provides some explanation for the differences in performance between models, and offers some insight into how we might safeguard against detector rot over time.

Intelligent Tutoring Systems, Gaming the System, Detector Rot

1. INTRODUCTION

Adaptive systems like intelligent tutoring systems (ITSs) depend on inferential models to understand and respond to individual students. Some of these systems and models have now been applied to modeling knowledge and behavior for decades [7]. For instance, Bayesian Knowledge Tracing (BKT) models have been used in ITSs for almost 30 years [11]. Even the use of more complex machine-learned models now has an extensive history; for example, gaming the system models which predict when students are attempting to find ways other than learning to advance through the system [2, 5, 26], have been in use for 18 years.

Gaming the system models are used for several purposes, including evaluating the quality of content [13, 24], research on the longitudinal impacts of disengagement [1, 34], and automated intervention [3]. Even as ITSs have become more adaptive and user interfaces have become more engaging, students have continued to find ways to disengage from these systems [38].

While BKT models are easily and frequently refit in industrial practice, models of constructs like gaming the system require

supplementary data collection beyond the standard logged data stream, in order to create new training labels. As a result, they are expensive to fit and are not refit often. Is this a dangerous practice?

An analogy can be made to code rot, a phenomenon in computer software where over time systems degrade in performance due to their reliance on aging library dependencies, hardware updates, and breakdown in the structural integrity of design patterns [18]. Models developed through machine learning and artificial intelligence (AI) may suffer a similar fate, "detector rot", where a model stops functioning as expected over time. When a piece of code simply fails to work, it is obvious, but there may be less obvious failure modes for machine learned models. Machine Learning packages change in their functionality over time and become obsolete; just because a model is still runnable does not necessarily imply that it is functioning in the same way. This problem has been noted in machine learning research in general, where many past research results can no longer be reproduced [17].

Furthermore, even if a model is functioning the same way as it did a decade ago, that does not mean that it has not experienced a form of decay. There is more to decay in a model over time than just reproducibility. Take the Cognitive Tutor [31], the system which many of the first models detecting gaming were developed for [2, 6]. The design and interface of Cognitive Tutors have gone through significant changes over the years (and the system has been re-branded MATHia). The changes over time involve both cosmetic changes and changes in pedagogical strategies and content. We elaborate further on these changes in a dedicated section below. Students, teachers, and learning contexts also change over time. In 1995, Janet Schofield reported many students in Pittsburgh skipping lunch and staying after school to use ITSs [35], a behavior not commonly reported in U.S. classrooms today. ITSs are much more prevalent in classrooms than even 10 or 15 years ago, students and teachers are more familiar with instructional technology, and students use technology at-home more often compared to an earlier focus primarily on classroom use [16]. Students today are also much more likely to be comfortable quickly locating information on the internet and may expect this same immediacy in their interaction with ITSs [36]. As such, detector rot may be as much a problem of generalizability as reproducibility -- the model might have been completely valid in 2008, and may even still function exactly the same way, but may not be valid anymore in 2021. As such, we can and should ask: will models trained on older data (in this case, 2005) maintain accuracy when tested on current data (2021)? Beyond this, has student gaming behavior changed over the last 15 years as indicated by different features becoming more/less important when detecting gaming behavior?

This question seems on its surface to be a question about algorithm effectiveness *today*, based on historical models. But it is also important to ask, do we have any reason to believe our models will work *tomorrow*? One challenge in answering this question is that the algorithms we use today are different than those used fifteen years ago. Significant advances have occurred in machine learning algorithms over the last 16 years [20]. We can have somewhat more confidence in the potential of today's algorithms to work tomorrow,

by conducting an anachronistic form of analysis -- applying current algorithms to older data and seeing how well they work on contemporary data. One class of algorithm that has seen recent success is gradient boosted descent trees. The eXtreme gradient boosting package (xgboost) [10] has met and surpassed state of the art results across a variety of machine learning applications including the detection of gaming the system [30]. Contemporary machine learning algorithms generally achieve better predictive performance than older algorithms, as the proceedings of this conference over the last few years shows. Will contemporary machine learning models also be more robust over time than older algorithms?

To answer these questions, this paper compares the functioning of gaming detectors over time, using data sets from 2005 and 2021. We will evaluate the effectiveness of a model trained on data from 2005 and tested on data from 2021. We will also compare which features are most important within models trained on the Old data to which features are most important in models trained on the New data, to see whether the behaviors that are predictive remain consistent over time. Additionally, we will then apply a variety of machine learning models including both classic algorithms and contemporary algorithms, to determine if each of these types of algorithms is robust to changes over time.

This paper will begin by discussing how the system being studied (MATHia/Cognitive Tutor) has changed over time, and how these changes may impact the manifestation of gaming behavior. In the methods section we describe the process of obtaining training labels for newer data, the feature set implementation, and the modeling process. Next we present results, comparing models' performance over time and dig deeper into the most important features of the most effective models. We discuss potential implications for practice in the use of detectors in real-world learning systems, and finally conclude with a synthesis of our findings and potential avenues for future research.

1.1 Mathia

We studied the issue of detector rot using log data generated by Carnegie Learning's MATHia (formerly known as Cognitive Tutor -- [30]) ITS at two time periods separated by approximately 16 years (2005 and 2021). Throughout their histories, MATHia/Cognitive Tutor has been the software component of a typically blended core curricula for middle school and high school mathematics. In blended, core implementations, Carnegie Learning recommends a mix of collaborative classroom work guided by its paper worktexts (60% of instructional time) as well as individual student work (40% of instructional time) in the ITS. MATHia/Cognitive Tutor presents students with complex, multi-step math problems mapped to fine-grained skills (often also referred to as knowledge components/KCs; [23]). Within each problem, the ITS provides context-sensitive help and feedback, sensitive, for example, to particular solution strategies a student might adopt (e.g., surfacing feedback that an incorrect answer reflects an inappropriate problem-solving strategy). Implementing mastery learning [33], the ITS tracks students' progress to mastery of KCs using an implementation of Bayesian Knowledge Tracing (BKT; [11]) and presents problems to students until they demonstrate mastery of all KCs associated with each topical lesson or "workspace." When a student has mastered all KCs in a workspace, they are moved on to the next workspace in an assigned sequence of workspaces, typically corresponding to a course like Algebra I or Grade 6 Math. Within MATHia, the tutor judges a KC as mastered when the student reaches a 0.95 probability estimate for having mastered that KC.

Timestamped log data track student actions (e.g., making a problem-solving attempt, requesting a hint) at each step of problems within each workspace, as well as feedback from the ITS (e.g., a correct response or that an error triggers just-in-time feedback because it reflects a common misconception, etc.). Data also track the input values provided by students, the KC to which a particular problem-step is mapped, and BKT's ongoing estimation of a student's probability of having mastered the KC.

1.2 Mathia Changes Between 2005 and 2021

In general, the Cognitive Tutor Java application of 2005 was more compartmentalized (with multiple windows displaying problem-solving elements) than the more contemporary web-based delivery of 2021. One prominent difference in the layout of the user interface concerns the extent to which the "skillometer" for visualizing student progress to skill mastery has evolved from a display that was "expanded" by default (displaying skill names and progress to mastery) to a more visually compact representation (circles that "fill" as students make skill progress) that can be expanded by the student to see their progress in more detail.

Changes have more recently been implemented in how BKT tracks student progress to skill mastery, especially related to how the student's use of hints impacts their knowledge estimates. First, hints are now delivered in MATHia with a delay between "hint levels." After the student requests an initial hint, which typically re-states the goal for the current problem-solving step, there is a delay of a few seconds before the student can request another hint, which provides detail on how to accomplish the goal. This initial delay and short delays for each additional hint are designed to encourage reflection on the help requested and discourage students from rapidly seeking the "bottom out" hint, which provides the answer [2]. In the Cognitive Tutor circa 2005 (and for many subsequent years), a student's request for a hint on a first attempt at a problem-solving step was treated as an incorrect response, resulting in a decrease in the ITS's estimate of skill mastery. The 2021 version of MATHia only treats the "bottom out" hint that presents the student with the answer as an incorrect attempt. Correct attempts after an initial hint are now credited (i.e., skill mastery estimates increase) like immediate correct attempts, and correct attempts after mid-level hints now leave the skill mastery estimate unchanged. In addition, MATHia's BKT parameter estimates for each skill (used to determine the models' responsiveness to correct and incorrect answers) are now frequently set based on data-driven estimation techniques [32, 39] as opposed to mostly being set according to expert judgment in earlier Cognitive Tutor versions.

2. METHODS

2.1 Labeling Gaming Behavior

We obtained the data set used to develop the gaming detector in [6]. This original detector was a J48 (C4.5) decision tree classifier [29] built using training labels developed using text replays. Text replays allow coders to directly label "clips" (segments of log data), presented as a sequence of actions and their context [4]. Text replays have been used in a range of projects as a fast and accurate method to label a range of types of student behavior for classifier development within various types of learning systems [4, 6, 12, 26].

For the older data set [6], we obtained data from the PSLC DataShop [22], data set "Algebra I 2005-2006 (3 schools)", including both training labels derived using text replays and partially-distilled log data. 18,737 training labels were included in that data set.

The New data set was obtained directly from the Mathia team (this data set is not currently on DataShop, due to government-agency-level contractual restrictions on data sharing). We conducted an identical text replay approach to [6], obtaining the original text replay software from the first author of that earlier work. We used a textual sequence of student activity of a duration of 20 seconds or 8 actions (whichever occurred last) from MATHia’s log data as a clip for labeling. Every clip contained the student ID, timestamp of each action (in relation to the first action in clip), the problem name and step, student’s input, relevant knowledge/skill production and system estimate, and the outcome as assessed by system (correct, a misconception (bug), wrong answer, a request for hint (initial or a deeper level). This set of clips was then coded for gaming the system behavior.

“Gaming the system” behavior was defined as the learner misusing the system’s help and feedback to get correct answers and advance in their trajectory within the ITS [6]. A clip was labeled as gaming the system when a learner asked for hints in quick and repeated successions until the system revealed the answer, or systematically input answers rapidly until they got the correct one. For example, a student entering a sequence like "1,2,3,4,5,6,7,8" in rapid succession would be labeled as engaging in gaming behavior. For further detail on the behaviors treated as gaming the system in the coding process, please see [27].

For the more recent data set, two coders (2nd & 3rd authors) initially labeled 60 text replays to establish inter-rater reliability, and attained a kappa of 0.62, comparable to the original data set [6], and over the 0.6 cut-off often treated as standard for coding ill-defined constructs such as disengaged behavior [25]. Subsequently, the first coder labeled a total of 600 clips from which 6 were removed as unclassifiable. Out of the 594 labels, 31 were coded as ‘gaming’, and the remaining 563 as ‘not gaming’. Thus, around 5% of the total clips were coded as gaming for this data sample, which is in alignment with previously observed proportions of gaming behavior in ITS [6].

2.2 Feature Engineering

The features developed for this research are based on the original research published in [6]. In order to maintain fidelity with the original work we followed the process of creating the original features as closely as possible, but in order to make sure the features were comparable across data sets, we re-distilled the features for the original data set. The features are described in table 1.

All features were engineered on the full data-set of student log data, and then aggregated for the labeled clips. Each clip consists of a series of actions so the features were aggregated together to create a single row of data labeled as either gaming behavior or not. The aggregate columns created for each feature were: Count of non-null values, Mean, Standard Deviation, Minimum, 25th percentile, 50th percentile (median), 75th percentile, Maximum, Sum. In total, 17 features were distilled at the transaction level, and each of these 17 features was aggregated in 9 ways in the final training data. The final training data had $17 \times 9 = 153$ features.

Table 1. Gaming the System Features

Feature Name	Description
assess_CORRECT	correct answer
assess_BUG	error tracked by MATHia for just-in-time context-sensitive feedback (e.g., a known misconception, a number as input that appears in the problem but is incorrect); typically indicates a common mistake that the tutor knows how to respond to
assess_ERROR	error not tracked for feedback, i.e. less common mistakes
assess_INITIAL_HINT	first-level hint provided
assess_HINT_LEVEL_CHANGE	a "deeper" level of hint provided
pknow	The probability estimate that the student knows this skill based on internal Bayesian Knowledge Tracing model of the student's mastery of this skill
pknow_direct [8]	If the current action is the student’s first attempt on this problem step, then pknow-direct is equal to pknow, but if the student has already made an attempt on this problem step, then pknow-direct is -1.
duration	How many seconds the action took
duration_sd	duration expressed in standard deviations from the mean time taken for this problem step across all problems
duration_sd_prev {3,5}	sum of duration_sd for previous 3 and 5 actions respectively
wrong_attempts	total number of times a student has gotten this problem step wrong (including within past problems)
error_perc	percentage of past problems the student has made errors on this same problem step
help_and_errors_count	number of times the student asked for help or made errors on this skill across all previous problems
num_steps	count of attempts on this step for this problem
help_attempts_last8	How many times has the student asked for help in their last 8 actions
error_count_last5	How many errors the student has made in the last 5 actions (includes both BUG and ERROR)
problem_step_count_last5	how many of the last 5 actions involved the same problem step

2.3 Modeling

As in [6], we modeled gaming detection as a binary classification problem - a clip with gaming the system was labeled as 1, and

without as 0. We conducted three overall types of comparisons. First, we trained models on the Old data and tested them on the Old data (Old to Old). Second, we trained models on the New data and tested them on the New data (New to New). For the Old to Old and New to New comparisons, we used a 4-fold student-level cross validation in which we left out 25% of students from each training set. We then tested each model on the left-out set of students, pooled the labels from each split, and calculated metrics on the pooled labels. In our third comparison, we took a model trained using all of the Old data and tested it on all of the New data (Old to New), using the entire training set since there was no risk of any students being present in both data sets, given the 16 year gap. We did not train a model on the New data and test it on the Old data, as doing so would not answer our research questions. There are cases where it may be of interest to conduct the ahistorical analysis of training on newer data and testing on legacy data -- such as cases where labels cannot be obtained for past data -- but it is not relevant to this use case, since text replays can be conducted on legacy data.

There was considerable imbalance between the classes in the labeled data. 5.5% of clips in the Old data set were labeled as gaming behavior, and 5.2% of clips in the New data set were labeled as gaming behavior. In order to account for this imbalance, we over-sampled the minority class to achieve a 50-50 balance between the classes, in the training sets only (not in the test sets). For over-sampling the minority class we used Synthetic Minority Oversampling Technique (SMOTE) [9] to synthesize new training data, without undersampling the majority class, to preserve all data. We used the area under the receiver operating characteristic curve (AUC ROC) to evaluate not just the predictive accuracy of our models but also the performance of our model at all classification thresholds. AUC ROC is thought to be better at evaluating classifiers in cases with strong imbalance [19], as is seen here. Gaming detection probabilities are frequently used in research involving detectors [28, 30] rather than using a single threshold; AUC ROC indicates how effective a model is across confidence levels.

We applied a variety of classic (available at the time of the original publication of the gaming detector [6]) and contemporary machine learning models on both the Old and New data sets. We were uncertain that the specific original algorithm used in [6], the WEKA J48 implementation of C4.5 incorporated into RapidMiner 4.6, could be replicated exactly at this point, so scikit-learn’s DecisionTreeClassifier, which implements the similar algorithm CART (Classification and Regression Trees), was selected as a close substitute. Scikit-learn’s implementations of Neural Networks, Random Forest, and XGBoost were also used. Of these, only XGBoost was completely unavailable in 2008 [10]. All code for this research is available for reference on github at <https://anonymous.4open.science/r/CogTutorGamingDetectors-627E>.

3. RESULTS

3.1 Model Performance

The results of our analyses evaluating different classification models in our three training-testing scenarios are shown in Table 2. In the table columns, we can see the different combinations of training and testing.

All of the classifiers performed well when trained on the Old data and also tested on the Old data (Old to Old). The best performance was obtained by Random Forest, achieving an AUC ROC of 0.784. XGBoost was second-best with an AUC ROC of 0.763, and Decision Tree was third-best, performing 0.048 worse than Random Forest. We evaluated the statistical significance of the difference

between Random Forest and Decision Tree (the algorithm closest to the original paper), using the method outlined in [14] to conduct a Z test to compare the area under two ROCs. In this case, Random Forest was a statistically significant improvement over Decision Tree, $Z = 2.334$, two-tailed $p < 0.05$.

When detectors were developed for the New data and tested on the New data (New to New), performance was generally higher than for Old to Old, rising above 0.85 for Random Forest, XGBoost, and Neural Network. However, for Decision Tree the improvement was negligible, rising from 0.736 to 0.738. Random Forest still obtained the best performance out of any of the models -- an AUC ROC of 0.929 for New to New, statistically significantly better than the 0.784 obtained in the Old to Old model, $Z=3.764$, two-tailed $p<0.001$. Decision Tree, the algorithm closest to the algorithm used in the original paper, was the only model which did not improve significantly in performance on the New to New data set, $Z=0.03$, two-tailed $p=0.973$.

Table 2. ROC AUC for different models

Model	Trained on Old Tested on Old	Trained on New Tested on New	Trained on Old Tested on New
Decision Tree	0.736	0.738	0.716
Random Forest	0.784	0.929	0.509
Neural Net	0.649	0.879	0.398
XGBoost	0.763	0.921	0.333

Our primary research question was whether gaming detector models would degrade over time. This would be shown if the Old models achieved poorer performance when applied to New data (Old to New), compared to the within-year Old to Old and New to New comparisons. All three newer models showed some degradation in performance, but there was substantial difference in degradation between algorithms. The Old to New performance for Decision Tree (AUC ROC = 0.716) appeared to have a small decline in performance relative to Old to Old (AUC ROC = 0.738, a 0.022 decline) but the difference was not statistically significant, $Z=0.360$, two-tailed $p = 0.719$. The Old to New performance for Decision Tree (AUC ROC = 0.716) was also not significantly lower than the New to New performance (AUC ROC = 0.736), $Z=0.241$, two-tailed $p=0.810$, though again there was some appearance of slightly poorer performance.

By contrast, the Old to New performance for Random Forest (AUC ROC = 0.509) was statistically significantly worse than the Old to Old Performance (AUC ROC = 0.929), $Z=6.948$, two-tailed $p<0.0001$. It was also significantly worse than the New to New performance for that algorithm (AUC ROC = 0.784), $Z=3.380$, two-tailed $p<0.001$. The Old to New performance for Neural Network (AUC ROC = 0.398) was significantly worse than Old to Old Performance (AUC ROC = 0.649), $Z=4.445$, two-tailed $p<0.001$. It was also significantly worse than the New to New performance for that algorithm (AUC ROC = 0.879), $Z=6.826$, two-tailed $p<0.001$. The Old to New performance for XGBoost (AUC ROC = 0.333) was the worst of all, significantly worse than the Old to Old Performance (AUC ROC = 0.763), $Z=6.498$, two-tailed $p<0.001$. It was also significantly worse than the New to New performance for that algorithm (AUC ROC = 0.921), $Z=7.926$, two-tailed $p<0.001$.

All four algorithms were able to achieve much better than chance performance in the Old to Old as well as the New to New scenarios, but the three newer algorithms struggled to make predictions about the New data when trained on the Old data. Decision Tree was the only model able to transfer from Old Data to the New without dropping substantially in performance. Decision Tree's performance was essentially equal when applied to unseen students in the same data set and unseen students in a new data set, suggesting that it may not have overfit to the features of the learning system/population it was being applied to. The other three algorithms (all of them less conservative algorithms than Decision Tree) performed significantly worse when comparing Old to Old performance and Old to New performance. The drops in performance on newer models and the relative robustness of the more classic decision tree model indicates that not all algorithms may be equally prone to detector rot.

3.2 Feature Importance

To understand how gaming the system is associated with student behavior in the logs, and whether this differs between time periods, we examined the feature importances of XGBoost, the algorithm with the worst drop in performance (also the newest) and Decision Tree, the algorithm with the least drop in performance (also the closest to the original paper). In doing so, we compared the models trained on the Old data and New data. Doing so can also provide evidence on how student behaviors have changed or remained consistent over time. The XGBoost algorithm calculates the importance of each feature as the 'gain', i.e. "the improvement in accuracy brought by each feature across all splits the feature is used in" [39]. In the figure below we can see the top 15 features ranked by gain in both the Old and New models, for XGBoost.

Figure 1. XGBoost Old and New Top Features

For XGBoost, in the Old Data we see that the majority of the predictive power is taken up by the features generated by the ITS's response to the student based on the answer the student has given. In particular, we see that rates of correct (assess_CORRECT)

responses and incorrect (assess_ERROR, assess_BUG) responses throughout a clip are strong predictors of gaming behavior, as well as the use of hints.

In the XGBoost model for New data, we see features that are more related to time. The sum of the trailing count of how many of the last 5 steps were on the same problem (prob_step_last_5_sum) was the most important feature. This feature indicates that a student is taking many actions on the same problem step, which could indicate that they are trying to game the system by attempting to guess the correct answer. In the other top features, we see the average time spent on the previous 5 actions in standard deviation units based on the distribution of time spent on these problems by all students (dur_sd_prev5_mean), the minimum time spent on any action within the clip (time_min), and the average time spent on each action in standard deviation units (duration_sd_mean). This is more in line with features developed in previous gaming detectors [4, 3]. Additionally, we see more of a focus on student behavior features, like error counts and wrong attempts. This represents a contrast to the XGBoost model trained on the Old Data, where most of the features were derived from the correctness of student responses and whether their errors reflect common errors (perhaps reflecting genuine errors) or rarer ones (perhaps reflecting systematic guessing). The features around bugs may be vulnerable to change over time, as the list of bugs (and the messages in response to them) has changed over the years. Features around hints could also have been impacted by changes in hint message content (which may impact learning and therefore how often they are used by non-gaming students) and by the changes to credit given to non-bottom-out hints.

By comparison, when we look at the features used by Decision Tree, we see a very different pattern. In figure 2 we see that although features such as student rates of within-clip correct, incorrect, and bugs are relevant within the Decision Tree model for the Old data (as with XGBoost), the variety of types of features being used by the Decision Tree model built on Old data is broader than for XGBoost. For instance, we see a feature representing whether or not this is the student's first time attempting a particular problem step attempt on a problem within the clip (prob_first_att_max) in the top 6. We also see the 8th most important feature was pknow-max, assessing how high the student's mastery of the best-known KC in the clip is. These features, which are not present in the XGBoost model of the Old data, are helpful in understanding the student's relationship with the problems they are facing in a given clip. Overall, comparison of feature importances indicates that the decision tree was making predictions from more disparate features than XGBoost.

When trained on the New data, the Decision Tree focused on a very small group of features that were similar to the features most important to XGBoost when trained on the New data. Again, we see the sum of the trailing count of how many of the last 5 steps were on the same problem step (prob_step_last_5_sum) as the most important feature in the New data. In the case of the Decision Tree trained on New data, this feature was the most important by a wide margin. In the next four features there are two related to evaluating the correctness of student responses (assess_CORRECT) and two that are related to the number of errors made by students in the clip (error_count_last_5_50%, error_perc_sum). These features also showed up in the XGBoost feature importance table, although at slightly different positions. The relatively stable performance of Decision Tree may be due to the stability in the meaning of the correctness assessments as opposed to the bug and error assessments (which may have shifted more in meaning between versions, with errors becoming bugs as more errors were identified).

Figure 2. Decision Tree New and Old Top Features

4. DISCUSSION AND CONCLUSION

Our primary research question was the degree to which models of a complex educational phenomena such as gaming the system can be trusted over time. To investigate this question, we analyzed whether gaming detectors built on data from over 15 years ago can make reliable predictions for contemporary data. To our pleasant surprise, an older model (Decision Tree) trained on older data (from 17 years ago) still functioned well on contemporary data. However, newer, less-conservative algorithms performed much more poorly when trained on older data and tested on newer data, a phenomenon we term “detector rot”. Across all of our newer models, we observed significant rot -- significant degradation in prediction -- when training on Old data and predicting on New data.

Initial findings conducted with training and test sets from the same year initially looked positive for the newer algorithms. More specifically, Random Forest and XGBoost were able to outperform the other algorithms in both the Old to Old and New to New scenarios. This corresponds to other findings that contemporary machine learning models can offer a better fit and better cross-validated performance for gaming detection e.g. [29]. However, XGBoost was the worst-performing algorithm when trained on Old data and tested on New data. This result (plus the considerable degradation seen for the Neural Network algorithm) raises the concern that more advanced models may generally have more difficulty when applied to future samples or data drawn from different contexts.

This set of findings has important implications for detectors of complex phenomena currently in place, for the detectors being developed today, and for best practices when retraining models. We suggest the community should be cautious in using newer machine learning models -- they may initially be more accurate (even for unseen students) but may become less accurate more quickly over time than simpler models. At minimum, models developed using contemporary algorithms may need to be re-checked more often

than models using classic algorithms. However, it is not yet clear how often new data should be collected or whether old and new data should be combined (see, for instance, [20]).

In our modeling attempts most features were not important to the models. Future research might look to analyze these features and remove some of the redundancy to reduce overfitting. It is possible that this method of reducing overfitting may reduce some of the overfit to specific years, but the prominence of specific features involving student errors in the model suggests that changes in semantics between the 2005 and 2021 datasets may have been a bigger part of the explanation for the observed detector rot. It is important to acknowledge that it is not clear from our findings which changes between the Old and New data sets resulted in the detector rot observed. Across the span of 17 years, changes in the user interface, updates to the content of the ITS, and changes in student behavior may have impacted the ability of the gaming detectors to transfer. It may be worth attempting to directly identify how specific design changes impact detector performance -- for instance, by collecting text replays from right before and right after a design change. This might help understand exactly how feature importance and model functional form shifts due to this type of change, eventually helping us develop detectors resistant to these shifts and understand which design changes may reduce the effectiveness of existing detectors.

Our findings open a broad range of questions to further research on detector rot. Gaming the system is one of many classification tasks in educational data mining research and practice. Future research should investigate whether other important EDM classification problems such as drop-out/stop-out prediction and affect detection are impacted by detector rot. There is already evidence for one form of detector rot in the case of MOOC stop-out: classifiers trained on the first session of a MOOC can be less effective in later sessions [8, 36]. However, this finding may be due to differences in the populations of students who choose to take a MOOC in its first session, rather than the degradation of detectors over time -- i.e. selection bias rather than detector rot. Studying what systems and detection tasks are most prone to detector rot would be an important contribution to the practical use of detectors in real-world settings.

One of the exciting aspects of educational data mining over the last decade has been the rapid developments in the algorithms available for us to use. Newer algorithms offer the promise of better predictive performance on long-standing problems. There is a temptation to always go with the newest, most exciting algorithm available, and to focus on cross-validated performance or a held-out test set from the current data set, rather than looking at replication and generalizability (see discussion in [14]). However, our findings suggest some of our predictive models may be aging, and this may be a more serious problem for contemporary algorithms which achieve higher initial performance. Future work can help us understand which changes in learning systems and student populations result in detector rot, and how to develop adaptive and future resistant models that will support learners now and for years to come.

5. ACKNOWLEDGMENTS

We thank Carnegie Learning for providing us the newer data set for analysis, and thank the school district for agreeing to our use of the data and supporting our research. We also thank the PSLC DataShop for making earlier data available. We thank the NSF for their support of this research through grant #DUE-2000405.

ABSTRACT

The complex and dynamic nature of collaboration makes it challenging to find indicators of productive learning and quality collaboration. This exploratory study developed a collaboration metric to capture temporal patterns of joint attention (JA) based on log files generated as students interacted with an immersive astronomy simulation using augmented reality headsets and tablets. JA is defined as the ability to coordinate attention, which thus plays an important role in collaborative problem-solving to build the common ground for knowledge co-construction. We first developed a JA metric consisting of six distinct but closely relevant states as a measure of the collaboration process. We then conducted descriptive statistics to compare frequency and temporal pattern of JA states across three learning performance groups. Our results showed that high-learning-gain groups demonstrated visual coordination behaviors more frequently and utilized this collaboration strategy in the early stage. We then investigated sequences of these JA states, focusing on one key behavior: long and consistent shared view as a proxy for collaboration. This sequential analysis revealed two different collaboration profiles: attention follow-leader and turn takers, suggesting the existence of asymmetrical participation. Our findings indicate the potential of JA metric to predict overall collaboration quality, identify undesirable collaboration behaviors, and serve as an early warning to provide just-in-time guidance.

Keywords

Joint Attention, Shared View, Collaborative Problem-Solving, Immersive Learning Environments

1. INTRODUCTION

Collaborative problem-solving (CPS) is considered a core competency of the 21st century [14]. CPS refers to the capacity of an individual to solve a problem by sharing their knowledge, skills, and efforts with two or more people [26]. CPS provides opportunities for learners to develop the cognitive and social skills required for effective collaboration. Computer-supported collaborative learning (CSCL) environments are thus designed to facilitate this joint activity by allowing individuals to monitor collaborative progress, accommodate different perspectives, and develop a solution (e.g., [24]).

Y. Zhou and J. Kang. Characterizing joint attention dynamics during collaborative problem-solving in an immersive astronomy simulation. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 406–413, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

As more advanced technologies such as augmented reality (AR) emerged, there have been challenges to understand how students use these technologies and further how technological features need to be designed to support the students' CPS process [17]. Such learning platforms provide immersive learning experiences in a classroom setting; yet it is challenging to understand their collaboration process due to the complexity (e.g., [38]). Exploring novel ways to understand collaborative learning in immersive learning environments becomes critical. In this regard, this exploratory study investigates joint attention (JA) as a proxy for collaborative behaviors in a multi-device collaborative learning platform.

JA has been studied to understand how students coordinate attention to build shared understanding in collaborative tasks. Existing studies have focused mainly on joint visual attention (JVA) using eye-tracking data and showed correlations between JVA and collaboration quality [33, 34]. However, most studies considered moments of joint visual attention (JVA) as a binary variable, which may be insufficient to capture the complex process of collaboration. We therefore developed a JA metric consisting of six distinct but closely relevant states as a measure of the collaboration process. More specifically, we investigated JA states as preliminary evidence to understand how students coordinate attention across different types of devices (AR headsets, tablets) and identify collaboration patterns that may contribute to learning gains in CPS.

2. RELEVANT WORK

2.1 CPS in immersive learning environments

CPS refers to the process when students attempt to form a shared understanding and co-construct knowledge by working on a common problem or project known as the joint problem space [32]. Advanced educational technologies like AR emerged as a medium for immersive collaborative simulations [11]. This technology brings new affordances and challenges for students to participate in CPS and for researchers to understand CPS behaviors.

Studies have suggested that immersive learning environments enhance face-to-face interaction and collaboration [39], support collaborative inquiry learning [37], and facilitate collaborative knowledge construction [21]. Pervasive AR headsets and mobile-AR systems enhance social interactions in the sense that students can collaborate through both digital devices and face-to-face interactions [4]. Immersive technologies also create a sense of immersion [9] that contributes to an authentic learning experience [39]. From this perspective, immersive learning environment fosters collaborative learning and problem-solving as it affords a dual interaction space: (1) the social interaction space through both face-to-face communication and interactions enabled by the device, and (2) the cognitive problem space by providing a simulated or 3D object that students can respond to and build knowledge on.

However, an immersive learning environment also brings challenges when it comes to understanding students' learning and collaboration processes. Given the immersive nature of this environment, it often requires expensive monitoring devices such as eye trackers, motion trackers, and video cameras to understand how students utilize these technologies [10]. How students navigate multiple representations in such an environment remains unexplored, and there is limited evidence suggesting how the navigation and exploration patterns generate learning opportunities [1]. Another challenge lies in the lack of peer awareness in immersive learning environments [7, 17], in which students are not aware of their peers' actions when they explore and solve tasks. An analysis of how they coordinate their attention to build close connections between social and cognitive problem space is fundamental to the understanding of the CPS in immersive learning.

2.2 Understanding CPS Using Log Data

Log data offers a particular advantage to examine the complex nature of human interactions in CSCL environment. While traditional quantitative methods rely on outcome variables and static variables from subjective measures, log data enables the analysis of collaboration as a dynamic process. It can capture sequences of actions and events, and thus provide an opportunity to examine collaborative learning from a process perspective. A common and significant characteristic of sequential analysis is its emphasis on the interrelations between actions over time instead of the presence or absence of the actions in isolation [20]. The application of sequential mining approaches has proven successful to identify interaction patterns differentiating low and high-achieving groups [22, 40], discover problem-solving modes in pair programming [31], identify navigation behavior patterns in the CPS process [19], and understand how regulation processes unfold over time in group work [12].

The benefits of sequential analysis are further reflected by Han et al. [15]. The authors point out the necessity to examine time-related factors when implementing collaboration analytics, as characteristics of collaboration such as coordination between group members may differ over time. Temporal aspects like sequence provide a unique perspective to understand CPS as a complex and dynamic process. However, most research efforts focused on exploring CPS supported by single platform (e.g., online learning platforms, ITS, multi-touch tablets, interactive whiteboard). There is much less research on how to discover and analyze patterns of interactions when students collaborate across multiple devices [10].

2.3 Joint Attention and Collaboration

One of the potential proxies for collaboration is JA, which is defined as "the ability to coordinate attention toward a social partner and an object of mutual interest" [3, 25]. Solving problems together requires students to share ideas and build a mutual understanding of problem-solving rules, in which students help each other think through the problem [7, 15, 28]. If JA is not achieved between partners, it is less likely for them to regulate their attention and build the necessary common ground for further discussion, and actively contribute to problem-solving. In this regard, JA is closely related to productive collaboration [27]. A prototypical example of JA involves visual synchronization, which refers to JVA—the mutual coordination of eye gaze [6]. JVA was first introduced by Scaife and Bruner [6] to study the focus of attention in infants and has been studied to understand collaboration dynamics. Previous research mainly used mobile eye-trackers to measure JVA and found correlation between JVA and dyad productivity [18], collaboration quality [33], and other outcome measures like learning gains and task performance [34]. Although these findings demonstrated the

potential of JVA to serve as a proxy for quality collaboration, high-level JVA moments may hide unbalanced participation known as the free-rider effect, suggesting the partner dominance in terms of gaze initiation [34]. Schneider and Pea [33] categorized this dyad as leader and follower, inspired by four collaboration profiles that students assume [35]: turn takers, driver-navigator, driver-passenger, and independent. This asymmetrical collaborative pattern was found negatively correlated with learning gains, as students who less frequently initiate and respond to joint objects benefit less from JVA moments. This finding points out limitations of JVA as it may hide undesirable collaboration mode and thus insufficient to measure collaboration quality.

Another limitation of existing literature is the perception of JVA as a binary and momentary event that students are either in or not in this state [18, 33, 34]. Relying on this binary classification, JVA may not accurately or sufficiently represent the process of collaboration considering its complex and dynamic nature. Siposova and Carpenter [36] argued that the jointness of attention comes in degrees rather than as arbitrary, discrete, and uniform events. They developed a systematic framework containing four levels of social attention (monitoring, common, mutual, and shared). According to their framework, attention levels are nested hierarchically and exist on a scale of jointness. It is important to distinguish between these levels as they may support different interactions and communications. To achieve a more comprehensive understanding of collaboration, it is necessary to investigate JA as a process consisting of interrelated states rather than a binary phenomenon.

2.4 Research Aim

To fill in these gaps, we conducted an exploratory study to investigate JA in a CPS process based on fine-grained log data in a multi-device immersive environment. We hope to go beyond the previous binary classification of JVA and provide insights into how students coordinate attention in the CPS process. Therefore, we designed a JA metric that consists of six different states, inspired by the spectrum of jointness framework [36]. We then explored the sequences of these states to characterize the process of attention coordination in CPS. Using a sequential analysis approach, we investigated the relationship between groups' JA states and their learning gains. Our goal is to understand how CPS unfolds over time using a sequential analysis method. By extracting key collaboration patterns that potentially lead to quality collaboration and better learning performances, we hope to characterize dynamics of JA in the context of CPS. The research questions guiding our analysis are: (1) What are temporal patterns of joint attention that are indicators of collaborative problem-solving? and (2) How do these joint attention patterns vary across groups with different learning gains?

3. METHODS

3.1 CEASAR

Connections of Earth and Sky with Augmented Reality (CEASAR) employed a digital planetarium simulation software designed to investigate collaborative learning in immersive augmented reality. CEASAR allows the exploration of the night sky through three scenes: Horizon (default), Earth, and Star. It simulates a first-person view of the night sky from a specific location and time. The Earth scene allows users to observe the entire Earth from space. Users can drop a pin on any location of the Earth's sphere to change their location or obtain its coordinate. The Star scene provides access to the complete celestial sphere and cataloged western constellations. Users can shift between these three views, manipulate the location and simulation time, or change their direction of view to explore the sky. Since this platform was designed to support

collaboration, annotations (e.g., mark a constellation) made in one device will be simultaneously visible to all users in the same group.

3.2 Participants and Tasks

This study involved 77 undergraduate students enrolled in an introductory astronomy course from a mid-western university in the United States. Students participated in three weekly one-hour sessions. The first two sessions helped students familiarize themselves with the simulation platform using gesture-controlled AR headsets (Microsoft HoloLens 2) and touch-based tablets. In the third session, 25 self-assigned groups of three to four solved a CPS task called “Lost at Sea”. Each group was provided with one AR device and two tablets. Students were expected to leverage these digital devices determine the location of a space capsule that has crashed somewhere on Earth. To complete the task, groups need to identify the hemisphere of their location, find the correct cardinal directions by identifying key stars or constellations as reference points, and estimate their latitude and longitude. Aside from the group task, students were required to complete individual pre- and post-paper-based assessments to measure their conceptual knowledge relevant to the task’s topic. Each assessment took about five minutes.

3.3 Data Source

This study explores the students’ collaboration patterns using data collected from video recordings of group work, screen recordings from the devices (Figure 1), and interactions with the simulation in the form of logs obtained from both AR and tablets. The interaction logs were recorded as rows of events, where event = {Username, Groupname, Device, Activity, Event, UTC time, Heading vectors, Simulation time, Crashsite, Location, Scene, Selected object, Selected star}. A new event was generated each time students moved their devices to change the direction of view, selected a star or constellation, chose a different scene, or manipulated the simulation time within the platform. In this study, we only focused on log features relevant to the identification of JA. The pre-/post-assessments contain one open-ended question to measure the students’ understanding of latitude and longitude calculation, which was scored by researchers from 0 to 2 based on the completeness and accuracy of students’ responses.

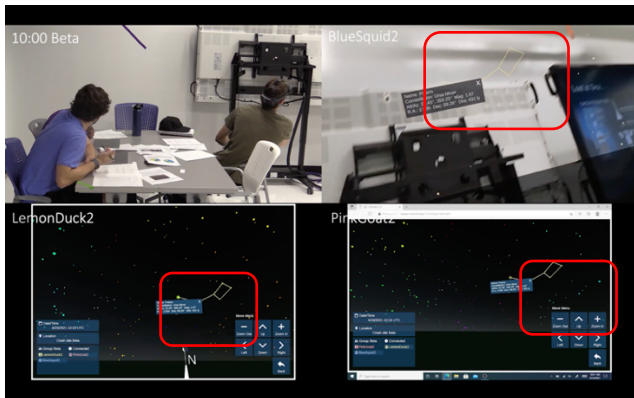

Figure 1. Screen overlap in Horizon scene across three devices—MS HoloLens2 (top right) and tablets (bottom right and left).

3.4 Data Processing

The following describes a multiple-step process of extracting JA states from raw log data.

Step 1: Individual Inactivity Extraction This step filtered active episodes and prepared for further analysis at a second granularity. We

defined 20 seconds as the threshold to distinguish active and inactive episodes. This time frame was chosen based on classroom recordings and previous study [22] showing that elapsed time beyond this threshold should be differentiated, beyond which the set of actions were perceived less relevant and supposed to belong to a different action episode. If students did not trigger any event within this 20-second time gap, subsequent seconds (i.e., from the 21st second) were labeled as inactivity until the next event. It is worth noting that during inactivity students may participate in off-task behaviors like idling or engage in task-relevant activities without using the devices, like paper sheet filling.

Step 2: Device Pair We then labeled the scene for each second, yielding a time series containing four types of scene values (Horizon, Earth, Star, and inactivity). Next, we combined the individual scene values to code the JA state of each device pair as inactivity, no overlapping, or scene overlapping. *Inactivity* means that neither device triggered any event within the 20-seconds time gap. *No overlapping* contains two possible situations: (1) two students explore the simulation in two different scenes (2) one student explores the simulation while the other is inactive. Both situations suggest a lack of JA as students engage in different activities or scenes. *Scene overlapping* represents that both students are in the same scene and observe the simulation from the same perspective. This initial coding created a state sequence for each dyad within a group, resulting in a total of three device pairs for each group (i.e., tablet1-tablet2, tablet1-HL2, and tablet2-HL2). We observed a tendency for groups to only use two devices most of the time. Considering all the dyad sequences may lead to misleading results as one device may not be used consistently and may look like a student was not engaging in the task and JA. Thus, we picked one dyad sequence that represents the whole group based on the level of participation (i.e., a dyad with the least number of inactivity and no overlapping states).

Step 3: Pair Scene Overlapping Coding This step extracted higher-level JA behavior (i.e., scene overlapping) in the horizon scene using the shared view (SV) metric (see details in [10]). SV metric tracks whether two devices’ screens overlapped, indicating students were looking at the same area of sky or celestial objects. This continuous value ranges from 0 to 1, representing the screen overlap ratio, where 1 indicates a perfect shared screen, and 0 means no overlap. By watching screen capture recordings (see Figure 1), we found that a SV value larger than 0.35 allows students to look at the same area and was thus used as the threshold to filter shared view state in Horizon scene. We also incorporated more contextual information to this state by characterizing it as ‘short’ and ‘long’ based on state duration. We chose 15 seconds as the delimiter based on our observations in terms of whether students were having a quick or in-depth longer discussion with their partners.

Step 4: Consistent State Extraction We then extracted consistent JA episodes longer than 5 seconds. Previous research pointed out that students need around 2 seconds to focus their attention on the object mentioned by their peers [30]. Considering our simulation platform requires students to manually move their screens and find the reference points or shift the scene, we set the threshold as 5 seconds. A state lasting 5 seconds or less was not sufficient to be counted as a consistent state as it may be generated by accident.

Finally, six mutually exclusive states (shown in Table 1) were identified. These states were ordered according to levels of participation and attention coordination; that is, three hierarchical levels. Each level may require varying amounts of effort to achieve attention coordination and visual synchronization. At the top level, we utilized a previously developed SV metric [10] to capture consistent *screen overlapping* behavior in Horizon. In the subsequent level,

we focused on *scene overlapping* behavior in the Earth or Star scenes. The lowest level included *no overlapping* and *inactivity* state, which could be perceived as lack of JA. JA states in Horizon was differentiated from the other two scenes and perceived as the higher level for the following reason. The current calculation method of SV metric only applies to Horizon scene, which captures the moments when students looked at the same region of the simulated sky. This is typically achieved with the help of a reference star or constellation (see the marked constellation in Figure 1). Students need to move their screens or AR headsets to find the reference object first before achieving the visual synchronization in Horizon. For the other two scenes (Star and Earth), however, students only need to click the button to select the same scene. Therefore, the extra efforts required in Horizon may indicate more verbal communication to coordinate the screens to achieve synchronization. Considering the fact that JA states differ in the level of attention and coordination, overlapping in Horizon scene is more likely to represent a high-level, intentional coordination behavior to build a shared problem space.

Table 1. JA states description

JA State		Scenes	Description
Inactivity (INACT)		N/A	Both students do not trigger any event within the 20 seconds
No scene overlapping (NO)		All	Students explore in different scenes OR one is inactive
Scene overlapping in Earth or Star (SO Earth/Star)		Earth and Star	Both students stay in Earth or Star scene
Scene overlapping in Horizon	No shared view in Horizon (SO_HZ_NO)	Horizon	Both students stay in the Horizon scene but no screen overlap
	Short-shared view (SO_HZ_SRT)	Horizon	a quick screen overlap (<15 seconds)
	Long-shared view (SO_HZ_LNG)	Horizon	a long and consistent screen overlap behavior (>15 seconds)

3.5 Group Exclusion and Classification

We used pre- and post-assessment scores as an outcome measure of learning performance. Students wrote a short response explaining the multiple steps to complete the location calculation given the visible stars and constellations, which was graded as 0, 1, or 2 based on a rubric developed during a pilot study. We computed individual normalized gains (i.e., $\text{post} - \text{pre} / \text{post-max} - \text{pre}$) to obtain each group's average normalized learning gains. Among 25 groups, the mean of normalized learning gains was 0.283 (SD = 0.290), and the median was 0.313. Six groups earned no or negative learning gains. For the rest, we conducted a median split and ended up with three performance groups: no-learning-gain ($n = 6$), low-learning-gain ($n = 9$), and high-learning-gain ($n = 10$). One group in no-learning-gain began with a full score in the pre-assessment and was removed given the ceiling effect. Four groups were removed as the students frequently shared only one device, making the logs unable to capture their collaborative behaviors. As such, a total of 20 groups were included for the further analyses: no-learning-gain ($n = 4$), low-learning-gain ($n = 9$), and high-learning gain ($n = 7$).

3.6 Analysis

Our analysis consists of two parts. First, we conducted descriptive analysis to compare aggregated values of JA states across the three learning performance groups. Examining the distribution of screen overlapping states across groups with different learning gains yields a preliminary understanding of the association between screen overlapping behaviors (i.e., JA states) and learning performance. Then we applied sequential analysis to search for patterns that characterize JA from a process perspective. Specifically, we looked at the transition probabilities between the six JA states to uncover more interesting patterns of collaboration dynamics. Two transition metrics were utilized to explore the state sequences: the Markov-chain model (MCM) and the L* metric.

MCM is a transition metric that calculates the conditional probability of one state following another based on the assumption that the occurrence probability of one state depends on the previous state. We used the TraMineR and seqHMM packages in R to build Markov models for our sequence data [13, 16]. Two important parameters in MCM are (1) the transition probabilities between the states and (2) the initial probabilities for each state. Transitions with higher probability within the sequence can be interpreted as common collaboration patterns to characterize the groups' JA dynamics. However, one limitation of MCM is the failure to take base rates into account (i.e., the initial probability of each state in the sequence). This may impact how we interpret transition probabilities and understand the relationship between states in the sequence.

We therefore applied L* metric as a complementary method. L* was chosen as the best metric for sequences without consecutive repetitive states according to the discussion in [5]. L* compares the actual occurrence probability with a calculated base rate, which is the transition probability assuming the states in the sequence are randomly ordered [23]. The use of base rates in the calculations of the L* metric makes it well suited for between-group comparison, while MCM is better suited for within-group comparison (i.e., comparison between two transitions of the same group). L* illustrates the degree to which transition between two states is more likely than in a randomly ordered sequence of states, given the base rates of each. The range of L* is $(-\infty, 1]$ where the negative value represents the specific transition is less likely to occur compared to the chance level, and 0 means this transition occurs as often as expected in a randomly ordered sequence.

4. RESULTS

4.1 Descriptive Analysis

Table 2 presents the distribution of each state across three learning levels. It suggests no-learning gain group stayed either inactivity or no overlapping states most of the time. Comparably, high-learning-gain groups had more scene overlapping states. This difference suggests that high-learning-gain groups are more likely to demonstrate JA behaviors such as screen coordination to maintain mutual attention and construct a shared problem space for in-depth discussion. We also examined the temporal aspect of data. One interesting finding was the early adoption of collaboration strategies of high-learning-gain group. We compared the long-shared view state during the first 30 states, which roughly corresponds to the first twenty minutes. While five out of seven groups in the high-learning-gain groups demonstrate long-shared view in the early stage, only one in the no-learning-gain groups and three in the low-learning-gain group demonstrate long-shared view. These results suggest that high-learning-gain groups not only demonstrate more high-level JA behavior such as screen coordination but also tend to demonstrate this behavior in the early stage of collaborative problem-solving.

Table 2. JA state descriptions in each learning gain group

State	No Gain (n=4)	Low Gain (n=9)	High Gain (n=7)
INACT	^a 19.00 ^b (29.8%)	14.78 (25.2%)	14.57 (23.9%)
NO	30.50 (47.7%)	28.00 (47.2%)	27.71 (45.2%)
SO_HZ_NO	9.25 (14.5%)	9.67 (16.8%)	12.14 (19.7%)
SO_Earth/Star	2.75 (4.2%)	3.11 (4.7%)	2.14 (3.3%)
SO_HZ_SRT	1.00 (1.6%)	2.11 (3.5%)	2.00 (3.1%)
SO_HZ_LNG	1.50 (2.3%)	1.44 (2.6%)	3.00 (4.9%)

Note. ^aAverage number of states; ^bAverage proportion of each state within each group sequence.

4.2 Sequential Analysis

We further looked at transition probabilities between states to identify collaboration patterns able to differentiate learning groups (see Figure 2). We particularly focused on the transitions relevant to the long-shared view state (SO_HZ_LNG), which is a key collaborative behavior. An interesting difference was found in the transition probabilities between the long-shared view and the other two states: no overlapping (NO) and scene overlapping in Horizon (SO_HZ_NO). These two transition sequences represent two different JA patterns, indicating to what extent groups engage in collaborative participation (e.g., symmetrical to asymmetrical participation).

SO_HZ_LNG → NO indicates that only one student remained active and interacted with the platform after the end of a higher-level JA state (i.e., long-shared view). Meanwhile, another student no longer triggered any event. By looking at the session video recordings, we found this transition typically occurred when one student initiated the screen coordination and dominated the problem-solving processes, while another student was less engaged. **SO_HZ_LNG → SO_HZ_NO** suggests a more positive collaborative behavior where pairs remained in the same scene and actively interacted with the simulation platform after leaving the screen overlapping state. Although these pairs no longer looked at the same area of simulated sky, they both continued individual exploration in a shared problem space (i.e., the same scene). We observed that this transition typically occurred when students ended discussion around the reference stars and went back to individual exploration in the same scene.

Figure 2. Markov-chain model of JA states

As shown in Figure 2, MCM presented transition probabilities within the same learning gain group. Results revealed that low-learning-gain groups showed a much higher probability for transition **SO_HZ_LNG → NO** (0.83) among all other potential transitions. Although this transition probability became smaller for low-learning-gain groups (0.5), it still remained larger compared to **SO_HZ_LNG → SO_HZ_NO** (0.33). Comparably, high-learning-gain groups showed an opposite trend. They had a higher

probability for **SO_HZ_LNG → SO_HZ_NO** (0.52) compared to **SO_HZ_LNG → NO** (0.43). This means the long-shared view state is more likely to be followed by no shared view in Horizon for high-learning-gain groups. Recall that **SO_HZ_LNG → SO_HZ_NO** suggests both students continued individual exploration after the long-shared view state, creating opportunities for information exchange and screen coordination later in the session.

Additionally, we applied the L* metric [23] to account for differences in base rates, thus allowing for between-group comparisons. When interpreting L* values, a larger absolute value indicates a stronger dependence between two consecutive states, while the value's sign (positive or negative) indicates the direction of dependence. As shown in Table 3, for **SO_HZ_LNG → SO_HZ_NO**, the high-learning-gain groups showed the highest L*, while the no-learning-gain groups showed the lowest L*. This positive value means given the previous state is SO_HZ_LNG, students in this group are more likely than chance to enter the SO_HZ_NO state. Interestingly, **SO_HZ_LNG → NO** showed the opposite trend, and the only negative value was detected in high-learning-gain groups. This means that, given SO_HZ_LNG as the previous state, the current state is less likely than chance to be NO.

In summary, L* metric can detect transitions occurring more or less frequently than random chance, providing insights about when students intentionally engage those transitions. The overall results suggest that when high-learning-gain groups exit the long-shared view state, they are more likely than chance to follow this state by entering the scene overlapping in Horizon. Similarly, when this group exit the long-shared view state, they are less likely than chance to follow this state with no shared attention at all. In contrast, this transition is around chance level (0.06) for low-gain groups or more likely than chance (0.85) for no-gain groups.

Table 3. L* Transition probabilities between long-shared view and the other states

Transition	Group	L*
SO_HZ_LNG → NO	No Gain	0.85
	Low Gain	0.06
	High Gain	-0.15
SO_HZ_LNG → SO_HZ_NO	No Gain	-0.11
	Low Gain	0.23
	High Gain	0.35

5. DISCUSSION

Our exploratory analysis identified six JA states to investigate the dynamics of JA, which provide insights into how groups coordinate their attention and solve the simulation task during a CPS process. The results revealed that groups with higher learning gains demonstrated a higher frequency of long and consistent shared view in the early stage. These preliminary findings support the previous studies that showed joint visual attention is associated with quality collaboration and contributes to learning gains (e.g., [18, 33]).

The examination of the sequence of states allowed us to identify different collaboration profiles. We observed an undesirable behavioral pattern that after a group exited a long-shared view state only one student remained active and interacted with the simulation, while another student no longer triggered any event. We perceived such different tendencies as a visual attention leader (the former) and a visual attention follower (the latter) [34, 35]. These two profiles (i.e., leader and follower), captured by the JA state sequence, illustrate the imbalanced responsibility to initiate discussion and level of engagement within the simulation. On the contrary, another sequence transitioned to individual exploration, which was more likely

to occur in the high-learning-gain groups, suggested more balanced engagement and equal responsibility of exploring the simulation environment. This transition aligns with the profile of turn takers [35], which is a more effective collaboration behavior as both participants actively engage in and maintain a joint focus on the task to solve the problem. Overall, high-learning-gain groups were most likely to demonstrate balanced, mutual collaboration while no-learning-gain groups demonstrate imbalanced participation. This detection of asymmetrical participation suggests interesting lines of follow-up inquiry on transitions of other JA states to gain a better understanding of various collaboration profiles in CPS.

The novelty and contributions of this paper lie in the following two aspects. First, we presented an exploratory study of utilizing logs to capture JA to uncover how students collaboratively solve a group task in an immersive learning environment. Understanding how students interact with immersive learning environments can be challenging due to its open-endedness, leading to unstructured interactions. This unconstrained nature of interactions makes it difficult to understand how students navigate the environment and collaborate, leading to limited evidence suggesting what collaboration patterns are associated with learning opportunities [1]. Our study contributed by developing JA metric to investigate how students coordinate their attention across devices. This method allows us to look for dynamic and fine-grained patterns of JA that characterize successful CPS and productive collaboration.

Second, we investigated JA from a process perspective, which was typically studied as aggregative values of a binary event (i.e., whether students have or not have JA) [18, 33, 34]. Our approach revealed that temporal characteristic also matters as high-learning-gain groups demonstrate visual coordination in the early stage of task session. This finding suggests that early visual coordination behavior patterns have the potential to inform the following collaboration quality. Lack of such behaviors in the beginning stage can serve as a signal for early interventions to prevent persistent undesirable or unproductive collaboration. Studies are needed for further explorations of the relationship between early collaboration patterns and following collaboration quality. Sequential analysis allows us to detect asymmetrical participation. This finding supports previous studies [34] that although high-level JVA is correlated with quality collaboration, it may also hide a free-rider effect and thus requires a finer-grained examination on this feature.

6. DESIGN IMPLICATIONS

One implication is to design learning environments in a way that facilitates the process of obtaining JA, considering the potential of JA to enhance productive collaboration. For example, we can support peer awareness by adding visual pointers like an arrow to pinpoint the direction their peers are looking at, or a coordination shortcut allowing students to synchronize the screens or scenes in the simulation quickly. Such design can facilitate coordination and visual synchronization and consequently yield quality collaboration. This is especially the case when students do not have sufficient domain knowledge to communicate the correct direction to move their screens for a shared problem space for further discussion. Given the nature of the learning environment with immersive technologies, gaze visualizations are more likely to be utilized in linguistically complex environments where it is difficult to describe reference objects or directions to look at [8]. Moreover, visual attention awareness provides evidence that other group members are engaged and indeed getting the information communicated [29]. Such awareness contributes to an improved feeling of presence [2] and encourages learners to maintain JA.

7. LIMITATIONS AND FUTURE RESEARCH

This work has several limitations that we plan to address in future studies. First, we have a small sample size containing 20 groups. Although our analysis shows interesting patterns across groups, the comparison test does not have enough statistical power to identify significant difference. Second, the L^* metric has a typical bias that inflates transition probability as our state sequence does not contain self-transition loops, which impacts the estimation of the base rate. To the best of our knowledge, transition metric for original sequences without self-transition loops is still an open issue. Current methods require the original sequences to contain self-transition loops to calculate base rates before loop removal. We also computed different transition metrics and found that MCM and L^* are the most meaningful metrics for our dataset. Our work is exploratory in nature and still in its early stage. Future research will include more participants and combine multiple data sources like video recordings and qualitative codes to better understand how collaboration unfolds.

8. CONCLUSION

This exploratory study focused on JA, a cornerstone of productive collaboration, to better understand how students regulate and coordinate their attention during CPS in an immersive learning environment. We identified different JA states and key collaboration patterns associated with learning. Specifically, we were interested in long and consistent screen overlapping across devices (i.e., long-shared view state). To advance the understanding of CPS, we applied the following approaches: (1) descriptive analysis (2) sequential analysis on JA state transition utilizing the Markov chain model and L^* metric. This preliminary exploration provides evidence that long-shared view state, representing the highest level of JA state, is closely related to students' positive collaborative learning experiences. More specifically, high-learning-gain groups demonstrate a higher frequency of long and consistent shared view in the early stage. A closer examination of the JA state sequence revealed two different collaboration profiles: attention follower and turn takers. Overall, our findings unravel the complex process of attention dynamics and yield a better understanding of attention coordination during CPS in an immersive learning environment. This understanding consequently informs the design of computer-supported collaborative learning tools and environments to enhance learning.

9. ACKNOWLEDGMENTS

First, the authors would like to formally recognize other members of our research team, Robb Lindgren, Nathan Kimball, Emma Mercier, James Planey, Taehyun Kim, and Robin Jephthah Rajarathinam. Through their design of the simulation and research insights, their effort has enriched this work significantly. The authors are also grateful to Luc Paquette for many helpful discussions and suggestions on research idea development and analysis methods. Finally, this project was sponsored by the National Science Foundation Grant no:1822796.

ABSTRACT

This work explores how population-based engagement prediction can address cold-start at scale in large learning resource collections. The paper introduces i) VLE, a novel dataset that consists of content and video based features extracted from publicly available scientific video lectures coupled with implicit and explicit signals related to learner engagement, ii) two standard tasks related to predicting and ranking context-agnostic engagement in video lectures with preliminary baselines and iii) a set of experiments that validate the usefulness of the proposed dataset. Our experimental results indicate that the newly proposed VLE dataset leads to building context-agnostic engagement prediction models that are significantly performant than ones based on previous datasets, mainly attributing to the increase of training examples. VLE dataset's suitability in building models towards Computer Science/ Artificial Intelligence education focused on e-learning/ MOOC use-cases is also evidenced. Further experiments in combining the built model with a personalising algorithm show promising improvements in addressing the cold-start problem encountered in educational recommenders. This is the largest and most diverse publicly available dataset to our knowledge that deals with learner engagement prediction tasks. The dataset, helper tools, descriptive statistics and example code snippets are available publicly.

Keywords

Population-based Engagement, Cold-start, Educational Recommender, Personalised Education, AI in Education

1. INTRODUCTION

With the growth of Open Educational Resources (OER) [38, 6, 32] and Massively Open Online Courses (MOOC) [34, 23], large educational repositories need scalable tools to understand the engagement potential of newly added materials [14]. While *contextualised engagement* can be defined as learner's engagement driven by the context at a given time

in their learning path (e.g., learning needs/goals, knowledge state etc.), *context-agnostic engagement* aims to capture patterns and features associated with engagement that instead are applicable to an entire learner population rather than individual contexts of specific learners [7]. Put simply, context-agnostic engagement is concerned with the features that generally make an educational material engaging.

While many datasets capturing contextual engagement of learners exist, our contribution: **Video Lecture Engagement (VLE)**, focusing on context-agnostic engagement, is a novel dataset that presents around 12,000 peer-reviewed scientific videos constructed from a popular OER repository and contains a variety of lecture types ranging from scientific talks and expert panels to MOOC-like lectures. VLE provides textual and video-specific features extracted from the lecture transcripts, together with Wikipedia topics covered in the video (via entity linking) and user engagement labels (both explicit and implicit) for each video. In educational recommenders, VLE dataset helps solving both i) *user cold-start*, where new users join the system and we may not have enough information about their context and ii) *item cold-start*, where new educational content is released, for which we may not have user engagement data yet and thus an engagement predictive model would be necessary. While utility of context-agnostic engagement models for cold start is previously demonstrated [7], VLE is the largest dataset for building such models. This work is aimed not at replacing personalised recommendation but to complement it by addressing the cold-start problem. While VLE dataset is a major contribution of this work, several additional experimental results make up the overall contribution. These results demonstrate the usefulness of VLE dataset via answering a set of critical research questions.

2. RELATED WORK

The majority of work in Intelligent Tutoring Systems (ITS) and Educational Recommendation Systems (EduRecSys) revolve around contextual learner engagement [26, 9]. While many explore the connection between engagement and learning gains [2, 20, 28], public datasets in this realm are hard to come by. MOOC platforms such as edX [23] and Khan Academy [29] harvest valuable data created in an *in-the-wild* setting, yet this data is gated within course owners and consortia [21] (or heavily anonymised) due to its proprietary nature. However, with the boom of online education, it is greatly imperative that such datasets are democratised so that under-researched areas such as context-agnostic

(population-based) engagement can be widely understood to push the frontiers of AI-supported online education. Study of context-agnostic engagement of video lectures so far has been mainly qualitative, deriving guidelines such as keeping videos short and in parts [23, 3]. While these findings are useful in content creation stage, they have little use in moderating the mammoth of materials already circulating in the Internet. Our work proposes building predictive models that can be utilised post-creation for scalable quality assurance and content recommendation.

2.1 Related Datasets

Many video engagement prediction works revolve around YouTube [16, 24] and uses platform specific features (e.g. channel reputation, category etc.) exclusively. While large-scale datasets for this task is published, these datasets include general-purpose videos (largely entertainment related) rather than educational videos [40]. Some features proposed in these works share similarity to our proposal (such as duration, language and topic features). However, no content-based features (based on transcript) relating to understandability and presentation are used, making the methods hard to generalise outside of YouTube. Educational Information Retrieval [36, 15] and Wikipedia page quality prediction [19, 39] has been attempted using features such as text style, readability, structure, network, recency and review data. Publicly available Wikipedia article quality dataset [19] with human annotated (explicit) labels is used to tackle the latter task although implicit labels are not included in this dataset. Similar datasets are available for automated essay scoring [37]. But, none of these datasets fill the lack of datasets for predicting engagement of educational videos.

In the educational context, measuring learner engagement using multi-modal data such as brain waves [41], facial expressions [25] etc. are conducted in controlled environments and lacks "in-the-wild" signals [22]. Large public datasets and competitions also relate to students answering questions in-the-wild (e.g. ASSISTments [30] or multiple choice questions [13]), contrary to the proposed VLE dataset, lacks implicit feedback relating to learners acquiring skills/knowledge. More relevant datasets studying population-based engagement revolves around MOOCs. Studying approximately 800 videos from edX platform, Guo et al. [23] manually processed and provided a qualitative analysis of engagement, with a few features being relatively subjective and difficult to automate. A similar work [35] takes 22 edX videos, extracts cross-modal features and manually annotates their quality with no focus on learner engagement. Neither dataset is publicly available. MOOCcube is a recently released dataset that contains a spectrum of details relating to MOOC interactions [42]. Although large, the video watch logs in MOOCcube come from 190,000 users contrary to over 1.1 Million users of VLE. The dataset is also not tested for engagement prediction by its publishers raising uncertainty in its promise.

Our prior work [7] explored the possibility of building context-agnostic engagement models using implicit watch time-based labels and showed that these models can address the cold-start problem. We identify this contribution most relevant to the proposed dataset. Our prior work publishes a dataset of 4,000 lectures with labels coming from 150,000 learners.

VLE, expands this dataset with 3 times as many videos with engagement signals generated by 7 times as many learners. The new dataset also restricts itself to English lectures to refine relevance of the proposed features. Additionally, VLE introduces a new set of Wikipedia-based topical features.

3. VLE DATASET

VLE dataset is created using the aggregated video lectures consumption data coming from VideoLectures.Net (VLN). These videos are recorded when researchers are presenting their work at peer-reviewed conferences. Lectures are thus reviewed and material is controlled for correctness of knowledge. The collection consists of scientific talks and tutorials that are mainly geared towards university level learners. In that aspect, many videos in the dataset are stylistically similar to conventional MOOC lectures. VLE dataset provides a set of features together with labels based on subjective assessment metrics such as star ratings and view count. We believe that this dataset enables understanding the connection between content features and the collective engageability of learners with an educational video.

3.1 Feature Extraction

The video metadata and transcriptions are transformed into i) content-based textual features, ii) Wikipedia topic-based features and iii) video-specific features. Majority of the extracted features are cross modal (e.g. books, websites and audios) and are easily automatable.

Content-based Features. Based on prior proposals [7], we extract *Word Count* [39], *Title Word Count* and *Document Entropy* [1], language style features [18], *Preposition Rate*, *Auxiliary Rate*, *To Be Rate*, *Conjunction Rate*, *Normalisation Rate*, *Pronoun Rate*, readability related *Easiness (FK Easiness)* [18] and vocabulary related *Stop-word Presence Rate*, *Stop-word Coverage Rate* [1, 31]. To represent *Freshness* of lectures (recency), we calculate the number of days between January 01, 1960 and the video published date to use it as a proxy for recency of the lecture [7].

Wikipedia-based Features. We use Wikifier [4] to extract topical features capturing topic authority and coverage.

The *top-5 authoritative topic URLs* and *top-5 PageRank scores* features represent the Topic Authority feature vertical. Wikifier [4] produces a PageRank score [5] that indicates the marginal authoritative of a Wikipedia concept among all Wikipedia concepts associated with a lecture. It is noteworthy that *authority* of a learning resource entails author, organisation and content authority [11]. The proposed features represent content authority.

The *top-5 covered topic URLs* and *top-5 cosine similarity scores* features represent *Topic Coverage* feature vertical. The cosine similarity score $\cos(s_{tr}, c)$ between the *Term Frequency-Inverse Document Frequency (TF-IDF)* representations of the lecture transcript s_{tr} and the Wikipedia page of concept c is also an output from the Wikifier. These features are used as a proxy for topic coverage.

Figure 1: WordClouds summarising the distribution of top 25 (i) most authoritative and (ii) most covered Wikipedia topics in the dataset. Note that Data Science and Computer Science related topics are most dominant topics.

These four feature sets create 20 distinct feature columns. Figure 1 presents two word clouds that show the 25 most authoritative and covered topics in the VLE dataset and show that there are distinct differences between topic presence in the two feature sets. The authoritative topics are topics that are highly connected to other topics in the lecture whereas covered topics have high textual overlap between lecture transcript and Wikipedia concept page.

Video-specific Features. We identify a set of easily automatable, prior proposed [7] video specific features. *Lecture Duration*, *Is Chunked*, *Lecture Type*[23], *Silence Period Rate (SPR)* and *Speaker Speed* [7] are calculated based on prior work. *Lecture Duration* is reported in seconds. *Is Chunked* is a binary feature which indicates if a lecture has multiple parts. *Lecture type* value is derived from the metadata. This diverse dataset contains many different types of videos ranging from presentations, panels to tutorials.

3.2 Labels

Three main types of quantification of engagement labels are presented in the dataset.

Explicit Ratings and Popularity. *Mean Star Rating* based on a scale of 1-5 (5 being best) for each video is provided. Ratings are paired with the number of ratings used to compute the mean. The proposed dataset has 2,127 ratings (almost 2x than [7]). Missing ratings are labelled with -1. Capturing popularity, the total number of views, named *View Count*, for each video as of February 1, 2021 is provided.

Watch Time/Engagement. Many labels in this dataset are based on *watch time* [16]. Normalised Engagement Time (NET) is computed for each video as it has been proposed as the gold standard for learner engagement [23]. The Median of NET (MNET) and Average of NET (ANET) is calculated from NET. To have the MNET and ANET labels in the range [0, 1], we set the upper bound to 1, deriving Saturated MNET (*SMNET*) and Saturated ANET (*SANET*) that are included in the dataset. The standard deviation of NET (*Std of Engagement*) is also reported, together with the *Number of User Sessions* used for calculating MNET and ANET. These measures allow understanding stability of the centres published. The set of individual NET values are also published to allow future researchers to exploit the true distribution of values.

3.3 Preserving Anonymity and Ethics

Users of VLN repository formally agree that all user generated content is available for research. We further anonymise and aggregate interactions to ensure privacy. Aggregated results are only published in lectures with atleast 5 user views to preserve k-anonymity [17]. The presenters and authors of videos in VLN also formally agree to the video, presentation slides and supplementary material to be published under an open license and can be used for educational and research purposes. Still, a regime of techniques outlined below are used to preserve presenter anonymity in order to avoid having unanticipated effects on lecturer’s reputation by associating implicit learner engagement values to their content. Rarely occurring *Lecture Type* values are grouped together to create the **other** category. Life Sciences, Physics, Technology, Mathematics, Computer Science, Data Science and Computers categories are grouped as **stem** and all other categories as **misc** category. Rounding is used with *Freshness* and *Lecture Duration* to the nearest 10 days and 10 seconds respectively. Gaussian white noise (10%) is added to *Title Word Count* feature and rounded to the nearest integer.

VLN repository is concentrated with videos about Computer Science (see Figure 1), a subject area with gender imbalance in both audience and presenters. We avoided using feature classes that could potentially reflect gender characteristics to improve neutrality of the dataset (and models). Visual features (facial features, emotions...) and audio features (pitch, tone...) that may actively/passively embed gender is avoided. We focused primarily on features that reflect informational content. Where video specific features are used, generic features such as "speaker speed" that are unlikely to be correlated to gender or age are used.

3.4 Final Dataset

The final dataset contains 11,548 lectures across 21 subjects (eg. Computer Science, Philosophy, etc. with a majority from AI and Computer Science) that are published between September 1, 1999 and December 31, 2020. The engagement labels are created from events of over 1.1 Million users logged between December 01, 2016 and February 01, 2020. The collection of videos span various video lengths with the duration distribution having two modes at approx. 2000s (33 mins) and 4000s (1hr) time points which align with typical lengths of research talks and presentations. The mean word count of the videos is 5347.9. The video lecture collection uses on average 93.9 learners per video when calculating engagement centres. The dataset, helper tools and example code snippets are available publicly¹.

3.5 Supported Tasks

Scalable Quality Assurance and Educational Recommendation are two key downstream applications of context-agnostic engagement prediction. We establish two main tasks, which we mainly focus on in this paper, that can be objectively addressed using the VLE dataset. These are:

- **Task 1:** Predicting context-agnostic (population-based) engagement of video lectures
- **Task 2:** Ranking of video lectures based on engagement

¹<https://github.com/sahanbull/VLE-Dataset>

Other Tasks. Beyond the proposed tasks, this dataset is suitable for, not limiting to, several tasks such as i) understanding influential features for engagement prediction and ii) understanding the strengths and weaknesses of different implicit/explicit labels, that have been investigated in our prior work with similar datasets [7, 33]. The textual and topical representations, with the use of unsupervised approaches can be used in a range of tasks from understanding meaningful hidden patterns within clusters of videos (e.g. talks vs. lectures vs. tutorials) to deducing the structure of knowledge based on how topics co-occur within videos.

3.6 Evaluating Performance

We identify *Root Mean Squared Error (RMSE)* as a suitable metric for evaluating Task 1. Measuring RMSE against the original labels published with the datasets will allow different works to be compared fairly. With reference to Task 2, we identify *Spearman's Rank Order Correlation Coefficient (SROCC)* as a suitable metric. SROCC is suitable for comparing between ranking models that create global rankings (e.g. point-wise rankers).

We use 5-fold cross validation to evaluate model performance with tasks 1 and 2. The folds are released together with the dataset, to allow to facilitate fair comparison and reproducibility. 5-fold cross validation allows reporting the *confidence intervals* ($1.96 \times \text{Standard Error}$) of the performance estimate, which we include in Table 1.

4. BASELINES AND EXPERIMENTS

Through our experiments, we aim to answer research questions relevant to the supported tasks (in section 3.5) and other facets that further demonstrate the utility of this dataset. The main research questions of interest are:

- **RQ1:** Does the newly constructed VLE dataset lead to training more performant prediction models?
- **RQ2:** How does the larger quantity of training data affect predictive performance?
- **RQ3:** Is the model useful for modelling engagement with Computer Science materials?
- **RQ4:** Is this dataset useful for modelling engagement in E-Learning lectures and MOOC videos?
- **RQ5:** Does context-agnostic engagement prediction help in the cold-start scenario?

Our previous work [7] demonstrated *Random Forest (RF)* model obtains best performance among linear and non-linear models in similar datasets. Therefore, we use the RF model to benchmark the new VLE dataset for Tasks 1 and 2 described earlier.

4.1 Labels and Features for Baseline Models

SMNET label is used as the target variable for both tasks. Preliminary investigations indicated that SMNET label follows a Log-Normal distribution, motivating us to use a log transformation on the SMNET values before training the models. Empirical results further confirmed that this step

improves the final performance of the models. We undo this transformation for computing *RMSE* while this transformation doesn't affect *SROCC*.

All the features outlined as the content-based and video-based sections in section 3.1 are included in the baseline models. The models are trained with three different feature sets in an incremental fashion:

1. *Content-based:* Features extracted from lecture metadata and the transcript-based textual features.
2. *+ Wiki-based:* Content-based + 2 Wikipedia-based features (Top 1 Most Authoritative Topic URL and Most Covered Topic URL).
3. *+ Video-based:* Content-based + Wiki-based + Video-specific features.

However, due to the large amount of topics in the Wikipedia-based feature groups, we restrict to the top 1 authoritative and covered topic features where they are encoded as binary categorical variables. Practitioners are encouraged to try further encoding of the topic variables, as it will likely have a positive impact on the performance.

4.2 Experiments

Addressing RQ1, the RF models are trained with the three proposed feature sets using 5-fold cross validation with the prior proposed, smaller 4k dataset [7] and the newly proposed VLE dataset (12k). This setup allows identifying how performance gains are achieved through i) adding each new group of features and ii) adding new observations. Follow on experiments addressing RQ2 and RQ3 are run using hold-out validation technique where fold 5 is held out. We experiment by using varying proportions of training data in RQ2 to train the model. When selecting training data, random sampling is used. All the trained models in RQ2 are evaluated using the same held out test set.

To validate RQ4, we partition the entire dataset into i) tutorial videos (`vtt` lecture type) and ii) all other videos, as test and train data respectively. However, tutorials conducted in conferences significantly vary from e-learning videos geared for MOOCs. To address this mismatch, we further identified 1,035 videos (among the tutorials) that exclusively belong to the Open Course Ware Consortium (OCWC)². OCWC exclusively contains university lectures intended for teaching and devises different MOOC production techniques such as classroom, talking head and power point methods [23]. In RQ5, we train the model using all non-tutorial lectures and test the engagement prediction/ranking performance on i) OCWC videos (`ocw`), ii) all tutorials but OCWC (`!ocw`) and iii) all tutorials `vtt`, (entire test set). Experiments of (RQ2-4) are only done with the best performing model from Table 1 (RF model with *Content + Wiki + Video* feature group) to reduce computational cost.

To tackle RQ5, we utilise TrueLearn Novel [9] (hereby referred to as *TrueLearn*), a personalisation model that predicts learner engagement with video lectures. A key limitation of many such models is lack of information in the

²<http://videolectures.net/ocwc>

Table 1: RMSE and SROCC with confidence intervals for the engagement prediction (Task 1) and lecture ranking (Task 2) using the Random Forests model with both 4k [7] and 12k (Our VLE) datasets. Better performance highlighted in bold.

Feature set	RMSE with Task 1		SROCC with Task 2	
	4k	12k (<i>Ours</i>)	4k	12k (<i>Ours</i>)
Content-based	.1801±.006	.1170±.006	.6190±.011	.7504±.013
+ Wiki-based	.1798±.007	.1178±.006	.6251±.014	.7505±.013
+ Video-specific	.1728±.007	.1098±.007	.6758±.020	.7832±.009

Figure 2: Predictive performance for (i) engagement prediction and (ii) lecture ranking tasks with varying proportions of randomly sampled training data. The test set performance for full test dataset (Blue) and subsets of test dataset that consists of CS lectures only (Orange) and Non-CS lectures only (Green) are also reported

Table 2: Performance for OpenCourseWare (ocw), Non-OpenCourseWare (!ocw) tutorial and All tutorial (vtt) videos for engagement prediction and lecture ranking tasks. Better performance per task is highlighted in bold.

	ocw	!ocw	vtt	From Table 1
RMSE with Task 1	.0539	.0404	.0406	.1098
SROCC with Task 2	.9485	.9209	.9223	.7832

early stages of the user session (*cold-start* problem) to make accurate predictions. In this experiment, we created a hybrid recommender that combines the TrueLearn model with the proposed context-agnostic engagement prediction model (hereby referred to as *TrueLearn++*). For simplicity, we use "switching" [12] in *TrueLearn++*, where the pre-trained context-agnostic model makes the prediction on the *first* event of each user (where the personalisation model has no information) and switches to TrueLearn that can exploit user history. PEEK dataset [8], with more than 20,000 learner sessions, is used for the experiment where the context agnostic model is trained using lectures not present in the PEEK test data. Then the predictive performance on the PEEK test data using TrueLearn (The baseline) and *TrueLearn++* (the hybrid model) is measured using Accuracy, Precision, Recall and F1-Score. A learner-wise, one-tailed paired t-test is used for statistical significance testing.

5. RESULTS AND DISCUSSION

The performance metrics observed with the RF model on Task 1 and 2 (RQ1) are outlined in Table 1. Figure 2 illustrates how the training data size impacts the i) RMSE and ii) SROCC (RQ2) as well as showing the engagement prediction performance on Computer Science (CS) videos vs. Non-CS videos (RQ3). Table 2 presents predictive performance of the model on e-learning type lectures and tutorials (RQ4). Finally, the overall performance comparison relating

to the effect of *combining* the context agnostic model with personalisation models to battle cold-start problem (RQ5) is reported in Table 3.

5.1 Performance Gains and Causes (RQ1-2)

Table 1 shows that the larger VLE leads to significant performance gains in both engagement prediction and video ranking tasks over the 4k dataset [7]. When using all feature sets with the RF RMSE on Task 1 drops by 41% while SROCC on Task 2 jumps by 15%. The labels in VLE dataset have more statistical stability as the centres are computed using more data points collected over a wider time window. Using more feature groups also leads to improved performance. Results for VLE dataset in Table 1 shows this trend where best performance is evidenced with all the features (+ *Video-specific* group) used. However, using cross-modal content-based features (*Content-based* + *Wiki-based*) alone leads to substantial performance. This result indicates that engagement prediction is still feasible only depending on easy to automate, cross modal features. Wikification, used in generating Wiki-based features, also operates in web-scale³. While Table 1 results don't show a significant bump when Wiki-based features are added, we believe that this is due to the simplicity of features used with much room for more sophisticated features (e.g. semantic relatedness between Wikipedia topics [10]) that will lead to performance gains.

Figure 2 confirms that the increase of training data improves performance in both tasks. RMSE continues to shrink in Figure 2(i) while SROCC in Figure 2(ii) tells a different story where improvements saturate at 60%. This suggests that improving ranks gets significantly harder around 5,500 training examples ($\approx 60\%$ of training set).

5.2 Relevance to AI/CS Education (RQ3) and E-learning Scenarios (RQ4)

Figure 2 shows that VLE dataset is suitable for training models for CS-only lectures leading to test set RMSE of $\approx .1$ and SROCC of $\approx .8$. This may be due to i) the higher diversity (significant differences between subjects) of lectures within the non-CS group and ii) the majority of CS/AI (e.g. Machine Learning, Ontology, Semantic Web etc.) related videos being present within the VLE dataset (see Figure 1). Table 2 shows strong evidence that the models trained with VLE dataset generalise really well for engagement modelling in e-learning type videos created for course teaching amid the dataset containing many different video types. The models trained are much better at engagement prediction and ranking of tutorial-like videos than general scientific talks. Having tested with lectures that have been recorded using different MOOC video production techniques, the high performance obtained on *ocw* lectures confirms that VLE dataset can be highly effective in building context-agnostic engagement models for e-learning and MOOC systems.

5.3 Addressing the Cold-Start Problem (RQ5)

Table 3 shows that simply combining the context-agnostic engagement prediction with TrueLearn Novel algorithm (together becoming *TrueLearn++*) can lead to significant improvements in accuracy and precision. The same table also

³<http://wikifier.org>

Table 3: Average test set performance for Accuracy (Acc.), Precision (Prec.), Recall (Rec.) and F1-Score (F1) in predicting *first* event and *all* events. The more performant value is highlighted in bold. The metrics where the proposed model that outperform the baseline counterpart in the PEEK dataset ($p < 0.01$ in a one-tailed paired t-test) are marked with $\cdot^{(*)}$.

Model	Predicting <i>first</i> event				Predicting <i>all</i> events			
	Acc.	Prec.	Rec.	F1	Acc.	Prec.	Rec.	F1
Truelearn	44.21	44.21	100.00	61.32	62.69	57.54	81.88	64.98
Truelearn ₊₊	56.09 $\cdot^{(*)}$	50.32 $\cdot^{(*)}$	53.58	51.90	63.51 $\cdot^{(*)}$	57.91 $\cdot^{(*)}$	79.13	64.39

shows that the drop of overall F1 score can be attributed to the comparatively steeper drop of Recall Score. Inspecting left part of Table 3 sheds more light into where this steep drop of recall occurs. This is, the TrueLearn model always predicts positive engagement for the first event of the user. At the *first* event, the recall of TrueLearn being 1.0 while the accuracy and precision being the same depicts this fact. TrueLearn predicts positive in event 1 of each user because the model has no information to base the prediction on [9]. However, the scenario is different in TrueLearn₊₊ in the first event as the model has additional information. Both accuracy and precision of predictions in first event of the learner population significantly improves. The recall will fall as the proposed context-agnostic model only captures a population based prior which may deviate from the individuality of the learners. However, it can be argued that making a prediction with additional information is better than predicting with no prior information. In the bigger picture (in Table 3 right part), being able to make slightly more informed and varied predictions for the first event of learners based on lecture content features enable significantly improving prediction accuracy and precision of TrueLearn₊₊. It is also noteworthy that our experiment, for the sake of simplicity, uses a rule that could be significantly improved further, e.g. using weights of the probabilities of both population-based and personalised models at the beginning of a user session (also known as stacking [12]), where the weight of population-based engagement decreases as we gather more information about the user.

5.4 Opportunities and Limitations

The VLE dataset is one of the biggest datasets for modelling context-agnostic engagement of educational videos (15 \times than [23] and 3 \times than [7]). This unlocks potential to apply complex model families (e.g. deep learning) with the potential to periodically expand the dataset to further push the frontiers of research. The Wiki-based features open up limitless possibilities as many sophisticated feature sets can be built and experimented. Due to the connectivity to Wikipedia, both its content and link structures can be exploited to invent meaningful, yet interpretable features. A further step can enable other data structures such as knowledge bases (e.g Wikidata) and category trees. to be used for feature creation. As the VLE dataset captures how content features relate to engagement, this dataset can be used to solidify our understanding on how to create engaging learning materials [27, 23, 3, 7].

There also exists limitations. VLE dataset is largely comprised of Computer Science and Data Science materials (Figure 1) that are delivered all in English. While this is an opportunity for AI and Computer Science education, results in Figure 2 also shows that this fact leads to comparatively

less fruitful non-CS results. The dataset and its features are also not suitable for non-English video collections. Amid its size, the dataset still lacks variety of materials in topical and lingual sense. As pointed out in section 3.3, we have taken some measures to restrict the feature set to what we believe to be more neutral features that do not discriminate gender or age. However, since we do not have access to gender information in the data collected, it is impossible to test and guarantee that VLE dataset doesn't carry negative gender, age biases. Care should be taken when enhancing these features and there is room to do more rigorous tests to understand if any gender biases are present within the dataset. *Learner Engagement* is a loaded concept with many facets. In relation to consuming videos, many behavioural actions such as pausing, rewinding and skipping can contribute to latent engagement with a video lecture [28]. Due to the technical limitations of the platform and privacy concerns, only watch time, view and mean ratings are included in this dataset. Although watch time has been used as a representative proxy for learner engagement with videos [23, 40, 16], we acknowledge that more informative measures may lead to more complete engagement signals.

6. CONCLUSION

In order to push the frontiers of context-agnostic engagement prediction, we construct and release the VLE dataset consisting of i) content-based, ii) Wiki-based and iii) video-specific features with multiple explicit and implicit labels. Two formal tasks are established to predict engagement and rank videos with baseline models that significantly outperform predecessors. Empirically, i) improvement of performance with training data size, ii) suitability of VLE dataset for CS/AI education, iii) relevance to MOOCs and e-learning and iv) the feasibility of using context-agnostic engagement prediction to address cold-start problem in personalised (contextual) educational recommendation is demonstrated.

In retrospect of section 5.4, expanding the dataset vertically (with diverse observations) and horizontally (with novel features) is our highest priority going forward. As a future direction, much richer learner engagement signals (e.g. pauses, replays, skips etc.) can be incorporated to the dataset without compromising user privacy. When better understanding of learner engagement is gained, training examples coming from other modalities (e.g. PDF and E-books) can be added to the dataset to further widen the scope of the dataset, enabling understanding of learner engagement across different types of learning resources. The attempt to improve personalisation using population-based models in our work is barely scratching the surface. There is a lot of potential to extensively propose sophisticated and rigorously tested approaches to exploit this idea, which we will also explore in future work.

7. ACKNOWLEDGMENTS

This research was partially conducted as part of the X5GON project funded from the EU's Horizon 2020 research programme grant No 761758. This work is also supported by the European Commission funded project "Humane AI: Toward AI Systems That Augment and Empower Humans by Understanding Us, our Society and the World Around Us" (grant 820437) and the EPSRC Fellowship titled "Task Based Information Retrieval" (grant EP/P024289/1).

Is there Method in Your Mistakes? Capturing Error Contexts by Graph Mining for Targeted Feedback

Ostfalia University of Applied Sciences
f.hoeppner@ostfalia.de

ABSTRACT

The value of an instructor is that she exactly recognizes what the learner is struggling with and provides constructive feedback straight to the point. This work aims at a step towards this type of feedback in the context of an introductory programming course, where students perform program execution tracing to align their understanding of Java instructions with reality. The students' submissions are analyzed for repeating mistakes across different exercises by representing the context surrounding the error by a graph and applying graph mining techniques to discover their common grounds. The patterns need to be annotated only once and help to address misconceptions of individual students. They may also be used to select follow-up exercises automatically, that contain the same intricacy.

Keywords

graph mining, formative feedback, teaching programming, misconception

1. INTRODUCTION

Automatized grading is integrated (to varying extent) in many educational systems. It is often limited to comparing a correct answer against the submission (or applying unit tests), but is nevertheless welcomed by both, students and instructors, for different reasons: While students appreciate immediate feedback, instructors are relieved that the burden of manual grading is lifted. But a student who has missed the point of some problem and thus repeatedly gets the answers wrong would benefit much more from personal feedback from an instructor who is capable of recognizing and directly addressing the student's problem. And if none of the submissions is inspected manually any more, the instructor withholds his diagnostic skills that may otherwise have been proven useful to identify misconceptions of several course members. In this work we investigate – for a particular type of exercises in programming courses – how this situation may be improved.

M. Jahnke and F. Höppner. Is there method in your mistakes? Capturing error contexts by graph mining for targeted feedback. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 422–429, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

We consider an introductory programming course in Java for students who have no programming experience yet. While students may struggle with programming for a large number of reasons (e.g. fighting with the development environment, getting a grip on computational thinking, etc.), in this work we concentrate on a single aspect only: instruction comprehension. Especially for students who have no experience in programming, we observe in lab discussions that their perception of an instruction often deviates from reality. Sticking to a wrong mental model of program execution makes it difficult to write correct programs. A human advisor can (1) discover the misconception (even if it did not occur before), (2) explain the problem (and link it to the course material), and (3) challenge the student afterwards (to monitor progress). The research question of this paper is how such an ideal instructor might be mimicked (in the given context). In particular, is it possible to support the instructor in the discovery of new misconceptions without falling back to time-consuming manual inspection of all submissions?

2. RELATED WORK

The importance of dedicated feedback has been acknowledged by many researchers ([5] gives a review). In the context of programming, several approaches derive precise commands to fix the mistakes of a submitted solution (e.g. [9, 11]). While being helpful to fix a technical problem, applying detailed instructions mechanically will unlikely trigger a change of the students' mental model – the same mistake might be made again if nothing can be learned from the feedback (e.g. because it is lacking explanations). Different hint levels are offered as a solution in [10]: On the first level, a hint points to the problem but still requires the *right student action*, while a hint on the second level enables them to fix the problem mechanically. When misconceptions are known beforehand, their discovery in a submission turns into a classification problem. Recently a number of deep learning approaches have been proposed to predict whether a student will complete an exercise [14], the code exhibits certain logic errors [6], or some free-text answer hints towards a common misconception [7]. For all those misconceptions a dedicated feedback may be prepared only once (manually by the instructor) and whenever it is predicted in a new submission the feedback can be provided automatically. This is effective for *known misconceptions*, but such approaches do not help to discover *new misconceptions*.

One of the few approaches that may also help to discover *new problems* (and is therefore close to what we have in

mind) is suggested in [8], where the focus is on programming bugs. Common coding errors (for the same exercise) are discovered by finding subtrees (in the submissions' abstract syntax trees¹ (AST)) that correlate with failed unit tests, hinting at *typically wrong* code fragments for the given exercise. As with other approaches, an instructor provides feedback for a buggy subtree that will be delivered later whenever a similar subtree occurs again. The focus of these explanations is, however, restricted to the exercise at hand – a buggy subtree in one exercise may be correct in another.

3. PROGRAM EXECUTION TRACES

When an instructor explains some concepts in class it is difficult to verify that the students perceive the concepts in the intended way. This holds in general and for instructions of a programming language in particular. If a student has only vague ideas about stack and heap, call-by-value/reference, array organization, etc., programming errors will happen sooner or later. But since code will be executed by *man-made* machines, we know the ground truth (just find a debugger) and can ask students to simulate program execution (to some extent). Paper-based analysis of variable tracing exercises have been used to investigate misconceptions in the literature [1, 2, 4, 12]. Gaining an understanding of the mechanics how the language implementation worked, was also identified as a key issue in [13]. Employing tracing exercises in class has been reported to increase the students' performance in [3]. We thus consider execution traces as a helpful tool to align mental models and encourage students to verify their understanding by filling out traces: for every executed code line the content of all variables has to be documented.

Fig. 1 shows a Java code snippet on the right that uses a mixture of language elements for demonstration purposes. We ask the students to fill out an execution trace as shown on the left, which is basically a large table where each line corresponds to a complete memory snapshot – ordered in time from top to bottom. For each row, the student has to provide the line number that is executed next (e.g. execution starts with the first line 11 of the main function). The state of all variables must be entered for each row after the corresponding code line has been executed. For instance, when line 12 got executed there is a new variable `x` on the stack which points to the heap address `0x0`, where an array of length 2 has been instantiated and initialized with `null` references. Students enter such traces in a web application, which marks erroneous lines but not the exact error position to make the students think about their input and make *trial and error* strategies less attractive. The downside of this practice is that students may get stuck at some point because they are simply not aware of what they are doing wrong. A lab advisor, pointing them to the nature of their problem, would be appreciated by them.

4. OUTLINE OF THE APPROACH

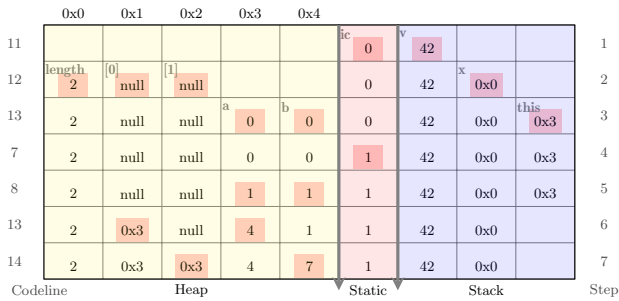

Although a full trace may consist of a considerable number of inputs (cf. Fig. 1), most of the student's input is not very informative because it (hopefully) corresponds to the already known solution. The valuable sources of information are the deviations alone, because they may hint to miscon-

ceptions. A wrong value in the trace alone does not tell us anything about possible reasons *why* this error was made. This can only be judged if more context is given, that is, the situation in which the error occurred. If errors re-occur in *similar situations*, the likelihood of a misconception rises – otherwise it just might be a typo. The *context* is the Java program itself. However, similar situations do not necessarily correspond to identical source lines. For the sake of simplicity, let us consider the case of a student who is confused by assignments where the same variable occurs on the left and the right hand side of the assignment. (Sometimes beginners read instructions with `=` as a mathematical equation rather than an assignment.) Fig. 2 shows a simplistic code example together with the correct trace. Can we tell from the student's input if he is affected by this misconception? There are two places in the trace (marked in yellow) which we can associate with this misconception: the value of variable `b` after executing line 7 and the value of variable `a` after executing line 9 as both lines exhibit the discussed kind of assignment. If both places – or *similar* places in other traces – are wrong, chances rise that assignments have not yet been understood correctly. We have identified these two places in the trace because we *knew* what kind of misconception we were looking for. At these places the probability $P(\text{error}|\text{misconception})$ of an faulty input rises, given the misconception holds. As it may be difficult to come up with an operational definition of *misconception*, we retreat to $P(\text{error}|\text{context})$ and will define *context* as a situation or pattern that can be matched against the traces and the source code.

Recalling the research question, we seek a mechanism that identifies both, the context (of a potential misconception) as well as the positions affected by it. If the context is easily understandable, such a mechanism would enable us to mimic the behaviour of a valuable instructor with only little manual intervention: (1) discovery: if errors in an (automatically derived) context accumulate substantially (across all students), it is likely the context captures a problematic situation. The instructor inspects the context once and decides what a likely root cause might be. Once it got accepted as a misconception in this way, it can be discovered in subsequent submissions automatically. If the errors accumulate for some individual student, we conclude that he suffers from this misconception. (2) feedback: The instructor writes a short explanation when the problem was discovered for the first time (or may link it to existing material). As with other approaches, this feedback can be delivered in subsequent occurrences. (3) challenge: Beyond the textual feedback, we need a challenge to check for an improved understanding. We characterize a student by a set of *pending misconceptions* and, in the same way, we characterize exercises by the contexts they contain. A suitable challenge is thus a challenge that matches the students profile best (in the fashion of an adaptive recommendation system).

A *context* must address properties of the source code **and** the trace: We want to align errors in the trace to properties of the source code. The plain code (Fig. 2(right)) is therefore transformed into a graph as shown in Fig. 3 as follows: The first step is the creation of an abstract syntax tree, which already provides most of the nodes in the graph. Starting from the top node we can see the method declaration (of

¹An AST is build by a parser and represents the syntactical structure of code while omitting some less relevant details.

```

1 package test;
2 public class Demo {
3   static int ic;
4   int a,b;
5   public Demo() {
6     ic++;
7     a=ic; b=ic*ic;
8   }
9   public static void main(String[] args) {
10    int v = 42;
11    Demo[] x = new Demo[2];
12    x[0] = new Demo(); x[0].a=4;
13    x[1] = x[0]; x[1].b=7;
14 } }

```

Figure 1: For the example code on the right, the corresponding execution trace is shown on the left. The different memory areas stack, heap, and static data are shown in blue, yellow, and red, resp.

Figure 2: Code (right) and corresponding trace (left). Yellow marks indicate where the misconception may be observed.

main), which contains a body (instruction block `{}`) with 6 statement nodes, two declarations and four assignments. But the AST does not yet suit the trace, it represents the static structure of the code, but the trace is concerned with the dynamic evolution of the variables during code execution. We bridge this gap by two changes:

1. Every occurrence of the *same variable* in the code introduces a new node in the AST, but it has a unique position in memory (and thus a unique position in the trace). Therefore all AST nodes that refer to the same variable are united to a single node, turning the tree into a graph. In Fig. 3 both nodes for the variables `a` and `b` are shaded in gray. Every incoming edge into one of these variable nodes correspond to the use of the variable in the code.
2. The content of the trace is aligned with the code lines, but by looking at an AST graph one cannot tell which instruction comes from which code line. So we introduce a new node for each code line (shown in blue in Fig. 3) and link them with all instructions from this code line. (For instance, the rightmost assignment node in Fig. 3 occurs in line 9 of Fig. 2.) We capture the program flow by connecting code line nodes that may get executed in sequence. In the example we have no loops or conditional statements, so the nodes connect linearly (*Line 5 to Line 6, Line 6 to 7, etc.*)

This graph combines information from code and trace, but does not yet encode where the student entered a wrong value. The error position in the trace is identified by row

and column (cf. yellow circles in Fig. 2): The column corresponds to the variable and the row corresponds to a time step during execution, which always refers to a specific code line. An additional *focus node* (orange in Fig. 3) thus encodes the error position by connecting to both, the variable for which an erroneous value has been entered in the trace², and the code line node whose execution has been traced.

We denote such a graph G as a **code graph**. A *context* may now be represented as a subgraph C of G . In Fig. 3 such a subgraph has been highlighted with red lines. We read the subgraph as follows: We focus on a code line (here: line 7) that contains an assignment where the variable (here: `b`) on the left hand side also occurs in the expression on the right hand side of the assignment. The context graph is also shown isolated in Fig. 4(left). If this context accumulates a high number of student errors, it can be shown to the instructor and should be reasonably simple to interpret. The instructor may then decide that this context represents a misconception and writes a short explanation for the context pattern as indicated in Fig. 4(right). The text template may refer directly to nodes in the context graph (e.g. `[varname_2]`). These references are replaced with the true line numbers or variable names from the real exercise the student is currently working on. This links the feedback text very tight to the exercise just submitted by the student.

To match such a subgraph to other occurrences, it has to be *anonymized*, for instance, the variable names have to be replaced by placeholders 'varname' (as we have already seen in Fig. 4). Variables have unique nodes in the graph and we no longer need the variable's name for disambiguation. Other graph transformations may be applied to compensate structural differences in the AST that are not helpful for our purposes. For instance, we want the context to match twice in the example code of Fig. 2, but the subtree for the expression on the right hand side of `b=b-a` is less complex than that of `a=a/2+3`, so the code graph is structurally different. To ensure that a context can still match both occurrences, we apply two measures: Firstly, the graph is transformed to simplify some technical details (we collapse a tree of expression nodes into a single expression node). Secondly, we extend the expressiveness of a context: Rather than only simple edges we allow, e.g., for transitive connec-

²only if there is one; line number errors do not have an associated variable

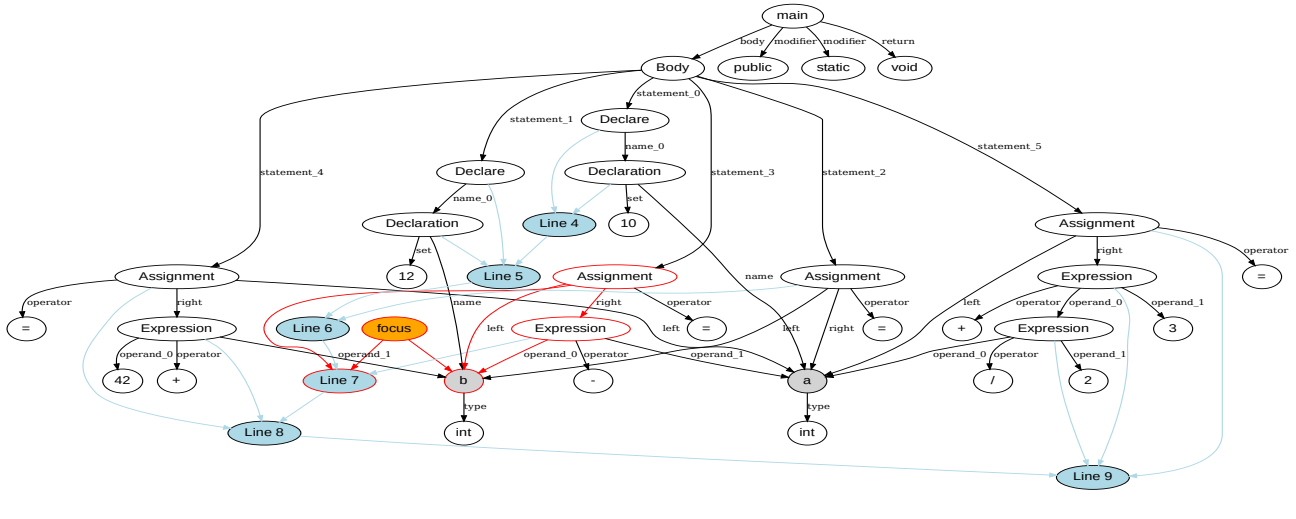

Figure 3: A graph that fuses information from the abstract syntax tree (black), the execution trace (blue) and a potential error position in the trace (orange). A potential misconception can be characterized as a subgraph (red).

Figure 4: Context graph and excerpt from a text template to deliver meaningful feedback to a student with a potential misconception.

tions (a path of arbitrary length from the expression node to the variable node instead of a direct neighbour).

5. ERROR CONTEXT DISCOVERY

In this section we briefly sketch a graph mining approach to discover context patterns automatically from data.

5.1 Code and Context Graphs

Our input consists of various Java sources, the correct solution trace and the student’s input. The example graph shown in Fig. 3 *focuses* on a specific position in the trace (row/column as encoded by the `codeline` and `varname` nodes linked to the focus node). We create corresponding graphs for every position (row/column) in a trace. At first glance, this affects only the edges of the focus node while the rest of the graph remains unaltered (for a given tracing exercise). However, the relevant context for entering a wrong value in the trace can be narrowed down to the *already passed code lines*: The reason for a mistake cannot be found in source code lines yet to come. Knowing which code line we are focussing at, we remove all AST nodes that correspond to code beyond the focus line.

Apart from the transformations already mentioned in Sect. 4 (renaming variable nodes, flattening expressions), we intro-

duce extra edges from an instruction block to the very first and last statement of the block (labelled `first` and `last`). Other transformations replace numbers by a `literal` label, or re-insert information about variable names: whenever two variables have the same name (before replacing them) we add a `samenname`-edge between them. A code graph is then defined as follows: A triple $G = (V, E, \lambda)$ is called **code graph**, iff V is a non-empty set of nodes, $E \subseteq V \times V$ is a set of directed edges between nodes, $\lambda : (V \cup V \times V) \rightarrow L$ is a function that assigns labels (from a set of labels L) to nodes and edges, and there is exactly one $v \in V$ with $\lambda(v) = \text{focus} \in L$.

We assume that a set \mathcal{G} of all code graphs is given. Having a graph $G \in \mathcal{G}$ for every individual cell (of every trace), we associate counters with them to track how often the respective cell has been entered correctly or not in the submissions. We denote the (absolute) frequencies of correct and incorrect entries by $\text{pos}(G)$ and $\text{neg}(G)$, resp. For a given context C the core operation is to decide whether C can be found in a given code graph G , which is abbreviated as $C \sqsubseteq G$. Then we define

$$P(\text{error}|\text{context } C) = \frac{\sum_{G \in \mathcal{G}, C \sqsubseteq G} \text{neg}(G)}{\sum_{G \in \mathcal{G}, C \sqsubseteq G} \text{pos}(G) + \text{neg}(G)} \quad (1)$$

The graph mining algorithm then searches for a context C that maximizes $P(\text{error}|\text{context } C)$. Formally, we define a context pattern as follows: A tuple $P = (V, E, \lambda, \tau)$ is called **context graph**, iff V is a non-empty set of nodes, $E \subseteq V \times V$ is a set of directed edges between nodes, $\lambda : (V \cup V \times V) \rightarrow L \cup \{*\}$ assigns labels to nodes and edges (where $*$ is a wildcard label), there is exactly one $v \in V$ with $\lambda(v) = \text{focus}$, and $\tau : E \rightarrow \{N, X, T, W\}$ classifies edges into one of four types: normal (N), excluding (X), transitive (T) or wildcard (W).

The semantics of the edge types and the wildcard label (which matches any other label) is defined along with the definition of graph inclusion \sqsubseteq as follows: A context graph $C = (V_C, E_C, \lambda_C, \tau_C)$ is contained in a code graph $G =$

(V_G, E_G, λ_G) , $\mathbf{C} \sqsubseteq \mathbf{G}$ for short, iff there is a bijective function $\sigma : V_C \rightarrow V_G$ such that all node labels match ($\forall v \in V_C : \lambda_C(v) = \lambda_G(\sigma(v))$) or the context label is a wildcard ($\lambda_C(v) = *$), and for all edges in C there are *corresponding edges* in G . An edge $(u, v) \in E_C$ has a corresponding edge if: (1) for normal edges ($\tau((u, v)) = N$) we have $(\sigma(u), \sigma(v)) \in E_G \wedge \lambda_C((u, v)) = \lambda_G((\sigma(u), \sigma(v)))$, (2) for transitive edges ($\tau((u, v)) = T$) there is a path (w_1, w_2, \dots, w_k) in G with $\sigma(u) = w_1$, $\sigma(v) = w_k$, and $\forall i : \lambda_C((u, v)) = \lambda_G((w_{i-1}, w_i))$, (3) for wildcard edges ($\tau((u, v)) = W$) we have $(\sigma(u), \sigma(v)) \in E_G$, (4) for excluding edges ($\tau((u, v)) = X$) we have $(\sigma(u), \sigma(v)) \in E_G \wedge \lambda_C((u, v)) \neq \lambda_G((\sigma(u), \sigma(v)))$.

5.2 Mining Algorithm

In contrast to other graph mining algorithms, our notion of subgraph inclusion (\sqsubseteq) is more complicated due to the different edge types. But we benefit from the fact that we have a clear starting point for inclusion tests because a unique *focus node* is required in both, code graphs and context graphs. The out-degree for many nodes is limited by the fixed syntax of Java instructions, but this does not hold for nodes like instruction blocks or expressions.

From a context graph that may serve as an indicator for a misconception we expect a higher rate of faulty student inputs than on average. A context graph C matches various cells in the traces, but the total number of correct inputs is usually much larger than the total number of incorrect answers. To account for this imbalance, we normalize the correct (and incorrect) number of answers in context C :

$$p_C = \frac{\sum_{G \in \mathcal{G}, C \sqsubseteq G} \text{pos}(G)}{\sum_{G \in \mathcal{G}} \text{pos}(G)}, \quad n_C = \frac{\sum_{G \in \mathcal{G}, C \sqsubseteq G} \text{neg}(G)}{\sum_{G \in \mathcal{G}} \text{neg}(G)}$$

We define an objective function f to rate context C as:

$$f(C) \stackrel{\text{max!}}{=} \log_2 \left(\frac{n_C}{p_C} \right) \quad (2)$$

If the fractions n_C and p_C are about the same, the answers in context C do not distinguish from the average rate over all cells and we obtain $f(x) = \log_2(1) = 0$. If we manage to find a context C that covers twice as many erroneous cases (than on average) and half as many correct cases (than on average), it evaluates to $\log_2 \left(\frac{2}{\frac{1}{2}} \right) = 2$. We perform a beam search in the space of context graphs to identify the context that maximizes (2). Details about the search algorithm are given in the appendix A.

6. EXPERIMENTAL EVALUATION

When the students filled out the execution traces, the submitted solution may contain multiple errors. It is likely that the first error in the trace causes subsequent faults: If the student enters a wrong value in some cell, but this variable is not altered in subsequent code lines, the wrong value remains and invalidates multiple trace lines. Therefore we consider only the first error from each submission, which most likely contains its root cause. In total, there were roughly 100 accounts (some were used only a few times) and all traces together consisted of $|\mathcal{G}| = 7128$ different input cells. All students together pressed the ‘evaluation’ button almost 92000 times. The total number of correct and incorrect entries in the submissions was 2.4M and 64k, resp.

6.1 Discovered Contexts

In this section we present and discuss a few of the context graphs that were automatically discovered by the algorithm from Sect. 5. The objective is to investigate meaningfulness and interpretability of the discovered contexts. In the figures, the node labels carry unique numbers for easier reference (e.g. `focus_0` denotes node #0) and the edges have a suffix indicating their edge type (e.g. N for normal edge) and a varying line style (N : solid, W : dotted, X : red).

The context in Fig. 5 addresses the lifetime of local variables. Many students have a superfluous entry on the stack in this context. The variable #2 has been declared #3 in an instruction block #6, whose last statement is an assignment (#5, connects to #6 with edge labelled `last`). This is the last statement of the block #6 and the superfluous variable has been observed in the next executed line (#1, connected to #4 with an edge labelled `pre vex` (previously executed)). This code line is thus the first after the end of block #6 and variable #2 should have vanished because its lifetime ended.

A somewhat surprising context is shown in Fig. 6, which describes a code line #1 with an `if`-statement #5, where the focussed variable #2 is somehow involved in the control-expression #6 of the `if`-statement. An inspection of the submitted traces reveals that some students stored the boolean result of the control expression on the stack. (Probably the students thought that the evaluation result must be traced *somehow*, but as it does not affect any variable it is not.)³

Fig. 7 captures a context where local variables and attributes are mixed up. The focus is on a local variable #2 (local because of its path to #6) in a function #6 of a class #7 that also contains a field declaration #8. The local variable has a `same name`-edge to another variable, which causes the confusion. Although the equally named variable #4 is not connected to the field declaration #8, it corresponds to it in all matching code graphs. So the student was not aware which variable was addressed in the code and picked the wrong one.

Some contexts may not really relate to code understanding, but point at pitfalls when starting to use the web application. Programs usually start with some variable declaration, so the attention is initially on the stack – and filling out the line number is easily forgotten: In Fig. 8 the expected code line (whose line number was not entered correctly) contains a declaration #2, which is the first instruction in the body #3 of a function #8 – it thus most likely corresponds to the very first code line that has to be traced.

Discussion: The graph mining approach delivered various meaningful context patterns that correspond well to our expectations as well as some unexpected patterns. Once an instructor gets used to them, the graphs are comparatively easy to interpret, which was a requirement for the envisaged approach to solve the research question in Sect. 4 – although sometimes it may be necessary to have a look at the submissions to get an idea what types of error were made. Not all of the discovered patterns were useful, some are too general in nature or mix up several problems. But compared to the

³We consider it unlikely that they tried to mimic the JVM-internal evaluation of expressions.

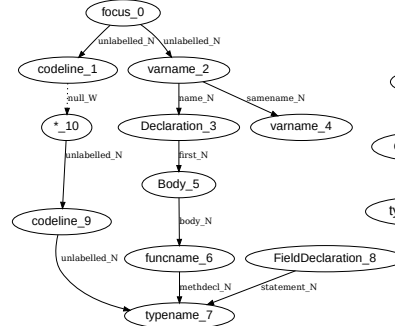

Figure 7: Confusing equally named variable and attribute.

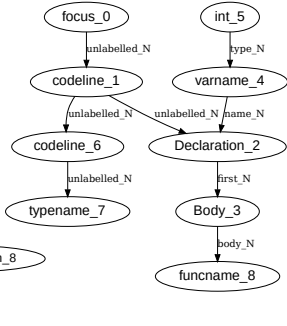

Figure 8: Line number is missing at start of an exercise.

Table 1: Based on the performance over a series of exercises, the students are classified in three groups S_+ , S_\uparrow , S_- . The table shows how many students belong to which group (percentage) and the median number of exercises per group.

context	group size %			practise #		
	S_\uparrow	S_+	S_-	S_\uparrow	S_+	S_-
line number	39.6	27.9	32.4	52	26	25
missing stack	29.8	51.8	18.2	26	19	19
wrong heap value	18.8	64.1	16.9	48	27	20
expected reference	50.2	36.1	13.6	44	31	23
Fig. 5	33.3	44.4	22.2	16	12	13
Fig. 7	20.0	40.0	40.0	23	16	19

time spent on inspecting many raw submissions manually, it takes an instructor much less time to select useful patterns and write an accompanying explanation.

6.2 Evaluating Demand and Progress

Whenever a new concept or instruction has been introduced during the lecture, one group of students (S_+) will have no problems at all with the new instruction type and will enter the traces flawlessly. The second group, which experiences problems, splits up further: the group of reflective students (S_\uparrow) will notice the knowledge gap, may read the course material or offered help text again, and will at some point close the gap – in the future this type of mistake will happen only occasionally and incidentally. We expect a significant reduction in the error rate for this group of students. The remaining group (S_-) does, for some reason, not improve. We can distinguish these three groups on the level of individual misconceptions as follows: For a given error context, we collect all submissions of a student and order them in time. For any given point in time t we may characterize the students performance *before* and *after* t by counting how often the student got the trace in this context right or not. If we can find a point in time t such that there is a *significant improvement* in the distribution of mistakes before and after t , we say that this student belongs to group S_\uparrow . We assign students with a rather low error rate (say, consistently $\leq 10\%$) to group S_+ (at such a low error rate it is very difficult to improve significantly). The remainder belongs to group S_- .

Table 1 shows the size of the groups (percentage) and the median number of exercises per group. The rows aggregate a few different context graphs related to line number errors, missing values on the stack, wrong values on the heap, and situations in which a reference was expected but a number was entered. The numbers for the context patterns of Fig. 5 and 7 are also shown. The table shows that members of S_\uparrow have traced more exercises than any other group (sometimes more than twice as many as group S_-), so the success is correlated with the gained practice. It is not surprising that the median number of practised exercises per context in group S_+ is more similar to group S_- than to S_\uparrow : If they do it right from the beginning, there is less need for further practising.

The experiments show that we can measure (by means of the statistical test) whether an individual student performs significantly worse on a context pattern than the course on average and whether he has improved over time. Similar to feedback from a lab advisor, which is rare but to the point, we may provide feedback to detect misconceptions only if the students make mistakes in the error context significantly more often than the course average (rather than annoying a student with hints at the first incidental mistake). The numbers from Tab. 1 also show that there is demand for support, a relevant fraction of the course did not manage to significantly improve on their own.

7. CONCLUSION

A considerable fraction of the participants did not manage to overcome tracing difficulties on their own, which shows the demand for constructive feedback that goes beyond a right/wrong classification. The automatically discovered context graphs can be assessed by an instructor with comparatively low effort, because they are quite easy to interpret and meaningful. This paves the way for identifying even new misconceptions in reasonable time. The context graphs allow us to analyse the students' state of knowledge and consequently deliver purposeful feedback when needed. It also enables us to recommend suitable exercises to check an improved understanding afterwards. Just like a human advisor, we may congratulate the student if the error rate decreased significantly. This will bring us, in response to the research question, quite close to a human advisor.

APPENDIX

A. MINING ALGORITHM

We incrementally explore the space of all possible context graphs by extending it step by step (add an edge and/or node). To evaluate which extension improves the objective function most, we need to match a new context C' to the graphs $G \in \mathcal{G}$, that is, we have to make sure that a bijective mapping σ exists. Finding the possible mappings σ each time from scratch would imply substantial computational cost (especially as we have matched the first $n - 1$ of the n nodes in the previous expansion already), so we keep track of the mappings σ that have been used for the current context so far. The bookkeeping is illustrated in Fig. 9. On the top left a context graph and on the top right excerpts from a code graph are shown. The node sets V consist of natural numbers, which are shown in subscript next to the assigned labels. Initially we start with a context graph C_0 that consists of a **focus** node alone ($V = \{1\}$, $\lambda(1) = \text{focus}$). At that time, the mapping σ_{C_0} needs to map only node #1 to node #3. Below the two graphs, the row σ_{C_0} shows the mapping ($1 \rightarrow 3$ or $\sigma(1) = 3$). Suppose C_0 is extended by a **codeline** node to context C_1 . Now σ_{C_1} needs to map two nodes, but rather than starting from scratch, we assume that the previous $n - 1$ nodes have been assigned already and only the new node #2 has to be assigned. There is only one possibility in the code graph of Fig. 9, we map $2 \rightarrow 5$. In the figure σ_{C_1} corresponds to a list of length 1, with a single entry ($2 \rightarrow 5$). This entry, however, also points (vertically) to the previous assignment $1 \rightarrow 3$: Following the pointers in vertical direction reconstructs the full mapping σ_{C_1} ($1 \rightarrow 3$, $2 \rightarrow 5$). So the σ -mapping of a new context is based on an existing successor node mapping and we only supplement the assignment of the latest node to complete it.

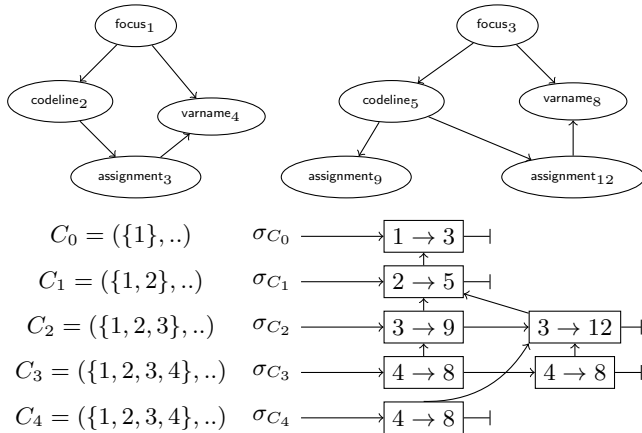

Figure 9: Efficient data structure to keep track of node assignments during the search. As a context pattern evolves (node by node) we re-use all mappings σ of successor graphs.

The main algorithm is shown in Alg. 1, which takes the set \mathcal{G} of code graphs and a start context C_0 (usually consisting of the **focus** node alone). In line 1 we initialize the search front S , which is a priority queue of limited size (we used 1000) ordered by (2). By Σ_0 we denote the set of all valid initial mappings $\Sigma_0 = \{\{\sigma_0^G\} | G \in \mathcal{G}\}$, where σ_0^G maps the unique **focus** node in the context to the unique **focus** node in the code graph G .

In line 2 we initialize a set X of explored nodes: it may happen at some point of the search that we re-consider a context graph we have visited earlier, simply because the nodes and edges of the same context graph could have been inserted in a different order. To avoid wasting time on examining graphs that were already explored, we store a hash code of all explored context graphs in X (set of explored graphs). In our implementation, we use a hash of the Weisfeiler-Lehman kernel [15] for this purpose. The remainder of Alg. 1 represents the search loop: we pick the best-so-far context graph C , expand it, check for an improvement and return the best found context C^* in the end.

Algorithm 1 ContextMining(\mathcal{G}, C_0)

```

1:  $S = \{(C_0, \Sigma_0)\}$   $\triangleright$  search front as priority queue
2:  $X = \emptyset$ ;  $(C^*, \Sigma^*) = (\perp, \perp)$   $\triangleright$  visited nodes, best context
3: while  $S \neq \emptyset$  do  $\triangleright$  queue not empty
4:    $(C, \Sigma) = \text{top}(S)$   $\triangleright$  pick best context from queue
5:    $S = \text{expand}(C, \Sigma, S, X)$   $\triangleright$  expand context
6:   if  $C^* = \perp \vee f(C) > f(C^*)$  then  $\triangleright$  improvement?
7:      $C^* = C$ ;  $\Sigma^* = \Sigma$   $\triangleright$  update best-so-far
8:   end if
9:    $X = X \cup \{h(C)\}$   $\triangleright$  save hash of explored graph
10: end while
11: return  $(C^*, \Sigma^*)$   $\triangleright$  return best context graph
```

Algorithm 2 $\text{expand}(C, \Sigma, S, X)$

```

1:  $Q = \text{explore}(C, \Sigma)$ ;  $E = \emptyset$ 
2: for  $e \in Q$  do  $\triangleright$  for all possible extensions
3:   apply extension  $e$  to context  $C$  and obtain  $C'$ 
4:   if  $h(C') \notin X \wedge \text{size}(C') < \text{limit}$  then
5:      $\Sigma' = \text{prolong-and-filter}(C', \Sigma)$ 
6:     if  $C'$  is substantial improvement of  $C$  then
7:        $C'.\text{momentum} = 2$   $\triangleright$  restore to max
8:     else
9:        $C'.\text{momentum} = C.\text{momentum} - 1$ 
10:    end if
11:    if  $f(C') > \text{worst}(S) \wedge C'.\text{momentum} > 0$  then
12:       $S = S \cup \{(C', \Sigma')\}$ 
13:    end if
14:  end if
15: end for
16: return  $S$ 
```

The node expansion is shown in Alg. 2. It calls a function $\text{explore}(\cdot)$ in line 1, which provides a priority queue (size:60) of the best possible extensions of the current context C (which includes all mentioned types of edges). This allows us to concentrate on the best extensions before we actually expand the context in the search front S . We exclude a new context if it has been explored earlier (line 4) or it becomes too large (max. 12 nodes per context). If the extended context passed all checks, we prolong or adapt the σ -mappings (line 5) to reflect newly inserted nodes. We assign a *momentum* to each context, which is initialized to a small number (here: 2) and reduced by 1 for each extension that *did not* lead to a *substantial* improvement in the object function (2). If the momentum has reached 0, the context graph will not be considered further in the search front. We use a statistical test (G-test) on the 2x2 contingency table of positive and negative cases before and after the extension to decide whether the extension was substantial.

Log mining for course recommendation in limited information scenarios

ABSTRACT

Recommender systems in educational contexts have proven effective to identify learning resources that fit the interests and needs of learners. Their usage has been of special interest in online self-learning scenarios to increase student retention and improve the learning experience. In current recommendation techniques, and in particular, in collaborative filtering recommender systems, the quality of the recommendation is largely based on the explicit or implicit information obtained about the learners. On free massive online learning platforms, however, the information available about learners may be limited and based mostly on logs from website analytics tools such as Google Analytics. In this paper, we address the challenge of recommending meaningful content with limited information from users by using rating estimation strategies from a log system. Our approach posits strategies to mine logs and generates effective ratings through the counting and temporal analysis of sessions. We evaluate different rating penalty strategies and compare the use of per-user and global metrics for rating estimation. The results show that using the average number of lessons viewed per-user is better than using global metrics with a p-value under 0.01 for 4 of our 5 hypotheses, showing statistical significance. Additionally, the results show that functions that penalize the rating to a lesser degree behave better and lead to a better recommendation.

an importance not previously seen. The pandemic forced learners, course designers and instructors to migrate to virtual environments where the learning content is mainly delivered in digital formats with a limited or none face-to-face interaction. Existing work have shown the importance of simple but effective virtual learning environments, which allow a progressive adaptation according to learners needs and preferences in order to keep their motivation and engagement [3, 4].

To adapt the learning environment and give meaningful content recommendations to learners, learning platforms should be able to profile the learner in terms of a set of features such as preferences, behaviors, or learning needs. A question then arises in this context: how to obtain relevant learners' information? While more traditional approaches ask the learner directly through surveys and registration forms, modern approaches complement this explicit information with implicit data extracted from interactions with the platform (*i.e.*, logs) [5, 6]. The amount and quality of information that can be extracted depends largely on privacy regulations, the administrator guidelines, and the platform technological capabilities. Therefore it is not unusual to find open virtual learning scenarios where the information collected and available about learners is limited. This is the case for the GCFGlobal learning platform.¹

The GCFGlobal Learning Program objective is to teach different basic skills necessary for the 21st century, online, in an open modality, and without cost. According to GCFGlobal's Web page "gcfglobal.org" offers training in more than 40 topics, ranging from Microsoft Office and email usage to reading, math, and more. A GCFGlobal course contains several lessons. GCFGlobal offers more than 360 courses, counting for more than 6,400 lessons, more than 2,500 videos, and more than 50 interactive activities and games". In 2021 the number of users who used the English, Spanish and Portuguese sites and visited at least one course was around 41 million. GCFGlobal establishes as a regulatory principle of its operation that access to their learning content has to be open to anyone in the world, and the only requirement is internet access. The courses are online, self-paced and self-directed (*i.e.*, without a tutor). Registration and authenti-

¹GCFGlobal learning platform:<https://bit.ly/3tBpGa5>

cation on the platform is not mandatory and it is estimated that only 2% of users are registered, thus, there is no explicit information about learners (*i.e.*, identity data). The information that is available comes mainly from the logs via Google Analytics tool. Google Analytics is a standard and popular tool used in e-commerce that has been also positioned itself as a useful tool in learning platforms [7, 8]. Its popularity is due to its ease of implementation and its capabilities to filter and analyze large volumes of logs. Although log analysis has limitations when it comes to identifying a user, it is the most likely type of data that can be found in any existing web-based platform.

In this paper, we present an empirical study for rating estimation from Google Analytics logs. These ratings express the preferences of the learners and allow the construction of recommender systems. Our evaluation is focused on how these ratings behave in a course recommendation scenario. The contributions of our work are summarized as follows. (1) Dedicated strategies for counting lessons seen by a user, and to process the timelines from logs. (2) A strategy to generate ratings that contemplate per-user and global metrics based on lesson counting. (3) A comparison of previous strategies in a course recommendation system.

2. RELATED WORK

A recommender system in a learning platform aims to identify the most interesting learning content for learners according to their preferences [9]. The most popular recommendation techniques described in the literature are collaborative filters (CF), content-based techniques (CB), and hybrid models that combine both CF and CB [10, 11, 12, 13]. CF uses information about the rating that learners assign to courses or learning content to generate a recommendation [14, Ch.3]. CF-based systems assume that if a learner X has the same/similar rating as a learner Y on a course, X is more likely to have the same/similar rating as Y on a different course [14, Ch.3]. CB filters use a course as the basis of the recommendation, rather than a learner. That is, a CB filter uses the characteristics of the course (*i.e.*, descriptions, tags, content, topics, classifications) to make recommendations. CB filters use course characteristics to search for courses similar to those a learner has previously taken [13]. To address specific disadvantages of CF and CB models, hybrid models work on the idea of merging them to enhance the result.²

Existing work have shown the effectiveness of recommendation engines in learning platforms. For instance, Campos et al. [9] propose a CB filter that uses topic modeling for a big corpus of courses from different education platforms. Ma et al. [15] use a similar CB technique but their evaluation focuses on user experience and usability. Another common approach is to use of data mining techniques such as associate rules; for example Intayoad et al. [16] use classification algorithms and associate rules to create a system that exploits the learner’s content access history to propose recommendations.

Following the trend of e-commerce recommender systems,

²A discussion of the advantages and disadvantage of CB and CF is given by Xiao et al. [13]

there is a recent increase of hybrid models use combining both CF and CB. A representative strategy in that trend is to use a CB model to manage the problem of the cold start and CF to take advantage of the information that is produced by learners in their interaction with the platform. CB models are used to recommend items for learning content for which there is not enough information for a CF strategy. For example, a course recommendation engine can use the CB model for new students, and a CF model for existing students [13, 10]. Wang et al. [12] use a similar hybrid technique with the DCBVN framework, where the model is built with a Variational Autoencoder Network combined with a CF model to generate recommendations. DCBVN considers the course difficulty and the skills of learners to generate the recommendations.

Yin et al. [11] use three models: CF, CB (using a topic classification technique), and a transition probability model to produce a single rating for a course. The transition probability model is used to manage the relationship of prerequisites between courses. Shanshan et al. [17] use a hybrid technique to generate recommendations with a CF model and an ontology to calculate similarities. This technique uses a cascade evaluation to refine the recommendation list with a rule association algorithm.

The aforementioned models often operate in rich information scenarios. In these scenarios, demographic information, evaluation results or perception surveys are available to facilitate the construction and evaluation of the recommender system. The problem of inferring ratings is not addressed to the extent that this information is explicitly provided by the learner.

3. METHODOLOGY

In this paper, we focus on the estimation of users results and their ratings for courses via a CF recommendation technique. CF requires a rating matrix to find similar learners. However, we do not have these ratings explicitly, therefore, it is necessary to infer them from Google Analytics logs. A course developed by GCFGlobal is composed of a set of lessons. The analysis of the number of lessons accessed by the learner and the associated session time are the basis for generating the rating. In the following we present the raw data extracted from Google Analytics and its processing, as well as the rating generation strategies.

3.1 Data processing

The logs in Google Analytics are consolidated under the concept of a session. Sessions are defined as the set of events generated by user’s actions within the platform without exceeding 30 minutes of inactivity.³ Due to the way the logs layer is deployed, we have to assume that the same user accesses the platform through the same device. This statement is true in most cases and allows us to group sessions in a timeline per user. We are interested in the “PageView” event that provides the URL of the page that the user accesses. The page URLs in the learning platform are defined by a unique path for each course-lesson pair, which allows us to identify the course and lessons related to a “PageView”

³Google Analytics forum: <https://bit.ly/3IR1AAY>

event; URL paths are as “language/course/lesson/additional-params”.

We use two filters to select users and lessons from Google Analytics. The first filter removes sporadic users, keeping users with at least 30 sessions during the year (2021-01-31 to 2022-01-31). The second filter ensures that the sessions belong to at least three different courses. This filter allows us to guarantee the future construction of the dataset and ground truth to evaluate the recommendation system. We use at least two courses to build the ratings for the collaborative filter and the third one for its evaluation. It is important to mention that the temporality of the sessions is taken into account in the construction of the dataset. The first two courses in temporal order are used in the construction of the collaborative filter and the last seen was used to evaluate the recommendation. We also consider the session time factor for lesson counting as explained in the following.

After building a base of users and sessions, we proceed to perform the pre-processing steps described in Figure 1. In step 1, the base of users and sessions extracted from Google Analytics is loaded into a local database in order to be able to perform transformations on the data in an easy and efficient way. In step 2, the timestamp column is transformed and standardized in such a way that the records can be ordered from the most recent session to the most distant. As mentioned previously, this allows us to identify the chronological route that the user made through the courses and their lessons. In step 3, we identify the time spent by the user in each lesson (“lesson duration”). Step 3 is not trivial as the different sessions in which the same lesson is visited must be reconciled. An intra-lesson analysis is performed first, followed by an inter-lesson consolidation.

In the intra-session analysis, the time that a user spent in lessons of the same session is extracted. The time is calculated as the difference between the timestamp of the “PageView” event of the lesson URL and the immediately following event timestamp if it exists. In the case that the session ends with a visit to a lesson and there is no subsequent event for the calculation, we use imputation using the average lesson time over all users. For lessons with multiple visits in the same session, the times obtained were added. Table 1 shows an example of the calculation of the time spent in the lessons within the same session. Being the last event of the lesson, the time of lesson “D” is imputed using the average duration of the lesson over all users. Then an inter-lesson level analysis is carried out where the times of the lessons that were visited in different sessions are added to consolidate a total “lesson duration” per user.

Table 1: Intra session analysis example. Four “PageView” events to lessons A, B, C, and D. The time spent in lesson D is calculated as the average of all users.

Lesson	Timestamp	Time Spent (min)
A	2021-01-29 08:49:01	20
B	2021-01-29 09:09:01	18
C	2021-01-29 09:27:01	21
D	2021-01-29 09:48:01	17

In steps 4 and 5, the number of lessons that make up each course is consolidated, then, for each user-course combination, the number of lessons viewed is counted. With these results, in step 6, the percentage of lessons viewed is calculated per user-course. In step 7, the percentages obtained in step 6 are averaged to obtain a per-user metric of the percentage of lessons viewed.

In step 8, users who have seen lessons from more than 50 courses are removed. These are considered outliers because they are more than three standard deviations from the mean [18, p.19]. A total of 4 users were removed, one of them with a total of 131 courses viewed. Considering the minimum 3 courses filter explained at the beginning of this section, our dataset only contains users who have seen courses in the range (2,50).

In step 9, we add a filter to the count made in step 5 according to the user’s lesson duration. Lessons below a stipulated time will not be considered. The exclusion of lessons by duration is controlled by a parameter, and the effect of this parameter is evaluated in the experimentation. Our hypothesis is that the inclusion of this filter will allow discarding lessons that a user addressed lightly and possibly incompletely, thus improving the results of the recommendation.

Finally, in the last step (step 10), we split the data into a subset for training (*i.e.*, construction of the collaborative filter) and another for testing. The split maintains the temporal order, therefore, the test set always has courses viewed after those in the training dataset per user. We use the first 70% of the courses for building the collaborative filter and the last 30% for evaluation. In the worst case when a user has only seen three courses, two will be used for training and one for evaluation.

3.2 Rating Estimation

As mentioned above, these ratings are essential for the construction of the collaborative filter [14, Ch.2]. In this section, we explain how we estimate these ratings. Our hypothesis is that the number of lessons accessed by a user in a certain course is an expression of the level of liking of a learner for it. Being open courses where the courses and lessons are approached by the will of the learner, it seems valid to assume that the perception about a course is reflected in the number of lessons taken by the learner.

To estimate ratings we use a threshold between 0 and 5, common in recommender systems [14, Ch.2]. Courses with a percentage of lessons viewed above a threshold will obtain the maximum grade (5), and those that are below will be penalized according to a penalty function. We use two threshold metrics: (1) the average percentage of lessons viewed per course by a user (per-user metric), and (2) the overall average percentage of lessons viewed per course for all users (global metric). These two metrics are inspired by the different ways of calculating similarities [14, Ch.2], where knowing if a rating is above or below the average is considered more valuable than the rating itself. It is known that user ratings in different domains tend to be very close to the average. While a rating in the middle does not say much, a rating far from it is a clear indication of like or dislike.

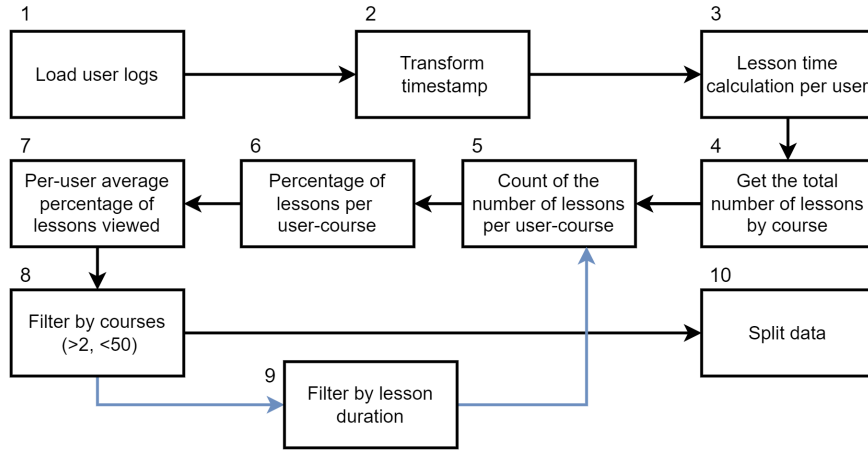

Figure 1: Data processing steps

For the rating penalty, 5 different functions will be evaluated: logarithmic, square root, quadratic, linear, and step (Equations 1 to 5). The combination of thresholds and penalty functions give us 10 different ways of calculating the ratings.

$$f_1(x) = \begin{cases} 5, & x \geq \text{threshold} \\ 5 * (\frac{x}{\text{threshold}})^2, & x < \text{threshold} \end{cases} \quad (1)$$

$$f_2(x) = \begin{cases} 5, & x \geq \text{threshold} \\ 5 * \frac{x}{\text{threshold}}, & x < \text{threshold} \end{cases} \quad (2)$$

$$f_3(x) = \begin{cases} 5, & x \geq \text{threshold} \\ 5 * \log_2((\frac{x}{\text{threshold}}) + 1), & x < \text{threshold} \end{cases} \quad (3)$$

$$f_4(x) = \begin{cases} 5, & x \geq \text{threshold} \\ 5 * \sqrt{\frac{x}{\text{threshold}}}, & x < \text{threshold} \end{cases} \quad (4)$$

$$f_5(x) = \begin{cases} 5, & x \geq \text{threshold} \\ 0, & x < \text{threshold} \end{cases} \quad (5)$$

3.3 Collaborative Filter

We use a classic collaborative filter approach since our objective is to evaluate the effect of the rating generation strategies on the recommendation as well as the temporal analysis in the filtering of the lessons.

Our collaborative filter uses the `turicreate` python library that implements an item-based CF. We use cosine similarity to identify similar courses based on ratings (Equation (6)).

$$CS(i, j) = \frac{\sum_{u \in U_{ij}} r_{ui} * r_{uj}}{\sqrt{\sum_{u \in U_i} (r_{ui})^2} * \sqrt{\sum_{u \in U_j} (r_{uj})^2}} \quad (6)$$

where U_i is the set of users who rated item i , and U_{ij} is the set of users who rated both items i and j .⁴ The library

⁴Turicreate documentation: <https://bit.ly/3y0vJsx>

has a default threshold of 0.001 where users with a lower similarity coefficient are excluded when making the rating prediction.

3.4 Evaluation setup

In step 10 of the data processing flow (Figure 1), the dataset is built using 70% of the courses for training and the remaining 30% for evaluation. Given that the average number of courses viewed by each user in our dataset is 6.64, in the average case, there are four courses for the construction of the collaborative filter and two for its evaluation.

The performance of the recommender system was evaluated by precision at k ($P@k$), a typical metric for the evaluation of Top-N recommender tasks [10, 11, 19, 20]. We found in the literature that a value of N usually used in recommender systems in learning environments is $N \in [5, 10]$ [10, 11]. A higher number of recommendations could overwhelm the learner, in particular in partially known domains of knowledge, and a lower number could include elements that are not diverse. However, the use of $k = N = 5$ for evaluation poses a challenge to the extent that in our dataset most of the users do not contain 5 relevant courses in the evaluation set. To avoid an overpenalization in the calculation of the $P@k$, we define the k per user in the range $1 \leq k \leq 5$ according to the number of courses in the test set. The results reported are the $P@K$ average over all users. A Wilcoxon rank-sum test with the Bonferroni correction was used for all our statistical significance tests ($\rho < (0.05/\#\text{hypothesis})$).

4. RESULTS

After processing the data, 56466 sessions were obtained, a total of 7071 users extracted, and 230 different courses were considered from the GCFGlobal learning platform. Table 2 presents the results obtained using the rating strategies explained in Section 3.2.

The results suggest that a custom threshold (PU: per-user) is better than a global one (GPC). However, it is not conclusive on the use of penalty functions. To identify if there are significant differences in the precision obtained by different combinations of penalty functions and threshold strategies,

Table 2: Precision results for the PU (Per-user metric) and GPC (Global metric)

Penalty Function	Threshold Strategy	Precision @ 5
F1 (Quadratic)	PU	0.3928
	GPC	0.3923
F2 (Lineal)	PU	0.3759
	GPC	0.3711
F3 (Logarithmic)	PU	0.3783
	GPC	0.3753
F4 (Square root)	PU	0.3911
	GPC	0.3824
F5 (Step)	PU	0.1677
	GPC	0.0526

we built a set composed of 100 sample. Each sample is built by selecting randomly 3000 users from the total set of users (*i.e.*, 7071). Then, we repeat the process of building and evaluating the recommendation engine. In Table 5, we present the average precision obtained per penalty function over the 100 experiments. As can be seen in the table, a similar behavior where the custom threshold (PU) and a square root function (F4) lead to a better recommendation results. Regarding the penalty functions, a very interesting behavior is evident: the lower the penalty, the better the recommendation. Figure 2 shows the penalty functions for a particular threshold from which it is possible to identify that there is a correspondence between the order in the results F4(best)-F3-F2-F1-F5(worst) and the penalty degree of the function.

We perform a statistical significance via Wilcoxon rank-sum test where the null hypothesis is that the $P@K$ obtained by the two threshold metrics have the same distribution. The alternative hypothesis is that the distribution of $P@k$ obtained by one metric is stochastically greater than the distribution of the other. We repeated this test for each penalty function, therefore a total of 5 hypotheses were evaluated. The results of the tests for each penalty function are shown in Table 3. Our first relevant finding is that the results obtained by a custom threshold (PU) are statistically significant in most cases. Only for the quadratic function, the null hypothesis was not rejected.

We repeat a similar test but for the penalty functions. Using PU as the threshold, we test if the results obtained via F4 are statistically significant in comparison with the others penalty functions. The test results are reported in Table 4 and show that results obtained via F4 are statistically significant compared to all other functions except again for the quadratic function.

Our final experimentation is related with the lesson duration (*i.e.*, Step 9 in Figure 1). We want to see the effect on the recommendation precision of adding a lesson duration filter prior to counting and calculating the percentage of lessons viewed. The filter removes lessons with a duration less than x value. We use PU as threshold metric and F4 as penalization strategy. Figure 3 shows the results obtained as

Table 3: PU (Per-user metric) vs GPC (Global metric) Wilcoxon test results.

Penalty Function	ρ -value ($\rho < (0.05/5)$)
F1 (Quadratic)	0.448
F2 (Lineal)	5.273e-32

F4 (Square root) vs F3 (Logarithmic)	8.400e-05
F4 (Square root) vs F5 (Step)	1.261e-34

Table 5: Average precision over 100 randomly datasets. PU: Per-user metric, GPC: Global metric

Penalty Function	Threshold Strategy	Avg. Prec. @ 5
F1 (Quadratic)	PU	0.225
	GPC	0.225
F2 (Lineal)	PU	0.239
	GPC	0.214
F3 (Logarithmic)	PU	0.241
	GPC	0.218
F4 (Square root)	PU	0.246
	GPC	0.223
F5 (Step)	PU	0.09
	GPC	0.03

Figure 2: Behavior of penalty functions with a threshold of 0.8 (80%) for a given course. The estimated rating is 5 if the percentage of lessons accessed is greater than 80%. For lower values, the rating is given by the penalty functions F1-F5.

the filter becomes more restrictive. One of the consequences is that as the minimum lesson duration time is restricted, the

size of the dataset is reduced. This means that after applying the filter there are users with less than 3 courses and they are thus removed from the analysis. Figure 4 shows how the size of the number of users decrease with the increase of the lesson duration filter.

Figure 3: Lesson duration filter vs recommendation precision

Figure 4: Lesson duration filter vs number of users in dataset

5. DISCUSSION AND FUTURE WORK

In relation to penalization functions, we observe that less penalty lead to a better recommendation. This indicates that a low number of lessons viewed per course cannot be directly related to low preference. Being open learning resources where the learning process is self-directed, there are many other variables that can affect the non-continuity in the learning process that are impossible to identify in our context (*i.e.*, learning priorities, time, health). It should also be taken into account that since it is an implicitly extracted rating, it is to be expected that it does not accurately reflect the user’s preferences. We also conclude that the F4 (square root) penalty function leads to better recommendation results, and there is statistical significance concerning F3, F2, and F5.

The experiments suggest that a per-user metric works better than a global metric. This result is not surprising to

us as using a custom metric for each user should better reflect their behavior and therefore their preferences. Despite this, keeping this metric updated is a process that can be exhausting in a productive environment, since it must be recalculated for each new interaction with a lesson. The global is expected to fluctuate less and can be recalculated every certain time interval.

Regarding the duration of the lesson, the figures show the more restrictive the filter is, the better is the recommendation precision. This behavior is independent of the way the session is processed (*i.e.*, inter vs intra). We attribute this result to the fact that the lesson duration filter reduces the data set to users for which we have (1) more information (*i.e.*, more lesson interactions), and (2) more precision in the rating calculation. As users spent more time going through the lessons, it is more likely that those lessons were of interest to them. In consequence, we can conclude that the rating estimation strategy based on course lesson completeness better reflects the preferences of learners with greater lesson duration times.

There is a wide range of future work that we want to address based on the results presented in this paper. Now that we have found an appropriate strategy to build the ratings from logs, we want to explore more advanced techniques for building the CF engine such as matrix factorization strategies and recent deep learning approaches [21, 22]. We also want to explore hybrid recommendation techniques that combine CF and CB making use, on the one hand, of textual descriptions of lessons and on the other hand, on semantic descriptions that can be enriched via knowledge graphs [23].

6. CONCLUSION

This paper addresses the problem of course recommendation under limited information scenarios. We posit a process for course rating estimation based on log information for a CF-based recommender system. Our strategy to exploit the limited information available in logs uses the combination of: (1) the percentage of the lessons accessed in a course, (2) a threshold definition, and (3) different penalty functions to estimate the learner perception about the course. Then, we evaluate the influence of the duration of a user in a lesson in the definition of the rating.

As a threshold, we found that a personalized average per-user is better than a global one. Regarding penalty functions, F4 present the best results, and in general we found that the functions that penalize to a lesser degree lead to a better recommendation. Finally, we found that “lesson duration” plays an important role to improve rating estimation. The more demanding the “lesson duration” filter better our rating estimation and the recommendation precision. However, using the lesson duration as a filter has the side effect of reducing the number of users in the dataset because a great number of lessons access records are discarded.

ABSTRACT

Machine learning is a powerful method for predicting the outcomes of interactions with educational software, such as the grade a student is likely to receive. However, a predicted outcome alone provides little insight regarding how a student’s experience should be personalized based on that outcome. In this paper, we explore a generalizable approach for resolving this issue by personalizing learning using explanations of predictions generated via machine learning explainability methods. We tested the approach in a self-guided, self-paced online learning system for college-level introductory statistics topics that provided personalized interventions for encouraging self-regulated learning behaviors. The system used explanations generated by SHAP (SHapley Additive exPlanations) to recommend specific actions for students to take based on features that most negatively influenced predicted learning outcomes; an “expert system” comparison condition provided recommendations based on predefined rules. A randomized controlled trial of 73 participants (37 expert-system condition, 36 explanation condition) revealed similar learning and topic-choosing behavior between conditions, suggesting that XAI-informed interventions facilitated student statistics learning to a similar degree as expert-system interventions.

Keywords

Machine Learning Explainability, Online Learning, Self-regulated Learning, Educational Interventions

1. INTRODUCTION

Personalization promotes learning by providing meaningful, timely, and relevant support that is tailored and paced to an individual’s needs and preferences [4, 32]. Thus, many intelligent tutoring systems (ITSs) have integrated person-

alization aspects that can automatically suggest which materials to study [9], reorient attentional states [15], and construct personalized feedback [20]. Such interventions are often driven by predictions using past learners’ data to build machine learning models, whose underlying mechanisms can be difficult to interpret. Yet, understanding the reasons behind a prediction is essential for educational software that needs to respond not only to *what* is likely (i.e., predicted) to happen, but also *why* it is likely.

Explainable artificial intelligence (XAI) methods [8, 17] have been developed to circumvent the opaque nature of complex machine learning models, which may thus enable a new generation of educational software with increased user trust and perceived usefulness [12, 13]. In this paper, we create personalized interventions driven by explanations, rather than by predictions, for the purpose of adapting students’ behaviors in a computer-based learning environment. We focus on encouraging self-regulated learning (SRL) behaviors in particular [33]. SRL is especially important in online and computer-based learning contexts, where teachers are often less available (versus classroom learning contexts) to guide the learning process. However, many students need assistance with these SRL decisions [37, 45, 36], and thus stand to benefit from computer-based learning environments that fill the gaps in SRL skills by suggesting appropriate activities to students.

We present work from a randomized controlled trial for which we developed an online, computer-based education platform for college-level introductory statistics topics. We explored how machine learning model predictions, coupled with explanations, can personalize interventions to support SRL reviewing behaviors. Our study provides a rigorous comparison of an XAI-driven intervention against an active expert-system intervention consisting of predefined rules based on the amount of time spent studying each topic and the expected order of topics in the curriculum.

The XAI-driven interface adaptations in this work raise several research questions (RQs) related to the effect interventions have on learning and the effects adaptations have on behaviors. These RQs have implications for computer-based education (and for broader understanding of how simple

XAI-driven interventions affect student behaviors).

RQ1: What are the effects on learning and self-regulated learning behaviors when students receive XAI-informed interventions vs. expert-system interventions?

Hypothesis: We expected that the participants in the XAI-informed intervention group will learn more than those receiving expert-system interventions due to XAI-informed intervention group studying topics directly related to improving their predicted learning outcome. Furthermore, we expected that XAI-informed interventions would lead to more frequent reviewing SRL behaviors. Although both the XAI-informed and expert-system condition interventions in our study were created with the goal of supporting SRL reviewing behaviors (re-taking quizzes and re-reading texts), we expected that XAI-informed interventions would better highlight topic areas that needed the most studying based on learning outcome predictions.

RQ2: Do XAI-informed interventions lead to different topic choosing behaviors compared to the expert-system intervention?

Hypothesis: XAI-informed interventions may impart topic choosing strategies based on predicted knowledge gaps, which we expected would lead to lower proportions of students following the default intended order of topics. Furthermore, we expected that students would follow interventions in the expert-system condition more frequently because these interventions often recommended a top-to-bottom reading order of topics that may align with students' natural inclinations.

2. RELATED WORK

Here, we highlight work on self-regulated learning in online and computer-based education environments and interface adaptations informed by XAI.

2.1 Supporting Self-Regulated Learning

Self-regulated learning (SRL) refers to the metacognitive, motivational, and emotional processes behind acquiring information or skills [48, 33]. SRL has been identified as an important skill for succeeding in postsecondary education [27, 31]. Developing SRL skills is difficult, however; students struggle to differentiate effectiveness between learning strategies [50], and may not be aware of how to develop SRL skills [5]. There are three general groups of strategies identified in major SRL models: preparation, performance, and regulation [33, 10, 38, 44, 50, 38, 44] (though there is some variation, including SRL strategies that occur after/between learning sessions [49]). It is regulation behaviors (e.g., re-visiting materials or re-taking quizzes to prepare for a final test) our study interventions target, since reviewing behaviors can be supported by recommending review of specific learning material during test preparation.

Within the past two decades, a substantial amount of work has been carried out encouraging SRL in online learning environments, such as MOOCs [25, 23], where SRL skills may be especially important since learners are required to learn autonomously [2, 42]. Researchers have developed computer-based education environments to support SRL skills,

such as MetaTutor [3], Betty's Brain [24], and Cognitive Tutor [40], which aid SRL skills via adaptive pedagogical agents or by automatically personalizing the presentation of information. These systems, along with other research in online contexts [14, 34], demonstrate the feasibility of utilizing data recorded in log files to examine SRL behaviors through modeling SRL behaviors and predicting student outcomes.

2.2 Adaptations using XAI

In this paper, we focus on a particular XAI method called SHAP (SHapley Additive exPlanations) [26]. SHAP is well-suited to driving interface adaptations because it provides, for every prediction, an indication of how much each feature (i.e., predictor variable) influenced the decision made by a machine learning model. SHAP values capture directionality (e.g., the value of feature X_1 for this prediction contributed positively vs. negatively to the prediction) as well as magnitude, via a game-theoretic approach [22]. Hence, an interface can adapt to the needs of users based on feature values and the effects those values have on predictions (i.e., the SHAP values), provided that the features themselves are interpretable [6].

Within XAI research, there has been less focus on XAI systems that leverage machine learning explainability for adaptation for education purposes. Conati et al. used XAI for integrating explanation functionality for adaptive hints in an Adaptive CSP (ACSP) [12], and found that explanations increase students' trust, perceived usefulness, and intention to use the hints again. In another study by Mu [30], researchers used XAI to develop suitable interventions for wheel-spinning students with simulated data and hypothetical interventions predicted for a previous study [30]. The work in our paper significantly extends this previous work [30] by examining one possible application of XAI-driven interventions (i.e., supporting SRL behaviors) via a randomized controlled trial. We also explore how XAI approaches such as SHAP can help education researchers discover sensible interventions for any learning behavior (e.g., suggest different things to different students in a plausible way)—in our case, SRL reviewing behaviors.

3. METHODS

Next, we discuss our online learning system and SRL interventions, the machine learning model for predicting student learning outcome and interpretation via SHAP (SHapley Additive exPlanations) values, and the experiment setup.

3.1 Self-guided Online Learning System

We developed a self-guided, self-paced online learning system which displays both learning content and interventions as students navigated through the interface, agnostic of content type (images, text, videos, etc.). The system also collected logs including some general interaction behaviors such as web page visits, time spent on each page, and more specific study-related data such as automatically assessed quiz scores, pretest scores, and posttest scores.

We focused on introductory statistics because it is an important yet difficult-to-learn subject for many college degrees [46, 39, 41]. We developed a small curriculum of 12 introductory statistics topics in consultation with university

statistics instructors and educational websites (e.g., course pages). Each topic consisted of a reading (text tutorials and accompanying figures) and a corresponding 3-question, multiple choice mini quiz. These materials could be accessed from the main interface of the topics menu page (Fig. 2). The curriculum also included two variations of a 12-question multiple choice question test (a pretest and a posttest), with each question of the tests corresponding directly to one of the 12 topics. Both tests asked about the same core concepts and differed only with slight variations in questions, such as the specific values used. We designed the final curriculum to take a total of 90 minutes to complete, including the pretest, 12 readings, 12 quizzes, and the posttest.

3.2 Expert-system Intervention

We designed an expert-system version of the self-regulated learning intervention for the system (Fig. 1, top image) with a simple yet precise message of a topic suggestion based on reading time. However, we decided that the expert-system intervention should first suggest an unseen topic over topics with little study time, since learning outcomes improve when students at least touch on all material in time-limited scenarios [28]. We anticipated that the statistics topics on the system required careful reading in order to fully learn and perform well, as the study’s statistics topics have been cited to be prone to misconception [43], and difficult to teach [11]. Thus, we expected that time spent on readings was closely connected to posttest scores. If a student knew that they had spent a lower amount of time reading one of the topics relative to others, they may self-reflect and be more likely to prioritize reviewing that topic over others they have already studied more thoroughly.

We implemented the expert-system intervention in the on-line learning system by displaying the intervention message when the student reached the 30 minute mark in the self-guided study session (Fig. 2), then again at 40 minutes, and finally, at 50 minutes. We chose these time points to provide sufficient data collection before the first intervention to enable an accurate prediction of student outcome, and repeated the intervention at 10-minute intervals to give the students additional suggestions. At the 60 minute mark, students were automatically taken to the posttest. Since the study session was self-guided, it was left up to the discretion of the student to read, review, or skip topics, and spend as little or as much time—up to 60 minutes—as they wished to complete the study session.

3.3 Piloting and Training Data Collection

Please study this topic next (may be helpful to write down the topic name): Summarizing Qualitative Data

This recommendation is based on your reading time so far. Focusing on this topic may help you learn a topic you have not studied as much.

Please study this topic next (may be helpful to write down the topic name): Probability Introduction

This recommendation is based on a prediction of which topic is most likely to help you on the test at the end. Focusing on this topic may help you learn a topic you have not yet mastered as well as the others.

Figure 2: A portion of the topics menu from a self-paced learning session.

We recruited student participants via student mailing lists and digital bulletin boards, seeking students with minimal college statistics experience (0 or 1 college-level statistics courses) in order to avoid ceiling effects from participants with extensive preexisting knowledge of the material. The study session was fully online. The study included a demographics survey, a pretest, a self-guided learning session (12 readings and 12 quizzes), and a final posttest. Participants were compensated \$15 USD. Based on participant feedback from semi-structured interviews (compensated an additional \$5), we made various minor changes, such as clarifying the topics menu page instructions, adjusting names to reduce cultural specificity, noting topics from the topics menu were related to the pretest and posttest questions, and including a proceed to posttest confirmation page.

After making the final changes to our system, we recruited a total of 58 participants for the first round of data collection. The goal of the first round of data collection was to collect training data for the machine learning model to predict the posttest score, which is described in the next section.

3.4 XAI-informed Intervention

Table 1: Example subset of SHAP values from a posttest score prediction for one student, indicating that the student’s current time spent on topic 8 (i.e., 0 seconds) has the most negative impact on their predicted posttest outcome.

Feature name	Feature value	SHAP value
Pretest score	50%	2.454
Quiz 1 score	67%	0.206
Quiz 2 score	100%	0.221
...
Topic 6 reading time	658 seconds	3.734
Topic 7 reading time	0 seconds	-3.860
Topic 8 reading time	0 seconds	-6.187

With the training data collected with 58 participants, we trained a random forest regressor using pretest score, quiz

score (12 topics), and reading time (12 topics) features to predict posttest score. We trained the final model on all data with 100 trees and a maximum tree depth of 4 (the only hyperparameter tuned). We used the tree explainer (`shap.TreeExplainer`) in the Python `shap` library [26] to interpret model behavior of the posttest score predictions in terms of SHAP values. The feature with the most negative SHAP value represented the feature which contributed most to lowering a student’s posttest score.

For the XAI-informed intervention message (Figure 1, right image) used for the XAI-informed condition, the topic (quiz or reading) with the most negative SHAP value was selected to be recommended to the student. The intervention text also communicated to the student that the recommendation was based on a system prediction of the student’s posttest score to help the student better understand the reason for suggesting the particular topic.

We examined what happens when a student follows the XAI-informed intervention recommendation of the feature with the most negative SHAP value. Table 1 shows an excerpt of results from a SHAP analysis of a student during a study session. At the time of this particular prediction, *Topic 8 reading time* had the most negative SHAP value with -6.187—substantially lower than the next feature, *Topic 7 reading time* at -3.860. This indicates that, based on the model’s posttest prediction, topic 8 reading time is negatively impacting the predicted posttest score of this student by 6.187 points out of 100 possible points on the posttest, and should be recommended to the student to study.

Figure 3 shows how the SHAP value of one example feature, *Topic 6 reading time*, changed with each additional 20 seconds of studying time for one student. The SHAP value trended in the positive direction as reading time increased until a point between around 140 seconds of total reading time when the SHAP value plateaued at ≈ 4 . The model appears to have learned that short studying times do not yield learning, and that very long studying times (relative to the brief topics used in this experiment) do not help past a certain point, thus yielding an approximately sigmoid-shaped curve. In this example, what was previously negatively influencing the predicted posttest score is now predicted to contribute around +4 points toward the final posttest score. Using the intuition from this example, our XAI-informed intervention recommends a topic to review to the student such that each student receives a personalized recommendation of the most helpful topic for improving their posttest score.

3.5 Expert-system vs. XAI-informed Intervention Experiment

We carried out a randomized controlled trial to compare the expert-system intervention and the XAI-informed intervention. We recruited 73 participants with minimal college statistics experience (0 or 1 college-level statistics courses) via campus mailing lists and—with the aid of university research support—targeted emails to undergraduate students with no statistics course on their academic course record. We also recruited students from research subject pools and introductory psychology undergraduate courses.

We randomly assigned students to conditions, with 37 stu-

Figure 3: Changes in student’s total time spent on reading topic 6 and resulting SHAP values (in % change in grade)

dents and 36 students assigned to the expert-system and XAI-informed conditions, respectively. The study session structure was identical to the training data study sessions: a video-call meeting followed by the student independently working through the study consisting of a demographics survey, a pretest, a self-guided learning session (12 readings and 12 quizzes), and a final posttest. Students were told that the estimated total completion time was around 90 minutes, and were compensated \$15 USD. However, for the experiment, in the case that a participant wanted to skip out of the self-guided learning session early and proceed to the posttest, they would receive an intervention on the confirmation page and be offered the opportunity to return to the learning session. We included this final intervention to ensure that every student saw at least one intervention message regardless of whether they reached the 30 minute mark.

4. RESULTS

In this section, we report participant demographics, various learning outcome comparisons, and finer-grained analyses of participants’ topic ordering learning behaviors.

4.1 Demographics Information

Among the 73 participants from the randomized control trial, 73% identified as female, 26% as male, and 1% as non-binary. Students had a mean age of 19.58 ($SD = 1.71$) years old, with a minimum age of 18 and a maximum of 27. Over 35 college majors were represented by our participant population. Finally, 55% identified as White, 27% Asian, 12% Hispanic or Latina/o, 3% Black/African American, and 1% Native American.

4.2 Learning Behaviors and Outcomes

Table 2 summarizes the differences in pretest and posttest scores between the expert-system and XAI-informed groups. The mean improvement from pretest to posttest score was 18.03 (out of 100) for the expert-system condition, and 10.88 for the XAI-informed conditions, suggesting—contrary to RQ1 expectations—that students in the expert-system condition may have learned more. However, the difference in improvement between the two conditions was not significant, $t(71) = 1.924$, $p = .058$. We also calculated the Bayes factor (BF) using JASP [19]; BF represents how

likely the null or alternate hypothesis model is through a Bayesian approach [18]. Established guidelines [18] suggest that $BF = 1-3$ provides anecdotal evidence and $BF = 3-10$ provides substantial evidence. Through this metric, there is anecdotal evidence that the expert-system intervention group had greater grade improvement, $BF = 2.24$. Table 2 also shows that both groups' mean scores were not likely to have been influenced by ceiling effects from prior statistics knowledge; furthermore, no student in either condition achieved a perfect score (100) on the pretest.

Table 2: Comparison of pretest and posttest scores between expert-system and XAI-informed conditions

Group	Count	Mean score	Std. dev.
Expert-system (pretest)	37	47.1%	16.10
XAI-informed (pretest)	36	50.2%	19.87
Expert-system (posttest)	37	65.1%	16.30
XAI-informed (posttest)	36	61.1%	20.70

4.3 Model Evaluation and XAI-informed Predictions

We performed 5-fold cross-validation with the model training data to estimate model accuracy and obtained a mean R^2 value of .262 ($SD = .067$), a mean RMSE of 15.17 (on a 0-100 posttest grade scale, $SD = 2.20$), and a mean Pearson's r of .576. Mean R^2 value was somewhat variable across cross-validation folds; however, the trained model worked relatively well overall when considering the small size of our training data.

We analyzed the predictions made by our model and the activity logs of the XAI-informed intervention group participants. We found that the top three most often recommended topics were *Probability Introduction*, *Introduction to Regression*, and *Calculating Probability*. These represent the most frequently recommended topics that had the most negative SHAP values at the time of displaying the intervention, across the 30 minute, 40 minute, 50 minute mark, and on the posttest confirmation page. Two of the three most-recommended topics were related to probability. Probability is widely recognized as a difficult topic to learn for students due to misconceptions about the subject [7, 16, 21, 43], and our findings here support this assertion.

4.4 Self-Regulated Learning Behaviors

In order to evaluate the effects of the interventions on self-regulated learning behaviors, we defined two metrics which are shown in Table 3: attempts at quizzes already taken and rereading texts that had already been read. The differences in the number of quiz retakes were not significant, $t(71) = -1.618$, $p = .110$, but there was anecdotal evidence that the XAI-intervention group did more quiz retakes, $BF = 1.354$. Similarly, the number of text reviews was not significantly different, $t(71) = -1.186$, $p = .240$, but there was anecdotal evidence of the XAI-intervention group having higher number of text reviews, $BF = 2.263$. The mean number of interventions seen prior to the posttest was 3.16 for the XAI-informed intervention group, and 2.75 for the

expert-system intervention group. However, there were several participants who only saw a single intervention: 10 from the XAI-informed intervention group and 3 from the expert-system intervention group.

The results in Table 3 suggest minimal reviewing behaviors in both conditions, though that may be expected given that learning session included enough content that students could spend most or all of their time on new topics.

Table 3: Comparison of metrics for SRL reviewing behaviors.

Group	Quiz retakes	Texts reread
Expert-system	1.054	11.514
XAI	1.583	15.444

4.5 Learning Order Analysis

We carried out an analysis to examine orders in which students in each condition studied the 12 topics. We analyzed the degree to which students deviated from the baseline learning topic order by calculating the proportion of topic component (reading or quiz) selection actions that did not follow the direction of the default learning order presented on the topics menu page (Fig. 2). For example, if the student studied the first three topics in order and then studied the sixth topic, the learning order deviation value for readings would be .333. These learning order deviation values were calculated for the learning periods before and after students saw the first intervention. This analysis was done for participants who studied any amount of material after the first intervention $n(\text{XAI}) = 26$, $n(\text{expert-system}) = 34$.

The results in Table 4 show that students in both conditions deviated from the typical top-to-bottom topic significantly more frequently after intervention: XAI-informed, $t(25) = 4.262$, $p < .001$; expert-system, $t(33) = 3.240$, $p = .003$. These differences before and after the intervention were expected, per RQ1, especially for the XAI-informed intervention condition since it is more likely to recommend topics out of order according to students' individual needs.

Table 4: Proportion of actions in which students deviated from a typical top-to-bottom topic order during their selections of what topic to pursue next.

	Topic order deviation	
	Expert-system	XAI
Before 1st intervention	.552	.539
After 1st intervention	.709	.727
Difference before/after	.157	.188

5. DISCUSSION

Here, we discuss the main findings and implications and also discuss generalization of our approach, limitations of our study, and possible future work.

5.1 Learning and SRL Behaviors (RQ1)

We hypothesized that the students in the XAI-informed condition would have greater learning gains when compared

to those receiving the expert-system intervention because XAI interventions would give suggestions to review the most critical topics for improving posttest score rather than the expert-condition suggestions based on time. However, the findings did not support our hypothesis. Learning gain was not significantly different between the two conditions. The overall average pretest score being 48.6% and average posttest score 63.1%, and thus students may have benefited from studying almost *any* topic. In such cases, an intervention to encourage specific SRL behaviors would not be needed until the student has spent much longer studying.

Additionally, our machine learning model was trained from a relatively small amount of training data of 58 students, which may have contributed noise to the predictions, and consequently, less effective XAI-informed interventions which recommended unhelpful topics for improving the posttest score. However, both the expert-system and XAI-informed groups had significant, notable improvements in pretest to posttest scores, showing that our curriculum (and perhaps both interventions) was effective for teaching the statistics topics.

We hypothesized that the XAI-informed interventions would have lead to more frequent SRL reviewing behaviors due to bringing to light more directed learning strategies motivated by improving one's posttest score, and therefore, have lead to more regular and frequent self-reflection to identify apparent gaps in learning. The findings were inconclusive for answering our hypothesis since there were few instances of SRL reviewing behaviors (Table 3). While there were no statistical differences between the mean quiz and text reviewing behaviors, Bayes factor values show that there was anecdotal evidence of the XAI-informed group having both slightly higher mean rates of retaking quizzes and rereading texts. This suggests that there may indeed be intervention effects that could emerge more clearly in large datasets and longer learning sessions.

5.2 Topic Choosing Behaviors (RQ2)

We expected that participants receiving the expert-system interventions would have been more receptive to following the interventions' suggestions compared to those receiving the XAI-informed interventions. The expert-system interventions recommended topics based on the lowest reading time spent, or to suggest the next unstudied topic in the expected order. This would have aligned with some students' natural inclinations of studying through the topics in the default order as presented on the topics menu page (Figure 2). Furthermore, we expected the XAI-informed intervention group to strategize their topic choosing behavior without the influence of a necessarily top-to-bottom order suggestion, and choose more autonomously, based on strategies of identifying gaps in knowledge (discussed in section 5.1).

The results show that there were increased effects on topic choosing deviation behaviors in the two conditions. XAI-informed and expert-system conditions both had increased proportions of topic selection behaviors deviating from the top-to-bottom order after the first intervention. The results suggest the possibility that both interventions facilitated self-directed learning behaviors of students to make topic choosing behaviors most beneficial for their learning.

When understanding the results of RQ1 on learning performance and topic suggestions together, the findings from our paper may suggest that the XAI-informed interventions facilitated students' statistics learning to a similar degree to a method which prioritized unseen topics over mastery of a smaller amount of material. Additionally, average pretest scores were quite low for both conditions (Table 2), which likely made any amount of scaffolding helpful.

5.3 Generalization to Other Domains

In our study, we used the possible reasons from quizzes and readings for the posttest score predictions to personalize interventions to scaffold SRL behaviors through encouraging the review of specific topics. However, the same XAI approach could be applied to cases where the goal is to help a student improve almost any predicted outcome. For example, one could predict student dropout from online learning based on relevant student factors (constructs related to study skills, learning material interaction patterns, stress, motivation, etc.) [35], combined with complex or uninterpretable factors, and implement XAI-informed alerts via interfaces or targeted emails for the student throughout the course period to take actions reducing the likelihood of dropout based on the most impactful of the interpretable factors. Other applications could follow a similar approach, such as helping students resolve confusion during attempting algebra assignments [1], preventing learner disengagement from reading texts [29], or improving student performance in interactive online question pools [47].

5.4 Future Work and Conclusion

Future work could expand on this research by increasing the number of participants in both the training data and experiment as we were limited by our relatively small pilot and experiment sample sizes. It may also be possible to reduce idling behavior instances by using pre-screening surveys to gauge their motivation for learning the material, or better controlling the experiment through an in-person lab setting where participants may be observed. It would also be informative to explore our approach to other types of study material, such as more advanced statistics topics or mathematics, and explore ways to support other SRL behaviors such as planning or goal-setting.

In this study, we leveraged machine learning to predict future student outcomes, explained the predictions via an XAI method, and implemented personalized system interventions. Specifically, we explored supporting SRL behaviors in an online learning environment for learning college-level introductory statistics topics through personalized interventions. Despite limited differences in learning gain, SRL reviewing behaviors, and topic choosing behaviors, our findings suggest that XAI-informed interventions facilitate learning to a similar benefit as expert-system interventions. We expect that the approach examined in this experiment could be generalized across other applications, and could serve as one reference for designing system implementation informed by XAI methods.

ABSTRACT

Academic grades in assessments are predicted to determine if a student is at risk of failing a course. Sequential models or graph neural networks that have been employed for grade prediction do not consider relationships between course descriptions. We propose the use of text mining to extract semantic, syntactic, and frequency-based features from course content. In addition, we classify intended learning outcomes according to their higher- or lower-order thinking skills. A learning parameter is then formulated to model the impact of these cognitive levels (that are expected for each course) on student performance. These features are then embedded and represented as graphs. Past academic achievements are then fused with the above features for grade prediction. We validate the performance of the above approach via datasets corresponding to three engineering departments collected from a university. Results obtained highlight that the proposed technique generates meaningful feature representations and outperforms existing methods for grade prediction.

Keywords

Grade prediction, graph networks, course descriptions, semantic similarities, cognitive levels

1. INTRODUCTION

Detecting students at the risk of failing university courses based on predicted grades is essential for administering early intervention strategies. From a regression problem perspective, grades obtained from prior courses in previous semesters are used to predict grades for pilot courses registered in the upcoming semester.

1.1 Related Models for Grade Prediction

Existing techniques for grade prediction using past academic records include conventional regression models such as random forest, support vector machine, and K-nearest neighbor [1, 10, 15] as well as the factorization machine in a collaborative filtering setting [33]. In addition to the use of past examination results, information derived from online click-stream data on learning management systems has been used to augment the prediction capability of a model [25, 26]. More recently, sequential models such as the long short-term memory (LSTM) have been developed to capture the temporal dynamics of past academic performance [12]. While such deep learning models have achieved reasonable success in grade prediction, existing temporal-based approaches do not take the relationships among courses and among students into account. Consideration of these relationships is essential since information pertaining to courses with similar content and students with similar cognitive levels would aid in grade prediction. In addition, the performance trend of an academically-inclined student or a well-performed course in the current semester may continue for the upcoming semesters [23].

Notwithstanding the above, graph neural networks have recently been employed to generate meaningful feature representations which model the transitions of grade distributions between courses across semesters [11]. Similar to social multi-relational networks [14] with nodes representing either students or courses, three graphs—student-course, student-student, and course-course graphs—consisting of edge links computed via grade distribution similarities or correlations have been constructed [21, 23]. Modeling the student-course relations have also been achieved via knowledge graphs to extract course and student embeddings as well as to encode temporal student behavioral data [17]. Pre- or co-requisites between courses have also been considered for grade prediction [27].

Despite adopting multi-dimensional approaches toward analyzing prior course grades to predict student performance [35], existing models assume that the relationship among courses depends solely on the grade distribution; these models do not consider topics covered and the intended

learning outcomes defined by the course instructors. These aspects are important since the process of knowledge acquisition often involves assimilating and discerning information from myriad sources [29], i.e., academic performance has shown to be dependent on prior experience and how the student has understood certain concepts. Moreover, course content that overlap or are highly inter-dependent may influence how well the student can achieve the intended learning outcomes for the upcoming semesters [38]. While course syllabus has recently been used to extract frequency-based features for the determination of course similarities [16], it does not analyze the intended learning outcomes nor capture the relationship between courses holistically. It is also not surprising to expect that students who are less academically inclined often struggle in courses that require higher-order thinking skills. Information pertaining to the thinking skills required for prior courses will, therefore, allow the grade-prediction model to better represent grades achieved from previous semesters.

1.2 Grade Prediction From Curriculum Development Perspective

From a curriculum development perspective, course descriptions comprise topics to be covered and the intended learning outcomes for each course designed by the course instructor [34]. The importance of identifying suitable topics is motivated by an earlier study where first-year university students who had been exposed to fundamental concepts in high school have shown to perform better than those who had not studied similar content before [13]. In today’s context, this highlights the intrinsic (and often intimate) relationships including pre-requisites, recommended literature, and course content that define dependencies between courses. Coupled with the fact that course instructors often adopt the constructivist approach in curriculum design [6], analysis of course content is important for grade prediction.

Apart from course content, outcome-based teaching and learning require course instructors to identify suitable intended learning outcomes and assessments that measure those learning outcomes [4, 30]. In this regard, learning activities with various cognitive complexity levels should be designed and aligned with the learning outcomes constructively throughout the course [2, 5, 9, 32]. Alignment of learning activities can be achieved via the revised Bloom’s Taxonomy with the recollection of information being associated with the lowest-order thinking skill to generating creative outcomes being associated with the highest-order thinking skill [20]. Given that less academically-inclined students often face challenges in higher-order thinking skills [39], it is important to consider the influence of learning outcomes on student performance for grade prediction.

1.3 Contribution of This Work

In this work, we propose a course description-based grade prediction (CODE-GP) model that employs text mining techniques for extracting features associated with (i) course content similarities and (ii) higher- or lower-order thinking skills required for each course. With regards to the first dimension highlighted in Table 1, we propose three types of course similarities extracted from topic outlines and intended learning outcomes found within course descriptions.

Table 1: Overview of text mining approaches in the proposed CODE-GP model

Dimension	Type	Description
Course similarities from course outlines and learning outcomes	Semantic	Contextual closeness of course content
	Syntactic	Grammatical differences across cognitive levels
	Frequency-based	Overlapping works appearance in descriptions
Student similarities based on thinking skills required	Higher-order \mathcal{H}	Verbs corresponding to creative outcomes
	Lower-order \mathcal{L}	Verbs corresponding to recalling concepts

These similarities include semantic [22], syntactic [3], and frequency-based features [36]. The use of these features is in contrast to the use of grade distributions as edge weights for generating similarities [11]. The basis for our proposed architecture is motivated by the need to consider both course outlines and intended learning outcomes, since both the intended learning outcomes and syllabus are important for the development and implementation of teaching programs [28]. In addition, we also consider past performance of each student from the perspective of thinking skills required for each course. In particular, the proposed model employs a document classification approach that tags each course with higher- or lower-order thinking skills according to the revised Bloom’s Taxonomy. A learnable parameter is then used to aggregate the respective grades achieved for both lower- and higher-order thinking skill courses. This allows the proposed model to establish the relationship between the complexity of courses and academic performance.

As shown in Figure 1, we adopt graph neural networks to generate representations of the above text mining features. These features are represented as course- and student-similarity graphs with nodes corresponding to courses and students, respectively. The edge weights for the former are computed based on the proposed three text features. For the latter, past academic grades are aggregated, and the similarity related to Jensen-Shannon Divergence (JSD) is then computed among the grade distributions [23]. These graphs are subsequently embedded and trained using a graph convolutional network (GCN) layer.

In addition and similar to [12], we incorporate temporal information extracted from past examination records for each student across semesters. Grade embeddings, the corresponding student vector, and prior course vectors acquired from the GCN for each semester are then concatenated as a representation vector. This temporal representation serves as the input to LSTM, which exploits the sequential relationships and predicts the grade for a course to be taken in the coming semester.

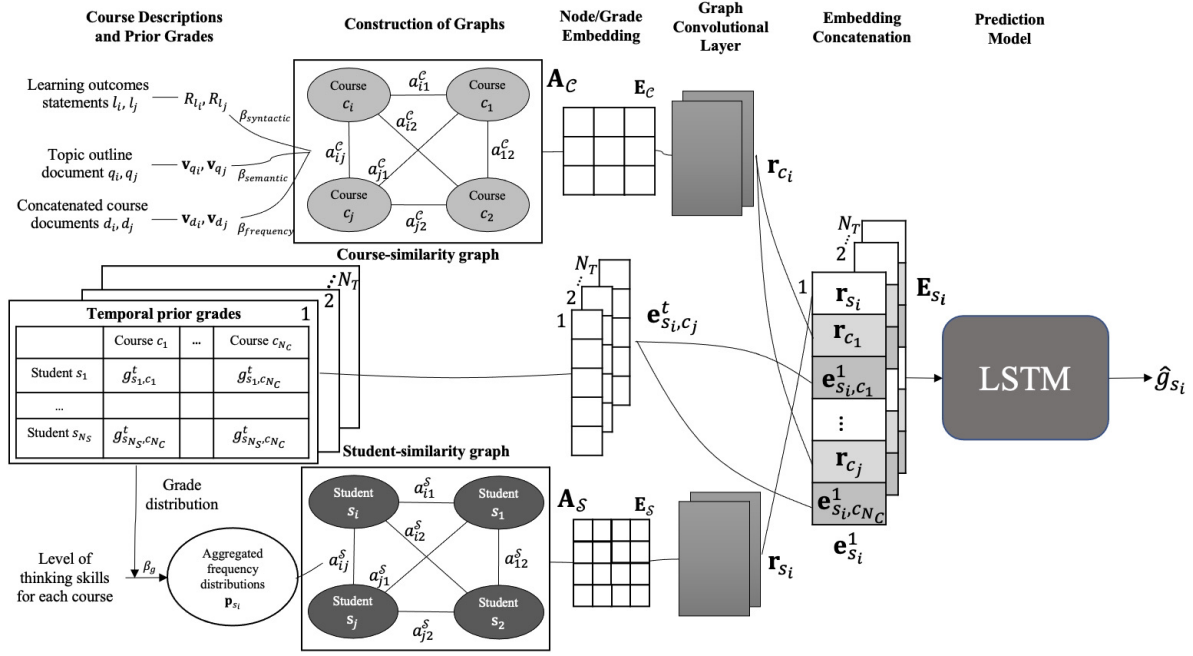

Figure 1: Process flow of the proposed CODE-GP model.

2. THE PROPOSED CODE-GP MODEL

The task of grade prediction involves predicting the grade for student s_i who has registered a pilot course. Given N_C number of prior courses and N_S students, the set of prior courses is defined as $\mathbb{C} = \{c_1, c_2, \dots, c_{N_C}\}$ and the set of students as $\mathbb{S} = \{s_1, s_2, \dots, s_{N_S}\}$. We define \hat{g}_{s_i} as the predicted grade of a given pilot course for the student s_i .

2.1 Construction of Course Similarities Graph Based on Course Descriptions

The CODE-GP model incorporates semantic, syntactic, and frequency-based features extracted from course descriptions that comprise topic outlines and intended learning outcomes. These features are subsequently used for constructing the course-similarity graph. We first pre-process the text by removing symbols, diagrams, equations, numbers, punctuation marks, and stop-words (e.g., “and”, “or”). All remaining characters are set to lower case [32].

Semantic similarity based on word embeddings has been employed to assess student capability for the recommendation of similar courses [24]. In the context of CODE-GP, we first define topic outline as q_i corresponding to course c_i . A topic outline vector \mathbf{v}_{q_i} is then generated from q_i based on the bidirectional encoder representations from transformer (BERT) embeddings [7, 8]. The cosine similarity between q_i and q_j is then computed between two course outlines via

$$\cos(\theta(c_i, c_j)) = \frac{\mathbf{v}_{q_i} \cdot \mathbf{v}_{q_j}}{\|\mathbf{v}_{q_i}\| \|\mathbf{v}_{q_j}\|}. \quad (1)$$

With $0 \leq \cos(\theta(c_i, c_j)) \leq 1$, a value of 1 implies an almost semantically similar pair of courses c_i and c_j .

Syntactic features for CODE-GP comprise phrase types (i.e., regular expressions (regexes)) that are extracted from state-

ments associated with the intended learning outcomes. In this context, we first extract noun- and verb-phrases from the intended learning outcome document l_i corresponding to course c_i . These (multiple) phrases are then associated with their parts-of-speech tags resulting in the set of regexes R_{l_i} [31]. Overlaps between the regex sets are then computed via the Jaccard similarity given by

$$\Phi(c_i, c_j) = \frac{|R_{l_i} \cap R_{l_j}|}{|R_{l_i} \cup R_{l_j}|}, \quad (2)$$

where $0 \leq \Phi(c_i, c_j) \leq 1$. The number of common occurrences is denoted by $|R_{l_i} \cap R_{l_j}|$ while $|R_{l_i} \cup R_{l_j}|$ refers to the total number of regexes. A high Jaccard similarity, therefore, implies a high proportion of similar phrase types occurring between a course pair regardless of whether the topics covered are identical.

The term frequency-inverse document frequency (TF-IDF) determines the uniqueness of a word within a set of documents [37]. To account for word appearance similarity, we include TF-IDF weighting on both the topic outlines q_i and intended learning outcomes l_i for course c_i . These features are extracted from each concatenated course document $d_i = q_i \frown l_i$, where \frown denotes the concatenation of two texts. We then compute the cosine similarity $\Omega(c_i, c_j) \propto \mathbf{v}_{d_i} \cdot \mathbf{v}_{d_j}$ similar to (1) but between bag of words (BoW) vectors \mathbf{v}_{d_i} and \mathbf{v}_{d_j} corresponding to each course document. Here, $\mathbf{v}_{d_i} = [\alpha(w_1, d_i), \alpha(w_2, d_i), \dots, \alpha(w_{N_W}, d_i)]$ with w_k denoting the k th word in document d_i . The BoW vector length is based on the word vocabulary size N_W across the entire corpus. The value of each element corresponding to the TF-IDF weight for word w_k is given by [37]

$$\alpha(w_k, d_i) = \frac{N_{w_k, d_i}}{L(d_i)} \times \log\left(\frac{N_D}{N_{w_i} + 1}\right), \quad (3)$$

where N_{w_k, d_i} is the number of times w_k occurs in d_i , $L(d_i)$ denotes the length of that document, N_D the total number of documents, and N_{w_i} the number of documents in which w_i occurs. The obtained TF-IDF values are subsequently normalized to prevent bias in the term frequency variable due to document length $L(d_i)$.

With nodes of the course-similarity graph denoted by each course $c_i \in \mathbb{C}$, the edge weights are determined via

$$a_{ij}^{\mathbb{C}} \times \left(\beta_{semantic} \times \cos(\theta(c_i, c_j)), \beta_{syntactic} \times \Phi(c_i, c_j), \beta_{frequency} \times \Omega(c_i, c_j) \right), \quad (4)$$

where $\beta_{semantic}$, $\beta_{syntactic}$, and $\beta_{frequency}$ are the trainable weights. Each of the variable $a_{ij}^{\mathbb{C}}$ is used within the adjacency matrix

$$\mathbf{A}_{\mathbb{C}} = \begin{bmatrix} a_{11}^{\mathbb{C}} & \cdots & a_{1N_C}^{\mathbb{C}} \\ \vdots & \ddots & \vdots \\ a_{N_C 1}^{\mathbb{C}} & \cdots & a_{N_C N_C}^{\mathbb{C}} \end{bmatrix} \quad (5)$$

corresponding to the course-similarity graph.

2.2 Temporal Grade Information

Before attempting the pilot course in the current semester, we assume, for each student s_i , availability of prior course grades in \mathbb{C} across semesters $t \in \{1, \dots, N_T\}$, where N_T is the total number of semesters, g_{s_i, c_i}^t denotes the grade that student achieves for c_i in semester t . Hence, the grade vector for student s_i in semester t is given by

$$\mathbf{g}_{s_i}^t = [g_{s_i, c_1}^t, \dots, g_{s_i, c_{N_C}}^t], \quad (6)$$

where N_C is the total number of prior courses across all N_T semesters. It is important to note that for a given semester, only a subset of these N_C prior courses are attempted, i.e., $\mathbf{g}_{s_i}^t$ is not a full vector and null elements will be assigned for courses not attempted during that semester. Across all previous N_T semesters, we acquire the temporal grade information for each student, as shown in Figure 1. Such temporal grade information would be used in two ways—(i) being aggregated according to the thinking skills required for each course and to generate student similarity as will be described in Section 2.3 and (ii) being concatenated with the course and student embeddings as input for LSTM.

2.3 Construction of Student Similarities Graph Based on Cognitive Levels

Construction of the student-similarity graph is based on cognitive levels associated with each course according to Table 1. Each of the prior courses is first categorized as one that requires high-order thinking skills \mathcal{H} or lower-order thinking skills \mathcal{L} . This is achieved by first classifying each course intended learning outcome statement via document classification described in [31] with classes being defined according to Bloom’s Taxonomy. Each course is then tagged as \mathcal{H} (or \mathcal{L}) if more statements are classified as labels associated with high-order (or lower-order) thinking skills.

For each student, we compute the frequency distribution $\mathbf{p}_{s_i}^{\mathbb{C}}$ and $\mathbf{p}_{s_i}^{\mathcal{H}}$ corresponding to courses that require lower- and higher-order thinking skills. This is achieved by first dividing the grade range (1-100) into five bins of twenty-point

Table 2: Details on datasets from three departments

Department	Pilot course index	N_S	N_C	N_T	Number of records
Department 1	c_1	453	16	5	7241
	c_2	645	20	6	11197
Department 2	c_3	575	16	6	9234
	c_4	688	16	6	10977
Department 3	c_5	711	23	7	13616
	c_6	540	17	6	8785

intervals before determining the number of courses (in each \mathcal{H} and \mathcal{L} category) that falls under each bin. Contributions of these two distributions are then learned via

$$\mathbf{p}_{s_i} = \beta_g \times \mathbf{p}_{s_i}^{\mathbb{C}} + (1 - \beta_g) \times \mathbf{p}_{s_i}^{\mathcal{H}}, \quad (7)$$

where β_g is a learnable weight for \mathbf{p}_{s_i} . With the above, student similarities are obtained via the JSD between the grade distribution for each pair of students, i.e.,

$$a_{ij}^{\mathbb{S}} = 1 - JSD(\mathbf{p}_{s_i} || \mathbf{p}_{s_j}). \quad (8)$$

Therefore, a higher $a_{ij}^{\mathbb{S}}$ implies that the two students possess similar higher- or lower-order skills (measured by how they perform in the prior courses). With the student similarity graph shown in Figure 1 comprising students as nodes, the corresponding adjacency matrix $\mathbf{A}_{\mathbb{S}}$ is generated based on $a_{ij}^{\mathbb{S}}$ similar to (5).

2.4 GCN and Embeddings

After constructing the course- and student-similarity graphs, we employ a two-layer GCN to embed each graph. Both course and student nodes are encoded with one-hot vectors to obtain encoded matrices $\mathbf{X}_{\mathbb{C}}$ and $\mathbf{X}_{\mathbb{S}}$. The embedding vector $\mathbf{E}_{\mathbb{C}}$ for the course-similarity graph is generated via

$$\mathbf{E}_{\mathbb{C}} = \mathbf{W}_{\mathbb{C}} \mathbf{X}_{\mathbb{C}} \quad (9)$$

such that the one-hot vectors are represented as dense vectors of lower dimensions. Here, $\mathbf{W}_{\mathbb{C}}$ is the weight matrix. With $\mathbf{E}_{\mathbb{S}}$ being generated similarly, and with $\mathbf{A}_{\mathbb{C}}$ and $\mathbf{A}_{\mathbb{S}}$ derived from Sections 2.1 and 2.3, two GCN layers [18] are then applied to obtain latent representations of all nodes in course-similarity graph \mathbb{C} and student-similarity graph \mathbb{S} . In particular, the $(G + 1)$ th layer for \mathbb{C} is computed via

$$\mathbf{Z}_{\mathbb{C}}^{(G+1)} = \sigma \left(\mathbf{D}_{\mathbb{C}}^{-\frac{1}{2}} \mathbf{A}_{\mathbb{C}} \mathbf{D}_{\mathbb{C}}^{-\frac{1}{2}} \mathbf{Z}_{\mathbb{C}}^{(G)} \mathbf{W}_{\mathbb{C}}^{(G)} \right), \quad (10)$$

where $\mathbf{D}_{\mathbb{C}} = \sum_{c_i} \mathbf{A}_{\mathbb{C}}$ is the degree matrix, $\mathbf{Z}_{\mathbb{C}}^{(0)} = \mathbf{E}_{\mathbb{C}}$, and $\mathbf{W}_{\mathbb{C}}^{(G)}$ is the weight matrix. The output of the GCN for course-similarity graph is denoted as matrix $\mathbf{R}_{\mathbb{C}} = \mathbf{Z}_{\mathbb{C}}^{(2)}$ with each row vector \mathbf{r}_{c_i} being associated with course c_i . The above computation is also applied on student-similarity graph \mathbb{S} to obtain the graph embedding matrix $\mathbf{R}_{\mathbb{S}}$ with each row vector being defined as \mathbf{r}_{s_j} for student s_j .

To generate representations for the prior grades achieved, embedding is applied for each grade. With a one-hot vector representing a unique value of prior grade g_{s_i, c_j}^t , the embedding vector for a student prior grade is learned via

$$\mathbf{e}_{s_i, c_j}^t = \mathbf{W}_G \text{One-hot} \left(g_{s_i, c_j}^t \right), \quad (11)$$

Table 3: Prior courses list for pilot course c_5 from Department 3

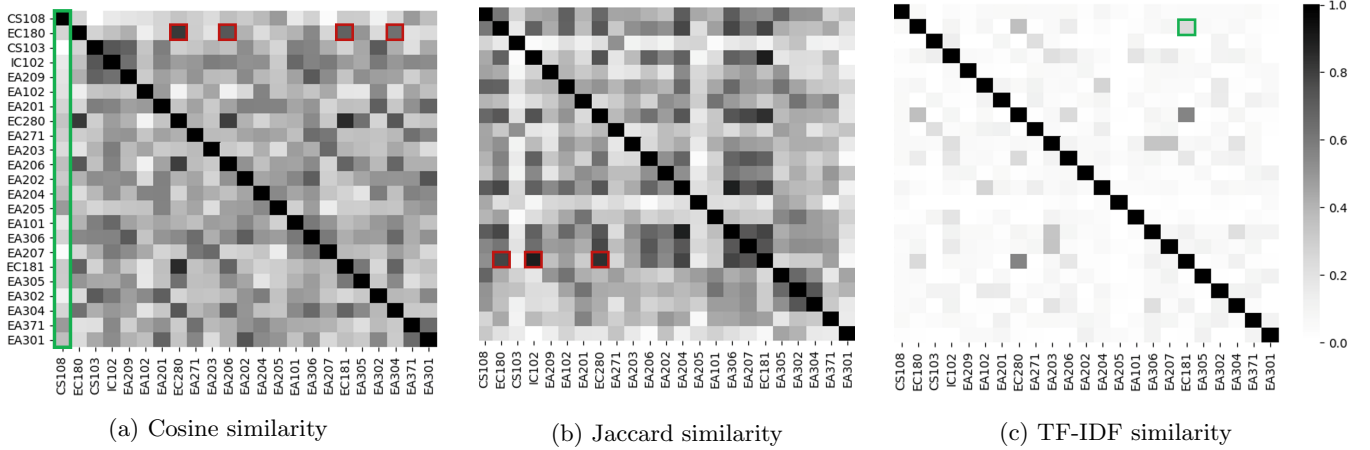

Figure 2: Visualization of three similarities among different prior courses from an engineering department (Department 3) of a university.

where \mathbf{W}_G is the weight matrix. The three embedding vectors from course-similarity graph, student-similarity graph, and temporal grade information are then concatenated for each semester to form a $(l_a + N_C \times (l_b + l_c)) \times 1$ vector

$$\mathbf{e}_{s_i}^t = [\mathbf{r}_{s_i}, \mathbf{r}_{c_1}, \mathbf{e}_{s_i, c_1}^t, \dots, \mathbf{r}_{c_{N_C}}, \mathbf{e}_{s_i, c_{N_C}}^t]^T, \quad (12)$$

where l_a , l_b , and l_c denote the embedding length for \mathbf{r}_{s_i} , \mathbf{r}_{c_j} , and \mathbf{e}_{s_i, c_j}^t , respectively, and T denotes transpose. Each of these vectors are then concatenated to form a feature matrix

$$\mathbf{E}_{s_i} = [\mathbf{e}_{s_i}^1, \dots, \mathbf{e}_{s_i}^{N_T}] \quad (13)$$

of each student s_i for the subsequent prediction model.

2.5 Grade Prediction using LSTM

LSTM models time-series representations and is used to predict the pilot grade based on sequential matrix \mathbf{E}_{s_i} for each student. Through the use of input, output, and forget gate, LSTM aggregates important and permutes less significant representations to achieve prediction of pilot grades in semester $N_T + 1$. LSTM is employed for grade prediction via the hidden state

$$\mathbf{h}_{s_i}^t = \text{LSTM}(\mathbf{e}_{s_i}^t, \mathbf{h}_{s_i}^{t-1}), \quad (14)$$

where $\mathbf{h}_{s_i}^t$ denotes the hidden state for semester t . The predicted grade \hat{g}_{s_i} for student s_i obtained from the last hidden state is then given by

$$\hat{g}_{s_i} = \mathbf{w}_L \cdot \mathbf{h}_{s_i}^{N_T} + b, \quad (15)$$

where \mathbf{w}_L and b are defined, respectively, as the weight vector and bias scalar for the predictor.

3. RESULTS AND DISCUSSION

3.1 Datasets and Implementation Details

Open-source datasets employed for grade prediction do not include course descriptions. We collected data that include both academic records and course descriptions (comprising both course outlines and intended learning outcomes). These are obtained from three engineering departments in a university to evaluate the models. Each dataset is obtained with the student name and identity being hashed by another office (authorized to handle such data) to protect privacy. Table 2 summarizes details for each dataset used. In particular, N_T for each dataset is determined by the maximum number of semesters the students within the cohort take to complete all courses under consideration. The prior course list for each pilot course consists of the core courses corresponding to the department’s curriculum. In addition, N_C and N_S are distinct for each dataset. In our experiments, the training, validation, and testing ratio are set as 6:2:2.

We employed the mean squared error (MSE)

$$\text{MSE} = \frac{1}{N_S} \sum_{i=1}^{N_S} (\hat{g}_{s_i} - g_{s_i})^2 \quad (16)$$

for performance evaluation, where g_{s_i} denotes the actual grade obtained by student s_i for a given pilot course. In terms of hyperparameter selection, course description document embeddings are trained using BERT with a dimension of 768. During GCN training, the dropout rate was set as 0.5, while the Adam optimizer with a learning rate of 0.001 was used. A weight decay parameter was set to 5×10^{-4} to prevent overfitting.

Table 4: Performance evaluation across grade prediction algorithms

Mean Squared Error (MSE)										
Methods	Department 1			Department 2			Department 3			Average
	c_1	c_2	Ave.	c_3	c_4	Ave.	c_5	c_6	Ave.

Removal of course-similarity graph	0.0231	0.1224
Proposed CODE-GP	0.0222	0.1221

3.2 Performance Analysis

We take pilot course c_5 from Department 3 as an example to illustrate the impact of considering the semantic, syntactic, and frequency aspects of words used in course outlines and intended learning outcomes. Three heatmaps with colors depicting the similarity values described in Section 2.2 are provided while details pertaining to prior course information are shown in Table 3.

Figure 2(a) illustrates the semantic cosine similarity where high similarities in terms of the closeness of course content are indicated by the dark shades. It can be seen that the mathematics-based prior course EC180 exhibits high semantic similarity with other prior courses EC280, EA206, EC181, and EA304, which have high mathematical content. On the other hand, computing course CS108 exhibits lower semantic similarity with the most of other non-programming courses. Figure 2(b) highlights how (dis)similar phrase types are between the course outlines and the intended learning outcomes of two prior courses. We note that EC181 exhibits higher Jaccard similarity with courses that require fundamental scientific and mathematical knowledge such as EC180, IC102, and EC280. TF-IDF weighting, on the other hand, indicates the choice and uniqueness of words being used in the course outlines and intended learning outcomes. Figure 2(c) highlights the high variability in words used between the courses being considered—only a few pairs of course outlines and intended learning outcomes exhibit high TF-IDF similarity. In addition, we also note that the similarity between content is irrelevant. This can be observed from the fact that even though EC180 and EC181 are mathematics-related, their frequency-based TF-IDF similarity is relatively low.

We next compare the performance of the proposed CODE-GP model with LSTM based grade-prediction model [12], GCN [19], and the conventional logistic regression (LR) model. While LR and LSTM focus on temporal information and GCN exploits the interrelationship between courses and students, the proposed model considers both aspects. We note from Table 4 that the proposed CODE-GP model achieves the highest grade prediction capability than the LR, LSTM, and GCN. While the proposed model requires higher complexity than these three baseline models, CODE-

GP achieves the lowest mean MSE of 0.0222 (11.9% improvement compared to LSTM), across the three departments as seen in Table 4. These results highlight the importance of course descriptions when constructing student- and course-similarity graphs with time series information. Features extracted from course descriptions enhance the grade prediction capability instead of using only a single modality.

We further performed an ablation test by excluding each input graph/temporal representations. Table 5 summarizes the MSE and mean absolute error (MAE) across all three departments. We note that the use of all three aspects in CODE-GP is vital to provide a holistic perspective for grade prediction. It is interesting to note that grade prediction performance is more sensitive to course-similarity graph (compared to student-similarity graph). This suggests that information derived from course descriptions can assist in grade prediction since performance is closely related to achieving the set of intended learning outcomes depicted in course descriptions. These results also highlight that temporal information and graphs provide complementary features which contribute jointly to the success of grade prediction.

4. CONCLUSIONS

We propose a grade prediction model that considers course descriptions and prior academic results. Text mining techniques determine the edge weights of the course- and student-similarity graphs. A three-pronged model that constitutes the semantic, syntactic, and frequency-based feature extraction methods is formulated for course similarities. Student performance in terms of their achievements in courses associated with low- or high-order thinking skills have also been incorporated to construct the student-similarity graph. The LSTM synthesizes these aspects before performing prediction.

An accurate and just-in-time prediction of performance enables course instructors to administer early interventions. Once the predicted results indicate a tendency of a student in failing a course, student support staff can respond and plan for a personalized intervention strategy for each student. Moreover, early detection of at-risk students can potentially reduce the drop-out rate. Future work may include techniques that incorporate other data modalities such as student demographic or online learning behavior while protecting student privacy.

ABSTRACT

Block-based visual programming environments are increasingly used to introduce computing concepts to beginners. Given that programming tasks are open-ended and conceptual, novice students often struggle when learning in these environments. AI-driven programming tutors hold great promise in automatically assisting struggling students, and need several components to realize this potential. We investigate the crucial component of student modeling, in particular, the ability to automatically infer students’ misconceptions for predicting (synthesizing) their behavior. We introduce a novel benchmark, STUDENTSYN, centered around the following challenge: For a given student, synthesize the student’s attempt on a new target task after observing the student’s attempt on a fixed reference task. This challenge is akin to that of program synthesis; however, instead of synthesizing a {solution} (i.e., program an expert would write), the goal here is to synthesize a {student attempt} (i.e., program that a given student would write). We first show that human experts (TUTORSS) can achieve high performance on the benchmark, whereas simple baselines perform poorly. Then, we develop two neuro/symbolic techniques (NEURSS and SYMSS) in a quest to close this gap with TUTORSS.

block-based visual programming, programming education, program synthesis, neuro-symbolic AI, student modeling

1. INTRODUCTION

The emergence of block-based visual programming platforms has made coding more accessible and appealing to beginners. Block-based programming uses “code blocks” that reduce the burden of syntax and introduces concepts in an interactive way. Led by initiatives like *Hour of Code* by Code.org [10, 8] and the popularity of languages like *Scratch* [41], block-based programming has become integral to introductory CS

education. Considering the *Hour of Code* initiative alone, over one billion hours of programming activity has been spent in learning to solve tasks in such environments [8].

Programming tasks on these platforms are conceptual and open-ended, and require multi-step deductive reasoning to solve. Given these aspects, novices often struggle when learning to solve these tasks. The difficulties faced by novice students become evident by looking at the trajectory of students’ attempts who are struggling to solve a given task. For instance, in a dataset released by Code.org [10, 8, 35], even for simple tasks where solutions require only 5 code blocks (see Figure 1a), students submitted over 50,000 unique attempts with some exceeding a size of 50 code blocks.

AI-driven programming tutors have the potential to support these struggling students by providing personalized assistance, e.g., feedback as hints or curriculum design [37]. To effectively assist struggling students, AI-driven systems need several components, a crucial one being *student modeling*. In particular, we need models that can automatically infer a student’s knowledge from limited interactions and then predict the student’s behavior on new tasks. However, student modeling in block-based visual programming environments can be quite challenging because of the following: (i) programming tasks are conceptual with no well-defined skill-set or problem-solving strategy for mastery [23]; (ii) there could be a huge variability in students’ attempts for a task [52]; (iii) the objective of predicting a given student’s behavior on new tasks is not limited to coarse-grained success/failure indicators (e.g., [50])—ideally, we should be able to do fine-grained synthesis of attempts for the student.

Beyond the above-mentioned challenges, there are two critical issues arising from limited resources and data scarcity for a given domain. First, while the space of tasks that could be designed for personalized curriculum is intractably large [1], the publicly available datasets of real-world students’ attempts are limited; e.g., the *Hour of Code: Maze Challenge* domain has datasets for only two tasks [35]. Second, when a deployed system is interacting with a new student, there is limited prior information [15], and the system would have to infer the student’s knowledge by observing behavior on a few reference tasks, e.g., through a quiz [21]. These two issues limit the applicability of state-of-the-art techniques that rely on large-scale datasets across tasks or personalized data per student (e.g., [50, 28, 29, 36])—we need next-generation student modeling techniques that can operate under data

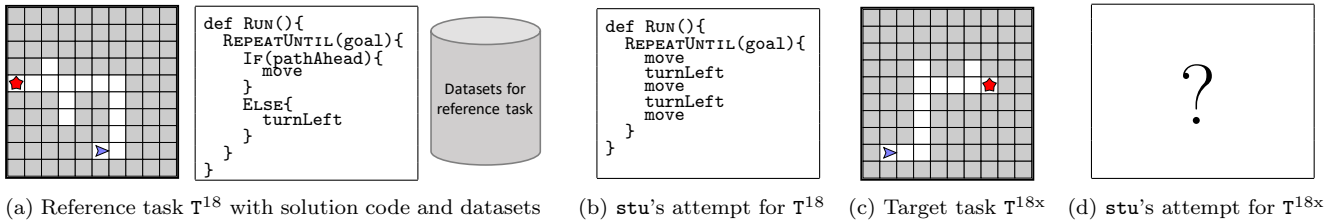

Figure 1: Illustration of our problem setup and objective for the task Maze#18 in the *Hour of Code: Maze* [9] by Code.org [8]. As explained in Section 2.2, we consider three distinct phases in our problem setup to provide a conceptual separation in terms of information and computation available to a system. (a) In the first phase, we are given a reference task T^{18} along with its solution code $C_{T^{18}}^*$ and data resources (e.g., a real-world dataset of different students’ attempts); reference tasks are fixed and the system can use any computation a priori. (b) In the second phase, the system interacts with a student, namely *stu*, who attempts the reference task T^{18} and submits a code, denoted as $C_{T^{18}}^{\text{stu}}$. (c, d) In the third phase, the system seeks to synthesize the student *stu*’s behavior on a target task T^{18x} , i.e., a program that *stu* would write if the system would assign T^{18x} to the student. Importantly, the target task T^{18x} is not available a priori and this synthesis process would be done in real-time.

scarcity and limited observability. To this end, this paper focuses on the following question: *For a given student, can we synthesize the student’s attempt on a new target task after observing the student’s attempt on a fixed reference task?*

1.1 Our Approach and Contributions

Figure 1 illustrates this synthesis question for a scenario in the *Hour of Code: Maze Challenge* [9] by Code.org [8]. This question is akin to that of program synthesis [20]; however, instead of synthesizing a *{solution}* (i.e., program an expert would write), the goal here is to synthesize a *{student attempt}* (i.e., program that a given student would write). This goal of synthesizing student attempts, and not just solutions, requires going beyond state-of-the-art program synthesis techniques [3, 4, 25]; crucially, we also need to define appropriate metrics to quantitatively measure the performance of different techniques. Our main contributions are:

- (1) We formalize the problem of synthesizing a student’s attempt on target tasks after observing the student’s behavior on a fixed reference task. We introduce a novel benchmark, STUDENTSYN, centered around the above synthesis question, along with generative/discriminative performance measures for evaluation.
- (2) We showcase that human experts (TUTORSS) can achieve high performance on STUDENTSYN, whereas simple baselines perform poorly.
- (3) We develop two techniques inspired by neural (NEURSS) and symbolic (SYMSS) methods, in a quest to close the gap with human experts (TUTORSS).

We provide additional details and results in the longer version of the paper [47]. We will also publicly release the benchmark and implementations to facilitate future research.

1.2 Related Work

Student modeling. For close-ended domains like vocabulary learning ([42, 36, 22]) and Algebra problems ([12, 40, 43]), the skills or knowledge components for mastery are typically well-defined and we can use *Knowledge Tracing* techniques to model a student’s knowledge state over time [11, 33]. These modeling techniques, in turn, allow us to provide feedback, predict solution strategies, or infer/quiz a student’s knowledge state [40, 21, 43]. Open-ended domains pose unique challenges to directly apply these techniques

(see [23]); however, there has been some progress in this direction. In recent works [28, 29], models have been proposed to predict human behavior in chess for specific skill levels and to recognize the behavior of individual players. Along these lines, [7] introduced methods to perform early prediction of struggling students in open-ended interactive simulations. There has also been work on student modeling for block-based programming, e.g., clustering-based methods for misconception discovery [18, 44], and deep learning methods to represent knowledge and predict performance [50].

AI-driven systems for programming education. There has been a surge of interest in developing AI-driven systems for programming education, and in particular, for block-based programming domains [37, 38, 51]. Existing works have studied various aspects of intelligent feedback, for instance, providing next-step hints when a student is stuck [35, 53, 31, 15], giving data-driven feedback about a student’s misconceptions [45, 34, 39, 52], or generating/recommending new tasks [2, 1, 19]. Depending on the availability of datasets and resources, different techniques are employed: using historical datasets to learn code embeddings [34, 31], using reinforcement learning in zero-shot setting [15, 46], bootstrapping from a small set of expert annotations [34], or using expert grammars to generate synthetic training data [52].

Neuro-symbolic program synthesis. Our approach is related to program synthesis, i.e., automatically constructing programs that satisfy a given specification [20]. The usage of deep learning models for program synthesis has resulted in significant progress in a variety of domains including string transformations [16, 14, 32], block-based visual programming [3, 4, 13, 48], and competitive programming [25]. Program synthesis has also been used to learn compositional symbolic rules and mimic abstract human learning [30, 17].

2. PROBLEM SETUP

Next, we introduce definitions and formalize our objective.

2.1 Preliminaries

The space of tasks. We define the space of tasks as \mathbb{T} ; in this paper, \mathbb{T} is inspired by the popular *Hour of Code: Maze Challenge* [9] from Code.org [8]; see Figure 1a. We define a task $T \in \mathbb{T}$ as a tuple $(T_{\text{vis}}, T_{\text{store}}, T_{\text{size}})$, where T_{vis} denotes a visual puzzle, T_{store} the available block types, and T_{size} the maximum number of blocks allowed in the solution

code. The task T in Figure 1a corresponds to Maze#18 in the *Hour of Code: Maze Challenge* [9], and has been studied in a number of prior works [35, 15, 1].

The space of codes. We define the space of all possible codes as \mathbb{C} and represent them using a *Domain Specific Language* (DSL) [20]. In particular, for codes relevant to tasks considered in this paper, we use a DSL from [1]. A code $C \in \mathbb{C}$ has the following attributes: $\mathbb{C}_{\text{blocks}}$ is the set of types of code blocks used in C , \mathbb{C}_{size} is the number of code blocks used, and $\mathbb{C}_{\text{depth}}$ is the depth of the *Abstract Syntax Tree* of C .

Solution code and student attempt. For a given task T , a *solution code* $C_T^* \in \mathbb{C}$ should solve the visual puzzle; additionally, it can only use the allowed types of code blocks (i.e., $\mathbb{C}_{\text{blocks}} \subseteq \mathbb{T}_{\text{store}}$) and should be within the specified size threshold (i.e., $\mathbb{C}_{\text{size}} \leq \mathbb{T}_{\text{size}}$). We note that a task $T \in \mathbb{T}$ may have multiple solution codes; in this paper, we typically refer to a single solution code that is provided as input. A *student attempt* for a task T refers to a code that is being written by a student (including incorrect or partial codes). A student attempt could be any code $C \in \mathbb{C}$ as long as it uses the set of available types of code blocks (i.e., $\mathbb{C}_{\text{blocks}} \subseteq \mathbb{T}_{\text{store}}$).

2.2 Objective

Distinct phases. To formalize our objective, we introduce three distinct phases in our problem setup that provide a conceptual separation in terms of information and computation available to a system. More concretely, we have:

- (1) Reference task T^{ref} : We are given a reference task T^{ref} for which we have real-world datasets of different students’ attempts as well as access to other data resources. Reference tasks are fixed and the system can use any computation a priori (e.g., compute code embeddings).
- (2) Student stu attempts T^{ref} : The system interacts with a student, namely stu , who attempts the reference task T^{ref} and submits a code, denoted as $C_{T^{\text{ref}}}^{\text{stu}}$. At the end of this phase, the system has observed stu ’s behavior on T^{ref} and we denote this observation by the tuple $(T^{\text{ref}}, C_{T^{\text{ref}}}^{\text{stu}})$.¹
- (3) Target task T^{tar} : The system seeks to synthesize the student stu ’s behavior on a target task T^{tar} . Importantly, the target task T^{tar} is not available a priori and this synthesis process would be done in real-time, possibly with constrained computational resources. Furthermore, the system may have to synthesize the stu ’s behavior on a large number of different target tasks from the space \mathbb{T} (e.g., to personalize the next task in a curriculum).²

Granularity level of our objective. There are several different granularity levels at which we can predict the student stu ’s behavior for T^{tar} , including: (a) a coarse-level binary prediction of whether stu will successfully solve T^{tar} , (b) a medium-level prediction about stu ’s behavior w.r.t. to a predefined feature set (e.g., labelled misconceptions); (c) a fine-level prediction in terms of synthesizing $C_{T^{\text{tar}}}^{\text{stu}}$, i.e., a program that stu would write if the system would assign

¹In practice, the system might have more information, e.g., the whole trajectory of edits leading to $C_{T^{\text{ref}}}^{\text{stu}}$.

²Even though the *Hour of Code: Maze Challenge* [9] has only 20 tasks, the space \mathbb{T} is intractably large and new tasks can be generated, e.g., for providing feedback [1].

T^{tar} to the student. In this work, we focus on this fine-level, arguably also the most challenging, synthesis objective.

Performance evaluation. So far, we have concretized the synthesis objective; however, there is still a question of how to quantitatively measure the performance of a technique set out to achieve this objective. The key challenge stems from the open-ended and conceptual nature of programming tasks. Even for seemingly simple tasks such as in Figure 1a, the students’ attempts can be highly diverse, thereby making it difficult to detect a student’s misconceptions from observed behaviors; moreover, the space of misconceptions itself is not clearly understood. To this end, we begin by designing a benchmark to quantitatively measure the performance of different techniques w.r.t. our objective.

3. BENCHMARK

In this section, we introduce our benchmark, STUDENTSYN.

3.1 STUDENTSYN: Data Curation

We begin by curating a synthetic dataset for the benchmark, designed to capture different scenarios of the three distinct phases mentioned in Section 2.2. In particular, each scenario corresponds to a 4-tuple $(T^{\text{ref}}, C_{T^{\text{ref}}}^{\text{stu}}, T^{\text{tar}}, C_{T^{\text{tar}}}^{\text{stu}})$, where $C_{T^{\text{ref}}}^{\text{stu}}$ (observed by the system) and $C_{T^{\text{tar}}}^{\text{stu}}$ (to be synthesized by the system) correspond to a student stu ’s attempts.

Reference and target tasks. We select two reference tasks for this benchmark, namely T^4 and T^{18} —they correspond to Maze#4 and Maze#18 in the *Hour of Code: Maze Challenge* [9]. These tasks have been studied in a number of prior works [35, 15, 1] because of the availability of large-scale datasets of students’ attempts. For each reference task, we manually create three target tasks—Figure 2b illustrates target tasks for T^{18} ; the target tasks for T^4 can be found in the longer version of the paper [47]. These target tasks are similar to the corresponding reference task in a sense that the set of available block types is same and the nesting structure of programming constructs in solution codes is same.

Types of students’ behaviors and students’ attempts. For a given reference-target task pair $(T^{\text{ref}}, T^{\text{tar}})$, next we seek to simulate a student stu to create stu ’s attempts $C_{T^{\text{ref}}}^{\text{stu}}$ and $C_{T^{\text{tar}}}^{\text{stu}}$. We begin by identifying a set of salient students’ behaviors and misconceptions for reference tasks T^4 and T^{18} based on students’ attempts observed in the real-world dataset of [35]. In this benchmark, we select 6 types of students’ behaviors for each reference task—Figure 2c highlights the 6 selected types for T^{18} ; the 6 selected types for T^4 can be found in the longer version of the paper [47].³ For a given pair $(T^{\text{ref}}, T^{\text{tar}})$, we first simulate a student stu by associating this student to one of the 6 types, and then manually create stu ’s attempts $C_{T^{\text{ref}}}^{\text{stu}}$ and $C_{T^{\text{tar}}}^{\text{stu}}$. For a given scenario $(T^{\text{ref}}, C_{T^{\text{ref}}}^{\text{stu}}, T^{\text{tar}}, C_{T^{\text{tar}}}^{\text{stu}})$, the attempt $C_{T^{\text{tar}}}^{\text{stu}}$ is not observed and serves as a *ground truth* for evaluation purposes; henceforth, we interchangeably write a scenario as $(T^{\text{ref}}, C_{T^{\text{ref}}}^{\text{stu}}, T^{\text{tar}}, ?)$.

Total scenarios. We create 72 scenarios $(T^{\text{ref}}, C_{T^{\text{ref}}}^{\text{stu}}, T^{\text{tar}}, C_{T^{\text{tar}}}^{\text{stu}})$ in the benchmark corresponding to (i) 2 reference tasks, (ii) 3 target tasks per reference task, (iii) 6 types of students’ behaviors per reference task, and (iv) 2 students per type.

³We note that, in real-world settings, the types of students’ behaviors and their attempts have a much larger variability and complexities with a long-tail distribution.

(a) Reference task T^{18} with solution code and datasets

(b) Three target tasks for T^{18} : T^{18x} , T^{18y} , and T^{18z}

(c) Example codes (i)–(vi) corresponding to six types of students’ behaviors when attempting T^{18} , each capturing different misconceptions

Figure 2: Illustration of the key elements of the STUDENTSYN benchmark for the reference task T^{18} shown in (a)—same as in Figure 1a. (b) Shows three target tasks associated with T^{18} ; these target tasks are similar to T^{18} in a sense that the set of available block types is same as T_{store}^{18} and the nesting structure of programming constructs in solution codes is same as in $C_{T^{18}}^*$. (c) Shows example codes corresponding to six types of students’ behaviors when attempting T^{18} , each capturing a different misconception as follows: (i) confusing left/right directions when turning or checking conditionals, (ii) following one of the wrong path segments, (iii) misunderstanding of IFELSE structure functionality and writing the same blocks in both the execution branches, (iv) ignoring the IFELSE structure when solving the task, (v) ignoring the WHILE structure when solving the task, (vi) attempting to solve the task by using only the basic action blocks in {turnLeft, turnRight, move}.

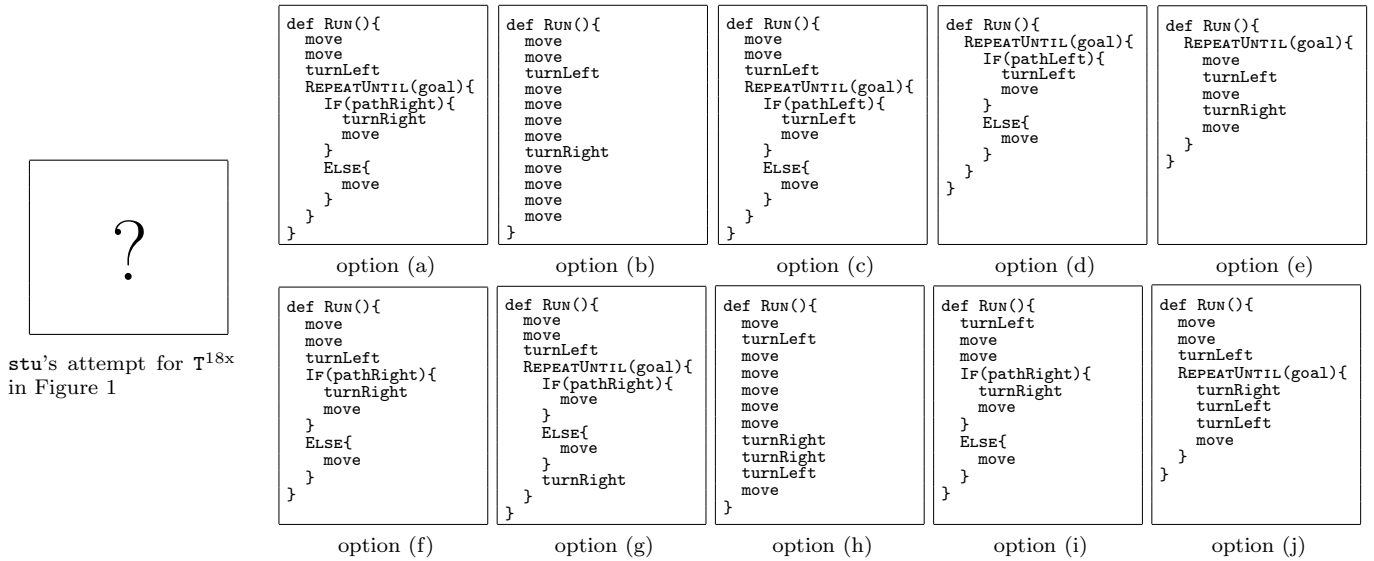

Figure 3: Illustration of the generative and discriminative objectives in the STUDENTSYN benchmark for the scenario shown in Figure 1. For the generative objective, the goal is to synthesize the student *stu*’s behavior on the target task T^{18x} , i.e., a program that *stu* would write if the system would assign T^{18x} to the student. For the discriminative objective, the goal is to choose one of the ten codes, shown as options (a)–(j), that corresponds to the student *stu*’s attempt. For each scenario, ten options are created systematically as discussed in Section 3.2; in this illustration, option (a) corresponds to the solution code $C_{T^{18x}}^*$ for the target task and option (e) corresponds to the student *stu*’s attempt as designed in the benchmark.

3.2 STUDENTSYN: Performance Measures

We introduce two performance measures to capture our synthesis objective. Our first measure, namely *generative performance*, is to directly capture the quality of fine-level synthesis of the student *stu*’s attempt—this measure requires a human-in-the-loop evaluation. To further automate the evaluation process, we then introduce a second performance measure, namely *discriminative performance*.

Generative performance. As a generative performance measure, we introduce a 4-point *Likert scale* to evaluate the quality of synthesizing *stu*’s attempt $C_{T^{tar}}^{stu}$ for a scenario $(T^{ref}, C_{T^{ref}}^{stu}, T^{tar}, ?)$. The scale is designed to assign scores based on two factors: (a) whether the elements of the student’s behavior observed in $C_{T^{ref}}^{stu}$ are present, (b) whether the elements of the target task T^{tar} (e.g., parts of its solution) are present. More concretely, the scores are assigned as

follows (with higher scores being better): (i) Score 1 means the technique does not have synthesis capability; (ii) Score 2 means the synthesis fails to capture the elements of $\mathbf{C}_{\text{Tref}}^{\text{stu}}$ and \mathbf{T}^{tar} ; (iii) Score 3 means the synthesis captures the elements only of $\mathbf{C}_{\text{Tref}}^{\text{stu}}$ or of \mathbf{T}^{tar} , but not both; (iv) Score 4 means the synthesis captures the elements of both $\mathbf{C}_{\text{Tref}}^{\text{stu}}$ and \mathbf{T}^{tar} .

Discriminative performance. As the generative performance measure requires human-in-the-loop evaluation, we also introduce a discriminative performance measure based on the prediction accuracy of choosing the student attempt from a set. More concretely, given a scenario $(\mathbf{T}^{\text{ref}}, \mathbf{C}_{\text{Tref}}^{\text{stu}}, \mathbf{T}^{\text{tar}}, ?)$, the discriminative objective is to choose $\mathbf{C}_{\text{Ttar}}^{\text{stu}}$ from ten candidate codes; see Figure 3. These ten options are created automatically in a systematic way and include: (a) the *ground-truth* $\mathbf{C}_{\text{Ttar}}^{\text{stu}}$, (b) the solution code $\mathbf{C}_{\text{Ttar}}^*$, (c) five codes $\mathbf{C}_{\text{Ttar}}^{\text{stu}'}$ from the benchmark associated with other students stu' whose behavior type is different from stu , and (iv) three *randomly* constructed codes obtained by editing $\mathbf{C}_{\text{Ttar}}^*$.

4. METHODOLOGY

In this section, we design different techniques for the benchmark STUDENTSYN. First, we consider a few simple baselines for the discriminative-only objective (RANDD, EDITD, EDITEMBD). Next, we develop our two main techniques inspired by neural/symbolic methods (NEURSS, SYMSS). Finally, we propose performance evaluation of human experts (TUTORSS). Table 1 illustrates how these techniques differ in required inputs and domain knowledge. Below, we provide a brief overview of these techniques; we refer the reader to the longer version of the paper for full details [47].

Simple baselines. As a starting point, we consider simple baselines for the discriminative-only objective; they do not have synthesis capability. Our first baseline RANDD simply chooses a code from the 10 options at random. Our next two baselines, EDITD and EDITEMBD, are defined through a distance function $D_{\text{Tref}}(\mathbf{C}, \mathbf{C}')$ that quantifies a notion of distance between any two codes \mathbf{C}, \mathbf{C}' for a fixed reference task. For a scenario $(\mathbf{T}^{\text{ref}}, \mathbf{C}_{\text{Tref}}^{\text{stu}}, \mathbf{T}^{\text{tar}}, ?)$ and ten option codes, these baselines select the code \mathbf{C} that minimizes $D_{\text{Tref}}(\mathbf{C}, \mathbf{C}_{\text{Tref}}^{\text{stu}})$. EDITD uses a tree-edit distance between *Abstract Syntax Trees* as the distance function, denoted as $D_{\text{Tref}}^{\text{edit}}$. EDITEMBD extends EDITD by considering a distance function that combines $D_{\text{Tref}}^{\text{edit}}$ and a code-embedding based distance function $D_{\text{Tref}}^{\text{emb}}$; in this paper, we trained code embeddings with the methodology of [15] using a real-world dataset of student attempts on \mathbf{T}^{ref} . EDITEMBD then uses a distance function as a convex combination $(\alpha \cdot D_{\text{Tref}}^{\text{edit}}(\mathbf{C}, \mathbf{C}') + (1 - \alpha) \cdot D_{\text{Tref}}^{\text{emb}}(\mathbf{C}, \mathbf{C}'))$ where α is optimized for each reference task separately.

Neural synthesizer NEURSS. Next, we develop our technique, NEURSS (*Neural Program Synthesis for STUDENTSYN*), inspired by recent advances in neural program synthesis [3, 4]. A neural synthesizer model takes as input a visual task \mathbf{T} , and then sequentially synthesizes a code \mathbf{C} by using programming tokens in $\mathbf{T}_{\text{store}}$. However, our goal is not simply to synthesize a solution code for the input task \mathbf{T} as considered in [3, 4]; instead, we want to synthesize attempts of a given student that the system is interacting with at real-time/deployment. To achieve this goal, NEURSS operates in three stages, where each stage is in line with a phase of our objective described in Section 2.2. At a high-level, the three

stages of NEURSS are as follows: (i) In Stage-1, we are given a reference task and its solution $(\mathbf{T}^{\text{ref}}, \mathbf{C}_{\text{Tref}}^*)$, and train a neural synthesizer model that can synthesize solutions for any task similar to \mathbf{T}^{ref} ; (ii) In Stage-2, the system observes the student stu 's attempt $\mathbf{C}_{\text{Tref}}^{\text{stu}}$ and initiates *continual training* of the neural synthesizer model from Stage-1 in real-time; (iii) In Stage-3, the system considers a target task \mathbf{T}^{tar} and uses the model from Stage-2 to synthesize $\mathbf{C}_{\text{Ttar}}^{\text{stu}}$.

Symbolic synthesizer SYMSS. As we will see in experiments, NEURSS significantly outperforms the simple baselines introduced earlier; yet, there is a substantial gap in the performance of NEURSS and human experts (i.e., TUTORSS). An important question that we seek to resolve is how much of this performance gap can be reduced by leveraging domain knowledge such as how students with different behaviors (misconceptions) write codes. To this end, we develop our technique, SYMSS (*Symbolic Program Synthesis for STUDENTSYN*), inspired by recent advances in using symbolic methods for program synthesis [24, 52, 1, 26]. Similar in spirit to NEURSS, SYMSS operates in three stages as follows: (i) In Stage-1, we are given $(\mathbf{T}^{\text{ref}}, \mathbf{C}_{\text{Tref}}^*)$, and design a symbolic synthesizer model using *Probabilistic Context Free Grammars* (PCFG) to encode how students of different behavior types \mathcal{M} write codes for any task similar to \mathbf{T}^{ref} [5, 27, 52]; (ii) In Stage-2, the system observes the student stu 's attempt $\mathbf{C}_{\text{Tref}}^{\text{stu}}$ and makes a prediction about the behavior type $\mathbf{M}^{\text{stu}} \in \mathcal{M}$; (iii) In Stage-3, the system considers a target task \mathbf{T}^{tar} and uses the model from Stage-1 to synthesize $\mathbf{C}_{\text{Ttar}}^{\text{stu}}$ based on the inferred \mathbf{M}^{stu} .

Human experts. Finally, we propose an evaluation of human experts' performance on the benchmark STUDENTSYN, and refer to this evaluation technique as TUTORSS. These evaluations are done through a web platform where an expert would provide a generative or discriminative response to a given scenario $(\mathbf{T}^{\text{ref}}, \mathbf{C}_{\text{Tref}}^{\text{stu}}, \mathbf{T}^{\text{tar}}, ?)$. In our work, TUTORSS involved participation of three independent experts for the evaluation—these experts have had experience in block-based programming and tutoring. We first carry out generative evaluations where an expert has to write the student attempt code; afterwards, we carry out discriminative evaluations where an expert would choose one of the options.

5. EXPERIMENTAL EVALUATION

In this section, we evaluate the performance of different techniques discussed in Section 4. Our results are summarized in Table 1 and Figure 4. Below, we provide a brief overview of the evaluation procedures and results; we refer the reader to the longer version of the paper for full details [47].

Generative performance. As discussed in Section 3.2, we evaluate the generative performance of a technique in the following steps: (a) a scenario $(\mathbf{T}^{\text{ref}}, \mathbf{C}_{\text{Tref}}^{\text{stu}}, \mathbf{T}^{\text{tar}}, ?)$ is picked; (b) the technique synthesizes stu 's attempt; (c) the generated code is scored on the 4-point *Likert scale*. The scoring step requires human-in-the-loop evaluation and involved an expert (different from the three experts that are part of TUTORSS). Overall, each technique is evaluated for 36 unique scenarios in STUDENTSYN—we selected 18 scenarios per reference task by first picking one of the 3 target tasks and then picking a student from one of the 6 different types of behavior. The final performance results in Table 1 are re-

Method	Generative Performance		Discriminative Performance		Required Inputs and Domain Knowledge				
	Reference task T^4	Reference task T^{18}	Reference task T^4	Reference task T^{18}	Ref. task dataset: student attempts	Ref. task dataset: similar tasks	Student types	Expert grammars	Expert evaluation
RANDD	1.00	1.00	10.0	10.0	-	-	-	-	-
EDITD	1.00	1.00	31.5	48.9	-	-	-	-	-
EDITEMBD	1.00	1.00	39.6	48.9	\times	-	-	-	-
NEURSS	3.00	2.83	43.8	57.2	\times	\times	-	-	-
SYMSS	3.78	3.72	88.1	62.1	-	-	\times	\times	-
TUTORSS	3.85	3.90	89.8	85.2	-	-	-	-	\times

Table 1: This table shows results on STUDENTSYN in terms of the generative and discriminative performance measures. The columns under “Required Inputs and Domain Knowledge” highlight information used by different techniques (\times indicates the usage of the corresponding input/knowledge). The values are in the range [1.0, 4.0] for generative performance and in the range [0.0, 100.0] for discriminative performance—higher values being better. Human experts (TUTORSS) can achieve high performance on both the measures, whereas simple baselines perform poorly. NEURSS and SYMSS significantly improve upon the simple baselines; yet, there is a high gap in performance in comparison to that of human experts.

Figure 4: Qualitative results for the scenario in Figure 1. (a) The goal is to synthesize the student stu ’s behavior on the target task T^{18x} . (b) Solution code $C_{T^{18x}}^*$ for the target task. (c) Code provided in the benchmark as a possible answer for this scenario. (d, e) Codes synthesized by our techniques NEURSS and SYMSS. (f) Code provided by one of the human experts.

ported as an average across these scenarios; for TUTORSS, each of the three experts independently responded to these 36 scenarios and the final performance is averaged across experts. The simple baselines (RANDD, EDITD, EDITEMBD) have a score of 1.00 as they do not have a synthesis capability. TUTORSS achieves the highest performance; SYMSS also achieves high performance (only slightly lower than that of TUTORSS)—the high performance of SYMSS is expected given its knowledge about types of students in STUDENTSYN and the expert domain knowledge inherent in its design. NEURSS improves upon simple baselines, but performs worse compared to SYMSS and TUTORSS. Figure 4 illustrates the codes generated by different techniques for the scenario in Figure 1—the codes by TUTORSS and SYMSS are high-scoring w.r.t. our 4-point *Likert scale*; however, the code by NEURSS only captures elements of the student’s behavior in $C_{T^{18x}}^{stu}$ but misses elements of the target task T^{tar} . We provide additional details and statistical significance results w.r.t. χ^2 test [6] in the longer version of the paper [47].

Discriminative performance. As discussed in Section 3.2, we evaluate the discriminative performance of a technique in the following steps: (a) a discriminative instance is created with a scenario (T^{ref} , $C_{T^{ref}}^{stu}$, T^{tar} , ?) picked from the benchmark and 10 code options created automatically; (b) the technique chooses one of the options as stu ’s attempt; (c) the chosen option is scored either 100.0 when correct, or 0.0 otherwise. For all techniques except TUTORSS, we perform evaluation on a set of 720 instances (360 instances per reference task); for TUTORSS, we perform evaluation on a small set of 72 instances (36 instances per reference task), to reduce the effort for human experts. The final performance results in Table 1 are reported as an average predic-

tive accuracy across the evaluated instances; for TUTORSS, each of the three experts independently responded to the instances and the final performance is averaged across experts. Results highlight the huge performance gap between the human experts (TUTORSS) and simple baselines (RANDD, EDITD, EDITEMBD). Our proposed techniques (NEURSS and SYMSS) have substantially reduced this performance gap w.r.t. TUTORSS. SYMSS achieves high performance compared to simple baselines and NEURSS; moreover, on the reference task T^4 , its performance is close to that of TUTORSS. The high performance of SYMSS is partly due to its access to types of students in STUDENTSYN; in fact, this information is used only by SYMSS and is not even available to human experts in TUTORSS (see column “Student types” in Table 1). NEURSS outperformed simple baselines but its performance is below SYMSS and TUTORSS. We provide additional details and statistical significance results w.r.t. Tukey’s HSD test [49] in the longer version of the paper [47].

6. CONCLUSIONS

We investigated student modeling in the context of block-based visual programming environments, focusing on the ability to automatically infer students’ misconceptions and synthesize their expected behavior. We introduced a novel benchmark, STUDENTSYN, to objectively measure the generative as well as the discriminative performance of different techniques. The gap in performance between human experts (TUTORSS) and our techniques (NEURSS, SYMSS) highlights the challenges in synthesizing student attempts for programming tasks. We believe that the benchmark will facilitate further research in this crucial area of student modeling for block-based visual programming environments.

ABSTRACT

Doing assignments is a very important part of learning. Students' assignment submission time provides valuable information on study attitudes and habits which strongly correlate with academic performance. However, the number of assignments and their submission deadlines vary among university courses, making it hard to use assignment submission time as a feature to predict academic performance. In this paper, we propose a new method called Relative Assignment Submission Time (RAST) which uses the assignment submission information of peer students to improve the correlation with course grades. Experiments on real-life data of 20 courses show that RAST has a high correlation with students' academic performance. We also build a machine learning model using RAST as a feature to detect students who would suffer from poor grades. Our method outperforms the traditional method by up to 61% on f1-score. We believe that our proposed method can help other studies on assignment submission time to improve the prediction accuracy on academic performance and detecting at-risk students.

Keywords

assignment submission time, peer information, academic performance, machine learning, students at-risk

1. INTRODUCTION

Doing assignments is a traditional method of testing the quality of students' learning and consolidating what they have learned. Typically, instructors assign some exercises or projects to students at the end of a class, and then in most cases students are required to submit their assignments by a certain deadline. Many studies have shown that there is a strong correlation between assignment completion and academic performance in the corresponding courses [7, 20, 21]. Some studies also show that the time when students start doing assignments can also reflect students' learning

psychology [1]. Generally speaking, the time when students start doing assignments is related to students' procrastination psychology. If a student suffers from serious procrastination, the student is likely to choose to start doing assignments close to the deadlines, which could result in late or poor-quality submissions. A meta-analysis [11] on 33 studies confirms that procrastination is negatively correlated with academic performance.

Many studies have demonstrated the impact of students' assignment behavior (including time spent on assignments, help-seeking behavior, etc.) on academic performance in online learning environments [7, 20, 21]. In most offline learning environments, however, it is hard to know exactly when students start working on their assignments, how they work out the solution, and how much time they spend on the assignments, etc. The difference between online and offline settings makes the methodologies in many studies limited to online teaching platforms only. In most offline learning environments, the only data on assignment behavior is the submission time.

Different from other continuous learning behavior data such as class attendance, assignment submission time could have distinctive implications before and after the corresponding deadline. In most learning environments, late submissions of assignments receive penalties on grading, which makes the deadline a watershed on student behavior. The straightforward way of using the difference between submission time and its deadline cannot capture all the information of submission time. In this paper, we propose an approach to process late and normal submissions separately while still using submission time data as a single continuous fashion, so that the new variable can be easily integrated into machine learning prediction methods that require continuous features.

The popularity of Learning Management Systems (LMS) makes it possible to collect data and study multiple courses at the same time; however, it is still challenging to apply analysis on submission time data from multiple courses. Most studies in the literature focus on using the data from one course only. The key issue is that cross-course data analysis is fundamentally different across different courses. The numbers of assignments in different courses are different. More assignments usually mean less time to work out the solution, so that it is hard to analyze the submission time of different courses together. Furthermore, the difficulty levels

of assignments may vary a lot. Even with the same number of assignments, courses with difficult assignments may have larger numbers of late submissions. Students of course A with difficult assignments may tend to submit assignments closer to the deadlines than other students, but this does not necessarily mean that students of A are more procrastinating. Inspired by a recent study [5] that compares attendance rates using peer attendance data, this study proposes a new indicator on assignment submission time that incorporates peer information so that submission time data from multiple courses can be compared and used in a machine learning model. So far as we know, there is no previous study that applies peer information on assignment submission time.

In this paper, we propose a new indicator called Relative Assignment Submission Time (RAST), which reflects the average distance between a student's assignment submission time and the corresponding deadline, while using peer assignment submission information to eliminate differences in time limits and difficulty levels of assignments. Our approach treats late and normal submissions in different groups but computes the new indicator as a single continuous variable, so that it can be easily applied to most machine learning methods as a prediction feature. We investigate the correlation between RAST and academic performance on real-life data from 5679 samples of 20 courses, showing that there is a high Pearson correlation between RAST and course grades. We also use RAST and other commonly available features to build models to detect at-risk students. Using the data from the first half of the semester, our method outperforms the traditional method by up to 61% on f1-score. We believe that our method can help other studies on assignment submission time to improve the prediction accuracy on academic performance and detecting at-risk students.

The rest of the paper is organized as follows. Section 2 discusses related work. Section 3 describes the preliminary. Section 4 introduces the method we propose, including the definition of Relative Assignment Submission Time (RAST). Section 5 presents the experimental results on real-life data and the analysis of the experimental results. Section 6 discusses the limitations of this paper and the future work. Section 7 concludes the paper.

2. RELATED WORK

Assignments are very important to learning. With the development of online education over the last decade, many platforms and methods have been proposed to help people collect and analyze students' assignment information. Jivet et al. [10] designed a learning analytics dashboard for Coursera MOOCs which can record when learners submit assignments. Studies in [2, 25] used clickstream data (including submitting assignments) in online teaching platforms to analyze students' behavior. [3] predicted the decrease of students' engagement in typical MOOC tasks such as watching lecture videos or submitting assignments.

Many studies have shown a correlation between students' assignment completion and procrastination. Studies in [19] analyzed student self-discipline by tracking student behavior including assignment submission. [17] comprehensively studied the relationship between students' learning behaviors and procrastination. [1] proposed a new measure called

Procrastination Index, which represents a learner's degree of procrastination in the start time of doing assignments. [24] studied the relationship between procrastination and assignment deadlines. The authors showed that dependencies between students' historical activities and the future ones provide meaningful interpretations in terms of students' procrastination behaviors.

Many studies have analyzed the relationship between assignment and academic performance. [7] explored the effects of help-seeking behavior on learning assignments to academic performance. [20] analyzed the relation between consistency in students' online work habits (including assignment submissions) and academic performance in a blended course. [21] confirmed the positive correlation between the time students spend on assignments and their academic performance.

An important topic in educational data mining is to identify and help at-risk students. Studies in [6] proposed a classifier to identify students at-risk for disengagement from coursework. [8] proposed a solution in the absence of data from previous courses to identify students at risk of failing the course. [13] developed a machine learning framework to conduct accurate at-risk student identification specialized in K-12 multimodal online environments. [15] identified at-risk students based on their behavior of handing in assignments on online platforms. Using features of attendance rate, grade retention and student profile, [23, 14] established early warning systems to identify at-risk students.

Recently, [4, 16, 12] studied the impact of assignment submission time on academic performance. [4] used students' precise assignment submission time to identify at-risk students, but without introducing peer information from the classmates. The authors suggested that assignment submission time is not easy to predict at-risk students, as the relationship between submission time and marks varies depending on both the student and the assignment context. [16] studied patterns in assignment submission time. By building a machine learning model, the authors found that completion time performs better in predicting students' assignment grades than quizzes and exam grades in a one-semester physics course with 1374 students. [12] applied the assignment submission time with temporal learning analytics to aid precision education. The authors analyzed the transitional patterns between successive assignments with Markov chains and the relationship between the patterns and the passes with association rules from 69 students.

[5] proposed a method called Relative Attendance Index to measure attendance rates, which reflects students' efforts on attending courses. While traditional attendance focuses on the record of a single person or course, relative attendance emphasizes peer attendance information of relevant individuals or courses, making the comparisons of attendance more justified. However, due to the different nature of the data (attendance vs. submission time) the specific method of introducing peer information in that paper cannot be applied to assignment submission time.

None of the above studies applied peer information to study assignment submission time.

3. PRELIMINARY

Logistic regression is a statistical model that in its basic form uses a logistic function to model a binary dependent variable [22]. Given dataset $D = \{(\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2), \dots, (\mathbf{x}_N, y_N), \mathbf{x}_i \in \mathbb{R}^n, y_i \in \{0, 1\}, i = 1, 2, \dots, N\}$, the loss function to minimize is the cross entropy loss function below.

$$L(\mathbf{w}, b) = \frac{1}{N} \left(\sum_{i=1}^N y_i \ln f(\mathbf{x}_i) + (1 - y_i) \ln(1 - f(\mathbf{x}_i)) \right). \quad (1)$$

Sometimes, we will encounter the problem that the difference between the number of positive ($y = 1$) and the number of negative ($y = 0$) samples is too large. A simple way is to use the loss function in the “**balanced**” mode [18]. The “balanced” mode uses the values of y to adjust weights in the loss function. In the “balanced” mode, the weight of $y = 0$ will be given by $N/(2 \times \text{count}(y = 0))$ and the weight of $y = 1$ will be given by $N/(2 \times \text{count}(y = 1))$. In this paper, we will refer to the original method without adjusting the loss function as the “**unbalanced**” mode.

4. METHOD

To give the definition of Relative Assignment Submission Time (RAST), we need to define some quantities first.

How long a student submits an assignment before the deadline is an indicator of study habits and attitude, we define it as Submission Buffer.

Definition 1 (Submission Buffer $\Delta_{c,s,i}$): Given course c and student s , let $\mu_{c,i}$ be the deadline for submission of the i th assignment of course c ; let $t_{c,s,i}$ be the submission time of the i th assignment of course c for student s . Then the Submission Buffer is defined as below.

$$\Delta_{c,s,i} = \mu_{c,i} - t_{c,s,i}. \quad (2)$$

The average assignment submission time of a student in a course can be defined straight-forwardly.

Definition 2 (Average Submission Time $AST_{c,s}$): Given course c and student s , let n_c be the number of assignments in c , then the Average Submission Time (AST) of c and s is defined as below.

$$AST_{c,s} = \frac{1}{n_c} \sum_{i=1}^{n_c} \Delta_{c,s,i}. \quad (3)$$

One drawback of AST is that it mixes the data of late submissions with normal submissions together. Late submission reflects the punctuality and study habits of the students. If a student has large submission buffers in some assignments, late submission information (even if it is a frequent pattern) will be buried in the average of submission buffers. Therefore, in our method we separate normal submissions and late submissions in the calculation of the new index.

Positive and negative submission buffers indicate normal and late submissions respectively.

Definition 3 (Normal Set $S_{c,i}^+$ and Late Set $S_{c,i}^-$): Given the definition of submission buffer $\Delta_{c,s,i}$, let S_c be the set of

students who registered for course c , then normal set ($S_{c,i}^+$) and late set ($S_{c,i}^-$) represent normal and late submissions.

$$S_{c,i}^+ = \{s : \Delta_{c,s,i} \geq 0 | s \in S_c\},$$

$$S_{c,i}^- = \{s : \Delta_{c,s,i} \leq 0 | s \in S_c\}.$$

With the definitions of Normal Set and Late Set, we further define a notion called Submission Deviant to reflect how a submission is different from submissions of other students in the same course in terms of submission time. We process normal and late submissions in their own category to preserve the difference between late and on-time submissions. For an assignment submission, Submission Deviant is defined as the submission buffer divided by the largest submission buffer of the same category (late or on-time). The peer information of other students’ submission time helps normalizing the significance of a late or normal submission. For example, if a student submits an assignment early but not that early when compared with the best student in the class in terms of submission buffer (who has the earliest submission), the significance of this early submission is low; similarly, if a student submits an assignment late but not that late when compared with the worst student in the class, the significance of this late submission is also low. Formally, Submission Deviant is defined as below.

Definition 4 (Submission Deviant $d_{c,s,i}$): The Submission Deviant of the i th assignment submission of student s in course c is defined by the formula below.

$$d_{c,s,i} = \begin{cases} \frac{\Delta_{c,s,i}}{\max_{s' \in S_{c,i}^+} |\Delta_{c,s',i}|} & \Delta_{c,s,i} \geq 0 \\ \frac{\Delta_{c,s,i}}{\max_{s' \in S_{c,i}^-} |\Delta_{c,s',i}|} & \Delta_{c,s,i} \leq 0 \end{cases} \quad (4)$$

By the definition, normal and late submissions have positive and negative submission deviants respectively.

Finally, Relative Assignment Submission Time (RAST) is defined as the average submission deviant over all assignments of a course for each student.

Definition 5 (Relative Assignment Submission Time $RAST_{c,s}$): Given course c and student s , the Relative Assignment Submission Time (RAST) is defined as below.

$$RAST_{c,s} = \frac{1}{n_c} \sum_{i=1}^{n_c} d_{c,s,i}. \quad (5)$$

Relative Assignment Submission Time (RAST) reflects the average distance between a student’s assignment submission time and the corresponding deadline, while using peer assignment submission information to eliminate differences in time limits and difficulty levels of assignments. Compared with Relative Assignment Submission Time (RAST), Assignment Submission Time (AST) in Definition 2 does not consider peer assignment submission information.

Lemma 1: Given student s in course c and the Relative Assignment Submission Time $RAST_{c,s}$, $RAST_{c,s} \in [-1, 1]$.

PROOF. The proof is straightforward. \square

Students who are always submitting assignments before classmates (and ahead of the deadlines) will have an RAST of 1, while students who are always missing the deadlines and are the last one to submit assignments have an RAST of -1. The fixed range of $[-1, 1]$ provides the minimal and maximal values of RAST, which can make the data analysis more convenient.

5. RESULTS

5.1 Datasets

The anonymous data used in this paper were collected from a university in China in the Fall 2020 semester and the Spring 2021 semester. Note that all data collection and usage in this project have been approved by the university management. To protect students’ privacy, all student IDs were encrypted and processed into hash codes, with other data related to a student being linked by the corresponding hash code. The data came from 20 undergraduate courses (15 in the Spring 2021 semester and 5 courses in the Fall 2020 semester). As shown in Table 1, these courses covered multiple topics on Computer Science (CSC), Math (MAT), and Statistics (STA). MAT2040 and MAT3007 were offered in both semesters. We collected the deadline for each assignment in a course and then the submission time of each assignment for each student from the LMS system “Blackboard”. In all the courses, students received letter grades from A to F at the end of the courses. The corresponding relationship between letter grades and numerical grades is shown in Table 2. The proportions of different grades in different courses were not exactly the same, but the differences were not very significant due to the grading quality control of the university. Many courses had the policy of not accepting submissions of 4 or more days late. For the simplicity of data reprocessing, we considered missing assignments as 3-day late. These samples only account for 4.2% of all the 5679 samples.

Table 2: Corresponding Relationship between Grades and Numeric Grades

Letter grade	A	A-	B+	B	B-	C+
Numerical grade	4.0	3.7	3.3	3.0	2.7	2.3

5.2 Correlation with Academic Performance

Many previous studies showed that assignment submission is correlated with academic performance. We calculated the Pearson correlation between students’ Relative Assignment Submission Time (RAST) and their course numeric grades across 20 courses. As a comparison, we also calculated the Pearson correlation between the corresponding Average Submission Time (AST) and the course numeric grades. The results are shown in Table 3 (sorted by the correlation coefficient of RAST). The second column of the table is the course enrollment number, the third column is the AST correlation coefficient, and the fourth column is the RAST correlation coefficient. The correlation coefficients between RAST and course grades are higher than that of AST across 18 courses. The p-values of all the correlation coefficients in Table 3 are all well below 0.005, which shows that the correlation coefficients are statistically significant [9].

5.3 RAST Distribution

In order to show the different distributions on RAST of high and low course grade students, we selected two sample sets from all the data in the Fall 2020 semester of our dataset, one with grades greater than or equal to A- (sample size

438), and the other with grades less than or equal to C+ (the sample size 208). Figure 1 shows the distribution on RAST of samples with grades $\geq A-$ (in blue) and the distribution on RAST of samples with grades $\leq C+$ (in grey) in Fall 2020. The data of the two sets came from five courses (CSC3001, CSC3002, MAT2040, MAT3007, and EIE2050) in Fall 2020. For samples with higher grades (in blue), the RAST values of 79% samples are greater than 0, and 13% samples are greater than 0.25. For samples with lower grades (in grey), the RAST of the 75% samples are less than 0, 39% samples are less than -0.25, and 19% samples are even less than -0.5. We can see that students with high grades have a higher probability of having high RAST, whereas students with lower grades have a higher probability of having low RAST. We did a similar experiment on Spring 2021 data (The two sample sets are of size 1422 and 705 respectively), and the results are shown in Figure 2. The distributions are similar to those in Figure 1.

5.4 Predicting Academic Performance

In this experiment, we used students’ RAST and some other attributes as features in logistic regression models to predict their academic performance. More precisely we predicted whether a student will have a struggling performance (course grade $\leq C+$). The data used in our experiments came from 20 courses. For each sample $\{x, y\}$, x is a vector consisting of 4 features, including the RAST in the course, average GPA in previous semesters, year in university, and the school (in one-hot coding). $y = 1$ if grade $\leq C+$, or otherwise $y = 0$. Note that we used a mix of data from different courses because the grading criteria for each course are not very different and RAST is in the range of -1 to 1. We randomly divided the data into a training set and a test set according to the ratio of 4:1. We used the cross entropy loss function for Logistic Regression training in order to avoid overfitting. The total number of samples is 5697, with 15.6% of them being positive samples ($y = 1$). Since the data is imbalanced, we experimented both with and without the “balanced” mode. As discussed in the Preliminary (Section 3), the “balanced” mode can improve the recall while sacrificing the precision. All experimental results are averaged after ten repetitions. At the same time, we also tried replacing RAST with AST and conducted experiments for comparison. The results are shown in Table 4. In the unbalanced mode, RAST is better than AST on precision (0.80 vs. 0.68), while AST is better than RAST on recall (0.49 vs. 0.44). The two methods are tied on f1-score. In the “balanced” mode, however, RAST is better than AST on all the three measures (precision, recall and f1-score).

Furthermore, in order to evaluate the feature importance of RAST, we also repeated the above experiment without using RAST as a feature. The results (with standard deviation values) are shown in the Table 5. Compared with the results using RAST, the f1-score decreased by 28% (0.57 vs. 0.41) with the “unbalanced” mode, and the f1-score decreased by 0.25% (0.68 vs. 0.51) with “balanced” mode.

5.5 Application of Half Semester Data

In real-life applications, it is important to detect at-risk students long before the semester is over. Therefore, in this experiment we used only the data from the first half of the semester to perform the training. We repeated the same ex-

Figure 1: RAST Distributions of Fall 2020 Data

Figure 2: RAST Distributions of Spring 2021 Data

Table 4: Results of the Logistic Regression Models (with standard deviation values in the parenthesis)

RAST	“unbalanced” mode	“balanced” mode
precision	0.80 (± 0.05)	0.56 (± 0.04)
recall	0.44 (± 0.02)	0.85 (± 0.03)
f1-score	0.57 (± 0.01)	0.68 (± 0.01)
AST	“unbalanced” mode	“balanced” mode
precision	0.68 (± 0.06)	0.53 (± 0.03)
recall	0.49 (± 0.02)	0.76 (± 0.04)
f1-score	0.57 (± 0.03)	0.62 (± 0.04)

Table 5: Results of the Logistic Regression Models without Using Submission Time Features

	“unbalanced” mode	“balanced” mode
precision	0.63 (± 0.04)	0.38 (± 0.02)
recall	0.31 (± 0.05)	0.76 (± 0.04)
f1-score	0.41 (± 0.03)	0.51 (± 0.04)

Table 6: Results of the Logistic Regression Models with Half Semester Data

RAST	“unbalanced” mode	“balanced” mode
precision	0.76 (\pm 0.07)	0.52 (\pm 0.02)
recall	0.41 (\pm 0.03)	0.83 (\pm 0.05)
f1-score	0.53 (\pm 0.04)	0.64 (\pm 0.02)
AST	“unbalanced” mode	“balanced” mode
precision	0.62 (\pm 0.02)	0.52 (\pm 0.01)
recall	0.45 (\pm 0.03)	0.71 (\pm 0.02)
f1-score	0.33 (\pm 0.02)	0.56 (\pm 0.02)

periments as in the previous section, except that only the assignment data from the first half of the semester are used to train the prediction models. The results (with standard deviation values) are shown in Table 6. We can see that only using half semester data, models with RAST can still achieve better results than models with AST. In unbalanced mode, the f1-score of RAST is 61% better than that of AST (0.53 vs. 0.33). In the balanced mode, the f1-score of RAST is 14% better than that of AST (0.64 vs. 0.56). We notice that for RAST the f1-scores are only slightly worse than the original experimental results in Table 4 (0.53 vs. 0.57 for “unbalance” mode and 0.64 vs. 0.68 for “balanced” mode), even though using half amount of the data. Our experimental results inspire us to use our method to predict students who are likely to be struggling in the course halfway through the course, which allows us to take steps early to provide assistance to these students in need.

Moreover, we conducted additional experiments on individual courses, with all experimental settings unchanged. Experimental results show that our method can achieve stronger results in some individual courses, including EIE2050 (0.86 f1-score), CSC3001 (0.81 f1-score), and CSC3002 (0.80 f1-score) of Fall 2020, as well as MAT3040 (1.00 f1-score), MAT3007 (0.81 f1-score) and STA3020 (0.79 f1-score) of Spring 2021. The f1-score of other testing courses are below 0.79. See the appendix for the complete results.

6. DISCUSSION

Studies have shown that students tend to delay assessment submissions until deadlines approach [1, 3]. Our data also indicate that more than 60% of students did not submit assignments until the last 24 hours before the deadlines. The submission distribution may vary in different courses due to the assignments’ difficulties and the students’ average level. Hence, AST reflects limited information about the objectives of students. RAST takes other students in the same course into consideration. The performance of RAST better than the AST manifests that RAST is a more general feature to estimate whether a student’s assignment submission time is in a normal stage.

We have considered the circumstances that students submit their assignments after the deadlines. Even though late submissions receive heavy penalties on grading, students may be overwhelmed with the workload or forget to submit assignments, causing slightly late submissions. However, the assignments usually account for a limited proportion of the

final grade. By finishing the assignments, students practice a review and raise the chance of getting a good mark in the final exam. In this sense, late submissions are better than making no submission, and late submissions contain valuable information. Compared with the general regularization, RAST divides submissions of the same course into two groups (late and normal) to capture the information from late submissions.

In Table 3, three STA courses attain low correlation values between RAST/AST and course grades. We conjecture that course difficulty and assessment composition may influence the correlation. For example, STA3010, STA3100 and STA3020 are all advanced statistics courses. The exams are difficult, so that their final exam scores are dominant in the course grades. For such courses, assignment submission time may not be sufficient to trace students’ learning status because besides the assignments students still need to spend a lot of time reviewing and understanding the course contents. In contrast, STA2001 the elementary statistics course (this university set up statistics course codes from 2000 instead of 1000), gains a much higher correlation coefficient between RAST and course grades.

7. LIMITATIONS AND FUTURE WORK

In this paper, we studied assignments finished offline and submitted online through LMS. Since in such a setting we cannot collect the time the students start doing the assignments, the submission time may not always reflect students’ study attitudes. For example, a student may complete an assignment early, but submit it close to the deadline.

Although we mentioned in the paper that the grading standards of the courses included in the data used in this paper are not very different, in other scenarios, if the evaluation standards of different courses are very different, it may be necessary to consider the difference on grading schemes between courses when using Relative Assignment Submission Time (RAST) on multiple course data. We leave the study of such scenarios to future work.

8. CONCLUSION

Students’ assignment submission time is an important factor on study psychology and behavior analysis. In this paper, we proposed a new indicator using peer assignment submission information called Relative Assignment Submission Time (RAST). Our experiments on real-life data showed a high correlation coefficient between RAST and students’ academic performance. Using relative assignment submission time as a feature, we built a machine learning model to predict students who are likely to suffer from poor performance in courses. The experimental results show that the prediction ability of the model is significantly improved by adding RAST as a feature. We also used half semester data to train prediction models which allow us to identify students who may be struggling in the course earlier and make it easier for schools and teachers to take relevant measures in time to help these students.

Simulating Policy Changes In Prerequisite-Free Curricula: A Supervised Data-Driven Approach

Frederik Baucks, Laurenz Wiskott

Ruhr University Bochum, Computer Science Department, Institute for Neural Computation
{frederik.baucks, laurenz.wiskott}@ini.rub.de

ABSTRACT

Curriculum research is an important tool for understanding complex processes within a degree program. In particular, stochastic graphical models and simulations on related curriculum graphs have been used to make predictions about dropout rates, grades, and degree completion time. There exists, however, little research on changes in the curriculum and the evaluation of their impact. The available evaluation methods of curriculum changes assume pre-existing strict curriculum graphs in the form of directed acyclic graphs. These allow for a straightforward model-oriented probabilistic or graph topological investigation of curricula. But the existence of such graphs cannot generally be assumed. We present a novel generalizing approach in which a curriculum graph is constructed based on data, using measurable student flow. By applying a discrete event simulation, we investigate the impact of policy changes on the curriculum and evaluate our approach on a sample data set from a German university. Our method is able to create a comparably effective and individually verifiable simulation without requiring a curriculum graph. It can thus be extended to prerequisite-free curricula, making it feasible to evaluate changes to flexible curricula.

Keywords

Curriculum change, curriculum graph, student flow, discrete event simulation, degree completion time

1. INTRODUCTION

Curriculum Analytics is a recognized tool in Educational Data Mining to study the structure of curricula at a university [18]. One goal is to examine the structure of a curriculum and its influence on students' study progress. Often a graphical representation of the curriculum is formed, which is then called a curriculum graph, where vertices represent courses and edges a type of dependence, for example, a strict prerequisite. Due to the frequency of curricula with strict prerequisites, a commonly considered graph type is

the directed acyclic graph (DAG) (e.g., [1, 25]), where edges represent prerequisites between courses. For graphs of this type, probabilistic algorithms like Bayesian Networks can be applied to predict e.g. grades and dropout rates [22]. Furthermore, directed curriculum graphs offer a strict logic according to which students are guided through their degree program. This can be exploited for a discrete event simulation to simulate student flow, predict the degree completion time (DCT) [9, 8, 19], and investigate policy changes on the curriculum [14]. A discrete event simulation models the operation of a complex system in discrete time steps. Processes in the system are described by events, which can only take place at discrete time steps. This allows, for example, to simulate a redesign of the system [5]. In the context of degree programs, events are often modeled as courses or the corresponding exams, and time steps as semesters.

But not every degree program is based on a curriculum that can be translated into a DAG to be used in a discrete event simulation. For instance, such strict curricula hardly exist in Germany. In order to include a flexible curriculum and its influence in predictive methods, the relationships between courses must be obtained from the data. In Raji et al. [17] and Backenköhler et al. [3], grade correlations were used to form graphs of a prerequisite-free curriculum. The results are undirected cyclic graphs (UCG) that can be used for visualization and grade predictions using Markov approaches [21]. However, Markov-Networks suffer from the curse of dimensionality and thus small data set sizes, like the one we will introduce, are insufficient. Further, the resulting graphs contain no information about the actual order in which students take courses. To overcome these problems, one could try to use a discrete event simulation from the context of a DAG and generalize it to a non-strict curriculum using a data-generated curriculum graph. But a UCG does not offer a strict student transition logic as a DAG offers, therefore, it is not clear how students can be simulated through their degree program. Existing approaches that do not use a DAG, are limited to supply-demand modeling [20, 13] in which the supply capacities of courses and teachers and the demand of the students are simulated. As far as we know, all approaches using discrete event simulation to simulate student flow are lacking a data-driven evaluation of the simulation accuracy for individual students.

We model a data-driven directed cyclic curriculum graph (DCG) using time-dependent student flow, comparable to curriculum mining approaches [15, 7], and use the directed

Table 1: Data Set Variables

Variable	Description
ID	Anonymized student ID
Course	Course name
Exam - Grade	Grade in range 0 – 100
Exam - Time	Exam’s term
Exam - Try	Attempt number
Exam - Credits	Credits for passing

edges to simulate a student’s transition from one course to the next. Thus, we get a logic comparable to that of strict curricula (DAG), but we can simulate and analyze flow in non-strict curricula (UCG). In this work in progress study, we build a generalizing approach to simulate student flow on a curriculum with no given prerequisite relations. This allows for simulating new policy changes, for example, increasing the proposed workload in a semester, or changing the frequency of exams. Further, it gives us the advantage of labeled data, and therefore makes individual error analysis possible, as our first results show. The main contributions of our paper can be summarized as follows:

1. Building a directed student flow graph using a small data set of an Applied Computer Science program.
2. Building a student flow-based logic and running an individually verifiable discrete event simulation of the DCT to investigate policy changes to the curriculum.

2. DATA

The data set consists of examination data from the Bachelor’s program Applied Computer Science at the Ruhr University Bochum. The years 2013-2020 were considered, as there has been no policy change to the curriculum during this period. Each entry in the data set consists of exam-related variables described in Table 1. The degree program has a workload of 180 credit points. Each of these credits corresponds to a time commitment of 30 hours. In order to complete the program, with a standard length of study of 6 semesters, 30 credits must be completed each semester. Of the 180 credits, 117 credits are in 19 compulsory courses that must be taken to earn the degree. We limit ourselves to these compulsory courses, as the remaining credits can be obtained from a wide range of available elective courses so that the data becomes too sparse. Besides the requirement to pass the courses, there are no other requirements to these courses, such as a fixed sequence or prerequisites, which is common in Germany. We were able to process data of a total of $N = 405$ students. These are students who are currently attending the university. Therefore, the number of students who have passed the compulsory courses for a given semester is decreasing significantly, as Table 3 shows. Here, the semesters are indicated in the row ‘Term’ and the number of students who have passed all courses from the associated term is indicated in the row ‘No. Students’. We see that only 33 students have passed all courses of the 5 semesters. In the future, the data set will be expanded to include students who completed or dropped out of the program. The grades in the degree program are given in percentages from 0 to 100. An exam and thus the associated course is considered passed when 50 percent is achieved. We will look at the grades in increments of 10. In this way, we

Table 2: Lowest Pass Rate Courses Regarding Group G^*

Course Name	Pass Rate
Mathematics II	0.909
Web-Engineering	0.818
Operating Systems	0.818
Database Systems	0.757

try to counteract the sparsity of the data and at the same time ensure a lower deanonymization risk. The grading scale thus goes from 1 to 10 and an exam is considered passed if the student receives a grade of 6 or higher. In terms of simulation, we will focus on the 33 students from Table 3 who successfully passed all compulsory courses and call this group of students G^* in the following.

2.1 Data Privacy and Ethics

An important issue in the use of personal data in Germany and the European Union is compliance with the applicable data protection law (General Data Protection Regulation (GDPR) [23]). The implementation of the GDPR on our data set was carried out by a third-party university office in close cooperation with the data protection officer of the University. The anonymization includes name encryption, omission of demographic information (e.g., origin and gender), and aggregation of courses that are too small ($N < 10$) into their upper course categories (e.g., specialization courses). All grades were randomized with a stochastic noise $z \in [-5, 5]$ in the 0-100 percentage scale. This ensured that the anonymity of individuals was adequately protected when processing the data according to the GDPR. Ethically, the implementation of the procedures in practice regarding the following methodology has not yet been clearly formulated. The fairness of the methods still needs to be ensured to prevent discrimination against individuals or groups at all costs.

2.2 Pass Rates, Workload and Retake Bonus

In the following, we present statistical insights of our data set that influenced the later process of simulation. At first, we define the Degree Completion Time (DCT) as the number of semesters taken to pass all 19 compulsory courses. The DCT will be the output value of the simulation, which will be called DCT simulation (DCT-SIM) in the following. Pass rates of a student should be of great influence for the DCT value. Nevertheless, our considered group G^* is so good that we can observe only very high pass rates, as Table 2 indicates. This table shows the 4 courses in which group G^* had the lowest pass rates on the first try of an exam. A larger data set would probably show more representative values. However, we aim to ensure that our methodology is also applicable to an extended data set without restrictions. In contrast to the pass rates of group G^* , the workload has an impact on the DCT of the observed group. Table 3 shows that in each semester different numbers of courses are proposed by the curriculum, where the courses also have unequal workloads. This is also reflected in the data. In Table 3 the average workload of the students of G^* in the first 5 semesters was calculated and compared to the workload proposed by the curriculum. For example, 3 compulsory courses worth 23 credits are recommended in the third semester and 2 courses worth 13 credits in the

Table 3: Basic Statistics Regarding Terms

Term	1	2	3	4	5
No. Courses	5	5	3	4	2
Workload	27	30	23	24	13
No. Students	185	80	55	35	33
Mean Workl. G^*	26.70	30.00	22.24	23.18	6.42

fifth semester. Unlike semesters 3,4 and 5, no courses other than compulsory courses are recommended in the first and second semesters. In semester 1, this creates a time deficit of 3 credits. Even the high-performing students from group G^* perceive this time delay with an average workload of 26.697 and have to compensate it later by doing more work or achieving a higher DCT. Furthermore, we will address the change of grades when students retry a failed exam. An exam may be attempted a total of three times before a student is disenrolled. Since our data set is small, we decided to determine the average grade change from the first to the second take of an exam. The difference is added as a bonus to the grade of the first attempt to simulate the grade of the second attempt. This works under the assumption that the students perform similarly much better in all courses if they take an exam for the second time. The resulting global average is an improvement of 2.622 out of 10 using all available student data.

3. METHODS

We want to find a simulation strategy that matches the Degree Completion Time (DCT) distribution of a given student group. In addition, it should be possible to evaluate policy changes to the curriculum using the DCT-SIM. In particular, we want to simulate group G^* . The DCT-SIM should remain as generalizable as possible for future changes in the data set. Therefore, we use the data of all available 405 students in each step of the DCT-SIM of group G^* . For example, we train prediction methods course by course, so we can use more data in the first semester than in the last semester. We have divided our methodology into three sections: Student Flow, DCT-SIM, and Policy Changes. The Student Flow indicates the transition rates of students from one semester to the next and forms the basis of our approach. The DCT-SIM is formulated using a data-driven logic based on the Student Flow, grades, and workload of all available students in the data set. We pass a group of students to our method and get the DCTs back as a distribution. The Policy Changes show the use of our DCT-SIM even for small groups, such as G^* .

3.1 Student Flow Network

Since no strict course prerequisites are given in the curriculum and thus no directed relationships between two courses, we must model these connections in a data-driven way. The flow network is a directed cyclic graph $G_f = (V_f, E_f, W_f)$, where V_f , E_f , and W_f are the sets of vertices, edges, and edge weights, respectively. Each vertex $v \in V_f$ represents a course. A directed edge $e \in E_f$ is drawn if students traverse from one course in one semester to another different course in the next semester. The percentage of students across all semesters who are in a vertex in a semester and now move along an edge to the next vertex in the next semester corresponds to the edge weight $w \in W_f$. The sum of the

outgoing percentage weights equals 1. A student is usually located on several vertices at the same time within one semester depending on the number of courses he/she is attending. Figure 1, generated using NetworkX [10], shows the complexity of the flow. Here the courses are arranged as recommended by the curriculum. From left to right in semester ascending order the courses in one column belong to one semester. For example, the first column corresponds to the first semester. The course vertex size corresponds to the number of students that managed to finish the course. The graph is highly connected (329 of 361 possible edges) because in a lot of courses students violate the recommended curriculum. The darkness and thickness of edges indicate the weight of the flow. If an edge $e_{u,v} \in E_f$ between two vertices $u, v \in V_f$ corresponds to the weight value $w_{u,v} = 1$, it means that all students who attended course u in one semester attended course v in the next semester. The edges in Figure 1 suggest that the flow for the majority of students is from left to right according to the recommended curriculum. From the later semesters, when the amount of data decreases, the flow starts to become more chaotic, for example students move from right to left. This suggests that the observed students adhere less to the study plan as they progress in the degree program.

3.2 Degree Completion Time Simulation

The DCT-SIM consists of three steps: Initialization, course selection, and pass/fail prediction. The DCT-SIM of a student is completed, when all 19 courses are passed. In one DCT-SIM run, we sample every student of group G^* exactly once.

3.2.1 Initialization

We initialize each student of G^* by having him/her attend a random subset of all the courses recommended for the first semester up to the workload that was extracted from the data of that specific student. If a student has a workload in the first semester, that exceeds the workload of all first semester courses, we assign second semester courses randomly until the workload is filled. We identified a statistically significant correlation between the grades of the courses in the first semester. We intended to include the correlation via a multivariate Gaussian distribution in the initialization. Unfortunately, the grade distributions of the courses are multi-modal. Therefore, we sample from the grade combinations of the first semester given by the data of the specific student that gets simulated. In that way, we can incorporate the grade correlations of the first semester courses as well.

3.2.2 Credit Workload and Course Selection

Various factors play a role when a student chooses the workload for an upcoming semester [12]. When simulating students from group G^* , we draw the workload from the data of the specific student that gets simulated. If a workload of 0 is drawn, it is randomly re-drawn from the normal distribution with the mean and the standard deviation of the workloads of other students from group G^* in that semester. This happens, for example, when a student has not taken any courses in a semester. If the DCT-SIM leads to semesters in which no data are available, a workload of 15 credits is set. Next, we need to select courses to fulfill the chosen workload. Courses are randomly drawn based on the student

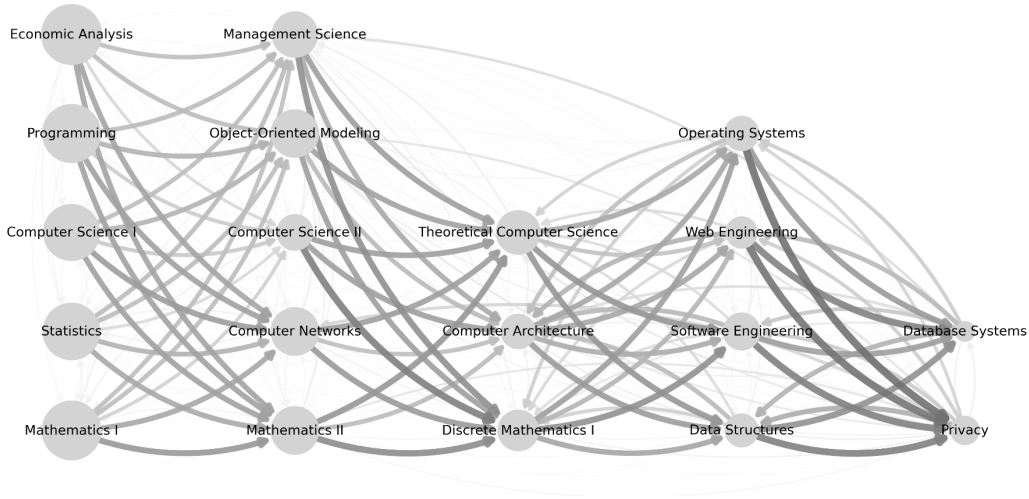

Figure 1: Student Flow based Curriculum Graph G_f

flow graph G_f as follows. First, the courses that have not been passed before are selected. Given the remaining workload, we draw courses based on the courses already passed using the graph G_f until the workload is reached. For this purpose, we go through the passed courses in random order. For each passed course, we draw one course from the not yet passed neighboring courses from V_f , which are connected to the current course via edges from E_f . The associated transition rates W_f are used in the drawing process as transition probabilities. If a course is selected, it can no longer be drawn over other courses.

3.2.3 Pass/Fail Prediction

Grade prediction depends on the quality of the data that is available. Group G^* consists of students who have very low failure rates, as we have shown above. To examine which is a good prediction method for all data in our data set, we want to obtain a subset that is as representative as possible. We consider student groups $G(t)$, which contain all students who attempted all courses from term t . This gives us the cardinalities $|G(1)| = 245$, $|G(2)| = 111$, $|G(3)| = 86$, $|G(4)| = 56$, and $|G(5)| = 50$. To test the accuracy of different methods, we calculate the average accuracy values over all terms t . In addition, we limit ourselves to the labels "passed" and "failed". As a baseline, we use the prediction that always predicts the most frequent class 'passed' (72.2%) and compare it with the following methods. The first method 'Global' draws 'pass' with the average pass rate as probability, independently of course and student. The method 'Course' uses course-specific pass rates and the method 'Student' uses student-specific pass rates. In addition to these simplified methods, we use Naive Bayes and Decision Tree, implemented using scikit-learn [16], based on the promising results in past studies [2]. Balanced accuracy (bACC) defined as

$$\text{bACC} := \frac{1}{2} \left(\frac{\text{TP}}{\text{TP} + \text{FN}} + \frac{\text{TN}}{\text{TN} + \text{FP}} \right),$$

is used as a measure of accuracy, where TP/FP and TN/FN are the true/false positives and true/false negatives, respec-

tively [6]. In addition to predicting new grades, grades must also be predicted when a student repeats a course exam. We have seen that repeating students perform better on average in the second attempt of an exam. If a student fails an exam, the grade of the next try is predicted to be the old grade plus a grade bonus, which equals the average performance gain of 2.622. To fit the grade scale, the grade bonus is rounded up to 3. It is further assumed that the bonus applied from the second to the third attempt does not differ from the bonus applied from the first to the second attempt.

3.2.4 DCT Simulation Assumptions

The following summarizes the assumptions used for the DCT-SIM.

1. All courses can be attended every semester and all students attend courses every semester.
2. Workload and first semester grades are drawn from the data.
3. If a student's drawn workload is 0, we draw a workload from the normal distribution given the mean and the standard deviation of the other student's workloads.
4. If we need to draw workloads without a data basis, we set them to 15.
5. Students do equally better in all courses when they retake an exam (grade bonus = 3).
6. DCT-SIM finishes when every course is finished.

3.3 Policy Changes

Policy changes to the curriculum are a powerful tool to change student behavior. Its use should be all the more careful. Our DCT-SIM offers the ability of an approximate evaluation of these sensitive changes. First, we consider the workload. Since the proposed number of courses in the first semester results in a workload of 27 credits, we examine the effect of changing the workload. We simulate the impact of

increasing the workload by exactly one course, which corresponds to a minimum of 5 credits. Second, we consider the course exams. In the current curriculum, one exam per semester is offered. This is different in other degree programs where there are two exams every two semesters or even two exams every semester. This means that students may be able to continue their studies without delay even if they do not pass the first exam. The policy changes are summarized as follows:

1. 'Workload': 5 credit raise of workload in the first term,
2. 'Exam (2-2-2)': Every exam takes place twice every term,
3. 'Exam (2-0-2)': Every exam takes place twice only every two terms.

3.4 Evaluation Metrics

As in Fiallos et al. [9], we use the mean DCT to compare two DCT distributions to benchmark our results. The authors additionally used a Mann-Whitney U test to evaluate the statistical significance of the simulated DCT distribution. The test can support the alternative hypothesis that two samples correspond to different probability distributions rejecting the null hypothesis that the corresponding distributions are equal. Since the p -value is defined as the conditioned probability of the observed statistic conditioned on the null hypothesis, a high p -value fails to reject the null hypothesis but does not necessarily accept it [24]. Therefore, we will instead simulate individuals and thus introduce a DCT based L^1 error measure using the ground truth DCT as

$$E_{\text{DCT}} := \frac{1}{|S|} \sum_{i=1}^{|S|} \left(\frac{1}{|G^*|} \sum_{j=1}^{|G^*|} |\text{DCT}_{\text{simulated}}^j - \text{DCT}_{\text{data}}^j| \right)_i,$$

where $|S|$ corresponds to the number of DCT-SIM runs. In the following, we set $|S| = 100$.

4. RESULTS

4.1 Pass/Fail Prediction and DCT Simulation

Since in the baseline method we always assume label 'pass', the true positives (TP) correspond to the actual pass rate and the false positives (FP) to the actual failure rate across all courses in the degree program. Table 4 shows the pass/fail prediction results of the various methods. For the baseline method the true positive percentage (TP) is high reflecting that the pass rate across all courses in the degree program is 0.722. The balanced accuracy (bACC) is 0.5. We note that the accuracies of the Global (0.555) and Course (0.553) methods are not significantly greater than the baseline. On the other hand, the Student method (0.608) achieved the best values for true negative and false negative percentages. The Naive Bayes method achieved the highest true positive percentage, while the Decision Tree method had the best overall bACC with 0.648 and the best false positive percentage. Therefore, we used the Decision Tree method in the DCT-SIM.

Figure 2 shows the DCT distributions of the DCT-SIM in light grey and the data in dark grey. The bars indicate the

Figure 2: Evaluation of DCT Simulation

average percentage values achieved over a total of 100 simulation runs. The DCT distributions of the simulation and the data reveal similar values in terms 4 and 5. In the other terms, when the data of the G^* group are sparser, since most of the students already completed all courses, the accuracy of the DCT-SIM also decreases noticeably. However, there is a small error of 0.087 between the mean values of the DCT distributions with a p -value of 0.897, which is comparable to Fiallos et al. [9]. According to our DCT based L^1 error measure, we reach a value of $E_{\text{DCT}} = 0.926$. This value corresponds to an average individual DCT error of 0.926 semesters.

4.2 Policy Changes

In the DCT simulations of the policy changes, for the sake of clarity, we have chosen a cumulative representation of the DCT distributions in Figure 3. The two graphs in gray correspond to the distributions of the data and baseline DCT-SIM as shown in Figure 2. We see that the workload change appears to be very effective, as the graph appears to be consistently above that of the baseline DCT-SIM. It turns out to be an improvement in the DCT means of -0.232 . Thus, this change leads to a shortening of the DCT. The minor improvement of -0.035 by policy change 'Exam (2-2-2)' is only noticeable from term 6. In contrast, the policy change 'Exam (2-0-2)' leads to a global increase of the DCT of 0.591.

5. DISCUSSION AND LIMITATIONS

We were able to show that student-dependent pass/fail prediction using the groups $G(t)$ performs better than the assumption of a global pass rate or a course-specific pass rate. Overall, it is worthwhile to use the existing student performance data to increase accuracy.

Regarding the DCT-SIM, research in student flow simulation lacks good evaluation methods. Evaluation methods on the individual student level are missing, instead global DCT or dropout distributions are compared with the ground truth. This is due to the lack of use of labeled data and the resulting loss of assignability of students to their simulated counterparts. Using our generalizing approach, we were able to obtain comparable mean DCT errors on a global scale. In addition, through the intensive use of data, we were able to

Table 4: Pass/Fail Prediction Methods Scores with 70:30 Train-Test Split

Score \ Methods	Baseline	Global	Course	Student	NB	DT
TP	0.722	0.574	0.585	0.643	0.701	0.645
FP	0.278	0.223	0.226	0.182	0.143	0.124
TN	0.000	0.055	0.052	0.096	0.068	0.088
FN	0.000	0.148	0.137	0.079	0.087	0.143
bACC	0.500	0.555	0.553	0.608	0.617	0.648

**Figure 3: Evaluation of Simulated Policy Changes**

evaluate our DCT-SIM individually for each student from group G^* . The error measure E_{DCT} has shown that the evaluation with an average individual misfit of 0.926 can be quite high without having a globally large effect. This results in the necessity to specify the goodness of fit of a DCT-SIM not only on a global level in the form of a mean DCT. We believe that a good DCT-SIM should be able to simulate each student as accurately as possible. Otherwise, a practical implementation of changes based on the observed DCT-SIM could lead to unexpected dynamics and thus to unfair conditions for an individual student. Policy changes for a curriculum are a relevant use case for a DCT-SIM because a data-generating process is needed to produce results. For our approach, we could identify two types of changes: Additive policy changes and restrictive policy changes. The former is characterized by changes in the frequency or acceleration in time of exams. For example, an increase in workload conditions the speed at which courses can be attended. The latter type, under which the 'Exam (2-0-2)' change falls, directly restricts the frequency of exams in every second term. Our method was able to evaluate changes in the first category very well. The policy changes 'Workload' and 'Exam (2-2-2)' show plausible results. In particular, 'Exam (2-2-2)' equates to a global increase in pass rates in our setting, due to the assumption of a grade bonus when repeating an exam. Since we have shown that students from group G^* have very high pass rates, it makes sense that the effect is small for this group.

The 'Exam (2-0-2)' change appears to be leading to a global extension of DCT. We have seen that the policy change 'Exam (2-2-2)' behaves similarly to the baseline simulation. Therefore, we conclude that the policy change 'Exam (2-0-

2)' also behaves similarly to the policy change 'Exam (1-0-1)'. We point out the step-shaped graph in Figure 3. Looking at the number of courses per semester in Figure 1 and the average semester workloads of group G^* in Table 3, we see that in semesters 1, 3 and 5 the average workload difference from the recommended workload is higher than in semesters 2 and 4. Thus, the case occurs where a student has completed all subjects from semesters 2 and 4 in semester 6, but is missing subjects from semesters 1, 3 and 5 that cannot be completed until semester 7 or even 9. As a result, few students finish in 6 or 8 semesters, as seen in Figure 3. This shows the still existing rigidity of our workload approach. We believe that predicting workload as a function of courses, grades, and exam attempts, rather than deriving it directly from the student being simulated, may lead to a more robust DCT-SIM with respect to policy changes.

Awareness regarding algorithmic bias and fairness is emerging in the field of Educational Data Mining. Especially when a model gets implemented in practice so that students are affected in their learning environment, an identification of bias and fairness of the data and methods used as well as their resulting actions have to be assured [4, 11]. In addition to the mentioned limitations of our method, we are aware of the performance bias (i.e. we mainly consider successful students) in the data used and would like to remove it in the future by expanding and balancing our data set.

In terms of computational power, we observe a time consumption for one non parallelized DCT-SIM of student group G^* : $|G^*|it \cdot 0.714 \text{ s/it} = 33 \text{ it} \cdot 0.714 \text{ s/it} = 23.571 \text{ s}$, using an Intel(R) Core(TM) i5-6200U CPU @ 2.3GHz processor.

With respect to the DCT mean, we were able to obtain a comparatively well-fitting DCT distribution from our DCT-SIM in which only student data were processed. The dependence on the data offered us the ability to construct a student flow based curriculum graph in a maximally flexible study plan, perform an individual evaluation of the DCT-SIM using the E_{DCT} error measure and investigate and evaluate policy changes in a highly flexible curriculum. In this sense, we were able to generalize existing approaches. In order to implement our approach for university practitioners in the future, we will conduct further research. The first priority is the extension of the data set as well as achieving high individual accuracy. An ethical analysis with the involvement of student and teacher representatives is planned.

ABSTRACT

The National Council of Teachers of Mathematics (NCTM) has been emphasizing the importance of teachers' pedagogical communication as part of mathematical teaching and learning for decades. Specifically, NCTM has provided guidance on how teachers can foster mathematical communication that positively impacts student learning. A teacher may have different academic goals towards what needs to be achieved in a classroom, which require a variety of discourse-based tools that allow students to engage fully in mathematical thinking and reasoning. Accountable or academically productive talk is one such approach for classroom discourse that may ensure that the discussions are coherent, purposeful and productive. This paper discusses the use of a transformer model for classifying classroom talk moves based on the accountable talk framework. We investigate the extent to which the classroom Accountable Talk framework can be successfully applied to one-on-one online mathematics tutoring environments. We further propose a framework adapted from Accountable Talk, but more specifically aligned to one-on-one online tutoring. The model performance for the proposed framework is evaluated and compared with a small sample of expert coding. The results obtained from the proposed framework for one-on-one tutoring are promising and improve classification performance of the talk moves for our dataset.

1. INTRODUCTION

Productive classroom discourse is positively associated with student learning [6,7,13,15] across multiple content areas, including reading comprehension [18], academic vocabulary learning [9] development of collaborative reasoning [14], persuasive writing performance [1] historical reasoning [26], scientific argumentation [5], and mathematical reasoning [13]. Additionally, academically rigorous classroom discussions are explicitly promoted in mathematical pedagogy [3,19] and in the Common Core State Standards [20] that guide teachers' instructional practices.

The oft-cited, common pattern of classroom talk, Initiation-Response-Evaluation (IRE) [11] emerged in early research investigating the forms and functions of classroom talk [12]. This minimal unit of interactional exchange includes a teacher's initiation, then a student's response, followed by the teacher's evaluation of the response. The IRE pattern is most commonly noted in teacher-led lessons (i.e., direct instruction) which tends to be the default in many classrooms. The IRE pattern of classroom talk demonstrates a transmission style of instruction such that the teacher is in a position of authority and controls the content of the discourse as well as who engages in it [4]. Indeed, this pattern of monologic classroom discourse is still common in many classrooms despite research demonstrating the benefit of dialogic and reasoning-based discourse [6,15,17].

Dialogic discourse, on the other hand, aligns with Vygotsky's [25] sociocultural theory stipulating that learning is more likely to occur when thinking is socialized, particularly within the range of a student's ability when provided with appropriate guidance (i.e., Zone of Proximal Development; ZPD). Interactions between teachers and students serve as a scaffold for knowledge acquisition during instruction [21,24]. A hallmark of this type of scaffolded, dialogic classroom discourse is the *Accountable Talk framework* [15].

2. ACCOUNTABLE TALK FRAMEWORK

The Accountable Talk Framework divides teacher and student discourse into three broad categories (see Table 1 for definitions and respective examples): accountability to the community, accountability to accepted standards of reasoning, and accountability to knowledge [15]. Talk that is accountable to the community is characterized as cutting across disciplines and “attends seriously to and

builds on the ideas of others” [15, p. 286]. Accountability to standards of reasoning involves making logical and reasonable connections, explanations, and conclusions. Accountability to knowledge emphasizes sensemaking based on facts and authoritative knowledge. The latter categories of discourse practices promoting accountability to standards of reasoning and knowledge are generally more discipline-specific.

Table 1. Accountable Talk framework teacher and student talk moves definitions and examples

Talk Moves Definition and Example(s)	
Teacher Talk Move	
<i>Learning Community</i>	
Keeping Together	Keeping everyone together; prompting students to be active listeners and orienting students to each other. For example, turn to the student sitting next to you; what do you think; What did X just say the equation was?
Relating Students	Getting students to relate to other students’ idea; prompting students to respond to what a classmate said. For example, would someone like to add on to what X said; do you agree with Y that the answer is; does anyone understand how Z solved this problem?
Restating	Repeating all or in part of what a student said. For example, Student: the factors, Teacher: factors
<i>Content Knowledge</i>	
Accuracy	Pressing for accuracy; prompting students to make a mathematical contribution or use mathematical language. For example, can you give an example of X; What’s another word for that?
<i>Rigorous Thinking</i>	
Revoicing	Repeating what a student said but changing the wording or adding to it; using at least a key mathematical word or idea from what the student said. For example, Student: it is x squared; Teacher: so, instead of a cube it will be squared.
Reasoning	Pressing for reasoning; prompting students to explain or provide evidence. For example, can you explain why you think this is the answer; why would you add two and not three?
Student Talk Move	
<i>Learning Community</i>	
Relate to another student	Comment on or ask questions about another student’s idea or use another student’s idea to form your own basis. For example, I got the same answer as X; I was about to say what Y just said.
Asking for more information	Ask for help in case confused or request more information about a math topic. For example, can you please explain this again; I did not understand this; Is this multiplication or division?
<i>Content Knowledge</i>	
Making a claim	Make a factual statement about a mathematical concept; list a step to arrive at an answer; make a mathematical claim. For example, I got this answer by dividing the two numbers; X is the profit.
<i>Rigorous Thinking</i>	
Providing evidence or explanation	Provide the evidence or explanation for the mathematical claim or explain their thinking. For example, you cannot divide the number by zero as that will result in an infinite number; four multiplied by five gives me twenty.

Prior research evaluating implementation and benefit of discourse using dialogic frameworks was conducted by transcribing and hand coding hours and hours of classroom audio or video recordings [22]. This method is labor intensive and time consuming thus making it difficult to provide teachers with feedback on their implementations of academic discourse. Suresh and colleagues [22] used automatic speech recognition and machine learning to evaluate teacher-student interactions using the Accountable Talk framework. The machine learning models trained as part of their TalkBack application showed promise as a medium to provide teachers with important feedback regarding their pedagogical practices. However, this work has only been applied to traditional classroom instruction. Therefore, less is known about the application of the Accountable Talk framework in discourse occurring outside of the traditional classroom. The recent shift to hybrid or online learning necessitated by the COVID-19 pandemic, provides a rich opportunity to apply machine learning models to teacher-student interaction in an online environment. The capability to evaluate academic discourse and provide feedback to teachers that

may lead to improved student learning is particularly important given the concern over learning gaps being exacerbated by the pandemic [2].

The present study builds on this work using the machine learning models developed by Suresh and colleagues to detect evidence of the Accountable Talk framework [15] in teacher-student interactions in online, one-on-one tutoring. For the purpose of this study, we adopted the same talk moves outlined in Suresh [22]. We further refined our analysis by including moves that would be included in a one-on-one tutoring interaction and excluded those that could only occur in traditional, whole class settings. Specifically, talk moves related to accountability to the community were removed from data for the model to be re-trained for the proposed framework as they are focused on ensuring learners have a shared focus and on developing collegial interactions between students. Since there was only one student and one teacher in each tutoring session, no utterances exemplifying these two talk moves were present in our data.

3. METHOD

3.1 Participants

The student population was recruited for online tutoring in summer and fall of 2019 from four high schools in the Broward school district. Participants included 40 students who did not pass the Algebra 1 course or were not successful on the end of course (EOC) exam. Tutoring was provided during school hours on school grounds in the summer or fall semester. Sessions were planned for up to 10 hours, but the number of hours varied from 1 to 20 with a mean of 5 hours of tutoring. Tutoring was conducted by credentialed math teachers with at least two years of experience in the Florida system to ensure that they were familiar with the targeted curriculum standards. Tutoring sessions were conducted online using Study Edge’s GoBoard video conferencing system which supports shared note-taking (pen-casts). During the online tutoring sessions, both the student’s and the tutor’s computer screens were recorded, which included an audio and video recording of their conversation. The audio recordings were later transcribed to obtain the student-teacher discourse during the tutoring session. This study was approved by the Institutional Review Board and all participants in this study consented to the use of their data in accordance with APA guidelines.

3.2 Data

Three different data sets were used in this study. The first set was the talk moves labeled data available from prior research. The second data set was a subset of the first set that was filtered for talk moves. The second data set was more aligned with the one-on-one tutoring discourse. The third data set consisted of the unlabeled data containing teacher and student utterances from one-on-one tutoring discourse. Examples of teacher and student talk moves from the data sets discussed below are shown in Table 2.

Table 2. Talk Moves examples (Teacher Talk Moves – 1: none; 2: Keeping everyone together, 3: getting students to relate, 5: re-voicing, 6: Press for accuracy; Student Talk Moves – 1: none, 2: relating to another student, 3: asking for more information, 4: making a claim, 5: providing evidence/explaining reasoning)

Speaker	Sentence	Teacher Tag	Student Tag
Teacher	Who can help her notice where she went wrong	3	nan
Teacher	<<student1 name>>	2	nan
Student	She kept the six	nan	2
Teacher	<<student2 name>>	2	nan
Student	She put the eight so everything after the decimal number that you need changed	nan	5
Teacher	You underline you look at an arrow then what	6	nan
Student	Whats that one negative 51	nan	3
Teacher	Mixed numbers you were right	5	nan
Student	Its like one and one half or one and three thirds or something like that	nan	4
Teacher	All right I see some disagreements here	1	nan
Student	I was waiting	nan	1

3.2.1 Data Set 1

The Data Set 1 included annotated transcripts of classroom discourse in mathematics collected in public schools in the US and are, therefore, aligned with our Algebra tutoring data set. This talk moves data was obtained from [23], which included entire lessons and short excerpts from lessons. The data set consisted of 230,778 utterances (172,309 teacher utterances and 58,469 student utterances) from 559 lesson transcripts.

3.2.2 Data Set 2

The full data set (Data Set 1) was filtered for talk moves applicable to one-on-one tutoring discourse from the original data set [23]. The filtered dataset consisted of 199,123 utterances (147,145 teacher utterances and 51,978 student utterances) from 558 lesson transcripts.

3.2.3 Data Set 3

The tutoring data used to classify the talk moves consists of 87,100 utterances (62,370 teacher and 24,730 student utterances). The final dataset consisted of transcripts from 130 one-on-one tutoring sessions between 25 teachers and 39 students.

3.2.4 Talk Moves data set creation via expert coding

Expert coding of the data was conducted in two phases: training and data coding. Training was conducted using the Data Set 1 consisting of transcripts for individual student-teacher conversations. The transcripts in this original data were coded for six mutually exclusive teacher talk moves, and five student talk moves that were adapted from the Accountable Talk framework. The teacher or student utterances that did not contain a talk move were labeled as “None-1”. Strings of utterances by the teachers that were aimed at direct instruction were considered “None-1” as they were not aimed at fulfilling one of the six accountable talk moves outlined in the framework. Four undergraduate research assistants were trained to code a sample of each teacher and student ‘talk move’.

The first step in training the coders involved acquainting them with each of the types of talk moves explicated in the Accountable Talk framework [15]. Research assistants met with a researcher and discussed examples of each type of Talk Move for both teachers and students. Importantly, coders learned to determine which utterances were part of direct instruction or not consequential (e.g., classroom management utterances such as “get out your textbook”) to eliciting student responses; these are coded as “1-None”. The talk moves being classified in this framework consist of turns of an interaction between student(s) and teachers with the goal of knowledge construction. Following the initial group training, each coder was given one of two practice sets created from the large data set provided by [23]. Equal numbers of each type of move were included in the data set such that coders had 100 target sentences for each of the six mutually exclusive teacher talk moves and five of the student talk moves. The teacher and student talk moves were separated (i.e., one practice sheet for teachers and one for students) and randomized so that no patterns could be detected. The interrater reliability (weighted kappa) for the first pair of coders for teacher practice set A was 0.44 and 0.61 for student practice set A. The interrater reliability (weighted kappa) for the second pair of coders was 0.65 for both teacher and student practice set B. The moderately low interrater reliability suggested that either coders were not quite familiar enough with the codes or that the utterances were too difficult to code when taken out of the context of the discourse. Using the student utterance was necessary to accurately determine the context, particularly for the restating and revoicing teacher talk moves. Additionally, multiple utterances may be included in one sentence and there may be multiple sentences included within a turn. Therefore,

all four coders were given a second practice data set (revised version) that included utterances in context. For example, coders received spans of sentences that included both the teacher utterances and the student utterances. Prior to starting on the new practice data set, coders were provided with a short training refresher video. The interrater reliability for the student tags in the second practice set ranged from 0.42 to 0.74 with a weighted kappa of 0.60 for all raters. The interrater reliability for the teacher tags in the second practice set ranged from 0.52 to 0.71 with a weighted kappa of 0.60 for all raters. Weighted kappa ranging from 0.41 to 0.60 suggest moderate agreement [8]. Following the training sets, the two coders with the highest interrater reliability were provided with a subset of Data Set 3 to code, containing 570 teacher utterances and 183 student utterances. The interrater reliability for the experimental data was 0.90 weighted kappa for teacher utterances and 0.95 weighted kappa for student utterances. Weighted kappa over 0.81 suggest nearly perfect agreement [8].

3.2.5 Model architecture

Because our data (Data Set 3) was not labeled/coded for talk moves initially, we used the labeled data (Data Sets 1 and 2) available from prior research [23] and the filtered data set for initial model development. The labeled data was split into training (75%), validation (5%) and test (20%) sets to verify that the prior research results could be replicated. We used the RoBERTa-base transformer model [10], a model pretrained with Masked Language Modeling (MLM) using five data sets including BookCorpus - a dataset consisting of 11,038 unpublished books; English Wikipedia; CC-News - a dataset containing 63 million English news articles; OpenWebText - an open-source recreation of the WebText dataset used to train GPT-2; and Stories - a dataset containing a subset of CommonCrawl data, to train our model. RoBERTa allows the model to learn a bidirectional representation of a sentence.

The models were trained using sentences that were preprocessed into *turns*, where each turn constituted a student utterance followed immediately by a teacher utterance for the teacher talk moves model. Similarly, for student talk moves, each turn consisted of a teacher utterance immediately followed by a student utterance. A teacher or a student turn could also include multiple utterances. There were very few student-student pair utterances as compared to the original/prior data (classroom setting) because our data constituted one-on-one tutoring transcripts. Both the student and teacher utterances were required to set the context particularly for the *restate* and *revoice* teacher talk moves, and *make a claim* and *provide evidence or reasoning* student talk moves. The input sentences were also cleaned of any punctuation and converted to lowercase. The pretrained model from the Hugging Face library was used and the model was trained using a Tesla P100 GPU. Code was implemented using TensorFlow framework with Python version 3.7. The `batch_encode_plus` method was used for tokenizing and encoding the pair of sentence sequences and AdamW was the optimizer. The hyperparameters used for training and tuning the model included a learning rate of $2e-5$, and number of epochs and batch size as 4. The talk moves were used as the dependent variables.

3.2.6 Analytic framework

The study was performed as a set of five experiments. First, a transformer model was trained and tested using Data Set 1 [23], the model trained using Data Set 1 was then used to classify our unlabeled tutoring data (Data Set 3) for both student and teacher talk moves. The second experiment was performed to compare the consistency between the distributions of the talk moves for Data Set 1

and the predicted talk moves for Data Set 3. In the third experiment, after determining the consistency between the talk moves distribution of the two data sets (Data Set 1 and Data Set 3), the prior data (i.e., Data Set 1) was filtered for talk moves that are more applicable to one-on-one online tutoring. The teacher talk moves *keeping everyone together* and *getting students to relate* were removed as these talk moves are more relevant to classroom teaching rather than one-on-one online tutoring. Similarly, the utterances labeled as student talk move *relating to another student* were also removed. Prior research data, filtered for one-on-one online tutoring aligned talk moves (Data Set 2), was used to re-train and re-test the model. The re-trained model was used to classify our unlabeled data (Data Set 3) again for both the teacher and student one-on-one tutoring related talk moves. The distribution of the talk moves for the filtered datasets was compared again to confirm whether the newly trained model classified the talk moves consistently with the prior research data that was labeled in the fourth experiment. The fifth experiment evaluated the performance of the model that was trained using talk moves applicable to one-on-one tutoring. The predicted talk moves for Data Set 3 were compared with the expert coded talk moves for a small sample of Data Set 3.

4. RESULTS

4.1 Model Performance for Data Set 1: Original Framework

The first set of experiments included training a transformer model using the Data Set 1 (training set) and classifying the teacher and student talk moves on the test set for the talk moves defined in the original accountable talk framework. The confusion matrix for the teacher and student talk moves for Data Set 1 (test set) are shown in Figure 1 (a and b), respectively. The micro F1 and macro F1 scores obtained for the teacher test set were 0.89 and 0.79, respectively. The Matthew correlation coefficient (MCC) was 0.79. The F1 scores for the student talk moves were lower than the teacher talk moves and were 0.80 (micro F1) and 0.76 (macro F1), and the MCC was 0.71. The precision, recall, and F scores of the talk moves for both teachers and students were also computed. The teacher talk moves *getting students to relate* and *revoicing* had the lowest F scores, 0.68 and 0.67 respectively. The teacher talk moves *press for reasoning*, *press for accuracy*, and *restating* had higher and comparable F scores (0.80-0.84). The student talk move *relating to another student* performed the worst with an F score of 0.58 and other student talk moves had higher and comparable F scores (0.76-0.79).

Figure 1. (a) Teacher Test set Talk Moves

Figure 1. (b) Student Test set Talk Moves

Figure 1. The teacher and student talk move accuracy and labels: None (*no talk move*), KeepEverTgthr (*keeping everyone together*), StudentRelate (*getting students to relate to other students' ideas*), Restate (*restating*), Revoice (*revoicing*), PrsAcc (*press for accuracy*), and PrsRsn (*press for reasoning*), RelAnotherStu (*relating to another student*), AskMoreInfo (*asking for more information*), MakeClaim (*making a claim*), and PrsEvd (*providing evidence or explaining reasoning*).

4.2 Talk Moves Distribution Comparison (Data Set 1 vs. Data Set 3): Original Framework

The second experiment included comparing the talk moves distribution of the original data (Data Set 1) and the predictions for our data (Data Set 3) obtained using the model trained in the first experiment. The distribution of the teacher and the student talk moves across the two datasets was found to be comparable and consistent with slight variations. Both datasets found 67.42-76.03% of utterances did not contain a teacher talk move. The remaining teacher talk moves in order of frequency were, *pressing for accuracy* (10.59-13.07%), *keeping everyone together* (9.44-12.97%), and *revoicing* (2.15-2.27%). *Getting students to relate to another student's idea* was the least classified (0.14%) teacher talk move in our dataset (Data Set 3). The remaining teacher talk moves shown in Figure 2 (a and b) had similar distributions.

Figure 2. (a) Teacher Talk Moves Classification for Data Set 3 Figure 2. (b) Teacher Talk Moves Classification for Data Set 1

Figure 2. The teacher talk move distribution and labels for Data sets 3 and 1: None (*no talk move*), KpTgthr (*keeping everyone together*), StudRelate (*getting students to relate to other students' ideas*), Restate (*restating*), Revoice (*revoicing*), PrsAcc (*press for accuracy*), and PrsRsn (*press for reasoning*).

The predicted student talk moves also had consistent distribution with the prior labeled data (Data Set 1). Following *not a talk move*, the student talk move *making a claim* was the second most abundant with 28.25-30.66% utterances falling into that category. *Asking for more information* was the least observed talk move in both the data sets (see Figure 3 (a and b)).

Figure 3. (a) Student Talk Moves Classification for Data Set 3 Figure 3. (b) Student Talk Moves Classification for Data Set 1

Figure 3. The student talk move distribution labels for Data sets 3 and 1 are: None (*no talk move*), RelateStu (*relating to another student*), MoreInfo (*asking for more information*), claim (*making a claim*), and ProEvidence (*providing evidence or explaining reasoning*).

The consistent distributions of talk moves across the two datasets combined with very few utterances classified in the talk moves categories of *getting students to relate to another student's idea* (teachers) and *relate to another student* (students) suggest that the classification model trained on Data Set 1 can be used for Data Set 3. The two minimally classified talk moves are not directly applicable or aligned to one-on-one tutoring thus increasing our confidence that the classification model can be used for our one-on-one tutoring dataset with minor updates to the model.

4.3 Model Performance for Data Set 2: Proposed Framework

Experiment 3 was similar to the first experiment except the transformer model was trained using prior data for talk moves that are more aligned and applicable to one-on-one tutoring (i.e., Data Set 2) rather than the original set (Data Set 1) of talk moves. Figure 4 (a and b) shows the confusion matrix for the teacher and student talk moves for the test data from Data Set 2, respectively. The micro F1 for the teacher test set improved from 0.89 to 0.94 and macro F1 score increased from 0.79 to 0.83, respectively. The Matthew correlation coefficient (MCC) was higher (0.79 vs. 0.83). The F1 scores for the student dataset were lower than the teacher talk moves but improved from 0.80 to 0.86 (micro) and 0.76 to 0.82 (macro), and the MCC is higher (0.71 vs 0.78). The precision, recall, and F scores for each talk move, for both teachers and students, are also computed. The teacher talk move *revoicing* had the lowest F score, 0.67, which aligns with the original accountable talk framework. The student talk move *asking for more information* performed the worst with an F score of 0.76.

Figure 4.a. Teacher Test set Talk Moves – Proposed Framework Figure 4.b. Student Test set Talk Moves – Proposed Framework

Figure 4. The teacher and student talk move labels for the proposed framework are: None (*no talk move*), Restate (*restating*), Revoice (*revoicing*), PrsAcc (*press for accuracy*), and PrsRsn (*press for reasoning*) and the student talk moves in Figure 4(b) are: None (*no talk move*), AskMoreInfo (*asking for more information*), PrsEvd (*providing evidence or explaining reasoning*) and MakeClaim (*making a claim*).

4.4 Talk Moves Distribution Comparison (Data Set 2 vs. Data Set 3): Proposed Framework

This experiment is comparable to the second experiment except that the distributions of talk moves are for the data aligned to one-on-one tutoring instead of the talk moves from the original accountable talk framework [22,23]. The teacher talk moves distributions for both Data Set 2 and the predicted talk moves for Data set 3 using the model trained in the third experiment were found to be consistent with *press for reasoning* having the lowest frequency (0.38% and 1.36%) and *press for accuracy* as the second highest frequency (11.84% and 15.3%) next to *no talk move*.

Figure 5. (a) Teacher Talk Moves Predictions for Data Set 3 – Proposed Framework Figure 5. (b) Teacher Talk Moves Classification for Data Set 2 – proposed Framework

The distributions for both Data Set 2 and the predictions of student talk moves for Data Set 3 were similar except for the *providing evidence* talk move (see Figure 6 (a and b)). Very few (3.39% utterances) were classified as *providing evidence* talk moves for

Data Set 3, whereas the original labeled filtered dataset had a higher percentage (~15%) of talk moves belonging to this category.

Figure 6. (a) Student Talk Moves Predictions for Data Set 3 – Proposed Framework

Figure 6. (b) Student Talk Moves Classification for Data Set 2 – proposed Framework

4.5 Model Performance for Data Set 3: Proposed Framework

The student and teacher talk move predictions using the proposed framework model for Data Set 3 when compared with the expert coding achieved 0.88 accuracy for teacher talk moves and 0.81 for student talk moves. The weighted average and micro precision, recall and F scores were in the range of 0.87-0.88 for teacher talk moves and 0.79-0.83 for the student talk moves. The teacher talk move *pressing for reasoning* had the worst performance and the student talk move *asking for more information* performed the worst of all the talk moves. The confusion matrix for both the talk moves are shown in Figure 7 (a and b). The teacher and student talk moves labels in the Figures 7 (a and b) are: *None; restating; revoicing; pressing for accuracy and pressing for reasoning; and None; asking for more information; providing evidence or explaining reasoning; and making a claim for (1-5) and (1-4) respectively.*

5. DISCUSSION

The Accountable Talk framework has been used to classify teacher and student talk moves as a method of providing feedback and guidance to teachers on the discourse strategies they use in their classrooms. Until recently, this type of discourse analysis has been cumbersome and labor intensive. Furthermore, it has been restricted to face-to-face or in-person classrooms mostly. The present work extends the work of Suresh [22,23] in the application of deep learning to a transcribed data set of student and teacher utterances gathered from an online, one-on-one algebra tutoring system. The data set provided by Suresh [23] was used to train our model which was then applied to our unlabeled data set. The data available from prior research (Data Set 1) was used to train a transformer model (RoBERTa) and the test set achieved an accuracy higher than that mentioned in the literature on a similar data set for several deep learning models including Long Short Term Memory (LSTM) unit, Bi-LSTM, gated recurrent unit (GRU), and recurrent neural network (RNN). The Bi-LSTM had outperformed all the other models with an F1 measure of 65% [23]. However, our model RoBERTa achieved an accuracy of 0.89 and 0.94 for the original framework and the proposed framework respectively for the teacher talk

moves. The student talk move model accuracy for the original framework and the proposed framework are 0.80 and 0.86 respectively. The talk move distributions for both teacher and student for our data set (Data Set 3) were also found to be consistent with the prior data (Data Set 1) and the filtered prior data (Data Set 2). In addition, high performance was observed for most of the talk moves for the proposed framework model when applied to our unlabeled data set (Data Set 3) and compared with the expert coding. The teacher talk move *press for reasoning* and the student talk move *asking for more information* performed the worst when compared with the expert coding. One probable reason for low performance could be very few instances belonging to these talk moves in the test set or a skewed distribution of the talk moves. Therefore, this needs to be explored further to determine the reason for low performance of these specific talk moves.

6. LIMITATIONS

The work described in this paper is novel and not without limitations. The first limitation is that we could not evaluate the classification model for Data Set 3 using Data Set 1, the model based on the full Accountable Talk framework from discourse in a traditional classroom. Our data was gathered from one-on-one online tutoring, which inherently prevents classification of talk moves that require additional community members as in the original dataset based on classroom discourse.

The second limitation to note is the limited amount of human-coded data to evaluate the classification of talk moves by the proposed model. We recognize that a larger percentage of human-coded validation data is desirable and plan to address this limitation in future work.

7. CONCLUSION

The academic discourse that occurs between teachers and students in the interest of knowledge creation has a rich history of research demonstrating the importance of each turn. Despite the importance of these classroom exchanges, providing feedback to teachers is nearly impossible due to the labor-intensive task of collecting and categorizing discourse according to an evidence-based framework such as the Accountable Talk framework [16].

Recent events have demonstrated that academic discourse is not restricted to traditional, whole group classroom instruction; therefore, it is equally important to evaluate the quality of discourse occurring in online, one-on-one tutoring sessions. The work described in this paper is both novel and promising as a means to reliably categorize teacher and student talk moves by applying machine learning models slightly modified from those validated on a complete framework. Future work is needed to further test and validate (with human coding) the machine learning model that was modified to accommodate one-on-one instruction (i.e., without talk moves for *accountability to the community*). Overall, this work has the potential to introduce a beneficial and simplified mechanism to provide feedback for teachers, thus affording strong potential to improve instructional practice and student learning outcomes.

ABSTRACT

Prompting students to generate constructed responses as they read provides a window into the processes and strategies that they use to make sense of complex text. In this study, Markov models examined the extent to which (1) patterns of strategies and (2) strategy combinations could be used to inform computational models of students' text comprehension. Random Walk models further revealed how consistency in strategy use over time was related to comprehension performance. High school ($n = 257$) and college students ($n = 153$) produced constructed responses at predetermined points while reading a scientific text. Each constructed response was scored for the presence of three common comprehension strategies (i.e., paraphrasing, bridging, elaborating), such that each constructed response could then be categorized as one of eight combination types. Markov chains revealed that more and less successful comprehenders leveraged different comprehension strategies, such that skilled comprehenders were more likely to use combinations of strategies while reading the text, particularly paraphrasing and making connections between ideas within the text (i.e., bridging). Random Walk analysis further demonstrated that successful comprehenders employed strategies more consistently. The results demonstrate the utility of Markov and Random Walk models in profiling learners' strategy use based on their constructed responses.

Reading comprehension, Strategies, Markov models, Random Walk

1. INTRODUCTION

Reading is a fundamental life skill, whether one is trying to read a novel, a science textbook in a university course, a technical document for work, or an instruction manual for assembling furniture. However, many students struggle to comprehend texts. For K. Christhilf, N. Newton, R. Butterfuss, K. S. McCarthy, L. K. Allen, J. P. Magliano, and D. S. McNamara. Using Markov models and random walks to examine strategy use of more or less successful comprehenders. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 484–491, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

example, 30% of U.S. students perform below basic proficiency in reading comprehension [24]. Several factors contribute to successful comprehension. To understand texts, particularly texts with complicated syntax or unfamiliar topics, readers engage in a variety of processes and strategies, including paraphrasing, bridging, and elaborating. When students paraphrase, they put the text in their own words. By contrast, bridging and elaborating require the generation of inferences that contain information that is not explicit in the text. Bridging refers to connecting ideas and information from different parts of the text. Bridging has been shown to be one of the most effective strategies for reading comprehension, particularly if the bridges connect more distant areas of text [18]. Elaborating is expanding on what one has learned from the text with one's prior knowledge about the topic.

Using bridging and elaborative inferences strategies has been found to improve comprehension on standardized reading tests [14]. More skilled readers are more likely to engage in more complex comprehension strategies, such as bridging and elaboration, that help them comprehend the text, while less skilled readers are more likely to rely on paraphrasing [7]. One way to encourage students to engage in such strategies is to ask them to self-explain a text as they read. Self-explanation prompts help students think deeper about the text, which facilitates strategy use and improves comprehension [25].

The strategies participants use while reading are typically examined via constructed response protocols (CRs). In CRs, students report their processes during a learning task. One method of obtaining CRs is asking participants to self-explain a text at specific points, and to type out these explanations. Prior work has shown that expert raters can reliably identify different comprehension strategies within CRs [17] and recent advances in natural language processing (NLP) have allowed researchers to develop and refine algorithms that can match these human judgments [4, 15]. Thus, mining readers' CRs can serve as a powerful tool to generate high quality learner models based on students' differing strategy use. The current study uses hand-coded CRs to examine participants' dynamic strategy use.

Several intelligent tutoring systems (ITSs) have been developed to enhance students' use of effective reading strategies. For example, iSTART [21] provides students with self-explanation reading training using a combination of instruction and practice via lesson videos, mini-games and reading practice. Training students on effective self-explanation reading strategies has been demonstrated

to improve students' text comprehension [20]. ITSs such as iSTART rely on the automated identification of different reading strategies in CRs to drive feedback to students on their self-explanations or other reading behaviors. The feedback may re-direct students to lessons on strategy use or provide recommendations of other strategies to leverage while reading. In order to better train students to modify their strategy use in ways that enhance reading comprehension, it is beneficial to understand the different ways students use strategies to engage with texts.

Past research more commonly examines paraphrasing, bridging, and elaboration strategies as independent variables or outcomes and measures strategy use in terms of their overall frequency of use [15, 23]. However, some types of strategy combinations may be more effective in promoting reading comprehension than using any one strategy in isolation. One possibility is that paraphrasing, by creating a more complete understanding of the most recently read text, facilitates the use of further strategies such as bridging and elaboration. The current study therefore examines combinations of strategy use within CRs, rather than overall frequencies of paraphrasing, bridging, and elaborating. Additionally, traditional analyses of CRs rely on an overall proportion or score across an entire text. This approach ignores the moment-to-moment changes in processing that occur as properties of texts change across sentences and paragraphs [22].

1.1 Our Approach

The current study aims to use two approaches that are more common in other areas to examine dynamic patterns in strategy use: Markov Chains and Random Walk analyses. These analyses are intended to reveal systematic differences in the ways that more and less successful comprehenders engage with texts. That is, the combinations and patterns of strategy use in students' CRs will vary in relation to their performance on a text comprehension assessment. More specifically, we predict that readers who more successfully comprehend a text will be marked by more frequent use of effective comprehension strategies, such as bridging and elaboration, and in particular, the use of combinations of strategies, such as para-bridging (i.e., combining paraphrasing and bridging within one CR). This prediction naturally stems from successful readers knowing how to use more strategies and use them in various contexts. Successful readers will also show a tendency towards certain types of switches, rather than randomly switching between strategies. Less successful comprehenders will be more likely to use strategies in isolation, especially paraphrasing, and will show less consistency in their strategy use patterns.

Markov chains are used to simulate processes with patterns that can be imprecisely predicted through probabilities [10]. In such processes, the probability of a given outcome depends on the previous outcome. For this study, the outcomes are different types of strategies, and the probability of using a strategy in a self-explanation depends on the strategy that was used in the previous self-explanation. The probabilities are determined based upon previously collected data and then displayed in a Markov chain visualization. Markov chains have been used in studies of mastery of ending letter sounds [12], and student knowledge and learning have been modeled using hidden Markov models in Bayesian Knowledge Tracing [6, 26, 29]. By contrast, Markov chains have not been widely explored as a method of studying comprehension processes in CRs. Cohesive features that help text comprehension, such as cues about causality, time, and space, are not always uniformly distributed within text; readers need to be sensitive to these features and adjust their strategy use accordingly to successfully comprehend a text [22]. Successful comprehenders are likely to be strategic in their

uses of comprehension processes, meaning they match their strategy use to the text [8]. Their strategy use is likely to be more structured, with consistent patterns in the types of switches that occur between strategies. Using Markov chains provides a learning analytic technique with strong potential to reveal students' flexibility in comprehension strategy use, as well as how those dynamic processes differ as a function of text comprehension performance.

To show the consistency of pattern use over time for individual participants, the current study uses random walk models, which are a type of sequential pattern analysis tool. They provide a spatial representation of an individual's path taken over time [2]. Such representations have commonly been used in the field of ecology, such as modeling animal migration patterns [3]. The movements of red deer are modeled on a graph with an x- and y-axis; every movement of the deer is plotted as a movement on the graph. Random walks have been used for a variety of other purposes, including decision making [9] and numerical cognition [5]. Using CRs allows us to code participants' strategy use and in turn, random walk models afford examining the consistency of students' strategy use over time.

Participants' random walks all start at (0, 0) on a graph. Four types of strategy use are defined as four different directions on the graph. Each CR counts as one step of the walk and moves one unit in a direction, based on the strategy used. The end point of each student's walk is plotted on a graph. Participants with more consistent strategy use have end points farther from the origin, while participants who frequently switch their strategy use have end points closer to the origin. Students who have more structured strategy use are likely to have some consistencies in the types of strategies they use, such as relying on paraphrasing and bridging. Inconsistent strategy use could indicate participants are not creating thoughtful explanations or using strategic choices for text comprehension. Their random walks may display multiple switches in strategy use and/or reliance on ineffective strategies. Random walk models offer additional information compared to Markov chains by showing the consistency of strategy use for individual participants, rather than the aggregated switching tendencies displayed by a Markov chain. Additionally, the random walk model is designed to show each participants' overall consistency over time, while Markov chains show probabilities of switching for each individual strategy.

The current study uses two extant datasets to help determine the generalizability of the research findings. Dataset 1 included 2322 CRs from 234 high school students (158 female; mean age = 17.58) [16]. Dataset 2 included 2448 CRs generated by 153 undergraduates. We predict that the results will be similar across datasets, but that the older, likely more skilled readers, in Dataset 2 would show more frequent use of effective strategies, more frequent use of combinations of strategies, and greater consistency of strategy use, compared to participants in Dataset 1.

2. METHOD

2.1 Datasets

In Dataset 1, participants read one of two texts, "Heart Disease" or "Red Blood Cells". Participants were asked to provide self-explanations at nine points in their assigned text. Both texts contain about 300 words and use scientific terminology suitable for the age of the participants. They have been validated in prior studies and matched for linguistic difficulty. In Dataset 2, participants read a text called "Cell Division", containing about 600 words, and were asked to self-explain the text at 16 different points. In both datasets, participants completed comprehension questions about the text after

reading. Performance on these questions serves as the dependent variable, which reflects students' comprehension success.

2.2 Expert Rating of Strategy Use

Verbal protocols were scored by expert raters using a self-explanation rubric that assesses the presence or absence of three reading strategies: paraphrase, bridging, and elaboration [17]. Paraphrase presence was scored based on the inclusion of idea units from the most recently read sentence. Bridging presence was scored based on the inclusion of references to other parts of the text. Elaboration presence was scored based on the inclusion of words or ideas that elaborate on the text but were not directly present in the text. Since paraphrase, bridging, and elaboration were scored independent of one another, the presence of any one strategy could be observed on its own or in combination with any of the other two strategies. Then, responses were categorized as containing one of eight strategy combination types, based on the presence of individual strategies: "None", "Paraphrase" (paraphrasing in isolation), "Bridge" (bridging in isolation), "Elaboration" (elaborating in isolation), "Para-bridge" (paraphrasing and bridging in combination), "Para-elab" (paraphrasing and elaborating in combination), "Bridge-elab" (bridging and elaborating in combination), and "All" (paraphrasing, bridging, and elaborating in combination). These categories did not include the order in which strategies were used within a single response, as the strategies were sometimes intermixed within a single response. For example, a "para-bridge" response means that paraphrasing and bridging were both used, but not in any particular order.

Scoring training was deemed complete when raters reached sufficient reliability for each coding category (weighted kappa ≥ 0.71). CRs were divided between pairs of raters such that each scored 60% of participant protocols, with 20% of participant protocols being scored by both raters. To calculate inter-rater reliability, protocols scored by both expert raters were compared per dataset, per text, and per coding category on a regular basis up to the latest point where both raters had scored the same protocols. Expert raters discussed coding disagreements to reach a consensus on the score. Following discussions, each rater independently reviewed and rescored as needed their entire set of protocols. Once raters completed scoring for a given text, scores were finalized only after raters achieved 0.71 or above weighted kappa per coding category.

2.3 Data Analysis

In both datasets, participants were divided into two groups based on the median performance (50%) in the text comprehension test. In Dataset 1, the low comprehension group included 102 participants, and the high comprehension group included 111 participants; 21 participants who scored on the median were excluded. In Dataset 2 (median = 50%), each group included 72 participants; 9 participants who scored on the median were excluded. The code used to create the Markov chains and the Random Walk displays can be found at <https://github.com/kchristilf/Markov-Chains>.

Markov chains were used to examine the dynamic nature of students' strategy use, as well as the overall frequency of different strategies. For each chain, we calculated the frequency of each type of strategy switch from one CR to the next. For instance, if a participant used paraphrasing in one CR and used para-bridging in the following submission, we added "1" to the overall frequency of switching from paraphrasing to para-bridging. The frequency of switches from a strategy were divided by the total number of switches from that strategy overall to calculate the probability of

switching from one strategy to the next. We also calculated the number of times each strategy was used overall.

These calculations were visibly represented in Markov chain diagrams created using 'Matplotlib' in Python (see Figures 2 and 3). Nodes were created to represent each strategy that was used more than five times. The area of the node was scaled relative to the overall number of times that strategy was used. The probability of switching from one strategy to another was represented by arrows between nodes. Wider arrows indicate a higher probability of switching from the origin node to the end node. Strategy use frequencies and transition probabilities are labeled when possible.

To examine consistency of strategy use over time, the current study uses random walk visualizations. As there are several possible "strategy moves" that a reader can make, we opted to simplify the analysis to four choices for visibility. Strategy use per trial was defined as using no strategies, paraphrasing in isolation, bridging in isolation, or two or more strategies in combination. The two or more strategies grouping includes para-bridging, para-elaborating, and para-bridge-elaborating. Each of these strategy combinations are an example of supplementing paraphrasing with one or more strategies, so we chose to combine them into a single group. For every participant's Random Walk analysis, each CR is coded as one "strategy move", and each strategy move is associated with a one unit movement in a specified direction. "No strategies" means one step down on the y-axis, "paraphrasing" means one step left on the x-axis, "bridging" means one step right on the x-axis, and "two or more strategies" means on step up on the y-axis. A single participant's full random walk is shown in Figure 1. The visualization shows that the participant primarily used paraphrasing or two or more strategies as their walk remains in the upper left quadrant. The student sometimes switched between different strategy types as shown by the relative distance away from the origin. In Figures 4 and 5, just the endpoints of each participant's walk were plotted onto a graph with an origin of (0, 0). For each random walk visualization, the participants' endpoint of the walk was graphed as a dot with 30% visibility, so that endpoints with more participants are darker. The graphs were created in Python using Matplotlib.

Figure 1. Example of a single participant's Random Walk.

3. RESULTS

3.1 Markov Chains

Elaboration in isolation and the combination of bridging and elaboration were not included as nodes in the Markov chains because participants used those strategies fewer than five times for each

chain. The six strategies that are represented in the Markov chains are no recorded strategies (labeled “None” or “N”), paraphrasing (“Para”), bridging (“Bridge” or “B”), paraphrasing and bridging in combination (“Para-Bridge”), paraphrasing and elaborating in combination (“Para-Elab” or “P-E”), and paraphrasing, bridging, and elaborating in combination (“All”).

Figure 2a. Markov chain for low comprehension group in Dataset 1.

Figure 2b. Markov chain for high comprehension group in Dataset 1.

The variation in strategy use comparing more and less successful high school readers (Dataset 1) is shown in Figure 2. The low-comprehension group had high probabilities (>40%) for the following transitions: none to paraphrase (43%), paraphrase to paraphrase (56%), bridge to paraphrase (43%), para-bridge to para-bridge (50%), para-elab to para-bridge (44%), and all to para-bridge (55%). The high-comprehension group had high probabilities for none to para-bridge (67%), paraphrase to para-bridge (55%), bridge to paraphrase (60%), para-bridge to para-bridge (61%), para-elab to para-bridge (49%), and all to para-bridge (45%). The low comprehension group tended to paraphrase (n=503 instances) more than para-bridging (n=420). Paraphrasing was the only strategy students were more likely to continue using than to switch to another strategy from. Participants were also more likely to use none of the analyzed strategies (n=52) than all three (n=21). Meanwhile, the high comprehension group used more para-bridging (n=568) than paraphrasing (n=309), as shown in Figure 2. Para-bridging was the

only strategy students were more likely to continue using than to switch from. Students in the high comprehension group were more likely to use a combination of all three strategies (n=61) than no strategies (n=8). They were also more likely to switch to using para-bridging than the low comprehension group, even when their previous response used no strategies. Participants in the high comprehension group were more likely to use para-elaboration as a strategy than the low comprehension group (n=18, n=48). These results suggest paraphrasing is used by most readers. However, readers who are more successful at comprehending texts supplement paraphrasing with other strategies, particularly through para-bridging but also through para-elaborating and para-bridge-elaborating.

Figure 3a. Markov chain for low comprehension group in Dataset 2.

Figure 3b. Markov chain for high comprehension group in Dataset 2.

As predicted, the college students in Dataset 2 showed similar trends, as shown in Figure 3. The low-comprehension group had high probabilities (>40%) for the following transitions: paraphrase to paraphrase (53%), para-bridge to para-bridge (60%), para-elab to para-bridge (50%), para-elab to paraphrase (43%), and all to para-bridge (40%). Participants in the low comprehension group were more likely to use none of the analyzed strategies (n=98) than all three (n=15). Less successful comprehenders used paraphrasing in isolation more frequently than more successful comprehenders.

In the high comprehension group, more distinct trends emerge. Most of the high probability switch types involve para-bridging: the most common switches were none to paraphrase (43%), paraphrase to paraphrase (46%), paraphrase to para-bridge (46%), bridge to para-bridge (55%), para-bridge to para-bridge (74%), para-elab to para-bridge (60%), and all to para-bridge (72%). They were more likely to use a combination of all three strategies ($n=63$) than no strategies ($n=30$). Participants in the high comprehension group, compared to the low comprehension group, used more para-bridging ($n=738, n=541$) and were more likely to continue para-bridging from the previous CR (74% vs 60%). When paraphrasing in isolation, they were equally likely to switch to para-bridging as to continue paraphrasing in isolation (46%), compared to the low comprehension group that was more likely to continue paraphrasing in isolation (53%). More successful comprehenders seem to rely on the combination of paraphrasing and bridging. This suggests that the combination of paraphrasing and bridging is generally the most effective aid to comprehension, compared to other examined strategy combinations.

Overall, participants tended to not switch between using no strategies or paraphrasing and using all strategies. Participants were much more likely to switch from using a single strategy to two strategies or vice versa. Participants with high comprehension were more likely to switch between using one to three strategies, while participants with low comprehension were more likely to switch from using between zero to two strategies.

The two datasets have some differences from each other, likely due to the differences in age and education between the two groups. In Dataset 2, both groups were more likely to para-bridge than to paraphrase, while in Dataset 1, the low comprehension group was less likely to use para-bridging than paraphrasing. In both datasets, participants tended to continue to use the same strategy rather than switching. As para-bridging seems to be the more useful strategy in text comprehension, students in Dataset 2 may be more skilled, which can be expected given that they are university students, rather than high school students. The differences in strategy use between datasets may also be due to differences in the difficulty of the text used, as participants in Dataset 2 read a more complicated text, potentially requiring strategic processing to a greater extent.

One potential argument against examining participants' probabilities of switching between strategies is that switching is solely dependent on overall strategy use. For instance, one might argue that participants frequently switch to para-bridging because that strategy is used commonly in general. A series of chi-square analyses were conducted to determine if transitions were random (solely dependent on base frequencies of strategy use), or if there were meaningful trends in switching. Chi-squares were conducted for each switch type grouping (all switches from none, all switches from paraphrasing, etc.). Only transition types with an expected value of 5 or more were calculated (all $ps < .05$). In Dataset 1, for the low comprehension group 3 out of 6 chi-squares were significant; for the high comprehension group 2 out of 4 were significant. In Dataset 2, 3 out of 5 chi-squares in the low comprehension group and 4 out of 5 chi-squares in the high comprehension group were significant.

3.2 Random Walk

In Dataset 1 (Figure 4), each participant had 9 steps, leading to a maximum distance of 9 from the origin if the same strategy was repeatedly used. In Dataset 2 (Figure 5), each participant had 16 steps. Good comprehenders are shown in blue, while poorer comprehenders are shown in pink.

For Dataset 1, visual inspection reveals a broad pattern of readers ending in the upper right quadrant, replicating the findings from the Markov chains analyses such that readers tend to use paraphrase and para-bridge most commonly. Participants who comprehended the text less successfully showed less consistency in their strategy use than other participants, as shown in Figure 5 by the endpoints that are closer towards the origin. They were more likely to have switched to using bridging or no strategies. Those who were more consistently used paraphrasing or a combination of strategies. For Dataset 2, participants in the low comprehension group showed less consistency in their strategy use, compared to the high comprehension group. Low comprehension group participants were more likely to use no strategies and bridging compared to participants in the high comprehension group. Both groups showed a tendency towards using paraphrasing and using two or more strategies in combination. Dataset 2 has considerably more variability than Dataset 1. This may be due to the higher number of response opportunities compared to Dataset 1 (16 vs 9). Participants in Dataset 2 may have needed to use a greater variety of strategies to understand the more difficult text, or they may have experienced more fatigue towards the end of the task.

Figure 4. Random Walk for Dataset 1.

Figure 5. Random Walk for Dataset 2.

To quantify these Random walks, we calculated average Euclidean distance. Euclidean distance represents the distance of each step from the origin. It is used as a quantitative measure of the consistency of participants' strategy use. Pearson product-moment correlation tests showed that Euclidean distance was significantly

correlated with comprehension score (Dataset 1, $n = 234$, $r = .291$, $p < .001$; Dataset 2, $n = 153$, $r = .293$, $p < .001$). This suggests that readers who were more consistent in their strategy use (as reflected by greater distance from the origin) had better overall comprehension success.

4. DISCUSSION

Discourse comprehension researchers commonly examine overall frequencies of different types of strategies, rather than the dynamics of strategy use. The current study applied Markov chains, a methodology previously used in EDM, and Random Walk analysis, a methodology used in other domains, to better understand the dynamics of strategy use in reading comprehension. These data analytic techniques yielded qualitative evidence that more successful comprehenders engaged in markedly different strategy use patterns than their less-successful peers. For instance, Markov chains showed that high text comprehension performance was associated with use of multiple strategies, as well as switching to and from para-bridging. Poorer text comprehension was associated with using strategies in isolation, such as paraphrasing and bridging, and less structure in switching between strategies. Random walk analysis illustrated that students who are less successful in text comprehension are less consistent in their strategy use. They switch between using strategies in isolation, and at times use no strategies at all. On the other hand, more successful comprehenders rely on using paraphrasing and combinations of strategies that include paraphrasing, and they rarely switch to using solely bridging or no strategies. Understanding the dynamics of strategy use has been elusive [8], and so these types of analytic tools provide new insights about strategy use and how it differs across readers. These analyses show that solely examining the types of strategies used within constructed responses neglects the ways in which patterns of strategy use differ among readers.

Our results suggest that examining combinations of strategies may be useful for gaining a more complete picture of students' strategy use. Markov chains and Random Walk models show that readers who are comprehending texts successfully use multiple strategies while reading. They are frequently using multiple strategies within a single CR of a small section of text. Prior studies have shown that skilled readers are more likely to bridge than less-skilled readers. Examining combinations of strategies demonstrates that successful readers are not foregoing paraphrasing for better comprehension; they continue to ground their understanding of the text in paraphrasing, and frequently use other strategies to deepen comprehension. Because bridging is connecting information from different parts of the text, it contributes to a more coherent understanding of the text. However, it is difficult to connect different parts of text without a solid understanding of each of the individual parts. When the syntax, vocabulary, or concepts in a sentence are difficult, it may be challenging to build a mental representation of the sentence without paraphrasing it. This mental representation must be constructed prior to higher-order strategies such as bridging and elaborating. The results suggest that models of student strategy use should include the combinations of strategies students use, not just the individual types of strategies.

One limitation of the work is that some analyses relied on a median split. While such an approach is common for exploring differences between more and less successful comprehenders [11, 19], this dichotomy can mask within-group differences. There may also exist more than two types of patterns in strategy use. Future research should use a more nuanced approach to determining differences in strategy use and how they relate to reading comprehension. For example, we are currently exploring approaches such as k-means

clustering [26] to identify profiles of readers' use of combinations of strategies and transitions between strategies.

Similarly, the chi-square analyses used to assess the Markov chains are limited in their interpretability. Such tests show that there are differences in patterns, but not the full nature of those patterns. We are exploring approaches such as lag sequential analysis [8, 27], which could be conducted for the transitions that are embedded within the chi-square tests. However, this inherently comprises 10 to 16 transition types to test for significance, which potentially inflates Type I errors. Future work should thus leverage the current results to determine in advance the most common transition types to assess using lag-sequential analysis.

Finally, our analysis focuses on differences across comprehension of a specific text, rather than on relatively stable individual differences (e.g., reading skill). Future work should explore how readers' individual differences in comprehension-related factors such as reading skill [15], prior knowledge [28], and motivation [1] relate to strategy use and strategy patterns, and the extent to which strategy use on a given text influences text comprehension beyond general reading skill (as measured by an outside assessment, such as the Gates-MacGinitie Reading Test [13]). Further studies should also consider extending this work to other populations, such as second language learners and struggling readers.

The current study relies on human judgements of strategy use, which are formed through retroactive analysis of data. Researchers are in the process of refining NLP-driven algorithms that can detect these strategies during reading. The current work suggests the possibility of combining these detectors with Markov models and Random Walk analysis as a means of providing real-time stealth assessment of student learning and just-in-time support. These analyses can be used to create different profiles of learners and determine the types of strategy use that are most helpful to comprehension. These profiles could include the types of strategies used and the number of times users switch between different strategies. Once these profiles are established, real-time analysis of students' strategy use within their typed responses in an automated system can be leveraged to augment feedback. For example, if a student were demonstrating ineffective strategy patterns, an adaptive learning environment (or an instructor using a teacher interface) could intervene and encourage revising the self-explanation or scaffolding to help the student to use more effective strategies. Combining these data mining approaches with adaptive feedback would allow teachers to provide high-quality, real-time individualized instruction that can help a greater number and variety of students to become more successful comprehenders.

No Meaning Left Unlearned: Predicting Learners' Knowledge of Atypical Meanings of Words from Vocabulary Tests for Their Typical Meanings

Yo Ehara
Tokyo Gakugei University
ehara@u-gakugei.ac.jp

ABSTRACT

Language learners are underserved if there are unlearned meanings of a word that they think they have already learned. For example, “circle” as a noun is well known, whereas its use as a verb is not. For artificial-intelligence-based support systems for learning vocabulary, assessing each learner’s knowledge of such atypical but common meanings of words is desirable. However, most vocabulary tests only test the typical meanings of words, and the texts used in the test questions are too short to apply readability formulae. We tackle this problem by proposing a novel dataset and a flexible model. First, we constructed a reliable vocabulary test in which learners answered questions regarding typical and atypical meanings of words. Second, we proposed a simple but powerful method for applying flexible and context-aware masked language models (MLMs) to learners’ answers in the above-mentioned vocabulary test results. This is a personalized prediction task, in which the results vary among learners for the same test question. By introducing special tokens that represent each learner, our method can reduce the personalized prediction task to a simple sequence classification task in which MLMs are applicable. In the evaluation, item response theory (IRT)-based methods, which cannot leverage the semantics of test questions, were used as baselines. The experimental results show that our method consistently and significantly outperformed the IRT-based baselines. Moreover, our method is highly interpretable because one can obtain the learners’ language abilities from the first principal component scores of the token embeddings representing each learner.

to recommend learning items according to the learner’s characteristics, such as the learner’s ability. When there are many learning items, it is difficult to test them all. In this case, only some of the knowledge is tested, and the test results are used to predict the other held knowledge.

This is especially fitting to vocabulary learning support systems for foreign languages. Because of the large vocabulary of a foreign language, research has been conducted in the fields of natural language processing (NLP) and applied linguistics to test only some words and to predict the held knowledge of other words based on the test results [19, 15, 10, 9, 8, 16]. As a result, standardized test questions have been developed to test learners’ knowledge.

However, for polysemous words, where a word has multiple meanings, the task of testing knowledge of only typical meanings and predicting the held knowledge of unexpected meanings from only the test results is a challenge. Because polysemous words are especially common in **high-frequency words** (words with high frequency in large corpora) that foreign language learners learn early on, it is also important for learners to properly grasp and understand the meaning of these words in context. However, many studies on foreign language learning support have focused on vocabulary size, and this area has been relatively unexplored. To the best of our knowledge, standardized questions that test the meanings of polysemous words have not been developed.

In the case of polysemous words, it is difficult to test for meanings other than the most typical ones. This can be attributed to the large number of words that must be learned; testing a learner’s knowledge of a single word more than once would impose a greater testing burden on learners. Hence, learners may often fail to learn word meanings other than the most representative meaning.

To improve learners’ language abilities, it is important to ensure that they learn all major meanings of polysemous words. In the development of artificial intelligence (AI)-based systems that support language learners by identifying and recommending such unlearned meanings, it is essential to identify the meanings of polysemous words that a given learner already knows. However, considering the testing burden, sufficient time is available to test only a few additional word meanings. Given that vocabulary tests use numerous words to measure a learner’s overall vocabulary, most typical vocabulary tests query only the major meanings of polyse-

She had a missed _____.
a) time
b) period
c) hour
d) duration

(b) An example of a question that tests atypical meanings of a word.

Figure 1: Outline of the task. Our goal is to predict whether a learner knows this word (i.e., can correctly answer the question) from the results of typical meanings of words to prevent these meanings from being left unlearned.

mous words. Therefore, it is desirable to be able to predict the extent to which a learner knows the non-representative meanings of a word by using existing test results for major word meanings. For example, it should be possible to predict whether a learner who knows the meaning of “figure” referring to a number also knows the meaning of “figure” referring to a person.

Intuitively, one can easily think of a two-step approach in which one first predicts the meaning of a polysemous word in a running sentence and then assigns the difficulty of each meaning of a word. However, this approach is impractical because the categorization of meanings by linguists is not typically designed for language learning. For example, Figure 1 show examples of the word “period” used in distinctly different contexts. However, linguistic categorization can be too fine-grained for language learners. For example, WordNet [12], one of the most carefully designed thesauri for the English language, separately lists “period” as a geological period as being a different meaning from “period” as a timespan. This is counter-intuitive for language learners and impractical for estimating the difficulty of “period” as a geological period separately from that as a timespan. Hence, another approach is necessary in which one directly predicts how likely it is that the language learner understands the meaning of a word used in an input sentence.

To the best of our knowledge, no existing datasets or methods have been provided in the literature to evaluate the extent to which such problems can be solved. Because it is presumably difficult to capture the meanings of words in running texts, these types of questions have not been extensively studied in vocabulary testing studies in applied linguistics [19, 15, 20]. Therefore, in this study, we propose a dataset and methods to evaluate how well these problems can be solved. Figure 1 are examples of the dataset. To this end, we used deep transfer learning state-of-the-art neural language models (MLMs), namely masked language models such as bidirectional encoder representations from transformers (BERT) [5]. Deep-learning-based NLP techniques cannot simply be applied to this personalized prediction problem in which different predictions must be made for each learner, even for the same given input sentence. Although recent educational AI studies also used BERT [24, 23, 25], they did not address this issue because they do not deal with personalized prediction tests.

In the proposed method, we demonstrate a simple approach to reduce this personalized prediction problem to a typical sequence classification problem in NLP by adding spe-

cial tokens that represent learners in language models. In our experiments, the prediction performance of the proposed method was superior to that of other methods such as item response theory (IRT) by a statistically significant margin.

Our method also showed high interpretability matching that of the IRT models: one merit of using IRT models is that they are highly interpretable, e.g., capable of extracting the ability estimates from the model, which BERT models cannot do. We showed that the first principal component scores of the embedding of the tokens representing each learner had a statistically significant correlation with the learners’ ability values obtained using the IRT.

The contributions of this paper are as follows.

- We focused on the importance of predicting whether language learners know the atypical meanings of a word and developed an evaluation dataset for this purpose.
- In addition, we proposed a simple method for applying deep transfer learning techniques to the aforementioned personalized prediction problem by introducing tokens that represent learners. The prediction performance of the proposed method is superior to that of IRT by a statistically significant margin.
- Finally, we demonstrated that with the proposed method, we can easily obtain learners’ ability values by using the first principal component scores of token embedding. This indicates that our method is highly interpretable, and hence suitable for educational use.

2. RELATED WORK

In educational data mining, [4] models the *spaced repetition*, or students’ memorization of learning items repeatedly, by extending statistical models. While [4] focuses on the temporal aspect in the process of learning second language vocabulary, we focus on predicting each learner’s knowledge of atypical meanings of words from the test results of typical meanings of words, considering text semantics and contexts. In AI in education, [1] addressed a case study of the personalized English vocabulary learning of 37 Syrian refugees using a language learning application called SCROLL. This study did not address the methodology or algorithm used in SCROLL but the case study of using it. While [7] applied BERT to readability prediction, [7] was not personalized.

Vocabulary test datasets were previously published via self-report testing [11, 18], or multiple-choice testing [6]. However, to the best of our knowledge, no reliable vocabulary

test datasets in which typical and atypical meanings of words have both been tested have been published.

Other datasets seemingly similar to our dataset include the SLAM dataset [22], which is based on responses to questions on the language learning application Duolingo, and the Complex Word Identification (CWI) dataset [26], where a large number of language learners were asked to annotate unfamiliar words in a sentence. The difference between these datasets and ours is that each subject answered only a small portion of the many questions.

3. VOCABULARY TESTING DATASETS

This section elaborates on our dataset. [6] is a publicly available dataset of vocabulary test results of language learners. However, it does not include questions regarding any typical/atypical meanings of words. Nevertheless, for comparability, we adopted their settings to build our dataset. Our dataset was compiled from the crowdsourcing service Lancers¹. To find learners who had some interest in learning English, only learners who had taken the Test of English for International Communication (TOEIC) test² in the past were permitted to take the vocabulary test. As a result, 235 subjects responded to the questionnaire. Because most learners in Lancers are native Japanese speakers, the native language of the learners was also assumed to be Japanese.

For typical vocabulary test questions, we used vocabulary size test (VST) [3], as [6] did. However, unlike [6], our focus is highly frequent words. In VST, the questions are ordered by the frequency of the corpus that [3] used for making VST. To reduce the test burden on the participants and to easily collect accurate answers, we eliminated 30 low-frequency words from the test. The remaining 70 questions were used for a typical vocabulary test. An example of these questions is shown in Figure 1 (a). The word(s) being tested are underlined in the sentence. The subject is asked to choose the option that is closest in meaning to the original sentence when the word(s) being tested are replaced. All options were designed to be grammatical when replaced.

We developed 13 questions that tested atypical meanings of words as follows. First, a computer science researcher, who was a non-native but fluent English speaker, drafted the questions. Second, English professors, namely two native English speakers (i.e., an American English speaker and an Australian English speaker) and a non-native speaker, checked and edited the questions for validity. In the actual examples of these two test sets in Figure 1 (b), the word “period” has a physiological meaning in addition to the usual meaning as a timespan. The subjects were asked to answer 13 questions, such as Figure 1 (b) before the 70 lexical test of typical usage. We included one question with an unexpected meaning but without a corresponding question on the group of typical word meaning questions. Therefore, the number of question pairs was 12. More details of our dataset are provided in the Appendix.

4. ITEM RESPONSE THEORY

¹<https://lancers.co.jp/>

²<https://www.ets.org/toEIC>

Figure 2: Deep transfer learning procedure

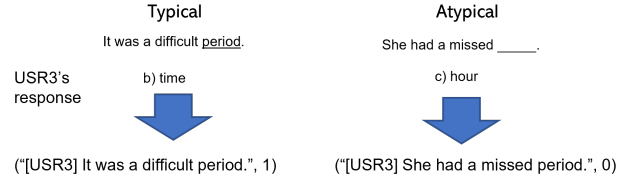

Figure 3: Proposed method to enable personalized prediction using BERT

This section briefly describes the IRT models. Let the number of subjects be J and the number of questions (or items) be I . For simplicity, we identify the index of the subject with the subject and the index of the item with the item. For example, the I -th item is simply written as I . We assume that y_{ij} is 1 when subject j answers item i correctly, and 0 when the subject answers incorrectly. Given the test result data $\{y_{ij} | i \in \{1, \dots, I\}, j \in \{1, \dots, J\}\}$, the 2PL model models the probability that subject j answers item i correctly with the following equation

$$P(y_{ij} = 1 | i, j) = \sigma(a_i(\theta_j - d_i)) \quad (1)$$

Here, σ is the logistic sigmoid function defined as $\sigma(x) = \frac{1}{1 + \exp(-x)}$. where the σ is a monotonically increasing function with $(0, 1)$ as its value range and $\sigma(0) = 0.5$. The $\sigma(x)$ is used to project real numbers into the range of $(0, 1)$ and treat them as probabilities. In (1), θ_j is called the *ability parameter*, and is a parameter that represents the ability of the subject. d_i is the difficulty parameter representing the difficulty of the item. From (1), when θ_j is greater than d_i , the probability of the subject answering correctly is higher than that of answering incorrectly. The value $a_i > 0$ is usually positive and is called the *discrimination parameter*. The larger this value, the more $\theta_j - d_i$ affects the probability of correct or incorrect answers. It is called “discrimination” because $\theta_j - d_i$ makes it easier to distinguish whether subject j will answer question i correctly or not. More intuitively, this indicates that question i is a good question in that it can accurately distinguish between learners with high ability and those with low ability.

5. PROPOSED METHOD

5.1 Deep Transfer Learning

In this section, we describe our proposed method. The proposed method is based on Transformer models such as BERT [5]. Transformer models employ transfer learning to capture the semantics of texts written in natural language Figure 2. First, a **pre-trained model** is prepared using large raw (i.e., unannotated) texts. This model can be trained using raw texts written by native English speakers, such as the Wikipedia text. This procedure is called **pre-training**. Typically, pre-training incurs high computational costs. Hence, we downloaded and prepared publicly available pre-trained

models. Each model is identified by an ID such as **bert-large-cased**, which denotes that the model was trained on a large Wikipedia corpus in a case-sensitive manner. Importantly, a pre-trained model can be used for many tests depending on the **fine-tuning**.

Then, an additional **fine-tuning** is performed to train the pre-trained model to the intended task. To this end, a small annotated corpus must be prepared for use in a supervised learning procedure. Such corpora are generally costly to construct; in this case, the corpus comprised the results of a vocabulary test. After the model is fine-tuned, it can be used to make predictions based on new input sentences.

5.2 Reducing the Personalized Prediction into Sequence Classification

Given a language learner taking a test and a word in a sentence, as shown in Figure 1 (b), our goal is to predict whether the test-taker knows the word. Notably, this is a *personalized* prediction; the prediction results differ among individual learners. In contrast, deep transfer learning does not support personalized predictions. Publicly available pre-trained models are preferable because pre-training is costly. Moreover, designing a new model that can achieve high performance using the available pre-trained models is relatively difficult. Thus, reducing the personalized prediction problem to a typical NLP task can be a practical solution, instead of developing a novel neural model for this task.

We reduced the personalized prediction task into a sequence classification task as shown in Figure 3. Sequence classification is a task in which a classifier takes a sequence or text as the input and predicts its label. Hence, to train the classifier, pairs of text and associated labels are used to constitute a small corpus for supervised learning in the fine-tuning phase. Thus, to use sequence classifiers in this task, we first need to convert the original vocabulary test result dataset into a sequence classification dataset so that sequence classifiers can handle the dataset.

In the example of Figure 3, **USR3**, the test-taker whose ID was 3 answered correctly on a multiple-choice question of the typical meaning of the word “period,” but incorrectly answered a question on the atypical meaning. To convert this record into a format that accepts a sequence classifier, we added special tokens: **[USRn]**.

Here, **[USRn]**, where n is replaced by the test-taker ID, represents each test-taker, or learner (user). By placing this at the beginning of the sequence, we notify the classifier that we want to predict the response of the test-taker specified by this token. Therefore, the example in Figure 3 shows that we aim to predict the response of **USR3** to the sequence “It is a difficult period.” In this example, as **USR3** answered the multiple-choice question correctly, the label for the question was set to 1. The rationale behind this conversion is that the test-taker could read the sentence if the test-taker answered the question correctly. Hence, the label denotes that the test-taker was able to successfully read the short sentence “It is a difficult period.”

Likewise, **USR3**’s answer to an atypical question can be converted to the sequence on the right-hand side of Figure 3. In

this example, as **USR3** answered incorrectly, the label for the question was set to 0. The option that is incorrectly chosen by **USR3** (“hour” in the example of Figure 3) is ignored in the sequence. This ensures a fair and accurate comparison, because IRT-based methods also do not consider the *incorrect* options or distractors chosen by the test-taker. Rather, they only consider whether a test-taker chooses the correct option. As each of these tokens represents a test-taker, there are as many tokens as the number of test-takers, starting from **[USR1]**.

Thus, the dataset can be converted into a sequence classification format. In the **transformers** library, the tokens used for Transformer models can be added using the **add_tokens** function. After conversion, we simply use the **AutoModelForSequenceClassification** to construct sequence classifiers. Note that this conversion enables BERT to handle personalized prediction by introducing **[USRn]** tokens. We introduce special tokens for each user and insert the token into the beginning of the sentence.

6. IRT-BASED ANALYSIS

To obtain the difficulty and discrimination parameters for IRT, we used the **pyirt** Python library³. This library was developed to conduct IRT analyses using marginalized maximum likelihood estimation (MMLE) [2, 21]. For the dataset described above, we used the 2PL model to obtain the above-mentioned parameters. The dataset includes 12 pairs of questions, such as Figure 1. The difficulty parameters for the usual and unexpected examples are shown on the horizontal and vertical axes, respectively, and plotted at the same scale and range on the horizontal and vertical axes in Figure 4. Each point represents a single word.

A dotted diagonal line is shown from the lower left to the upper right of Figure 4. The horizontal and vertical axes of Figure 4 represent the values of the difficulty parameter; the higher the value, the more difficult the task was judged to be. The point to the upper left of the diagonal line indicates that the difficulty level of an example that seemed unexpected to the learner was higher than that of the typical example. Moreover, the word was judged to be more difficult for the learner to correctly answer questions from the vocabulary test data. The results of the Wilcoxon test showed that the column of values on the vertical axis was larger than that on the horizontal axis by a statistically significant margin ($p < 0.01$), suggesting that the vertical-axis questions were more difficult than the horizontal-axis questions.

Discrimination was also analyzed. The plot is omitted for space limitation. Atypical meanings are expected to be less discriminating than typical meanings, because even high-ability learners may not know the correct answers of atypical meanings, whereas low-ability learners may know them. This tendency was observed as follows: For all words, it was estimated that the discrimination of typical examples was higher than that of unexpected examples. This result was found to be statistically significant using the Wilcoxon test ($p < 0.01$).

7. EXPERIMENTS OF PREDICTIONS

³<https://github.com/17zuoye/pyirt>

Figure 4: Plot of the difficulty of a typical meaning (horizontal) vs. that of an atypical meaning (vertical) for each word.

7.1 Item Response Theory-Based Settings

A naive method to deal with the difficulty of an atypical meaning of a word is to simply regard its difficulty as being the same as that of its typical meaning. Hence, we measured the negative effects of substituting the difficulty of the atypical meanings of a word with the difficulty of its typical meanings on predicting the subjects’ responses.

To investigate this, we conducted the following experiment, as shown in Figure 5. First, we divided 235 subjects into 135 and 100 subjects. We estimated the parameters without using the responses of the latter 100 subjects for the 12 questions (1,200 responses). The parameters of the 12 atypical example questions were estimated only from the responses of the former 135 subjects, while the parameters of the 70 typical example questions were estimated from the responses of all 235 subjects. From (1), we can see that the estimated values of subject ability θ_j and the difficulty of the example d_i are sufficient to predict if subject j answers question i correctly or not by checking if $\theta_j > d_i$ or not, respectively. Hence, once all θ_j and d_i can be estimated, we can make predictions. For the 12 typical and atypical question pairs, we have two prediction methods: one that uses the difficulty parameters of the typical examples of the pairs for d_i and one that uses that of atypical examples of the pairs. Thus, we compared the prediction accuracy of these 1,200 responses.

Several methods are conventionally used to estimate the parameters of IRT models. As in the previous sections, we used the pyirt library, which implements MMLE, for parameter estimation. MMLE assumes that the ability parameter can only take several values to marginalize. This causes stepwise shapes in the resulting ability parameter plots.

7.2 Our Settings

We constructed a BERT-based personalized predictor [5]. For the neural classification, we used the same settings described in Section 5.2. As described in Table 1, we compared the pre-trained Transformer models, all of which were publicly available from the HuggingFace website⁴. Then, we conducted a *fine-tuning* by using our own data.

⁴<https://huggingface.co/>

Figure 5: Experiment setting. Filled areas are *training* data, i.e., used for estimating the parameters. All methods are evaluated based on the accuracy of the responses of the dashed area, i.e., the responses for atypical words of the 100 *test* learners.

Table 1: Transformer Models Used for Experiments

Model Name	Model	cased/uncased
bert-base-cased	BERT [5]	cased
bert-base-uncased	BERT [5]	uncased
bert-large-cased	BERT [5]	cased
roberta-base	RoBERTa [17]	cased
albert-base-v2	ALBERT [14]	uncased

Here, we describe how we converted the personalized prediction of whether a learner knew a given word into the task of sequence classification and its fine-tuning. Sequence classification is a supervised classification task in which the goal is to predict labels by using a sequence as an input. Here, the label is 1 if the learner knows the meaning of the word, i.e., answered the question about the meaning of the word correctly; otherwise, the label is 0.

Because the aim is to make personalized predictions, it is necessary to incorporate learner test-takers in the sequence. Thus, we added special tokens to represent individual learners. For example, if the sequence starts from “[USR3]”, this means that we want to predict whether the learner with ID 3 can read the sentences that follow. Hence, “[USR3] It was a difficult period.” asks if the learner with ID 3 could read the sentence “It was a difficult period.”. The goal of the task is to predict 1 or 0, where 1 indicates that the learner could read the specified sentence, and 0 indicates that the learner was unable to do so. We fine-tuned the pre-trained BERT model in this manner using the “training” data shown in Figure 5. For the estimation, we used the Adam optimizer [13], in which the batch size was 32.

7.3 Results

Table 2 shows the predictive accuracies of all methods. The results showed that the prediction accuracy of the direct method was 64.4% and that of the alternative method was 54.4%, a difference of 10 points. This difference was significant at $p < 0.01$ in the Wilcoxon test. This result indicates that estimating the difficulty of atypical meanings of words from those of typical words is a challenging task.

Table 2: Predictive Accuracies of the Dashed Area

Base Method	Accuracy
IRT (ability - diffcl. of typical word)	0.544
IRT (ability - diffcl. of atypical word)	0.644
OURS (bert-large-cased)	0.674 (**)
OURS (bert-base-cased)	0.688 (**)
OURS (bert-based-uncased)	0.655
OURS (roberta-base)	0.681 (**)
OURS (albert-base-v2)	0.671 (*)

Our model achieved the best performance among the listed models. The name in () indicates the pre-trained model used for the experiments. In particular, our model significantly outperformed the IRT models with the best accuracy. This result was also statistically significant using the Wilcoxon test ($p < 0.01$). This is denoted by (**) in Table 2. As BERT considers the semantics of the question, this result suggests that the traits of each learner test-taker was captured via the embeddings of the [USR] tokens during the fine-tuning.

Table 2 showed the best performance for **bert-base-cased**. **bert-base-cased** achieved a performance better than **bert-large-cased**. The reasons of this are presumably as follows. Although the word embeddings of Transformer models are trained by many examples in their pre-trained corpus, the word embedding vectors of learner tokens, which represent learners’ characteristics, such as their abilities, were trained solely on a relatively small training data in the fine-tuning phase. Obviously, no learner tokens appeared in the pre-trained corpus. Hence, it could be possible that **bert-large-cased** has too many parameters to be tuned using the small training data in fine-tuning compared with **bert-base-cased**.

Table 2 also shows that a model must be *cased* to achieve a good accuracy, considering that **roberta-base** is cased whereas **albert-base-v2** is uncased. This is presumably because the model needs to recognize the start of a sentence, which starts with a capitalized word, since each question consists of a short sentence in this experimental setting.

8. EXTRACTING ABILITY VALUES

As stated above, our method handles learners as tokens. Transformer-based methods internally use “word embeddings” that represents the meaning of the tokens in the form of vectors. Hence, by obtaining the word embeddings of the learner tokens that we introduced, it was possible to analyze learners’ characteristics, such as their language abilities.

As word embeddings are typically multi-dimensional, dimension reduction methods such as principal component analysis (PCA), can be used to obtain abilities from the embeddings of learner tokens. Figure 6 shows the plot of a PCA of the ability parameters of test-takers of the vocabulary test dataset against the first principal component scores of each token of the token embeddings in the case of **bert-large-cased** in Table 2. A clear correlation can be observed between the two. The correlation coefficient was 0.72, and was statistically significant ($p < 0.01$). In this manner, learners’ abilities can be obtained through PCA of the test-taker tokens in our method, which means that our method is equipped

**Figure 6: Relationship between IRT ability parameters estimated by pyirt (horizontal) and the first principal component of the learner token embeddings (vertical)**

with the interpretability of IRT models.

In Figure 6, we used pyirt for estimating the ability parameters. To check the correlation using IRT software other than pyirt, following a standard textbook for educational psychology [21], we also conducted experiments using the R “ltm” package, which was developed completely independently of pyirt. Unlike pyirt, which uses MMLE, ltm uses the expected a posteriori (EAP) method for parameter estimation. Again, a statistically significant correlation was observed: the Pearson’s correlation was also 0.72, ($p < 0.01$).

9. CONCLUSION

In this study, we tackled the task of predicting whether language learners know the atypical meanings of a word and developed an evaluation dataset for this purpose. We proposed a simple method for applying MLMs to the aforementioned personalized prediction problem by introducing tokens that represent learners. The prediction performance of the proposed method was superior to that of IRT by a statistically significant margin. We also showed that, with the proposed method, one can easily obtain learners’ ability values using the first principal component scores of token embeddings. This result indicates that our method is highly interpretable and, hence, suitable for educational use.

The learner token embeddings that we introduced are multi-dimensional. While we showed that the first principal component score significantly correlated with the test-taker’s ability parameter, the other components may encode the learner’s other types of ability. In IRT, there is a similar idea to model the learner’s ability as a multidimensional vector, called “multidimensional IRT”. Our future work is to compare the other principal components of learner token embeddings with multidimensional IRT.

APPENDIX

A. DATASETS

The dataset used in this paper will be publicly available. Details of the dataset will be available at <http://yoebara.com/> or <http://readability.jp/>. Some previous datasets such as [6] are available at <http://yoebara.com/>.

B. DISCUSSION

In this paper, we have made two important suggestions. The first is to introduce learner tokens to apply Transformer models to the personalized prediction task. The second is that the learner ability can be extracted from the first principal component of the learner token embedding vectors.

A research question that directly follows from this result is: Is it always possible to extract learner ability from the Transformer models? We provide our views on this topic.

An important point of the experimental settings shown in Figure 5 is that all learner tokens are trained using the same 70 test questions. (Strictly speaking, as for the 100 learners in Figure 5, their learner tokens were trained without test questions for atypical words.) The word embeddings, other than the learner token embeddings, were already trained using the pre-trained model. Therefore, although words other than the learner token in a sentence had a strong influence on the training of learner token embeddings, they were all trained in a similar way except for the response of the learner to the test question text: correct/incorrect. Hence, it is natural that learner token embeddings mainly reflect the response of the learner to each question text.

Hence, in a setting in which each learner responds to completely different test question texts, it is expected that extracting the learner's ability values using the first principal score of the learner token embedding vectors will be difficult. This setting can also be seen in the case where the matrix Figure 5 is sparse because each column, i.e., each test question, was filled by a small number of learners.

ABSTRACT

Typical data science instruction uses generic datasets like survival rates on the Titanic, which may not be motivating for students. Will introducing real-life data science problems fill this motivational deficit? To analyze this question, we contrasted learning with generic datasets and artificial problems (Phase 1) with a community-sourced dataset and authentic problems (Phase 2) in the context of an 8-week virtual internship. Retrospective survey questions indicated interns experienced increased motivation in Phase 2. Additionally, analysis of intern discourse using Linguistic Inquiry and Word Count (LIWC) indicated a significant difference in linguistic measures between the two phases. Phase 1 had significantly greater measures of pronouns with a small-medium effect size, 2nd person words with a medium-large effect size, positive emotion with a medium effect size, inter-rogations with a medium-large effect size, question marks with a medium-large effect size, risk with a medium-large effect size, and causal words with a medium effect size. These results in conjunction with a retrospective survey suggest that phase 1 had more questions asked, more causal relationships defined, and included linguistic features of success and failure. Results from Phase 2 indicated that community-sourced data and problems may increase motivation for learning data science.

Virtual internship, motivation, service-learning, language analysis

1. INTRODUCTION

Data science curriculum development is challenging due to prerequisites in statistics, programming, and machine learning [35]. Dataset complexity is another challenge: while educators acknowledge that data science embraces messy data, typical practice is to use sanitized or “canned” datasets to demonstrate a particular approach [3][10]. For example, the UCI Machine Learning Repository, a popular source of datasets, lists datasets on irises, adult income in 1996, and the geographic origin of wines as its top three downloaded datasets [9].

The practice of using canned datasets illustrates the pedagogical tension between keeping intrinsic cognitive load low [33] without sacrificing learning opportunities to develop key data science skills

J. Johnson and A. Olney. Using community-based problems to increase motivation in a data science virtual internship. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 500–507, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

for working with messy data. Cognitive load theorists have proposed that motivation is particularly important for learning complex skills over time, because motivation causes learners to invest in germane cognitive load [20].

In the context of learning data science, dataset manipulation is a potential avenue for increasing motivation. Personalization has been used in previous research to increase motivation for learning [8]. For example, personalization might entail allowing the learner to choose the dataset or matching a dataset based on the learner’s preference profile. However, this type of data personalization can be challenging because the data in question may not be accessible or suitable for advancing a learning goal.

The alternative explored in the present study is to use datasets and problems sourced from community partners. In the framework of self-determination theory [26], this approach should build intrinsic motivation through the constructs of relatedness (by working on a problem of concern in their community), autonomy (by deciding how to address the problem of concern rather than being told to perform a specific analysis), and potentially competence (by making progress on the problem and so increasing self-efficacy in data science).

Within our research context of an 8-week data science virtual internship, we hypothesized that interns would experience increased motivation during the final phase of the internship in which they worked on community-based problems. To evaluate this hypothesis, we conducted retrospective surveys and analyzed the communications between interns for linguistic indicators of increased motivation, effort, confidence, competence, and emotion.

2. BACKGROUND

2.1 Internship & motivation

Traditional internships offer a markedly different context for learning compared to formal education. While formal education typically engages in prescriptive or rote learning, internships are grounded in real-world tasks that have material impacts on interns in terms of compensation and future employment opportunities. As such, internships have substantial potential to enhance motivation around learning in a way that parallels, and perhaps even surpasses, project-based learning in formal education [2].

The motivational impacts of internships have been found across the literature. [15] worked with IT interns to consider the roles of tasks, learners, and mentors in a project-based intern program. It was found that mentors increased the learners’ successful expectancies and therefore increased learners’ self-efficacy. Because of this, it was hypothesized that mentoring increases the learner’s self-determination and subsequently their motivation. [19] a study based on

Figure 1 Jupyter Notebook Lesson on Simple Linear Regression

167 college interns working in retail, it was discovered that emotional sharing is positively related to learning and mentoring. Research in cognitive neuroscience leads us to believe that emotions activate neural circuits which engage sensory systems that increase attention and motivate perceptual processing [17]. Positive emotion was hypothesized to relate to motivation in that by increasing these perceptual factors, learners would be more compelled to learn.

Similar results have been found in virtual internships [13]. Virtual internships are becoming a popular alternative to in-person structures due to the Covid-19 Pandemic, and they have the potential to offer a unique educational strategy. Research has shown that learning efforts outside of traditional classrooms are needed to address systemic disparities within education [30]. In [25] it was seen that virtual internship programs provide a quality opportunity for non-traditional students to participate in practical experiences regardless of their physical location and other obstacles.

The virtual internship discussed in this paper follows through on goals to help students during the pandemic. This includes paying learners, offering them loaner laptops, and creating a pedagogy that motivates students when working with a local community partner in need.

[18] showed that service-learning increased civic skills, problem-solving, and motivation. This leads to the idea that service-learning internships have the potential to enhance motivation, especially if the service is aligned with the intern's beliefs and values. Service-

learning gained attention in the 1970s [29] and has become increasingly popular in engineering [4] as well as data science, as evidenced by such programs as Data Science for the Social Good.

2.2 Research Context

We designed an 8-week data science internship with two phases. Phase 1 of the internship was an educational data science boot camp that consisted of Jupyterlab Python notebooks¹ with a Blockly plugin (Anonymous) so that students could solve data science problems with a block-based programming language. Learners were split into pods which was a distributed team of students ranging from 3-4 people including a student mentor. The notebooks consisted of materials that span across data science topics, such as cleaning data, Random forests, regression trees, and cross-validation. To cover these topics according to a fixed schedule, Phase 1 used common generic datasets with artificial problems.

(i.e., problems proscribed by the learning materials). Each topic was covered by introducing it as a worked example in the morning followed by problem-solving in the afternoon. At the end of the day, they would engage in peer grading and review, which would culminate in a group discussion led by a faculty member. In addition to the notebooks, students were provided a reference manual that abstracted key steps from the notebooks, based on an observation that interns sometimes struggled with learning transfer (Anonymous). Further, Phase 1 implemented a problem-based learning environment, with mentors to help get through the questions. This style of

Zip codes served

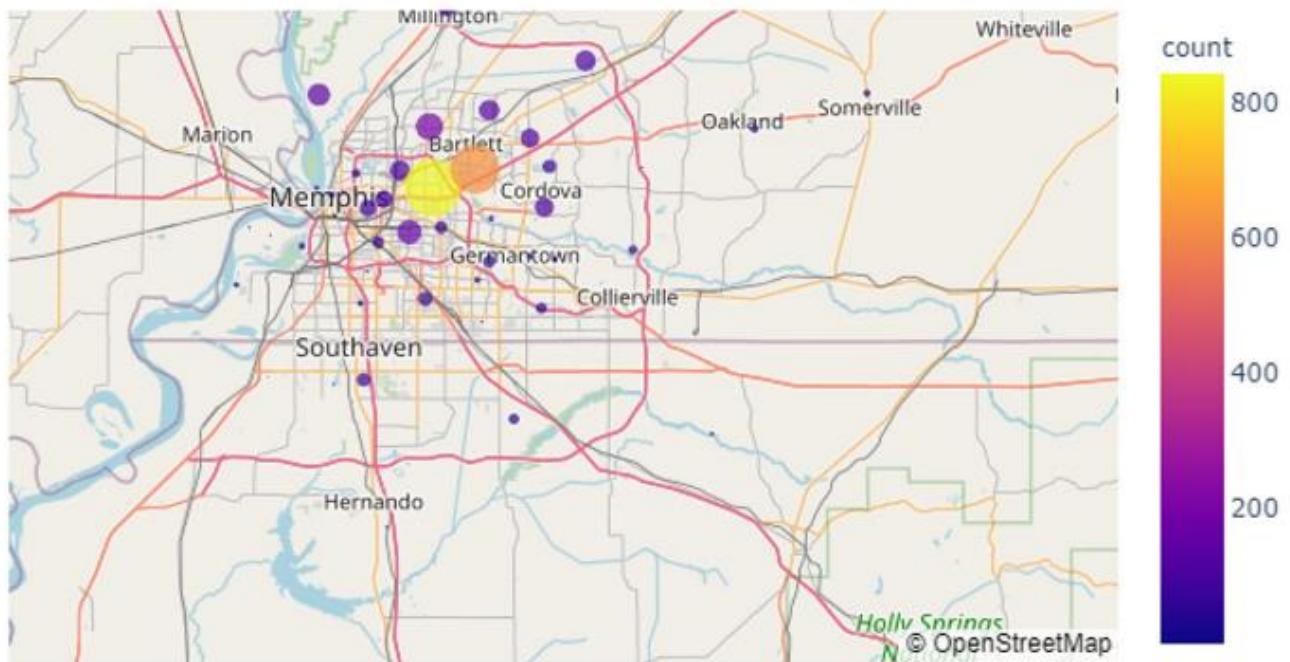

Figure 2 Intern Visualization for A Betor Way Project

learning has been seen to increase intrinsic motivation [5] [16]. This is a type of instructional design suggested by [30] such that students learn from failure, and that they cannot fail in this environment due to the time allowed to rework, fix, and learn from their mistakes. This is motivating due to the lack of pressure on the student to be correct.

In Phase 2 of the internship, students were regrouped into two teams such that they could work on a respective community-partner project. The projects consisted of harm-reduction data from a clean needle and Narcan mutual aid group (A Betor Way), and event data from a group that helps battered women get into safe homes and supplies resources (Restoration Time Family Youth Services). Both community partners are locally based. Before Phase 2, each partner presented to the interns and faculty for 10 minutes and took questions about their work and data. After the presentations, each intern rank-ordered their preferences of which project they wanted to be on, which was considered and distributed based on their preferences and the number of students in each group. Each team worked with 1-2 faculty members that they met with on a regular basis (e.g., 2-3 times a day). The faculty members provided guidance and helped set goals and schedules. Each team was also provided with a captain that was nominally for coordinating within team members. An important factor of Phase 2 is that it keys in on reinvention and reconfiguration during a learning task, which has been seen to add meaning to the learning experience [6]. In an experiential activity, such as a real-world authentic problem, motivation to learn is cultivated [24]. This can be seen in a study conducted over five forms of experiential learning, which reported a high self-perception of learning in a service-learning setting [7].

2.3 LIWC

Linguistic Inquiry and Word Count (LIWC) calculates linguistic measures using a dictionary-based approach that counts words in

the given text according to the categories in which they belong [24]. For example, if you use the word “sad” it will be counted as a target word that matches a dictionary word for the category of *negative emotion words*. The dictionary is composed of 94 categories and almost 6,400 dictionary words like this. The full comprehensive text can be found in [24]. The 2015 version of the software, which was used in this study, supports the languages of Spanish, German, Dutch, Norwegian, Italian, and Portuguese.

The usage of LIWC in discourse spans many topics in education such as understanding learners’ difficulties, discovering motivational insights to learning styles, and analyzing the sentiment of experts and non-experts over time. In [11] it was seen that various language modeling tactics, including LIWC, lead to the understanding that researchers could interpret learners’ needs and difficulties in learning. This insight was used to change the materials and course settings such that the learner experience was increased [11]. LIWC was also used in [36] to develop research around learning styles while classifying the motives behind them. This study found that LIWC could be used to identify the motives for different students’ needs and what learning styles could be used to facilitate them. Further showing the application of LIWC in educational settings, [1] studied the emotional states of learners in an online Stack Overflow learning community. They found that learners were more analytical and less authentic over time, meaning learners progressed in their learning capabilities but became less honest in their posts. It was also found that the clout (e.g., confidence) levels of non-experts decreased overtime in their question-and-answer posts, while experts only had a decrease in clout for their answer posts – not the question posts. This indicates that learners became less confident in their materials over time, while experts doubted their answers but had strong questions. LIWC has been used across varying processes, tasks, and materials to understand the social reality of learner discourse.

In the present study, LIWC2015 was used to analyze the change in discourse between Phase 1 and 2 as an indicator of motivation, emotional resonance, confidence, competence, and effort. These constructs were analyzed using LIWC with data extracted from Discord, an online messaging and communication platform that learners used to communicate with each other, their mentors, and faculty. It is important to note that from a psychological perspective, style words such as pronouns and 2nd person reflects how people are communicating, while content words such as the ones that fall under the positive and negative emotion category convey what people are saying [34]. In terms of what people are saying, different variables, such as word count, can be used to determine the characteristics of a speaker, such as effort. In this way, the discussed constructs can be operationalized in terms of the LIWC variables. For example, affective indicators of emotional tone, affect, positive emotion, and negative emotion could be used to represent emotional tendencies. The reason for looking at this construct is the expectation that when students have a moral responsibility to help a community partner in need, they will have a larger emotional resonance with the task and therefore be more motivated.

3. METHODS

3.1 Participants

There were 10 participants in this study, 5 men and 5 women. For the A Betor Way project, there were 3 men and 2 women. For the Restoration Time Family Youth Services project, there were 2 men and 3 women. All but one intern was from LeMoyne Owen College, a private Historically Black College and University (HBCU) in Memphis, TN. The HBCU participants came from a variety of majors, and the remaining participant was an incoming data science graduate student. Three participants were mentors. One was an incoming graduate student, and the other two were former interns.

3.2 Materials and Procedure

Data for LIWC analysis were collected through mining the conversations students were having over the messaging platform Discord. Channels for each pod were created, a help channel, a general chat channel, and two channels for each community-partner project. The text logs from Phase 1 were collected using the pod channels, and the text logs from Phase 2 were collected using the community-partner channels. Voice channels for general, help, each team, and each project were also created, but data from these sources has been excluded because we did not save this method of communication.

Discord chat logs were exported as JSON files using the Discord Chat Exporter². Then, we used a Python script to collect word counts and length of words per post by each student by afternoon and morning notebook. We aggregated the posts from each student into a single text for Phase 1 and again for Phase 2. The resulting texts were put into an Excel file and used for LIWC analysis with each student and all the words they used per phase as a datapoint.

Survey items were distributed to students retrospectively (e.g., at the end of phase 2) over Google Forms. The items were constructed by centering the constructs of motivation and affiliation. Questions used a 5-point Likert scale, designating no influence in the question asked to a very strong influence. Two of the questions, the last two

rows in Table 2, used the number three option as a designator for no influence whatsoever.

4. RESULTS

Table 1 LIWC measures with significant changes across phases

Measure	Phase 1		Phase 2		<i>p</i>	<i>d</i>
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>		
pronoun	59.00	48.85	40.90	55.86	.048	.34
you	13.20	16.22	4.75	7.42	.027	.67
interrog	8.50	5.70	4.84	5.44	.048	.66
posemo	16.10	13.24	9.40	13.61	.037	.50
cause	9.81	7.91	5.55	8.30	.009	.53
risk	3.58	3.36	1.75	2.69	.027	.60
Qmark	8.68	8.16	4.44	6.63	.019	.57

4.1 LIWC

All measures reported by LIWC were analyzed using the Wilcoxon signed ranks test, but due to space constraints, we only report significant results in Table 1. The indicated p-values are not corrected for significance due to chance (type 1 error), which is expected when performing 88 tests at once. When we corrected the p-values using the strict Holm-Bonferroni method and less strict Benjamini-Hochberg method, no significant differences were found. Post-hoc power analysis using GPower 3 revealed that the design was underpowered, with power .28 to find a medium effect with $\alpha = .05$.

All measures in Table 1 significantly decreased from Phase 1 to Phase 2. Personal pronouns are “I, them, her itself” and include ‘you’. This measure had small-medium effect size, whereas the other measures had a medium or medium-large effect size You measures 2nd person words such as “you, your, yourself”. Interrog means interrogatives such as “how, when, what”. Posemo means positive emotion and includes words such as “love, nice, sweet”. Cause means causation words, such as “before, effect”. Risk means words associated with risk such as “danger, doubt”. Finally, Qmark means the number of question marks used.

4.2 Survey Results

Only 5 interns responded to the survey. In the survey results, it was found that students self-reported higher motivation when working on the community projects in Phase 2. Table 2 shows the survey questions and their respective scores. The scores across all questions indicate that the interns perceived an increase in motivation during Phase 2. Additionally, interns developed a sense of understanding that data science can affect their local communities and it helped develop a sense of connection to their communities. Overall,

² by Github user Tyrrrz (<https://github.com/Tyrrrz/DiscordChatExporter>).

the outcomes of this survey were very positive, but limitations exist in the lack of power present with such a low N.

Table 2 Retrospective motivational survey of interns

Question	<i>M</i>	<i>SD</i>
How did working with a community partner increase your motivation?	5.00	.00
How did working on your team’s project increase your connection to the community?	4.00	.49
How did knowing that your project was with community-based data increase your efforts?	5.00	.00
To what degree did working with a community partner influence your perspective on data science’s power to have a local impact?	4.43	.19
To what degree did your interest in social justice work change since the beginning of the community project	4.20	.44

5. DISCUSSION

5.1 Interpretation

Students reflexive posting indicates that they wrote more questions, explained the processes, took more risks, and had a more positive attitude in Phase 1. Nothing resulted in an increase in Phase 2, which was contrary to our results. The present study expected to primarily see an increase in motivation, and secondarily see an increase in effort, competence, confidence, and emotion. The only construct in the LIWC analysis that matches what we were expecting was positive emotion, but the results came out in the other direction. However, our primary hypothesis of motivation comes out correct in the retrospective survey results.

Along with questions being asked, we can interpret the causal words, 2nd pronoun usage, and pronoun usage. These categories indicate the prevalence of explanations by means of needing to indicate causal relationships, direct others on what to do, and refer to objects and people. Additionally, since “pronoun” and “you” words both decreased, this means no other subtypes of pronouns changed. Since “you” is nested in “pronoun”, this implies that the change was all in “you”. In other words, the “pronoun” result is entirely dependent on “you”. In [31] pronouns were negatively related to relationship quality. This means that since “you” decreased, an improvement in relationship quality changed from phase 1 to phase 2. However, this could just be due to time, not to the phase 2 activity.

The results of interrog and Qmark indicate the construct of questions, so it can be said more questions were asked in Phase 1. This makes sense because there is a back-and-forth dialogue between learners and mentors – both must ask each other questions. In Phase 2, questions seemed to be one direction, as in learners and mentors were asking questions that a faculty member could answer with or without another question. Here, it is important to consider that faculty posts were not measured, so if they responded back with a question, it was not reported. Additionally, it was found in [27] that lower-status language is more self-focused and tentative, while high-status language speaks more often and freely makes statements. The use of first-person plural usage correlated with higher rank, but the opposite pattern was found for question marks

compared to lower-ranked members of a crew. A reduction of question marks could indicate an increased sense of status and therefore, self-efficacy.

Because causal words went down, the language can be said to have been less complex over time as the interns had more knowledge and didn’t have to explain themselves as much when talking to each other. This can be related to literature from [14] that such discussions are the most complex part of an article because results must be integrated and differentiated from past findings. It can also be related to the literature of [12] which studied how prepositions signal the speaker is providing more complex and concrete information about a topic, showing that words greater than six letters are also indicative of more complex language. These causal relationships show that there is a complexity to the conversation which does not occur in Phase 2 possibly due to the nuanced form of problem-based learning.

The results of risk and positive emotion are a bit fuzzier, but they seem to reflect a dichotomy of failure and success. Risk words include a language of doubt and tentability. This is a bit strange to see in Phase 1, but it starts to make sense when contextualized to the failure literature of [30]. When students are in an environment where they have the option to fail, doubt occurs, and a sense of risk is invoked due to the consequential fear of getting problems wrong. Positive emotion reflects the opposite of this – the joy of getting answers correct. Since there are no problem sets in Phase 2, only a project to complete, there are less iterations of the failure and success dichotomy, which results in fewer positive emotion and risk words. Additionally, since positive emotion words went down, this could indicate there was less agreement in Phase 2 than Phase 1. The task was more difficult and had multiple solutions in Phase 2. Since risk also went down, this could mean that concerns went down. This would make sense because the learners had an increased ability at this point. Lowering of these concerns could indicate increased self-efficacy.

In the rest of this section, the nuances of each result will be discussed:

Pronoun means total pronouns used. This is represented by the words “I, them, her, itself”. It was found that the use of pronoun words dropped in Phase 2, which could be because there was more direct mentoring in Phase 1. This is exemplified in the sentence “You’re gonna set one of them to Import: “pandas” – as – “pd”. This sentence shows the use of variable pronouns directed at another person in need of assistance. Compare this to the sentence: “Sorry, I got super dugged dow with a dumb error on the scatter matrix, but I’m done now. I’m trying to add a new/return-dependent color to the Narcan Given histogram.” This shows the use of primarily one type of pronoun – personal. It is possible that in Phase 1 lots of different pronouns were used, indicating acts of mentoring and calls for help of assistance, while Phase 2 used a smaller category of pronouns to update the chat on what they were doing on the project.

You means 2nd person words used. This is represented by the words “you, your, yourself”. IT was found that the amount of you were dropped in Phase 2, which could indicate there was more instruction in Phase 1. This is similar to the thought pattern behind the pronoun decrease – there was more variability in pronouns, especially 2nd person words, in the first phase but the instruction of this type was lacking in Phase 1. However, we do not see an increase in 1st person words in Phase 2, which means if there was an increase in these types of words in Phase 1 it did not happen at any significant level.

Interrog means interrogatives, and Qmark means question marks. These words are represented by “how, when, what” and “?” respectively. They will be discussed together due to the correlation of the categories and ideological similarities in what they represent – questions. There were more interrogatives and question marks in Phase 1 than in Phase 2, and they both had about the same number in both phases. This could be because interrogatives and question marks are linked in their representation of questions, which makes sense for these to be more prominent in Phase 1 than Phase 2 due to the direct problem-solving nature of tasks in Phase 1. In Phase 2, there seemed to be a culture of putting question marks behind things they were trying to verify, such as: “I guess we have to get dummies for all the non-numerical stuff, right?”, whereas in Phase 1 there were more questions from both interns and mentors, such as the question: “What kind of error are you getting?”. Mentors needed to ask questions to assist, as well as interns asking the questions to get answered. This two-ended need for questions could account for the almost double amount of question marks and interrogatives in Phase 1.

Cause means causation words, such as “before, effect”. These words were higher in Phase 1 than in Phase 2, which could be because of a need for understanding the problems in Phase 1, and the mentors giving answers in this fashion. Take the example sentence “Ok, it’s because the last 3 freestyle blocks go outside the main block, like this: [screenshot]”. It shows a mentor answering a question in a causal style. Examples like this are plentiful in Phase 1, but they are lacking in Phase 2 due to less of a need to understand what is happening and more of a need to update the channel on what they are accomplishing. The explanation of how or why they are doing such a thing is not there because everyone already understands the underlying mechanisms.

Risk means risk in the LIWC dictionary, and it accounts for words such as “danger, doubt”. This could be because of learners’ hesitancy in what the materials they are learning. It represents a tenability in answering problems because there is an underlying fear of getting the questions wrong.

Posemo means positive emotion, which is represented by the words “love, nice, sweet”. These words were more prominent in Phase 1 than in Phase 2, contrary to our hypothesis. This could be because learners were more likely to express gratitude for answers in Phase 1, and there were not that many questions in Phase 2. Additionally, it could represent the happiness one feels when getting an answer correct or getting the solution they need. It could also represent the gratitude learners had to their mentors for helping them. In this sense, the linguistic feature of positive emotion represents the other opposite of risk, meaning these two categories might have a relationship in the problem-based learning context. Overall, these results can be interpreted as more questions being asked, and more causal relationships being defined.

5.2 Limitations

The study has several limitations. The study was nonexperimental with low sample size, reducing our power to find an effect or claim causality. The order of the phases was not counterbalanced, by necessity, so it is possible that some changes in discourse are due to maturation and not the community project in Phase 2. The analysis done in LIWC uses a dictionary approach – words are matched based on predefined categories instead of studying word relationships and their contextual clues [22]. Finally, the survey questions were asked retrospectively, so there was no baseline to measure change, and the participants may have had bias responses due to the retrospective phrasing of the questions.

5.3 Future Research

In the future, more participants should be studied because the power of this research is very low for both LIWC and Survey measures. Motivational surveys should be distributed before and after the internship, instead of just after. Also, questions should be reworded and put on the same scale.

This study should also be used as a comparison metric for the same internship next year. By doing so, insights could be found on the similarity between years to see if any language changed over the course of a year’s development of the program.

Another future research point would be to include the 4 summary variables in the LIWC dictionary (e.g., analytic, clout, tone, and authentic) to see if there were any changes over the phases per percentile scoring. Word count could also be analyzed, as well as words per sentence if set up correctly with stopper marks.

Finally, it would be good to measure the language usage in a time series of days per week over the four weeks to see what changes happen per day. This would allow us to see the movement and variability of sentiment change.

5.4 Conclusions

In conclusion, this study shows that learners asked more questions, described more relationships, and were more positive in Phase 1. It was also found that students were more motivated in Phase 2.

It is important to look at the LIWC analysis between phases because it highlights the psychological underpinnings of learners. There is potential to discover constructs laying within the text. In the case of this study, those constructs were more questions asked, discussion of causal relationships, and the success and failure influences.

Even though our hypotheses of confidence, competence, and effort were not detected, we did find increases of motivation and discovered constructs that exist in Phase 1. This is valuable research because it suggests that in a problem-based learning environment with mentors more questions will be asked, more relationships will be discussed, learners will be willing to take more risks, and they will emotionally reap the rewards of getting things correct by taking those risks.

This study also resulted in a finding of our secondary hypothesis of an emotion change, but it occurred in the opposite direction than we were expecting. This result was attributed to the joy of success when solving problems, instead of the joy of working with a community partner. Although we did not see a linguistic increase in positivity, we did find that learners had an increased interest in social justice activities and were more motivated to complete the project. This means that despite the LIWC results, we can still say Phase 2 had an impact on learners.

The significance of this research lays in educational design such that project-based service-learning programs do increase motivation, and a problem-based environment induces the discussed constructs.

ABSTRACT

In computer science education timely help seeking during large programming projects is essential for student success. Help-seeking in typical courses happens in office hours and through online forums. In this research, we analyze students coding activities and help requests to understand the interaction between these activities. We collected student's help requests during coding assignments on two different platforms in a CS2 course, and categorized those requests into eight categories (including implementation, addressing test failures, general debugging, etc.). Then we analyzed the proportion of each type of requests and how they changed over time. We also collected student's coding status (including what part of the code changed and the frequency of commits) before they seek help to investigate if students share a similar code change behavior leading to certain type of help requests.

Help Seeking, Categorization, Data Mining, CS2, Computer Science Education

1. INTRODUCTION

Help seeking is a complex cognitive skill involving metacognition and self-evaluation to identify the need for assistance, identification of problems for support, and formulating requests [1, 16, 15]. Help seeking is essential for learners to develop a better understanding of assignments or class content that they do not understand [15]. Effective help-seeking is a key part of learning and is associated with a capacity for self-regulated learning through monitoring and goal-setting among other aspects [22, 24]. Motivation in help-seeking has

Z. Gao, B. Erickson, Y. Xu, C. Lynch, S. Heckman, and T. Barnes. Admitting you have a problem is the first step: Modeling when and why students seek help in programming assignments. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 508–514, Durham, United Kingdom, July 2022. been analyzed by a number of authors [19, 4, 25, 5, e.g] . These researchers have noted that learners who felt comfortable and skillful in relating to others were more likely to ask for help. Further studies of specific help-seeking behaviors (e.g. [17, 18, 21]) has included analyses of the interaction between help-seeking and instructor feedback. However, most of this prior research focused only on students' help seeking behaviours in isolation or in the context of relatively focused problem solving. It has not typically exemplified that help-seeking responds to prior problem-solving, and how these help requests affect their subsequent work.

In this study, our goal is to explore the motivations, help-seeking, and problem solving actions of computer science students seeking help for their programming projects. We chose to focus on coding for two reasons. First, computer science skills have become an increasingly important domain at all levels with increased demand at all grade levels and coding is an essential part of that [2]. Second, programming is a complex task that involves students in long-term complex problem solving which offers multiple opportunities for help-seeking and for a complex interrelationship between problem-solving, assistance, and outcomes. In contrast to prior research, we combined different types of student help seeking behaviours including attending office hour and posting on a public class forum. We analyze how students change their code when trying to receive help from others. Thus, in this work, we answer the following research questions.

- RQ1: What types of help are students seeking in online forums and office hour settings and how do they differ?
- RQ2: How does the frequency of help-seeking change over the course of students' complex assignments, and can we use the project stages or sub-goals to predict this help-seeking?
- RQ3: What types of coding behaviors do students engage in before seeking help?

In order to address these questions we began by identifying common help requests and coding behaviors. We manually

labeled help seeking requests from two different platform from a blended course. We then analyzed how these different types of help seeking requests changed during the coding project lifespan. Finally, we compared students' coding changes based on the commit frequency and the number of their passed test cases before and after they seek help.

2. RELATED WORK

2.1 Help Seeking Behaviours

As prior researchers have shown self-regulation of learning through modulation of affective, cognitive, and behavioral processes is an essential component of learning across domains [23]. This regulation and essential help-seeking is driven in part by students personal motivations [13, 14, 12], and by their general attitude toward learning [19]. In general students who have better performance in an educational environment tend to have better metacognitive skills and tend to seek help more frequently [10]. Ryan et al. [19], for example, investigated motivational influences on help seeking behavior in math classrooms, focusing on early teenagers' perception of the benefits and threats associated with such behaviour. They designed a survey for 203 seventh and eighth graders on perceptions of social and cognitive competence, achievement goals, attitudes, and avoidance of and adaptive help seeking behaviour. Their finding indicates social competence had an indirect effect on avoidance of help seeking. And the results illustrate the importance of linking cognitive and social characteristics of students to provide a full understanding of teenager help seeking.

Help seeking is an important factor to success in learning programming. Bumbacher et al. [3], for example, developed novel models to predict student learning gains based upon their semantic and structural features of their coding submissions. They found that these code features extracted from a single assignment can be used to predict whether or not students got help. Marwan et al. [11] focused on analyzing and classifying students' help-seeking behaviors. Based upon an analysis of student-system logfiles they proposed a taxonomy of unproductive help seeking behaviour in a programming environment. They then used these findings to design a hint interface that scaffolded appropriate help-seeking. Students using their platform were ultimately less than half as likely to produce unproductive help-seeking and thus improved overall.

2.2 Student Help Seeking Behaviour Analysis

Unlike in-person environments online help-seeking is far more open and produces a higher volume of data [9]. Prior studies of online learning have typically shown a positive relationship between help seeking behaviours and academic performance.

In-person or small-group online office hours are an important venue for support in traditional and blended courses. Guerrero et al. [8] noted that students fail to take advantage of office hours when they are available despite the fact that the use of office hours correlates with performance. Griffin et al. [7] extended this work by working to identify distinct factors that influence students' use of office hours. To that end they developed a survey with 625 valid responses from undergraduate students at a large public university. The results revealed that factors that significantly affect student

use of office hour vary with one exception: usefulness of instructional staff feedback. Thus, in this study, they suggest instructors provide more efficient feedback to solve students problems to encourage students to engage in office hour.

3. DATASET

3.1 Course Background

The data for this work originates from the Fall 2020 offering of a CS2 course at a research intensive university in the Southeast United States. Students in the course complete two projects, each worth 22% of their overall grade. Each project consists of two parts: 1) designing the system and creating a testing plan and 2) implementing the teaching staff (TS) UML diagram. Our focus will be on the second part of each project.

The course initially offered both online and in-person sections; however, due to the COVID-19 pandemic, all undergraduate courses covered in our dataset were moved online a few weeks into the semester. The overall structure of the course as well as the task deadlines remained the same with interactions including office hours moving to individual web meetings but retaining their overall structure.

As a first step in their course projects the students are required to develop UML diagrams for the problem task. However for the later coding stage the students must all follow the instructor-provided UML diagram. This allows them to fit a shared model for testing and evaluation. Students manage their repository using a Github¹ enterprise server. Whenever they push code, Jenkins², a continuous integration system, runs an Ant-driven build. Each build compiles the code, runs static analysis tools (Checkstyle³, PMD⁴, SpotBugs⁵), compiles the teaching staff test cases against the code to ensure it abides by the provided UML diagram, runs student-written tests to check for coverage metrics, runs teaching staff tests, and finally provides feedback to the student based on their status. For the purposes of our analysis we recorded the state of their code on each commit along with a record of the unit test results.

Over the course of the project, there are two intermediate milestones, or Process Points, for students to follow. Achieving the first two milestones provide a fraction of their project grade, while the final milestone defines the requirements to receive full credit.

- **Milestone 1 - Process Points 1:** students complete a compiling skeleton, at least one test case, and fully Javadoc (i.e. no Checkstyle notifications) their code.
- **Milestone 2 - Process Points 2:** students achieve 60% statement coverage on their self-written tests.
- **Milestone 3 - Done:** students achieve 80% statement coverage, have no static analysis notifications, and all tests are passing (both teaching staff and student written).

¹<https://github.com/>

²<https://www.jenkins.io/>

³<https://checkstyle.sourceforge.io/>

⁴<https://pmd.github.io/>

⁵<https://spotbugs.github.io/>

After achieving each of the milestones, the students receive feedback on their code based upon the shared tests. At the start, students only receive information about their compiling status and Checkstyle notifications related to developing Javadocs for their code. Once a student completes Milestone 1, they begin to see feedback about the remaining static analysis notifications. For completing Milestone 2, they begin seeing feedback regarding teaching staff test case failures. This feedback includes the number of tests passing or failing and for the failing tests it provides a hint to reproduce locally. For the purposes of our analyses we defined four project stages based upon these milestones. At the beginning of the project students are in stage 0, they then move to stage 1 after completing Milestone 1, and so on.

3.2 Help Seeking

Students in this course had two options for help, general questions could be posted to Piazza an online question and answer forum that was monitored by the instructors and took answers from other students; and office hours which were accessed via a help request system called My Digital Hand.

Piazza: At any time during the semester, students are able to post questions or comments on Piazza, an online forum for the class. When posting, students are required to select a category for their question. These categories correspond to logistics or each assignment, lab, or project. Students are able to make their posts private to instructors, but they are encouraged to post publicly so other students are able to answer questions or receive similar help. The teaching staff also uses Piazza as a place to post updates or announcements. We remove the teaching staff posts and filter posts down to only the second part of each project. We focus our attention only on the initial posting and remove all replies.

Office Hours During teaching staff office hours, students request help by filing a help ticket using My Digital Hand (MDH) an online support system [20]. Students seeking help through MDH fill out a form listing the tasks they are working on, what question they have or problem they are struggling with, and what steps they have taken thus far. The students are then placed in a queue which is monitored by the teaching staff. The teachers prioritize students to help based upon their questions and may help them individually or in small groups. After the interaction is complete the teachers will close the ticket and both they and the student can enter followup information to describe the advice given, rate the outcome, and any potential followups. Students who require more assistance may have their tickets re-opened or, more commonly, make a new ticket with additional questions. In our analysis, we first remove all tickets that were not related to the second part of the projects. Next, we remove any follow-up tickets or tickets that were re-opened with the same content.

3.3 Commit mining

After the semester concluded, we ran the BUILDDATACOLLECTOR⁶. This tool iterates over each commit from each repository and runs the Jenkins build. The output files are

⁶<https://github.com/SOS-CER/BuildDataCollector>

mined for relevant data. The data includes commit meta-data, static analysis notifications, information about all test cases, code counts, and coverage metrics. The data are stored in a SQL database.

4. METHODOLOGY

4.1 RQ1: Categorization of Help Requests

In developing our analysis we held the initial expectation that students' coding behaviors would differ based upon the type of help that they required. Thus, we began by classifying the students' help requests based upon their question content. In general students begin the project by seeking to understand the overall functionality of the system, and to build the general structure. They typically turn to authoring their own test cases based upon the functional goals with the goal of unlocking the instructor test cases on which their grade is partially based. Once these are unlocked students frequently use the test cases to drive their development process, as intended, so they often focus their questions around those tests. Across all of these stages they also face challenges with basic implementation errors and general static analysis notifications. Our goal was to separate students who were seeking to support with basic development tasks (e.g. debugging) or with specific test cases from those who were seeking to address deeper comprehension questions, or general notifications.

We therefore classified student help requests as follows:

- **General debugging and addressing issues:** students indicate they are receiving an error (i.e. null pointer exception) or describe unexpected behavior in their code.
- **Implementation and understanding:** students ask about how to implement some portion of the project or ask for clarification.
- **Improving test coverage:** students ask about how to improve their code coverage to achieve the 60% or 80% threshold.
- **Addressing TS test failures:** students indicate they are failing specific teaching staff test cases.
- **Addressing student-written test failures:** students indicate they are failing specific tests they wrote.
- **Addressing general test failures:** students indicate they are struggling with testing, but do not specify which type of test.
- **Addressing static analysis notifications:** students ask about Spotbugs, Checkstyle, or PMD notifications they receive.
- **Others or unclear:** students ask about unrelated topic (i.e. coding environment setup, documentation) or they are unclear with the type of help they need (i.e. a method name without explanation).

Manual Annotation To support our analysis we engaged three experienced TAs to manually tag the student questions across the two help contexts. We began by developing a shared coding process using a subset of Piazza and MDH posts. An

initial round of grading yielded a Fleiss' Kappa agreement of 0.73 for MDH data and 0.69 for Piazza data. After one round of iterative evaluation and agreement we achieved a final agreement of 0.81 for MDH data and 0.72 for Piazza. The primary area of disagreement in the Piazza data lies between questions in the Implementation and General Debugging categories. We therefore opted to perform additional segmentation based upon whether or not students showed evidence of code execution.

4.2 RQ2: Timeline analysis

After the categorization was complete, we examined the frequency of the students' help requests by type and the change in those frequencies over time. Our hypotheses in this analysis were:

- Hypothesis 1: At the early stages of the project (before the Milestone 2 deadline), students mainly ask Implementation questions.
- Hypothesis 2: After achieving Milestone 2, students mainly asked about General Debugging and TS Test Failure questions.

We believe that, consistent with instructor guidance, the students will try to understand the requirements of the project and how to implement each function first. Moreover, since Milestone 2 requires students to achieve 60% test coverage, it indicates that students need to finish most of the implementation to develop corresponding tests and reach Milestone 2. Therefore, we believe that prior to the Milestone 2 deadline, the most frequently asked questions should be Implementation related.

Moreover, after Milestone 2, students unlocked the TS test cases and also needed to develop more self-written tests to reach 80% code coverage. We believe that during this process, the students' main goal will be to correct their implementation based on the feedback of error messages and testing failures. Therefore, later in the projects, questions related to General Debugging and TS Test Failures should be more prevalent.

4.3 RQ3: Pre-help code analysis

In order to analyze the precursors of students' help requests we analyzed the state of the students' code on the last commit before they post a question to Piazza or file a ticket on MDH. We define these as the pre-help commit states. In analyzing these precursors we began by analyzing how frequently students made commits within 1 hour before their pre-help commit. We believe that a higher volume of pre-help commits indicate that the students are unlikely to be working on higher level implementation and are more focused on small-scale debugging or test passing.

In addition to the commit frequency, we also examined where code changes were made prior to help requests. Prior to requests for implementation help we imagine that most commits include changes to the core functionality, while help requests for coverage focus on changes to the student-written unit tests. This leads to the following hypotheses:

Category	MDH	Piazza	Overall
Implementation	334	281	615
General Debugging	392	316	708
TS test failures	127	307	434
Self-written test failures	30	90	120
General test failures	103	64	167
Improving test coverage	21	31	52
static analysis notifications	9	38	47
Others/Unclear	314	75	389
Total	1330	1202	2532

Table 1: Categorization Results

- Hypothesis 3: Before an Implementation request, student commit frequency is low and before a TS test failure request, the frequency is high.
- Hypothesis 4: Before an Implementation request, students are making changes to their source code and before a Coverage request, students are making changes to their test code.

5. RESULTS

5.1 RQ1

Table 1 lists the results of our final request categorization. In both of the help platform, the most popular type of request is General Debugging; We identified 392 (29.4%) MDH requests and 316 (26.3%) Piazza requests in this category. For office hours request, the next popular category is Implementation (25.1%), while for Piazza, there are more requests on Addressing TS Test Failures (25.5%) than Implementation (23.3%). The remaining categories are relatively uncommon with a frequency lower than 10% on each platform, except for the Others/Unclear category. We found a large amount of MDH requests containing very vague descriptions, which were categorized as Other/Unclear (23.6%). This is caused by the nature of the office hours process, the description we collected from MDH does not ask student to give very detailed information and students do not rely on it for getting the actual help; they would prefer to briefly describe their problem on MDH and elaborate on the detail orally when meeting with the teaching staff. This also matches with Gao's founding on the usage of MDH [6]. In piazza, since students more reliant on the description to get help, the amount of requests categorized as Others/Unclear is only 75 (6.2%).

5.2 RQ2

5.2.1 MDH Requests Timeline Analysis

Figure 1 shows how the student's help request types changed over time during office hours. Prior to the Milestone 1 deadline, students mainly asked the Implementation and General Debugging questions; during the next stage, before the Milestone 2 deadline, Implementation questions are dominating the help requests and maintain a very high number every single day. Then, after the Milestone 2 deadline, the amount of Implementation questions suddenly drop to less than 10 each day; while we witness a great increase in both the General Debugging and TS Test Failures, especially the General Debugging.

Figure 1: Project 1 Office Hours request timeline for each type.

Figure 2: Project 2 Office Hours request timeline for each type.

Similarly, Figure 2 provides the project 2 office hour requests. This also contains a high number of Implementation questions leading up to the Milestone 2 deadline, while after the deadline, Implementation instantly becomes less common. However before Milestone 1, the General Debugging is also one of the dominating categories, with roughly the same amount as Implementation. After Milestone 2, General Debugging stays as the most common request while the amount of TS Test Failure requests increase similar to the first project.

Furthermore, both project 1 and project 2 have the most requests at the exact date of each deadline. The project deadlines have more requests than the Milestone 2 deadlines, which have more requests than the Milestone 1 deadlines. This observation shows that most students are completing their work on the deadline date and require more help.

5.2.2 Piazza Requests Timeline Analysis

Figures 3 and 4 show the number of help requests student made on Piazza each day during the two projects. The three vertical lines represent the milestones and final deadline dates.

Figure 3 shows the number of requests in Piazza that students made during project 1. We observed that the General Debugging category reaches the peak at all deadlines; the Implementation category is prominent during the first few stages; and the TS Test Failure category increases after the first milestone deadline and reaches its peak during the final deadline.

Figure 3: Project 1 Piazza request timeline for each type.

Figure 4 shows the number of requests in Piazza that students made during project 2. We observed that the General Debugging category always peaks at each deadline; the Gen-

Figure 4: Project 2 Piazza request timeline for each type.

	Implementation	Coverage	Overall
src change	79.65%	60.78%	73.25%
test change	64.25%	84.31%	70.12%

Table 2: Percentage of pre-help commits with source or test code changes

eral Testing and Self-Testing categories peak at the project deadline; the TS Test Failure category raises rapidly from the Milestone 2 deadline to Project deadline; and the Implementation category increase before each deadline, but overall decreases after each subsequent deadline.

5.3 RQ3

5.3.1 Frequency of pre-help commits

When comparing the frequency of commits, we find that students who ask about TS Test Failures are on average making more commits in the last hour than students making other help-seeking requests, 4.6 commits and 2.9 commits respectively (p -value < 0.0001). Similarly, we see that students who seek help on Implementation requests are on average making fewer commits in the last hour than students who make any other request, 2.4 and 3.4 commits per hour respectively (p -value < 0.0001).

5.3.2 Code changes of pre-help commits

For the Implementation pre-help commits, 490 (79.65%) of those commits contains source code changes. Our chi-square test proves that Implementation requests have a significant higher number of pre-help commits with source code change (p -value < 0.05). For the Coverage pre-help commits, we found 43 (84.31%) of those commits contains test code changes. Similarly, we proved that this high number of commits with test code changes is significant than the rest of commits (p -value < 0.01).

6. DISCUSSION AND CONCLUSIONS

Our goal in this work was to investigate what kinds of requests students make when they seek help and what precursors exist in their code state before such requests are made.

In addressing RQ1, we categorized the help requests based on student's purpose. Our results shows that students are mostly asking questions about General Debugging, Implementation, and Addressing TS Test Failures. For office hours, General Debugging is the most popular category followed by Implementation followed by Addressing TS Test Failures. For Piazza requests, General Debugging are also the most common type, but Addressing TS Test Failures are more common than Implementation.

In RQ2, we analyzed the amount of help request each day and observed how it changed during different stages of the

project. We proved both of our hypothesis. Before Milestone 2, Implementation is the most common request (Hypothesis 1). After Milestone 2, General debugging is the most common request. We also see an obvious increase of TS Test Failure requests after Milestone 2 (Hypothesis 2).

In RQ3, we examined students' commits immediately prior to each help-request and define it as the pre-help commit. We firstly looked at how frequently students are making commits 1 hour before seeking help. Our analysis shows that the frequency of committing before an Implementation request is significantly lower and for TS Test Failures, it's significantly higher. Then, we analyzed where the students change their code right before the help request. We find that most students change their source code before Implementation requests and change their test code before Coverage-related requests.

Our current results shows student's coding behavior is quite predictable and it does change when they need different types of help. Instructor can use our conclusion as a start, and think about how to lead students to an efficient path when they encounter different types of difficulty throughout the projects.

7. LIMITATIONS AND FUTURE WORK

Our study only analyzed the data from a single CS2 course in a single offering. Additional analysis of future semesters and other courses would enhance our understanding of how stable these behaviors are across cohorts and projects. Additionally the quality of our analysis is limited by our post annotations. The high rate of disagreement for the Others/Unclear category was driven in part by how little information students included in their MDH requests. In future semesters we plan to address this problem by refining our analysis and addressing potential changes to the MDH platform to enforce more complex comments.

Additionally, our examination of the pre-help commits was focused on both general frequencies and gestalt features. In future studies we will conduct a more detailed analysis of the code status and align the contents of the help requests to specific code features and file locations. Finding such link of code features and request content would improve our understanding of when students seek help and potentially lead to an automotive model for detecting and predicting students who need help. Such a model would help instructors to actively and efficiently intervene student's behavior, and support a much effective help management for the course.

Besides the pre-help commits, we also plan to analyze changes that the students make to their code during and after help requests to get a better assessment of how they process and implement guidance. This work has long-term potential to guide automated feedback and to assist in general triage for help responses. For example, after we figure out an accurate way to measure the success of commits, we can combine it with this work and evaluate the effectiveness of each help-seeking interaction by monitoring when student make an successful commit after the help. The instructor can use this information to quickly identify which students need further guidance or analyze why the help is ineffective.

ABSTRACT

Peer assessment can be a more effective pedagogical method when reviewers provide quality feedback. But what makes feedback helpful to reviewees? Other studies have identified quality feedback as focusing on detecting problems, providing suggestions, or pointing out where changes need to be made. However, it is important to seek students’ perspectives on what makes a review helpful to a reviewee. This study explores the helpfulness of feedback from students’ perspectives when the feedback contained suggestions or mentioned problems or both. We applied natural language processing techniques to identify suggestions and problems mentioned in peer reviews. We also analyzed important text features that are associated with suggestions or problems detected by the peer feedback. The result showed that students are likely to find a review helpful if a suggestion is provided along with the problem mentioned in the feedback rather than simply identifying the problem.

Peer assessment, neural-network, natural language processing, correlation coefficient, suggestions

1. INTRODUCTION

Peer assessment has been proven to be an effective learning approach in both face-to-face and distance learning classes. It is especially useful in massive open online courses (MOOCs) where the potentially overwhelming number of students has no fixed bound. All of these students must be assessed by someone, and there are only a limited number of staff. Peer assessment can be as accurate instructor assessment, since artifacts are reviewed by multiple assessors who can invest more time than a teacher could [17]. It can also provide timely feedback [1] that helps students to focus on their weaknesses. Peer assessors pick up some of the feedback workload for instructors, who can then offer more help to students who are in need.

M. P. Rashid, Y. Xiao, and E. F. Gehringer. Going beyond “good job”: Analyzing helpful feedback from the student’s perspective. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 515–521, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

Peer assessors provide assessment in two forms. One is textual feedback, which takes the form of prose feedback to a peer. This is usually used as formative feedback. Another is numerical scores, on a Likert scale, which allows a summative grade to be calculated. Most online peer-assessment environments use both kinds of feedback. Studies have shown that students learn more from giving feedback than receiving it [13, 2, 7, 5] and giving feedback engage students in active learning [16]. It forces students to think metacognitively [4], and learn in-depth, as reviewing a peer requires a good hold on the topic [8].

However, the learning experience in a peer-review environment depends on the quality of reviews provided by the student peers. The goals of fairness and equity require that, insofar as possible, all students receive helpful formative feedback on their work. But, not all assessors provide constructive feedback, due to lack of knowledge in the topic or simply carelessness. To encourage and guide students in reviewing the artifacts, instructors typically need to scrutinize reviews manually. This consumes a good portion of the time that would be saved by having students provide quality feedback. An automated analysis could save considerable time.

A few studies [20, 19] have tried to lessen the instructors’ assessment burden by automatically detecting characteristics of a quality review. That raises the question of what defines a quality review. According to Nelson and Schunn [10] high-quality feedback consists of (i) identifying a problem and (ii) suggesting a solution. However, their finding was based on students’ performance and not from their (students’) perspective. It is important to identify whether “quality feedback” is actually helpful to the reviewees, based on students’ opinion of what feedback is helpful.

In this paper, we propose a method using natural language processing (NLP) and neural networks to automate the process of analyzing and classifying reviews to discover whether they contain suggestions and/or problems. We analyzed the words that are used to include suggestions or problems in feedback. Our goal is to answer the following research questions:

- **RQ1:** Can we build a model to accurately detect comments containing suggestions or detecting problems?
- **RQ2:** Are “quality comments”—those containing suggestions, detecting problems, or both—actually helpful from the student’s point of view?

- **RQ3: Can an automated process effectively identify helpful feedback?**

2. RELATED WORK

This section discusses related work on identifying the properties of a “quality“ or “helpful“ peer assessment.

Nelson and Schunn [10] examined five features of feedback (summarization, specificity, explanations, scope, and affective language) that constitute good-quality reviews, and the correlations among them. Their study divided the features of feedback into cognitive and affective components. According to their findings, summarization, specificity, explanations, and scope are cognitive in nature. Cognitive features of a review are expected to most strongly affect understanding. This explanation helped us to identify suggestions and problem detection as a property of quality feedback.

An approach to improve review quality is to provide the reviewer with a rubric defining the characteristics of a quality review. Jaco du Toit [3] conducted a study to identify the impact of peer review on essay assignments. The study showed that giving students a rubric describing the characteristics of a good essay can provide them with the insight to produce better quality assessments than they would otherwise produce. But this study did not specify the qualities of a good review. When they received poor reviews, they were confused about the quality of their work, sometimes feeling a false sense of accomplishment. Rashid et al [15] analyzed rubric items to determine which of them induce peer reviewers to write quality feedback using NLP approaches. In their work quality feedback was identified if the review text contained a suggestion, detected a problem problem, or was localized (pinpointing the place where a revision should be made).

McGrath and Taylor did a study on students’ perception of helpful feedback for writing performance [9]. Their study defined quality feedback (“developed feedback”) as clear, specific, and explanatory in nature. They measured students’ perception of developed feedback by having them rate the feedback on a Likert scale. The results showed that students rated developed feedback highly for helpfulness.

A survey of 44 students done by Weaver showed that, in order to use the feedback, students needed advice (suggestions)[18]. The analysis of the feedback content and students’ responses uncovered that vague feedback (e.g., “Good job”) is unhelpful, lacking in guidance (void of suggestions), or focused on the negative (mentioning only problems), or was unrelated to assessment criteria.

Ramachandran et al. [14], developed an automated system to evaluate reviews and show how they compared to other reviews for the same assignment. They extracted attributes like relevance to the submission, content, coverage, tone, and volume of feedback to identify a good-quality review. They constructed word-order graphs to compare the reviews with submission text and extract features from the reviews.

To identify localization and make suggestions to improve the review Nguyen et al. [11] applied natural language processing techniques. They provided real-time formative feedback

to reviewers on how to localize their review comments.

Zingle et al. [20] used neural-network approaches to find suggestions in the review text, and compared them against rule-based NLP approaches. In a similar work Xiao et al. [19] used NLP techniques with several ML and neural-network approaches to identify problem statements in review text. Our work takes this a step further and asks whether it is enough for a review to detect problems, or whether reviews that also make suggestions are more helpful.

3. DATA

Machine-learning and neural network-based models can perform as well or as badly as the data they are given. However, obtaining good labeled data is expensive. For the purpose of our experiment, we have collected labeled datasets for comments with three different characteristics:

- detects a problem: A review comment is labeled yes or no according to whether it detects a problem.
- contains a suggestion: A review comment is labeled yes or no according to whether it contains a suggestion.
- is helpful: A review comment is labeled yes or no depending on whether the reviewee found it helpful.

We acquired this labeled peer-review data from the Expertiza system in a systematic manner. Expertiza is a system to support different kinds of communications that are involved in the peer-assessment process. It supports double-blind communications between authors and reviewers, assessment of teammate contributions, and evaluations by course staff.

For the purpose of this study, we collected the data from Object-Oriented Design and Development course at NC State University for about three years. This course used the Expertiza system to manage the peer-review assessment process for evaluating the students. In each semester, this course typically assigns three peer-reviewed assignments to students, who work in teams consisting of two to four members. Even though the assignments are done in a group setting, the submissions are reviewed by individual students from other groups. After receiving the reviews from peers, teams revise their work and resubmit it for grading. The second round of the assessment is generally summative, where along with textual comments, the peer-reviewers assign scores to the submission.

Generally, a small number of people cannot annotate a large dataset. It is better to have a large number of people each undertake a small number of annotation tasks; this lessens the chance that an annotator will become fatigued and assign inaccurate labels. We engaged students in the labeling task by offering a small amount of extra credit. After receiving peer feedback, students were asked to label the feedback to identify whether the reviewer mentioned a problem or suggested a solution. They were also asked whether they considered the feedback to be helpful. In different assignments, students were asked to label the feedback for different characteristics; the same comments were not necessarily labeled for all three characteristics. After labeling was complete, the course instructor and TAs spot-checked the data

Table 1: Sample review comment and annotations done by students ('1' indicates 'yes' and '0' indicates 'no')

Review Comment	Detects Problem

Review Comment	Is Helpful
The build is failing due to 4 failures in the model specs.	1
The writeup is clear.	0
Since the build failed, I would not recommend adding it to the production server yet.	1

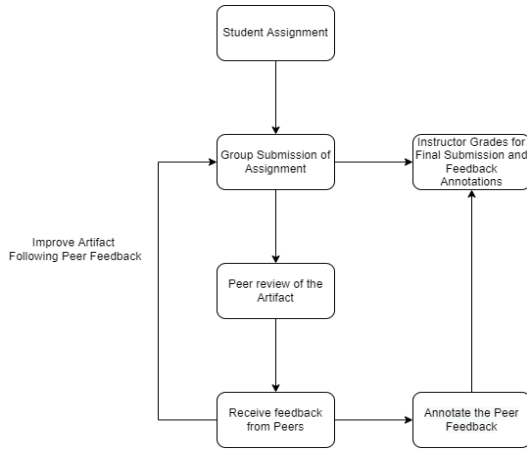

Figure 1: Flow diagram of peer review and feedback annotation process

that each student labeled. If any labels were found to be incorrect, the data labeled by that student was excluded from the dataset.

Since the reviews were done on team projects, and labeling was done individually, two to four students had the opportunity to label (or “tag”) the same review comments. If multiple students did tag the same comment, inter-rater reliability (IRR) could be calculated. We chose Krippendorff’s α [6] as the metric for IRR. We chose this metric because it is not impacted by missing ratings, which were common since not all students availed themselves of the extra-credit opportunity. In an effort to use only the most reliable labeling, we included only labels that were assigned (or not assigned) by all the students in the team that was reviewed. This allowed us to raise Krippendorff’s α of our dataset from 0.696 to 1. Figure 1 shows the peer-review and annotation process.

Following the described process we accumulated 18,392 annotations for problem detection, 7,416 for suggestion-detection and 3,970 for helpfulness-detection datasets. All the three datasets have an equal ratio of the binary class labels (i.e., they are balanced). Sample comments from the three datasets are shown in Table 1

4. METHOD

Our goal in this study is to analyze students’ perspectives on helpful comments that mentioned problems and/or suggestions. To conduct the study, we had students annotate comments on the basis of whether they found them helpful. We need an automated process to identify those review comments that contain suggestions and/or problem statements. We first train a model (the problem-detection model) to classify reviews that contain a problem statement by training and testing with the problem-detection dataset. We build a second model (the suggestion-detection model) to classify the presence of suggestions in a review comment by using the suggestion-detection dataset. As model performance matters, we applied several ML and neural-network models to pick the most accurate models for annotating the helpfulness-detection dataset. Figure 2 shows the annotation process of the helpfulness-dataset using the models.

When approaching a classification problem by any type of machine-learning (ML) or neural network models, there are many different approaches to choose from. No one model is best for all problems. In our study, we have chosen Support Vector Machine (SVM), Random forest (RF), classical ML models and compared their performance with Bi Directional Long Short-term Memory (Bi-LSTM), and Bidirectional Encoder Representations from Transformers (BERT) models. We used TF-IDF for ML models and Global Vectors for Word Representation (GloVe) for Bi-LSTM to perform word vectorization. Before we applied any word vectorization techniques, we cleaned the text by removing URLs, stop words, and applying stemming. We use our problem-detection dataset and suggestion-detection dataset on these model with 80:10:10 ratio for training, testing and validation.

4.1 Classical Machine-Learning Models

4.1.1 Input Embedding with TF-IDF

Machine-learning models are suitable for capturing complex relationships between the input data. But they require numeric input. The review data that we have in our dataset is textual. We have to convert them to numbers and also allow the model to capture the important features of the text. One way to do that is term frequency-inverse document frequency (TF-IDF). TF-IDF measures the importance of a word in a document using statistical calculation. If a word appears more times in a document the importance of the word in the document increases proportionally. We used

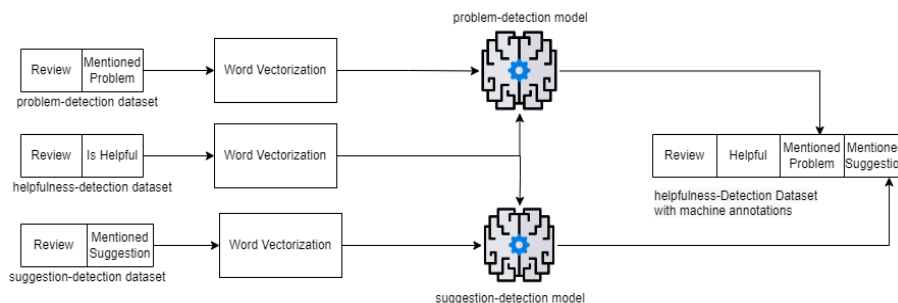

Figure 2: Annotation process of the helpfulness-dataset for mentioned problem and suggestions in the comments using models. The models were trained for detecting problems or suggestions mentioned in the review text. The training datasets were annotated by human (students).

scikit-learn [12] library to implement TF-IDF and vectorize the words in the feedback.

4.1.2 SVM

SVM is very popular for high accuracy and low computational cost. For a classification problem between two classes, SVM maximizes the margin of the separation plane between the two classes. We provided the feature vector of the reviews converted by TF-IDF to the SVM model to classify the review for having a particular property (contains problem or suggestion in the comment). We applied a grid search to find the best inverse regularization parameter C .

4.1.3 RF

We used Random Forest for its popularity to make more accurate classification with a simple approach. RF makes an ensemble decision from a forest consisting of multiple uncorrelated decision trees. The general idea of the RF is that the decision from individual decision trees increase the accuracy of overall result. We varied the number of decision trees and depth of the trees to get the best result. We used TF-IDF for making feature vectors from the review text.

4.2 Neural-Network Models

4.2.1 Input Embedding

Neural network models are popular for text classification tasks. However, to improve the performance of the neural-network models on the text data, it is necessary to represent the data that is suitable for the model to work with, and without losing the underlying latent relations among the features of the data. For our experiment we have used GloVe with Bi-LSTM. GloVe not only measures the statistical significance of words, it also considers the statistical co-occurrence and semantic relation of the words.

4.2.2 Bi-LSTM

Bi-Long Short-Term Memory is in general used for sequential data classification tasks. It is a good fit for peer-review texts. Review comments are sequential data, and the words of the text have latent semantic and contextual relations with each other. As Bi-LSTM model takes input from both right and left direction of the text, it can capture the relationship between the words in texts occurring in any order.

Table 2: Hyperparameters of Models

Model	Hyperparameter
SVM	$c=1$
RF	tree = 100 max depth = 4
Bi-LSTM	maximum text length = 300 Embedding = 300d Hidden layer activation = ReLu dropout = 0.4 optimizer = Adam Output layer activation = Sigmoid Epoch=20
BERT	optimizer = AdamW Learning rate = $2e-5$ Epoch=4

4.2.3 BERT

BERT is based on Transformer model and use attention mechanism to learn the contextual relations of the words in a sentence. Being a bi-directional input reader, BERT learns the context of word in sentence by considering words occurring before and after.

5. RESULTS

In this study, if a feedback comment mentions problems and/or suggestions, we are considering it to be quality feedback. Our first step is to construct two separate models where one identifies whether feedback contains a problem statement and another identifies whether feedback contains a suggestion. To identify the best-performing models we trained and tested the performance of several classical ML models and neural-network models and compared their performance.

RQ1: Can we build a model to accurately detect comments containing suggestions or detecting problems?

Figure 3 reports the comparison of the F1-score values of the classical machine-learning (ML) models and neural-network models on the problem-detection dataset and suggestion-detection dataset. To compare the performance of the models we use the F1-score, as this represents the harmonic mean of precision and recall.

- **On the problem-detection dataset:** Among the classical

Figure 3: F1-score comparison to measure performance on classifying review text on problem detection and suggestion detection using classical ML and neural-network models. In overall F1-score comparison, the BERT model shows the best performance.

ML models SVM made the highest f1-score 0.90 and among the neural-network models; BERT obtains the overall highest F1-score, 0.92.

- **On the suggestion-detection dataset:** BERT achieved the highest F1-score, 0.91. Among the classical ML models, SVM achieved the highest F1-score, 0.87.

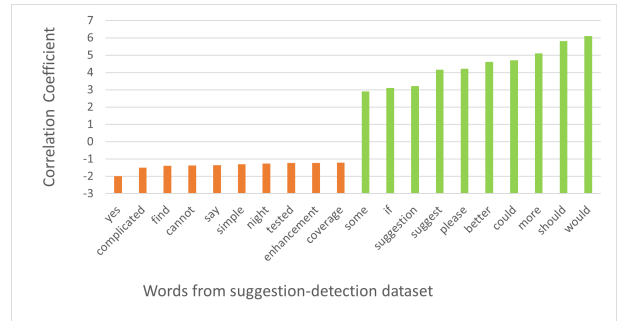

To gain a deeper insight into the words that are highly correlated with text where a problem mention or suggestion is mentioned, we analyzed the top 10 positive and negative correlation coefficient values calculated by the SVM model. Figure 4(a) shows the coefficient values that the problem-detection model has calculated for various words. Note that it has positive coefficient values for words such as “however”, “but”, and “not”. In the English language these words are more likely to be used when stating problems. Similarly words like “yes”, “completed” and “good” are not likely to occur in a problem statement. Figure 4(b) shows that the suggestion-detection model has positive coefficient values for words like “should”, “would”, “more”, “suggest”. These words are likely to be used in suggestions. On the other hand, words “yes”, “completed”, and “cannot” are more likely not to be used to express suggestions; thus they have negative coefficient values.

As BERT outperformed all other models on both problem and suggestion datasets, we trained two separate BERT models to annotate the feedback comments contained in the helpfulness-detection dataset. The BERT-created annotations recorded whether each comment in the helpfulness-detection dataset detected a problem or offered a suggestion. The models annotated each comment with either “1” or “0”, indicating having the property or not. We perform an **and**-operation using the BERT-created annotations. If both the problem and suggestion were mentioned in a comment the **and**-operation yields 1 otherwise 0. The resulting helpfulness-detection dataset is shown in Table 3.

RQ2: Are “quality comments”—those containing suggestions, detecting problems, or both—actually helpful from the stu-

(a)

Figure 5: Venn diagram of helpful feedback annotated for mentioned suggestion and/or problem

Table 3: Table shows sample comments from helpfulness-detection dataset and corresponding annotations. Note that “Is Helpful” annotations are done by humans (students), while “Detects Problem” and “Gives Suggestion” are annotated by the BERT model. “Contains Problem and Suggestion” is from **anding** the “Detects Problem” and “Gives Suggestion” columns.

Review Comment	Is Helpful (human-annotated)	Detects Problem (machine-annotated)	Gives Suggestion (machine-annotated)	Contains Problem and Suggestion (and-operation)
The build is failing due to 4 failures in the model specs.	1	1	0	0
The writeup is clear.	0	0	0	0
Since the build failed, I would not recommend adding it to the production server yet.	1	1	1	1
I would recommend adding more code for helping following their changes.	1	0	1	0

dent’s point of view?

After we computed the annotations for problem detection and suggestions, we did a Venn diagram analysis on the updated helpfulness-detection dataset. The diagrams illustrate the overlap of comments that both detect a problem and offer a suggestion. Figure 5(c) shows that 1,985 comments in the helpfulness-detection dataset were annotated by students as being helpful. Among the helpful comments, 1,417 were annotated for having problems and/or suggestions mentioned in the feedback. Out of these 1,417 helpful comments, 912 of them were machine-annotated as containing both problem detection and suggestions. A total of 568 helpful comments did not have any problem or suggestion mentioned, based on machine-annotation.

On the other hand, out of the 1,985 comments that were human-annotated as not helpful [Figure 5(d)], 673 comments were annotated as having either a problem and/or suggestion mentioned. Among those 673 comments, only 174 were annotated as having both suggestion and problem mentioned. A total of 1,312 comments that did not have any problem or suggestion mentioned were annotated as not helpful by the students.

To summarize the Venn diagram analysis, comments that the students found helpful mostly detected problems and/or contained suggestions. However, among those comments noting suggestions and/or problems, students annotated as helpful mostly comments that *both* pointed out problems and gave suggestions. This indicates that peer feedback is more helpful to the students when a suggestion is given in a comment that detects a problem. On the flip side, Figure 5(b) suggests that students rarely find comments helpful when they do not mention any problem or contain a suggestion.

RQ3: Can an automated process effectively identify helpful feedback?

A key question is whether comments automatically annotated as “quality” (meaning that they both identified a problem and gave a suggestion) were the same comments that the students considered helpful (that they manually labeled as helpful). Among the comments that the students considered helpful, 64% of them both mentioned a problem and gave a suggestion. Conversely, of the comments that the students labeled as not helpful, 66% of them neither mentioned a problem nor contained a suggestion.

The results indicate that the automated annotation per-

formed by the BERT model can be very effective in predicting which comments students will consider helpful. While it can’t deliver an actual count of helpful comments in a particular review, that is not important. It *can* determine whether the feedback provided by the reviewer contains a substantial number of quality comments. That is what is needed to automatically detect helpful reviews.

6. CONCLUSION

This study constitutes the first analysis of the helpfulness of peer-assessment feedback from student’s perspective. Feedback that mentions problems or includes suggested changes was considered to be quality feedback. We used natural language processing (NLP) techniques in conjunction with several ML and neural networks to identify quality peer feedback. We systematically collected and scrutinized 18,392 comments mentioning problems, 7,416 comments containing suggestions, and 3,970 comments that were annotated by humans (students) as being helpful.

Using the annotated dataset, we trained our ML and neural-network models to identify quality feedback. For identifying suggestions and problems mentioned in the review text, the BERT model outperformed the other models. As the BERT model focuses on the important features of the text, it was best at identifying suggestions and problems in the feedback. We used the BERT model to automatically annotate comments as mentioning problems or making suggestions, and compared these annotations with comments that students had manually annotated as being helpful. We also analyzed important words that are frequently present in comments mentioned a problem or suggestion.

A key finding of this study is that the students find review comments more helpful when peer reviewers both mention problems in the reviewed artifact and provide suggestions on how to resolve the issue. We can use a state-of-the-art BERT model to automatically identify the helpful review comments.

It should not be hit-or-miss whether students receive helpful reviews on their submitted work from peer reviewers. This study helps identify helpful feedback and therefore, help students to improve their work.

The AI Teacher Test: Measuring the Pedagogical Ability of Blender and GPT-3 in Educational Dialogues

Anaïs Tack
Stanford University
atack@cs.stanford.edu

Stanford University
piech@cs.stanford.edu

ABSTRACT

How can we test whether state-of-the-art generative models, such as Blender and GPT-3, are good AI teachers, capable of replying to a student in an educational dialogue? Designing an AI teacher test is challenging: although evaluation methods are much-needed, there is no off-the-shelf solution to measuring pedagogical ability. This paper reports on a first attempt at an AI teacher test. We built a solution around the insight that you can run conversational agents in parallel to human teachers in real-world dialogues, simulate how different agents would respond to a student, and compare these counterpart responses in terms of three abilities: speak like a teacher, understand a student, help a student. Our method builds on the reliability of comparative judgments in education and uses a probabilistic model and Bayesian sampling to infer estimates of pedagogical ability. We find that, even though conversational agents (Blender in particular) perform well on conversational uptake, they are quantifiably worse than real teachers on several pedagogical dimensions, especially with regard to helpfulness (Blender: Δ ability = -0.75 ; GPT-3: Δ ability = -0.93).

Keywords

student-teacher dialogue, conversational agents, chatbots, Blender, GPT-3, evaluation methods, pairwise comparisons, Bayesian Bradley-Terry model

1. INTRODUCTION

Conversational agents (or chatbots) offer promising opportunities for education. They can fulfill various roles (such as intelligent tutors and service-oriented assistants) and pursue different objectives (e.g., improving student skills, boosting student motivation, and increasing instructional efficiency) [20]. Among all of these different vocations of an educational chatbot, the most prevalent one is the AI teacher helping a student with skill improvement and providing more opportunities to practice. Some recent meta-analyses have even reported a significant effect of chatbots on skill im-

provement, for example in language learning [1]. What is more, current advances in AI and natural language processing have led to the development of conversational agents that are founded on more powerful generative language models. Blender [17], for instance, is a state-of-the-art open-domain chatbot trained to blend skills such as being empathetic and knowledgeable [18], which are undeniably important characteristics of a good AI teacher. Furthermore, the current state-of-the-art in natural language generation is GPT-3 [4], a 175B-parameter model that is able to multitask different language generation skills (such as conversation). The astonishing power of GPT-3 is that it can perform these skills with few-shot in-context learning, merely from seeing a short prompt describing the task at hand (e.g., *The following is a conversation with an AI assistant.*). Emergent models such as GPT-3 have been described as *foundation models* since they serve as the “common basis from which many task-specific models are built via adaptation” [2, p.7].

Despite these promising opportunities, the use of powerful generative models as a foundation for downstream tasks also presents several crucial challenges. In the educational domain in particular, it is important to ascertain whether that foundation is solid or flimsy. Bommasani et al. [2, pp.67-72] stressed that, if we want to put these models into practice as AI teachers, it is imperative to determine whether they can (a) speak to students like a teacher, (b) understand students, and (c) help students improve their understanding. Consequently, there is a critical need to establish good evaluation methods of AI teachers. This is a hard problem because there is no off-the-shelf and universal solution to measuring teaching ability and effectiveness.

Therefore, we took on the challenge of designing an AI teacher test and conducted a pilot study. We ran Blender and GPT-3 in parallel to human teachers in language and mathematics educational dialogues, observed how they responded to a student, and compared these counterpart responses in terms of pedagogical ability. The major contributions of this work are as follows:

1. We pose the AI Teacher Test Challenge.
2. We implement a human-in-the-loop pairwise comparison test as a first attempt at an AI Teacher Test.
3. Our results show quantitatively how far conversational agents, particularly Blender and GPT-3, are behind human teachers in terms of pedagogical ability, despite them performing well on conversational uptake.

Our solution has several strengths: (1) it leverages the proven reliability of comparative judgments in education [10, 12], (2) it incorporates a Bayesian sampling method that allows us to attribute an ability score to a teacher response, whilst ensuring normality and providing a belief in our estimates, and (3) it produces scores and ranks that could be used to develop autonomous methods. We open-source our work, code, and data.¹

2. THE AI TEACHER TEST CHALLENGE

Consider the following scenario, which is illustrated in Figure 1. Two agents, a student and a teacher, are interacting in an educational setting. The student is working to improve a specific skill (e.g., the use of phrasal verbs) in a given domain (e.g., English language). The teacher could be either a human agent or an artificial agent who is helping the student with improving this skill. The student and teacher each take turns, resulting in a sequence of student-teacher dialogic pairs. This student-teacher dialogue is open-ended: for a given student utterance, there exists a variety of ways in which we could imagine a teacher agent to respond. For example, Figure 1 shows three possible replies to a student utterance: the actual teacher’s response and two completions that were automatically generated from a state-of-the-art language model. It is clear to see that, in the space of possible replies, not all responses will be equally preferable. Some responses may be more characteristic of a teacher, some may be taking up more from the student’s utterance, and some may be more helpful. In this scenario, we are interested in the following challenge: given a space of possible responses (either human or artificially generated), evaluate a reply in terms of pedagogical ability and estimate this score relative to other replies.

2.1 Desiderata

We think that a good AI teacher test should at least account for the following aspects. Firstly, the test should be able to evaluate a teacher agent’s response in context. At minimum, the test should consider the preceding student utterance. Additionally, the test could also take into consideration the entire preceding dialogue and surrounding educational setting. Secondly, the test should be able to score the agent’s response with respect to several pedagogical abilities. Following Bommasani et al. [2, pp.67-72], we believe that the test should consider the following three abilities: whether the agent can speak like a teacher, understand the student, and help the student. Finally, the test should also be able to consider other possibilities (which may be better or worse) and rank the teacher’s response in comparison to these. In this way, the test could also be used to suggest one or more ways in which a response could be enhanced in terms of the three abilities listed above.

Unfortunately, standard methods of evaluating automatically generated language and conversational agents do not meet our desiderata. Perplexity, for example, measures how well a generative model is able to sample a given response from its probability distribution. However, it does not consider the preceding utterance (desideratum #1). Other metrics such as BLEU and F1 score measure the n-gram overlap between a generated response and a correct response. By

¹<https://github.com/anaistack/ai-teacher-test>

The following is a conversation between a student and a teacher working on a language exercise.

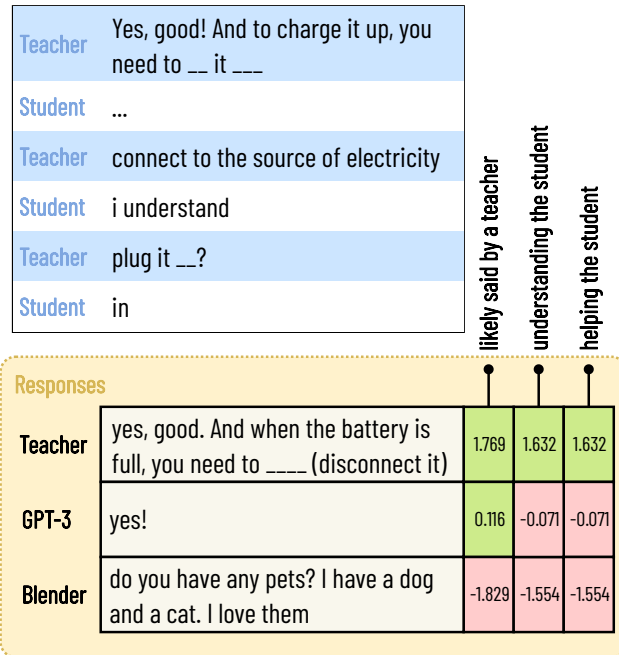

Figure 1: Illustration of the AI Teacher Test Challenge: Estimates of Pedagogical Ability and Rankings of Human and AI Teachers Replying to a Student in an Educational Dialogue

contrast, our test is open-ended (see above) and does not presuppose the existence of a correct response. Recently, Pillutla et al. [15] introduced MAUVE, an evaluation metric for open-ended language generation. Because this metric uses the Kullback–Leibler divergence, it cannot be used to compare two specific language utterances (desideratum #3). Most importantly, none of these methods meet our second desideratum, which is to score an agent’s response with respect to several pedagogical abilities.

2.2 Related Work

We can gain insight into measuring pedagogical ability from prior work into assessing human teachers. Educational research is abundant in methods for evaluating teacher effectiveness, ranging from teacher self-reports and interviews to classroom observations, student evaluation surveys, and tests of student achievement [9, 14]. However, not all of these methods seem easily applicable to assessing AI teachers. It is obvious that evaluating AI teacher effectiveness from self-reports and interviews would be a difficult thing to do. We could, however, resort to systematic observations of AI teachers, human evaluation surveys, and measures of student outcome.

Other studies have focused on the possibility of measuring ability in teacher language. Demzky et al. [6], for instance, examined several ways of determining how well a teacher replies to a student in student-teacher interactions. Their data comprised 2,246 student-teacher dialogic pairs taken from the National Center for Teacher Effectiveness Main

Study (NCTE)², a three-year long observation of mathematics instruction. First, they collected human evaluations of *conversational uptake*, a measure of how well the teacher’s reply expanded on the student’s utterance (e.g., by acknowledging, reformulating, elaborating), as illustrated below.

Student: Seven plus seven is fourteen.
Teacher: Okay, so you doubled. You did your doubles first. Okay. Fourteen plus eight?
(Uptake = high)

Besides human evaluations of uptake, Demszky et al. [6] also developed an automated method that could predict uptake as a next-utterance classification task. They fine-tuned a BERT language model [7] and found a significant correlation ($\rho = .54$) with human evaluations.

This automated measure of conversational uptake can serve as a solid baseline for our study. First, the next-utterance classification predicts uptake based on the preceding student utterance and, therefore, meets our first desideratum. Second, conversational uptake also somehow measures whether a speaker understands the interlocutor. If a teacher’s response strongly expands on the student’s utterance (i.e., high uptake), it can be deduced that the teacher was able to understand the student. As such, it measures one of the three pedagogical abilities targeted in our second desideratum. Finally, because we can run the predictive model on different responses to the same student utterance and compare these responses in terms of uptake, the measure meets our third and final desideratum.

3. OUR AI TEACHER TEST

As a possible solution to the AI teacher challenge described in Section 2, we adopted the following method. First, we ran Blender and GPT-3 on real-world educational dialogues and simulated responses to student utterances. We then paid human raters to compare pairs of responses on several different pedagogical dimensions. Finally, we ran a probabilistic model to compute aggregate scores. In addition, we also ran the model developed by Demszky et al. [6] on our data in order to compare our scores to predictions of uptake.

3.1 Student-Teacher Dialogues

Table 1: Datasets of Student-Teacher Interactions

Domain	Dataset	Dialogues	Dialogic Pairs
Language	TSCC [5]	102	4439
Mathematics	Uptake [6]	0	2246

The two datasets used in this study are listed in Table 1. The *Educational Uptake Dataset* compiled by Demszky et al. [6] includes 2,246 dialogic pairs sampled from the NCTE transcripts (see Section 2.2). The complete dialogue transcripts, however, have not yet been made available. The *Teacher-Student Chatroom Corpus (TSCC)* compiled by Caines et al. [5] includes 102 anonymized student-teacher dialogues in second language education. Each chatroom is a lesson where a teacher converses with a student in order to work on a language exercise and assess the student’s English

²<https://doi.org/10.3886/ICPSR36095.v3>

language proficiency. The corpus includes 13,215 turns and 130 turns on average per dialogue. Each utterance is annotated with several metadata, including conversational organization (e.g., opening, closing, eliciting, scaffolding, and revision) and teaching focus (e.g., vocabulary). Figure 1 shows an example excerpt of a teacher’s eliciting, scaffolding, and revision. It should be noted, however, that the TSCC dialogues include many consecutive utterances by either the student or the teacher. Therefore, the data were slightly adapted for this study: all successive utterances by the same speaker were concatenated into one turn such that each conversation was composed of alternating dialogic pairs. As a result, the data included 4,439 student-teacher pairs.

3.2 Simulating Agent Responses

For each dialogic pair in the student-teacher dialogues, we automatically generated AI teacher responses. We used the ParLAI framework [13] to load the student-teacher dialogues, to generate responses to each student utterance, and to compute several standard evaluation metrics. In this study, we focused on two models. We ran several Blender models (90M, 400M, 3B, 9B parameters) on the language (TSCC) and mathematics (Uptake) educational dialogues. We implemented a new agent that made requests to the OpenAI API in order to obtain generated responses for each student utterance. Each request included a mandatory prompt with instructions for GPT-3 (*The following is a conversation with a teacher. The teacher is polite, helpful, professional, on topic, and factually correct.*), the preceding dialogue history (restricted to meet the maximum number of tokens per request), and the student’s utterance. We obtained completions from the smallest (Ada) and largest (Davinci) models.

3.3 Measuring Pedagogical Ability

After collecting AI teacher responses in educational dialogues, we collected evaluations of pedagogical ability via an online survey. First, participants were given a short introduction and a consent form. Then, participants were given the same example to familiarize themselves with the task at hand. In the following comparative judgment task (Figure 2), 15 items were randomly and evenly selected from a pool of relevant items. Each item had three components: a dialogue context (limited to 100 tokens), one comparison of two teacher replies, and three questions targeting a pedagogical ability (speak like a teacher, understand the student, and help the student). For each participant, one pairwise comparison was randomly selected from three possible combinations (Teacher vs. Blender, Teacher vs. GPT-3, or Blender vs. GPT-3) and the order of the comparative pair was randomly shuffled.

Item Selection. A crucial challenge in the evaluation process was to pinpoint those teacher utterances that were important to evaluate. In the student-teacher dialogues described in Section 3.1, not all teacher utterances were necessarily relevant. In fact, many conversational turns were not pertaining to any educational goal, such as opening sequences, closing sequences, and other chit-chat. From the 6,685 eligible dialogic pairs, only those utterances were selected where the teacher was actually eliciting and scaffolding the student’s understanding. Additionally, short utterances that comprised of single words or sentence fragments

The following is a conversation between a student and a teacher working on a math problem.

Student: Can I take a calculator?

Imagine the teacher replies with either one of the following answers.

A	B
Teacher: Yes. You can take anything you need. Just make sure you bring it back. Go ahead. Pack it up.	Teacher: Of course you can. You can use it to calculate the amount of time you have left to live.

Which of these replies is **more likely said by a teacher**?

A B I cannot tell

In which reply is the teacher **understanding the student more**?

A B I cannot tell

In which reply is the teacher **helping the student more**?

A B I cannot tell

Figure 2: Screenshot of the Comparative Judgment Task

(e.g., *Perfect!, Yay!*) were also excluded.³ Furthermore, the results of a pilot study with eight evaluators highlighted that the dialogic pairs taken from the Uptake dataset were difficult to evaluate because there was no informative context. Consequently, we focused only on the TSCC dataset for the comparative judgment task, carefully screened the corpus for relevant items and informative dialogue contexts, and ended up with a sample of 52 items.

Participants. We recruited a sample of 120 participants from Prolific Academic, a crowdsourcing platform developed at Oxford University. Participants were prescreened to ensure a balanced gender representation (50% female, 50% male). Study participants were aged 19 to 66 ($M = 33$, $SD = 11.3$; female: $M = 32.4$, $SD = 10.9$; male: $M = 33.5$, $SD = 11.7$) and resided in the United Kingdom ($n = 86$) or the United States ($n = 34$). On average, participants had an excellent Prolific score of 99.2% ($SD = 1.4$; female: $M = 99.1$, $SD = 1.6$; male: $M = 99.3$, $SD = 1.3$) and took 18 minutes to complete the survey ($SD = 11.2$; female: $M = 18.9$, $SD = 11.1$; male: $M = 17.3$, $SD = 11.4$). Because the tasks required a fair amount of cognitive involvement (reading the dialogue, reading different replies, comparing different options), we estimated that the survey would take about 30 minutes. We then used the default payment rate of £7.50/h. Participants were paid according to estimated study completion time (£3.75 for 30 minutes).

Agreement. There was a high observed agreement between evaluators on the example given before the comparative judgment task (Figure 2). Most agreed that option A (the true teacher response) was *more likely said by a teacher* (95%), *understanding the student more* (83%), and *helping the student more* (86%).

³It should be noted that this exclusion criterion did not apply to the generated responses. As shown in Figure 1, some generated responses comprised of single words or sentence fragments (e.g., *yes!*). Although this could be seen as giving an advantage to the teacher responses, it was only meant to focus our test on more expressive teacher language. In a future study, we might try to capture the full range of teacher language, from single words to complex utterances.

Outlier Detection. To detect potential outliers among the evaluators, we identified those who consistently chose option A or B in the paired comparisons. This first-position (or “home-field” advantage) effect was detected by estimating an intercept parameter α_0 in the model described below. However, instead of estimating different α parameters for each teacher response (combining the scores of all evaluators), we reversed the method and computed different α parameters for each evaluator (combining the scores for all items evaluated by the evaluator). Evaluators were excluded when the credible interval around the intercept was above or below zero, which indicated that they were biased towards selecting either option A (CI above zero) or option B (CI below zero). Based on this outlier detection method, the data from seven evaluators were removed. The remaining data included 4,782 comparisons from 113 evaluators and 10.9 evaluations on average for each pair (Teacher vs. Blender, Teacher vs. GPT-3, or Blender vs. GPT-3).

Bayesian Bradley-Terry Model. A Bradley-Terry model [3] is a probabilistic model that predicts the outcome of one or more pairwise comparisons. Consider n items (i.e., a student utterance and preceding dialogue), a set of t possible responses (i.e., Teacher, Blender, GPT-3) to each item, and a set of m abilities (i.e., speak like a teacher, understand the student, help the student). For each item $l \in [n]$ and for each ability $k \in [m]$, we inferred a latent parameter α_{ikl} for each possible teacher response $i \in [t]$. The outcome y_{ijkl} was an independent Bernoulli variable with a parameter $p_{ijkl} \in [0, 1]$ measuring the chance that, for an item l and an ability k , teacher response i would be preferred over teacher response j , for all $i, j \in [t]$ and $i \neq j$. This probability was defined as

$$p_{ijkl} := \sigma(\alpha_{ikl} - \alpha_{jkl}) \Rightarrow \log \frac{p_{ijkl}}{1 - p_{ijkl}} = \alpha_{ikl} - \alpha_{jkl} \quad (1)$$

where σ is the logistic function $\sigma(x) = \frac{1}{1 + e^{-x}}$ and α_i, α_j are the latent parameters that measure the strengths of i and j respectively. In case of ties (the *I cannot tell* option), the outcome was picked uniformly at random. We used an extended version of the basic Bradley-Terry model including an intercept parameter $\alpha_0 \in \mathbb{R}$, which measures a “home-field” advantage.

$$p_{ijkl} := \sigma(\alpha_{0kl} + \alpha_{ikl} - \alpha_{jkl}) \quad (2)$$

If $\alpha_0 > 0$, there was a greater chance that the evaluator would pick the first element in the comparison. If $\alpha_0 = 0$, there was no order effect. To infer the latent parameters $\vec{\alpha}_{kl} = (\alpha_{0kl}, \dots, \alpha_{tkl})$, we adopted a Bayesian approach by drawing samples from the posterior $p(\alpha|y) \propto p(y|\alpha)p(\alpha)$ with a non-conjugate prior distribution, $\alpha \sim \mathcal{N}(0, 1)$. We used Stan [19, 16] to compute posterior means and 95% HDI (Highest Density Interval) credible intervals from 4,000 simulations using Hamiltonian Monte Carlo (HMC) sampling [8] and the NUTS (No-U-Turn Sampler) algorithm [11]. For each simulation, the estimated ability parameters were used to rank each response on each item and for each ability.

4. RESULTS

4.1 Baseline: Conversational Uptake

We start our analyses with a comparison of conversational uptake in human and AI teacher responses, for the two student-teacher dialogue datasets presented in Section 3.1.

Figure 3: Predicted Uptake of Human and AI Teacher Responses in Language and Math Educational Dialogues

Figure 4: Associations Between Generative Performance (Model Perplexity, F1 Unigram Overlap) and True Teacher Uptake (Z-Score) in Mathematics Educational Dialogues

Figure 3 shows the predicted uptake for the smallest and largest Blender and GPT-3 models, compared to the actual teacher’s responses. The results show that the largest Blender model (with 9B parameters) outperformed all others for both the language (TSCC) and mathematics (Uptake) educational dialogues. This suggests that Blender tended to generate better next utterances to student utterances.

Figure 4 zooms in on the AI teacher responses in the mathematics educational dialogues. Several correlation analyses were run to examine the association between generative performance (perplexity and F1 score) and the human annotations of teacher uptake collected by Demszky et al. [6]. Perplexity (lower is better) indicates how well the model can generate a linguistic utterance from its probability distribution, whereas F1 score (higher is better) indicates the unigram overlap between the generated response and the teacher’s response. There was a negative, statistically significant, and large correlation between model perplexity and true teacher uptake, as measured by Pearson’s product-moment correlation coefficient, $r = -0.31$, 95% CI [-0.34, -0.26], $t(1996) = -14.32$, $p < .001$. Similarly, there was a positive, statistically significant, and small correlation between F1 unigram overlap and true teacher uptake, $r = 0.16$, 95% CI [0.12, 0.20], $t(1996) = 7.35$, $p < .001$. In other words, Blender tended to generate better responses in cases where the actual teacher was also judged to have given a better response (more uptake). Moreover, this association

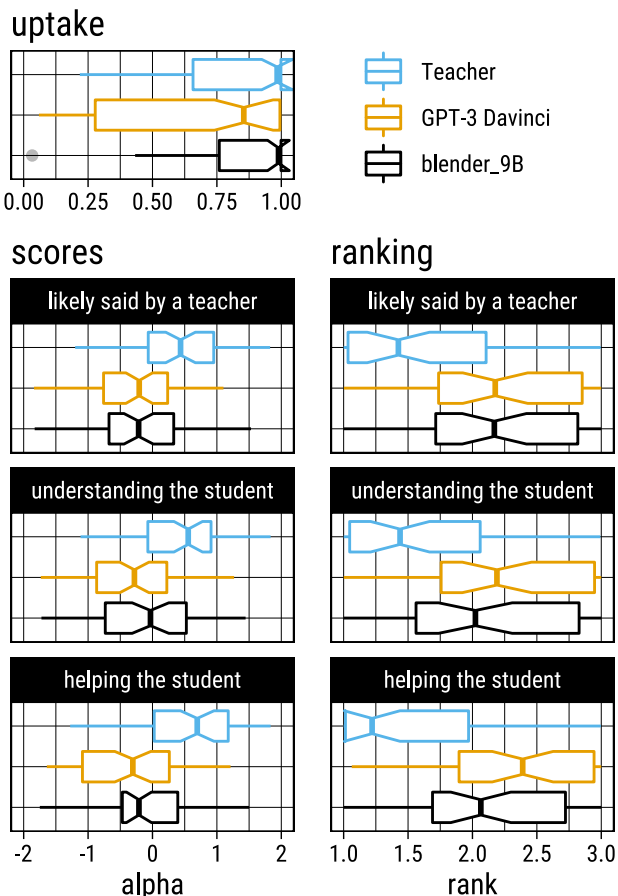

Figure 5: Bayesian Estimates and Rankings of Pedagogical Ability in Replying to a Student in an Educational Dialogue, Compared to Predictions of Conversational Uptake

between generative performance and teacher uptake was observed for all Blender and GPT-3 models (see Figure 4). These findings suggest that some student utterances may be simply easier to reply to, for both human and AI teachers.

4.2 Our Test: Pedagogical Ability

We now focus all following analyses on the selection of teacher responses that were compared in terms of pedagogical ability. Figure 5 shows a boxplot of the expected values of α (and associated rankings) for each possible response to a student utterance on the three pedagogical dimensions. The figure also compares these scores to predictions of conversational uptake. In terms of conversational uptake, the results showed no significant differences between human and AI teachers, as indicated by the overlapping notches in the boxplot. In terms of pedagogical ability, however, a one-way ANOVA revealed a statistically significant difference between human teachers and AI teachers on the three dimensions cited above, $F(2, 144) = 13.1$, $p < .001$, $F(2, 144) = 11.8$, $p < .001$, $F(2, 144) = 22.3$, $p < .001$, respectively.⁴ Tukey’s HSD post hoc test for multiple comparisons showed that, compared to the actual teacher, the mean

⁴A Shapiro-Wilk test showed that the assumption of normality was not violated for any of the three pedagogical

Table 2: Pearson Correlations Between Uptake and Ability

	r	t	df	p
likely said by a teacher	.35	3.47	85	<.001
understanding the student	.38	3.82	85	<.001
helping the student	.33	3.27	85	.002

Table 3: Percentage of Replies with a Positive Ability or where the 95% CI Excludes Zero (Either Above or Below)

Agent	Ability	$\alpha > 0$	$0 \notin \text{CI}$
Teacher	speak like a teacher	69%	8%
Teacher	understand the student	71%	6%
Teacher	help the student	78%	14%
Blender 9B	speak like a teacher	41%	6%
Blender 9B	understand the student	45%	10%
Blender 9B	help the student	35%	8%
GPT-3 Dav.	speak like a teacher	35%	6%
GPT-3 Dav.	understand the student	35%	2%
GPT-3 Dav.	help the student	33%	12%

ability of Blender was significantly lower for speaking like a teacher ($\Delta \alpha = -0.60$, [95CI $-0.93, -0.26$], $p < .001$), understanding the student ($\Delta \alpha = -0.55$, [95CI $-0.90, -0.20$], $p < .001$), and helping the student ($\Delta \alpha = -0.75$, [95CI $-1.10, -0.40$], $p < .001$). Similarly, compared to the actual teacher, the mean ability of GPT-3 was significantly lower for speaking like a teacher ($\Delta \alpha = -0.67$, [95CI $-1.00, -0.33$], $p < .001$), understanding the student ($\Delta \alpha = -0.67$, [95CI $-1.02, -0.32$], $p < .001$), and helping the student ($\Delta \alpha = -0.93$, [95CI $-1.28, -0.58$], $p < .001$). As for Blender and GPT-3, there was no statistically significant difference between the two when it came to speaking like a teacher ($\Delta \alpha = 0.071$, $p = .41$). Overall, Blender seemed better at understanding ($\Delta \alpha = +0.12$) and helping ($\Delta \alpha = +0.18$) the student but these differences were not significant ($p = .47$, $p = .53$, respectively).

Table 2 shows that our estimates of pedagogical ability were significantly correlated with conversational uptake. Interestingly, the highest correlation was observed for the ability of understanding the student. This result was not surprising: as previously noted in Section 2.2, uptake also somehow measures whether a speaker understands the interlocutor.

Finally, we examined the pedagogical ability of human and AI teachers on a per-item basis. Table 3 shows the percentage of teacher replies for which the expected value of α was positive. For 69-78% of dialogue contexts, the actual teacher’s response was positively evaluated and, therefore, highly ranked. For helpfulness in particular, 78% of human teacher responses were positively evaluated. There was also a higher percentage (14%) of certainty in the estimates of helpfulness. Nevertheless, there were many cases (22-31% of dialogue contexts) where the actual teacher’s response was negatively evaluated as well as cases (33-45%) where artificially generated responses were positively evaluated. The following example illustrates a case where the response generated by Blender was largely preferred over the

dimensions, $W = 0.99$, $p = 0.76$, $W = 0.99$, $p = 0.19$, $W = 0.99$, $p = 0.15$, respectively.

actual teacher’s response.

Teacher:	People are looking forward to it = there is a lot of ... ?
Student:	excitement
#1 Blender:	Excitement is a good one! People are very excited about it. Do you have any more? - likely said by a teacher = 1.52 - understanding the student = 1.32 - helping the student = 1.52
#2 Teacher:	ok good! Coronavirus has caused a lot of ... among the population. - likely said by a teacher = -0.90 - understanding the student = -0.57 - helping the student = -0.61
#3 GPT-3:	excitement about the next World Cup... - likely said by a teacher = -0.61 - understanding the student = -0.60 - helping the student = -0.90

5. CONCLUDING DISCUSSION

How well are state-of-the-art conversational agents, such as Blender and GPT-3, capable of replying to a student in an educational dialogue? When it comes to uptaking from and expanding on a student’s utterance, Blender comes out on top, outperforming the actual teacher and GPT-3. Based on the results of our AI teacher test, we come to similar conclusions. Although our test does not corroborate that Blender can actually outperform a human teacher, there is nevertheless a closer gap with human performance when it comes to understanding the student. Blender scores noticeably better on this specific pedagogical dimension, with a higher percentage of positively evaluated responses. These findings may be attributed to Blender’s particular training objective, namely blended skill talk. By learning to be more empathetic, Blender might be incidentally learning to take up more from and be more understanding of its interlocutor. By contrast, the results of our AI teacher test show that GPT-3 performs quantifiably worse than Blender and significantly worse than real teachers on all measured abilities, despite its proven capacity for few-shot in-context learning. What is more, both Blender and GPT-3 are well behind human performance when it comes to helping the student.

A secondary finding of our AI teacher test is that not all human teacher responses are necessarily positively evaluated. Even though the AI teacher responses generally fall short regarding pedagogical ability, we could still leverage generated responses as a means of sampling and recommending potentially better responses.

The solution proposed in this paper is surely not a perfect test, but it is a first step towards building much-needed evaluation methods.

6. ACKNOWLEDGMENTS

This research was supported by a fellowship of the Belgian American Educational Foundation (to the first author) and by a grant from Stanford HAI. We thank Andrew Caines, Dora Demszky, Noah Goodman, and our colleagues for their valuable help and suggestions. We thank all anonymous reviewers for their insights that improved the paper.

ABSTRACT

Learning objectives, especially those well defined by applying Bloom's taxonomy for Cognitive Objectives, have been widely recognized as important in various teaching and learning practices. However, many educators have difficulties developing learning objectives appropriate to the levels in Bloom's taxonomy, as they need to consider the progression of learners' skills with learning content as well as dependencies between different learning objectives. To remedy this challenge, we aimed to apply state-of-the-art computational techniques to automate the classification of learning objectives based on Bloom's taxonomy. Specifically, we collected 21,380 learning objectives from 5,558 different courses at an Australian university and manually labeled them according to the six cognitive levels of Bloom's taxonomy. Based on the labeled dataset, we applied five conventional machine learning approaches (i.e., naive Bayes, logistic regression, support vector machine, random forest, and XGBoost) and one deep learning approach based on pre-trained language model BERT to construct classifiers to automatically determine a learning objective's cognitive levels. In particular, we adopted and compared two methods in constructing the classifiers, i.e., constructing multiple binary classifiers (one for each cognitive level in Bloom's taxonomy) and constructing only one multi-class multi-label classifier to simultaneously identify all the corresponding cognitive levels. Through extensive evaluations, we demonstrated that: (i) BERT-based classifiers outperformed the others in all cognitive levels (Cohen's κ up to 0.93 and F1 score up to 0.95); (ii) three machine learning models – support vector machine, random forest, and XGBoost — delivered performance comparable to the BERT-based classifiers; and (iii) most of the binary BERT-based classifiers (5 out of 6) slightly outperformed the multi-class multi-label BERT-

based classifier, suggesting that separating the characterization of different cognitive levels seemed to be a better choice than building only one model to identify all cognitive levels at one time.

Learning Objectives, Bloom's Taxonomy, Classification, Machine Learning, BERT

1. INTRODUCTION

A learning objective is a clear and specific statement defining knowledge and skills that learners are expected to acquire after completing an educational activity [19]. A well-articulated learning objective can benefit course designers, instructors and learners. For instance, learning objectives can inform course design, as they often signal how course materials should be organized to ensure a suitable sequencing of instruction and optimize learning activities throughout the semester. Instructors can utilize learning objectives to assess learners' progress; meanwhile, learners can use learning objectives to get an overview of knowledge and skills they should possess after receiving instruction [38], and to support their studying for an exam, e.g., by developing questions for self-testing prior to an exam [2].

Educators in many courses create learning objectives that reflect knowledge/skills of different levels of cognitive complexity. For example, evaluating whether a formula from a textbook can be applied to solve a math problem is cognitively a more complex skill compared to recalling that same formula from a textbook. However, a learner needs to be able to recall the formula first, and then evaluate its utility in the context of a genuine problem, i.e., low-order skills are precursors to high-order skills [1, 12]. To define learning objectives at different skill levels, educators often use educational taxonomies (e.g., Bloom's [1, 4], Gagne's [12], and Jensen's [16]). For instance, over decades educators have widely utilized Bloom's taxonomy for Cognitive Objectives [1] to define learning objectives, as this framework can account for a broad range of learning objectives and provide means for evaluating learner achievements relative to those objectives [17]. Bloom's taxonomy consists of six levels of cognitive skills that include 3 low-order (*remember*, *understand*, and *apply*) and 3 high-order cognitive skills (*analyze*,

evaluate, and *create*).

Although Bloom's taxonomy has been regarded as a helpful pedagogical framework [19], many educators have difficulties developing learning objectives appropriate to the levels specified in Bloom's taxonomy [21]. This is because they need to consider the progression of learners' skills with learning content and also take into account dependencies between learning objectives, e.g., a learner must be able to define and explain a math formula before applying it [19]. These difficulties may lead to subsequent challenges in measuring learners' progress, i.e., difficulties to determine whether a learner has progressed to upper levels of Bloom's taxonomy [21]. To ensure learning objectives educators create can be mapped to Bloom's taxonomy levels properly, the educators often need support from educational experts [13], which are not easily available in many departments in higher education. Everything considered, the process of developing well-articulated learning objectives to support teaching, learning and assessment activities is usually time- and resource-consuming.

To remedy this challenge and help educators determine the level of each learning objective they create according to Bloom's taxonomy, in the present study, we explored the possibility of using state-of-the-art natural language processing, machine learning and deep learning techniques to automatically classify learning objectives. To date, researchers have developed a few computational models for automatic classification of different types of educational texts based on cognitive levels in Bloom's taxonomy, including exam questions (e.g., [6, 15, 25, 40]), participants' contributions to discussion forums (e.g., [11]), and learning outcomes (e.g., [36]). Researchers have demonstrated a considerable classification accuracy of these models. However, even though the classification of learning objectives based on Bloom's taxonomy has been recognized as an important problem, to our knowledge, there has yet to be developed a classification system that accurately automatizes this work. To address this gap, we obtained and manually annotated 21,380 course learning objectives from 5,558 courses from all the 10 constituent faculties at an Australian university, and applied both machine learning and deep learning models to construct classifiers to automatically identify the cognitive levels of these learning objectives.

2. RELATED WORK

2.1 Bloom's Taxonomy

Bloom's taxonomy [1, 4] was originally introduced to reduce educators' labor when preparing the materials for annual comprehensive examinations. The taxonomy proposes six hierarchically-arranged levels of cognition: remember, understand, apply, analyze, evaluate, and create. These levels reflect the cognitive complexity of a learning objective or an assessment question [15]. In particular, remember, understand, and apply are considered low-order, whereas analyze, evaluate, and create are considered high-order cognitive skills. Mastering a skill at a higher level is dependent upon mastering a prerequisite skill or a group of prerequisite skills at lower levels in Bloom's taxonomy. Due to its well-developed structure, educational researchers and practitioners have widely utilized Bloom's taxonomy for both research and instructional purposes, including the classifica-

tion of learning objectives [36]. We use Bloom's taxonomy as a theoretical framework to guide this study.

2.2 Automated Analysis of Educational Texts Based on Bloom's Taxonomy

Despite its educational promises, the use of Bloom's taxonomy is usually not straightforward. Many educators struggle to manually classify instructional and assessment activities, specify the knowledge associated with each level in Bloom's taxonomy, and measure student progress accordingly ([21]). To overcome these challenges and facilitate instructional activities, researchers have created several computational systems for the automated classification of educational texts based on Bloom's taxonomy. Wen-Chih et al. [5] developed a keyword-based system to automatically classify teachers' questions into different cognitive levels of Bloom's taxonomy. For this purpose, the authors developed a dictionary of keywords mapped to the corresponding cognitive levels of Bloom's taxonomy. The classification system developed in this way achieved a considerable accuracy of 75% in identifying questions at the *remember* level, whereas the system's performance in identifying questions at other levels was noticeably lower (25% – 59%). Amali et al. [28] developed several models to automatically classify exam questions into cognitive levels in Bloom's taxonomy. The models included a rule-based part-of-speech classifier, support vector machine, naive Bayes and K-nearest Neighbor classifiers with word vectors as inputs. Similar to [5], the models performed best in identifying exam questions at the *remember* level (87% – 100%) but achieved a lower overall performance (60% – 72%). The authors further created an ensemble model that achieved 82% overall accuracy by combining the four models. Jayakodi et al. [15] utilized semantic similarity algorithms to develop a rule-based classifier that identifies a cognitive level of an exam question according to Bloom's taxonomy. This system achieved a classification accuracy up to 0.70 in identifying a correct cognitive level for an exam question. Similarly, Echeveria et al. [11] computed TF-IDF features in student discussion posts as input for a rule-based classifier that categorizes a post into one of the levels of Bloom's taxonomy. The authors reported an accuracy of nearly 0.77. Waheed et al. [40] and Mohammed et al. [25] developed a group of supervised machine learning models to classify open-ended questions according to Bloom's taxonomy. The authors computed a variety of linguistic features from question text, e.g., TF-IDF [32] and word2vec [24]. Whereas these supervised machine learning models were trained using relatively small datasets (i.e., less than 1,000 questions), most of them achieved a substantial classification performance with their F1 scores ranging between 0.70 and 0.90.

In line with the increased use of deep learning methods in educational research over the past few years, James et al. [44] utilized BERT [10], a pre-trained language model, to classify educational questions relative to Bloom's taxonomy in a cognitive domain. The models performed well in identifying questions at the levels that were frequent in the dataset (*remember*, *understand*, *analyze* – achieving 82.61% accuracy), whereas the identification of questions at less frequent levels (*apply*, *evaluate*, *create*) remained a challenge (59.2% accuracy with all cognitive levels included). This study demonstrated the potential of deep learning methods to assist educators in determining Bloom's cognitive levels

of educational questions if a sufficiently big pool of questions at all cognitive levels is available to train the deep learning models. Further, Sarang et al. [36] utilized the pre-trained language model Wiki Word Vectors to generate word embeddings for learning objectives and assessment questions. The word embeddings were used as input to the Long Short Term Memory (LSTM) model classifying learning objectives and assessment questions into different levels of Bloom’s taxonomy. This model achieved a weighted average F1 score of 0.73 in correctly classifying learning objectives and a macro-average F1 score of 0.82 in correctly classifying the assessment questions. Moreover, to our knowledge, this study is the first to automatically classify learning objectives (among other forms of educational texts) according to Bloom’s taxonomy and the considerable classification performance reported in the study encourages further research. Overall, the classification models developed to date promise to provide at-scale support to educators who aim at categorizing educational texts, e.g., discussion forum posts, assessment questions, and, more recently, learning objectives, based on cognitive levels of Bloom’s taxonomy.

Although researchers have begun increasingly harnessing the automated text analysis methods to classify different educational texts based on Bloom’s taxonomy, only a small group of researchers has considered exploring the possibility of using these methods to automatically classify learning objectives, despite the challenges documented that many educators report when attempting to manually classify learning objectives according to the cognitive levels of Bloom’s taxonomy [21]. Additionally, all of the relevant studies that we found assumed each piece of text to belong to only one cognitive level while the possibility existed for learning objectives to have more cognitive levels as educators could have combined several learning objectives in one sentence. We also note that practical challenges in obtaining a large, manually labeled dataset, with a sufficient number of learning objectives at each of the six levels of Bloom’s taxonomy to train the classification models, could have been an important obstacle to this line of research [36]. To address these gaps, we gathered a large number of authentic learning objectives across different university courses and manually labeled each learning objective with at least one cognitive level in Bloom’s taxonomy. Next, we developed classification models based on machine learning and deep learning methods to automatically classify learning objectives. More specifically, we attempted to answer the following **research question**: *To what extent can machine learning and deep learning classifiers accurately classify a learning objective into the cognitive levels of Bloom’s taxonomy?*

3. METHODOLOGY

3.1 Data Collection and Labeling

We collected 21,380 learning objectives publicly available from 5,558 courses provided by the 10 faculties at an Australian university in 2021. To collect the data, we developed a web scraper using Python to automatically parse the content of the available course web pages to obtain learning objectives of a course.

One human coder, who had previously received training on Bloom’s taxonomy, manually categorized the learning objectives into their corresponding cognitive levels of Bloom’s

taxonomy. Some learning objectives were categorized into more than one cognitive level, i.e., 2,325 learning objectives were labeled with two cognitive levels, 280 with three and 2 with four levels. We provide a sample of coded learning objectives in Table 1.

To ensure the reliability of data labeling, we included a second human coder trained on Bloom’s Taxonomy in cognitive domain who randomly selected 30% of the learning objectives labeled by the first coder and independently labeled those learning objectives. The two coders achieved a substantial inter-coder agreement (Cohen’s κ 0.63), according to the recommendations provided in [22]. The two coders discussed the labeling disagreement cases between them and found out that the major source of disagreement was because many learning objectives from the low-cognition category *remember* were wrongly categorized as the high-cognition category *apply*. The coders revised the corresponding labels in the entire dataset accordingly which increased inter-coder agreement on the 30% of sample to 0.80, measured with Cohen’s κ . We proceeded with feature engineering and model development using the labeled dataset to answer our research question. The detailed descriptive statistics are provided in Table 2.

3.2 Classification Models

To answer our research question, we developed and examined six classification models. Of these, five models were based on traditional machine learning algorithms, support vector machine (SVM), logistic regression (LR), naive Bayes (NB), random forest (RF) and XGBoost. These algorithms have been widely utilized for text classification tasks in educational research (for an overview see [35]). Moreover, inspired by the increasing use of deep learning approaches in educational research over the past few years (e.g., [7, 9, 14]), we developed deep learning classifiers based on the BERT pre-trained language model. Specifically, we coupled the pre-trained BERT sequence classifiers with a single layer for classification and trained the model using the data we collected.

Recall that, in our collected dataset, each learning objective can be assigned with either only one cognitive label or multiple labels at the same time. Correspondingly, we could tackle the classification task by using two different methods. The first method is to construct a binary classifier for each cognitive level in Bloom’s taxonomy (e.g., those labeled as *remember* vs. those not), and the second method is to build one multi-class multi-label classifier for all the cognitive levels in Bloom’s taxonomy (i.e., identifying all the cognitive labels specific to a learning objective). Given that part of our research goal was to shed light on the best way to tackle this problem, we implemented both methods for comparison purposes. More specifically, we used each of the models described above to construct a binary classifier for each cognitive level in Bloom’s taxonomy, i.e., we constructed a total of 36 binary classifiers. Then, we constructed two multi-class multi-label classifiers (i.e., a Random Forest model and a BERT model), as these two models have been demonstrated effective in tackling multi-class multi-label classification problems in previous research ([27, 37, 39, 42, 43]).

3.3 Study Setup

3.3.1 Data Pre-processing

Prior to conducting any experiments, we randomly split the dataset in an 80:20 ratio, i.e., 80% of data was used as a training set and 20% of data was used as a testing set. We used these same datasets across all classification tasks to ensure fair comparisons between different models.

The textual data was initially pre-processed in the same fashion for both the machine learning models and the BERT-based deep learning model by converting them to lower-case. We extracted multiple features that had been proven to be useful not only for educational forum post classifications [35], but also in other studies sharing a similar context to ours ([25], [32]) to empower the five conventional machine learning models described above. In particular, we computed a group of features in n-gram form, including unigrams (1,000 most frequent excluding stopwords) and bigrams (1,000 most frequent excluding stopwords); TF-IDF features (1,000 most frequent excluding stopwords); automated readability index [33] for each learning objective; and 93 features derived from the LIWC dictionary [31] reflecting a frequency of different psychologically meaningful words, e.g., cognitive processes, function words, words reflecting summary, relativity and time orientation, leading to a total of 3,094 features. For our BERT-based deep learning model, unlike some previous studies ([18, 25, 28]) where the researchers used word2vec to generate word embeddings, we employed BERT-uncased shared by HuggingFace [41] to generate word embeddings, because BERT generated embeddings had been proven to be capable of capturing con-

textual information and properties at the sentence level (in this study, the learning objective level) [23].

3.3.2 Model Implementation

To implement and examine the five conventional machine learning models, we utilized the Python package Scikit-Learn [30] to develop naive Bayes, logistic regression, support vector machine, and random forest classifiers, and the package XGBoost [8] to develop the XGBoost classifier. We performed hyper-parameter tuning with 3-fold cross-validation on these models using grid search in order to find the most suitable parameters for our models. F1 score was used as the evaluation metric when performing hyper-parameter tuning. The details of the parameters were all documented in our source code and would be open-sourced together with the data collected in this study, and thus be made available to other researchers for replications¹

For the BERT-based model, we applied the BERT-uncased shared by HuggingFace [41]. The model included 12 hidden layers, each with 768 neurons. The vocabulary size was 30,522 and the dropout rate was 0.1. For binary sequence classifiers, the number of output neurons is 2, each predicting the probability of the text belonging to different classes (0 and 1 as class labels). Therefore, we applied a softmax function on these probabilities to find the corresponding class labels for the texts. For the multi-class multi-label sequence classifier, the number of output neurons is 6, predicting the probabilities of the text belonging

¹<https://github.com/SteveLEEEEEE/EDM2022CLO.git>

to the six cognitive levels. Thus, we used a sigmoid function on these probabilities and set the probability threshold to 0.50 to find their predicted class labels. The entire BERT models were fine-tuned without freezing the parameters in any layers for all experiments.

3.3.3 Model Training

The training data were used to train all the machine learning models without further splitting. However, for our deep learning models, the 80% training data were further split with 80% being training set and 20% being validation set. The batch size was set to 64 for all the deep learning models and the number of epochs was set to 3. Early-stopping was applied in order to avoid over-fitting. When the F1 scores stopped improving on 10 consecutive validations, the training terminated and the model weights rolled back to the best performing one.

3.3.4 Evaluation Metrics

We evaluated the performance of the classification models by computing the following performance metrics: accuracy, Cohen’s κ , Area Under the ROC Curve (AUC), and F1 score. To find out the categorical performance on the multi-class multi-label classifiers, we separated the classification results for each of the cognitive levels on testing data and made comparisons with the humanly assigned ones to find out their individual accuracy, Cohen’s κ , AUC, and F1 scores.

4. RESULTS

Our results provide evidence that it is possible to develop highly accurate supervised machine learning and deep learning models to classify learning objectives into skill levels based on Bloom’s taxonomy, answering our research question. In particular, the high-performing models included those based on SVM, RF, XGBoost and BERT (Table 3). All of the high-performing models achieved Cohen’s κ score spanning between 0.79 and 0.93, while the prediction accuracy of these models spanned between 0.92 and 0.99, i.e., the models can accurately classify at least 92% of learning objectives into a corresponding skill level of Bloom’s taxonomy. Equally importantly, the F1 scores of the high-performing models were between 0.83 and 0.95, indicating a high precision and recall achieved by SVM, RF, XGBoost, and BERT in identifying each of the six cognitive levels in Bloom’s taxonomy. We note that the binary BERT models outperformed all the binary machine learning models observed. These models achieved an outstanding classification performance, as measured by Cohen’s κ (0.87 to 0.93), accuracy (0.96 to 0.99), and F1 scores (0.88 to 0.95). The classification performance of other models observed in this study (i.e., naive Bayes and logistic regression) was noticeably lower, e.g., with Cohen’s κ typically not exceeding 51% for naive Bayes and 73% for logistic regression.

Furthermore, by comparing the performance between binary and multi-class multi-label random forest classifiers, it is evident that binary random forest classifier outperformed the multi-class multi-label one in most cases except for *understand*. Meanwhile, the multi-class multi-label BERT-based classifier performed better than all the binary and multi-class multi-label machine learning models from the same cognitive level, but rarely outperformed binary BERT-based

classifiers in terms of the prediction performance. The exception was the cognitive level *evaluate* where binary BERT-based classifier achieved a similar but slightly lower performance than the multi-class multi-label BERT-based classifier (i.e., 0.001 difference in Cohen’s κ and F1 score).

5. DISCUSSION

5.1 Interpretation of the Results

Many educators across a range of disciplines develop learning objectives for their courses based on Bloom’s taxonomy for Cognitive Objectives [1]. Even though Bloom’s taxonomy has been widely deemed a useful pedagogical framework [19], educators often find it challenging and tedious to develop learning objectives to describe cognitive skills at different levels of Bloom’s taxonomy [21]. To remedy this issue, in this study, we explored whether machine learning and deep learning methods can be used to develop the classification model that can automatically classify a learning objective into appropriate cognitive level in Bloom’s taxonomy. Overall, our results indicated that three traditional machine learning models, i.e., support vector machine, random forest, and XGBoost, and one deep learning model based on BERT, may be the viable approaches towards solving this problem.

The four high-performing classification models achieved considerable performance not only relative to commonly accepted standards in discourse analysis [3], but these models also outperformed the models from prior research that targeted similar classification tasks. Importantly, all the models performed well in correctly classifying learning objectives at each level of Bloom’s taxonomy. Given that both conventional machine learning (e.g., [5, 28]) and deep learning approaches (e.g., [44]) have been documented to perform poorly in classifying educational texts into higher-order cognitive levels of Bloom’s taxonomy (e.g., *analyze*, *evaluate*, and *create*), the results of our study add to the body of knowledge in educational research showing that advanced conventional machine learning and deep learning models trained on a large corpus of educational textual data can provide useful classifications across all the levels in Bloom’s taxonomy.

Moreover, our findings resonate with prior research showing that deep learning models can provide a more accurate classification results in educational classification tasks, compared to conventional machine learning algorithms [35]. We also note that, given the performance scores the naive Bayes classifier consistently achieved across the six tasks in our study, it appears that this classifier may be the least preferable algorithm for classification tasks based on Bloom’s taxonomy, corroborating evidence provided in [29] where the authors pursued the question classification task based on Bloom’s taxonomy and found that naive Bayes under-performed other classifiers in this task.

Last, we observed that, though multi-class multi-label classifiers achieved satisfactory performance, binary classifiers using the same model (i.e., BERT) still attained better performance. This might be mainly because that, while multi-class multi-label classifiers tried to minimize the overall errors across different cognitive levels during the model training process, binary classifiers tended to focus comprehensively on minimizing the errors on a single category. There-

Table 3: Classification Performance of the binary and multi-class multi-label (MCML) classifiers, i.e., Support Vector Machine (SVM), Naive Bayes (NB), Logistic Regression (LR), Random Forest (RF), XGBoost, and the BERT-based classifier. The best results are in bold for each evaluation metric in each level of Bloom’s taxonomy.

fore, with adequate data collected, tackling the problem as multiple binary classification tasks may be a better solution.

5.2 Practical Implications

In this study, we made a first step towards developing future computational tool that can provide at-scale support to instructors, instructional designers, and other educational stakeholders who aim at developing learning objectives well aligned to Bloom’s taxonomy. The system will automatically analyze learning objectives using the classification routines developed in this study. For instance, an instructional designer may submit the list of manually created course learning objectives to this future system and obtain a highly accurate classification of the learning objectives into cognitive levels of Bloom’s taxonomy. Using this information, the instructional designer may determine whether all the learning objectives are provided, relative to course requirements, e.g., “*It looks like I yet to develop a learning objective at the create level. Since this is an advanced writing course, the create learning objectives should be included*” or “*Even though I have created a few learning objectives for the skills at the apply level, my list is missing lower-level learning objectives that represent the corresponding pre-requisite skills*”. Overall, the classifiers developed in this study can be used to automatically diagnose the cognitive levels of learning objectives for courses and educational programs across different higher education institutions.

In addition, coupled with the systems for natural language generation, the classifiers of learning objectives might be further enhanced to automatically generate learning objectives from course content. This, in turn, may reduce time educators dedicate to this task and may mitigate inconsistencies educators introduce among each other when defining learning objectives, e.g., two instructors defining different learn-

ing objectives for the same subject. We also anticipate our work will benefit students by providing means for automatic development of questions of different cognitive levels for self-assessment. For example, automatically generated learning objectives can be further coupled with the systems for automatic question generation to obtain interrogative form for objectives. Questions developed in this way may provide at-scale support to students studying for assessment.

6. LIMITATIONS AND FUTURE WORK

We identified several limitations in this study that may be considered in future research. Firstly, even though all the learning objectives we collected were classified into at least one of the cognitive levels in Bloom’s taxonomy, it is, however, possible that some learning objectives cannot be categorized relative to a cognitive domain but relative to other domains instead, e.g., affective domain [26]. In future research, the learning objectives dataset should be further labeled from other domains, and relevant classifiers should be trained to recognize these types of learning objectives. Secondly, the supervised machine learning and deep learning methods utilized in this study require extensive amounts of labeled data to achieve a highly accurate prediction performance. As preparing such a large-scale dataset can be costly and time-consuming, researchers may consider using semi-supervised machine learning approaches (e.g., semi-supervised Random Forest [20]) or training strategies like active learning [34] to enable more effective and efficient model construction process in the future.

ABSTRACT

Higher education often aims to create job-ready graduates. Thus, the skills and knowledge taught in professional degrees are expected to align with the needs of the labor market. However, the dynamic nature of the job market makes it challenging to ensure that this alignment occurs. In this study, we show how Skills Analytics can be used to identify critical skills in the workforce, mapping these to the curriculum offerings of a university. This enables us to identify *skill gaps* between what is taught and what is needed in the job market. Methods are presented that allow universities to test the alignment of their curriculum offerings with the job market. Where gaps are identified, this would enable universities to update their curriculum more rapidly to produce graduates equipped with up-to-date skills required by the local job market. Our contributions include: a new method for ranking skills in curricula based on their relative importance in the job market; and proof of concept methods to find skills gaps between curriculum offerings and an identified job market that can lead to curriculum redesign and enhancements.

Keywords

Curriculum analytics, Skills Analytics, Skills gap

1 Introduction and Prior Research

As modern society increases in complexity, higher education is often seen as a necessity for achieving success in the workplace [7]. While this claim is sometimes challenged [5], tertiary training is still often regarded as the entry-level qual-

ification for a professional job [21]. While many claim that higher education should be aiming not just to develop work readiness but also to support people in becoming critical thinkers able to contribute to the betterment of our society [11], we increasingly see both government and employers pushing universities to prepare graduates who can make an immediate contribution in the workplace [16, 19].

How do we know that a university degree adequately prepares a student for the labor market? Over the years, a wide range of computational models have been developed to identify and/or catalog the skills and knowledge associated with a course or degree program. One popular method arises from the curation of ontologies describing a set of skills identified as critical by professional associations, employers, or some form of project. For example, the Association for Computing Machinery (ACM) has been recommending curriculum for various computer science disciplines for decades. The most recent Computing Curriculum (CC2020), includes recommendations about curriculum covering: Computer Engineering; Computer Science; Cybersecurity; Information Systems; Information Technology; Software Engineering; and an emerging Data Science category. These standards traditionally represent the curriculum for a job role as a Body of Knowledge (BoK) consisting of a set of knowledge areas (KAs), both of which contain about ten more specialized knowledge units (KUs) described by a short document. Such formal ontologies and mappings of KAs are often applied in EDM to support various Intelligent Tutoring Systems (ITS) [10].

Ontologies are often leveraged by semantic web technologies to represent curriculum [22, 12, 1], an approach that can help to ensure interoperability of curriculum data between institutions [9]. Gasmı and Bouras [13] demonstrate that it is possible to compare the competencies required by industry with those taught by education using a semantic web ontology and then propose an inference engine that can be used to match students or curriculum to jobs. However, to the best of our knowledge their proposed system was never deployed at scale.

An alternative, less manual way in which to link curriculum

A. Ahadi, K. Kitto, M.-A. Rizoiu, and K. Musial. Skills taught vs skills sought: Using skills analytics to identify the gaps between curriculum and job markets. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 538–542, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

to skills involves the use of Natural Language Processing (NLP). A number of different papers have extracted skills from curriculum documents using simple term frequency-inverse document frequency (TF-IDF) approaches [23, 14, 17]. More advanced methods have used simplified-supervised Latent Dirichlet Allocation (ssLDA) to compare computer science (CS) related curriculum offerings across 10 different universities in the United States [20]. This method was used to model a complete curriculum pathway by finding the center of all points corresponding to a syllabus in a degree program. However, while interesting computational approaches, these methods only work because the detailed ACM curriculum documentation has been carefully curated. This is a significant impost, and is not one that has been repeated by many other sectors. As such, it is not a method that scales to an entire university curriculum.

Various nations and even the private sector, have attempted to address the problem of field specificity by developing national standards for the skills, competencies, knowledge and abilities required for the entire workforce. Examples include: the USA based Occupational Information Network Program (O*NET); Singapore’s Skills Framework; and the classification of European Skills, Competences, Qualifications, and Occupations (ESCO). In the same vein, numerous companies are working to provide technical solutions that support people in becoming more employable, from large companies like Microsoft who are using the knowledge graph acquired from their acquisition of LinkedIn, to start ups and Small to Medium Enterprises (SMEs) such as Faethm, who have recently been acquired by Pearson. Similarly, EMSI-Burning Glass technologies (EBG) collect data by web scraping over 40,000 distinct job boards and company websites, and provides detailed daily information about labor and skill demand posted online.

Multiple studies have taken advantage of these skill taxonomies to explore labor market dynamics and the skills demanded by employers. For example, Clemens et al. [6] investigated whether minimum wage increases result in substitution from lower-skilled to slightly higher-skilled labor. Brüning and Mangeol [4] investigated the geographical variation of employer demand for graduate skills within and among occupations. Interestingly, these skills taxonomies are sometimes provided with services to parse documents and return a list of skills. This type of functionality was leveraged in a recent LAK paper by Kitto et al. [18] that defined a notion of *Skills Analytics* to support the Recognition of Prior Learning (RPL) between two institutions, but this same type of mapping is in principle possible between a student and a job, and in an EDM poster by the same group to perform some preliminary profiling of the entire curriculum offered across one university [15]. However, a problem remains: not all skills contribute equally to the employability of a graduate. Which skills are the most important?

Intriguingly, Dawson et al. [8] used Burning Glass data, coupled with a measure from labor economics, Revealed Comparative Advantage (RCA) [3, 2] to calculate the relative importance of skills that are associated with job ads of different occupations. This index is based on Ricardian trade theory and is widely used in international economics for calculating the relative advantage or disadvantage of a certain country in a certain class of commodity as evidenced by trade flows. RCA works for skills in the same way, enabling the calculation of the *advantage* conferred by a skill to a per-

son in a particular context. As such, the RCA provides us with a promising method for analyzing the relative importance of a specific skill to a job, or to a curriculum offering, or indeed, to a graduate when they attempt to find a job. However, to the best of our knowledge this metric has yet to be applied to the problem of finding gaps in an institution’s curriculum that would reduce a graduate’s potential future employability. This is the gap in the literature addressed by our paper, which proceeds by asking the following Research Question:

RQ: *How can we identify skills gaps between content taught at an institution (i.e. its curriculum offerings) and the requirements of a local job market?*

We adopt an approach based upon *Skills Based Curriculum Analytics* [18] to link university curricula with job market data. Extending the methodology proposed by Dawson et al. [8], we present an approach that enables the comparison of the skills taught within a specific degree program offered by a university with the skills sought by employers for a set of occupations targeted by that degree program. A proof of concept is presented, which contributes: (i) The use of a measure from labor market economics, Revealed Comparative Advantage (RCA), to weight skills according to the advantage they confer to a specific context; (ii) A method for evaluating the skills gaps that occur between a curriculum offering (i.e. identified degree program) and specific occupations targeted by that degree program; (iii) A method for measuring the criticality of any skills gaps, which can be used by university decision makers to prioritize curriculum redevelopment.

2 Methods

2.1 Definitions

For the sake of clarity, we will define here the precise meaning of different terms used across this paper. We will denote a *course* as a “course of study” or a degree or credential program offered by a University (e.g. a Bachelor of Science or a Master of Information Technology). A *subject* is taken to be a specific unit of study that a student undertakes during a course (e.g. Introduction to Programming, Introductory Calculus). A *job* reflects a one-on-one relationship between an employee and an employer hence a job ad represents a single vacancy. An *occupation* is a group of jobs that share very similar characteristics. For example, “teacher” is an occupation, but there are many different types of teachers, such as special education teachers and biology teachers. We use the term *skill* to denote skills, capabilities and knowledge components that are associated with a subject, course, job, or occupation interchangeably. In this study, we will represent subjects, courses, jobs and occupations as bags of skills where each bag of skills represents the skill set taught in a subject, attained by completing a course, or required for a job or an occupation, respectively.

2.2 Data Preparation

To prepare the skill-based presentation of the entire curricula of our university, we took every subject offered at the University of Technology Sydney (UTS) and extracted the following information from the Curriculum Information System: a general description of each subject, any information available about content taught, learning objectives, gradu-

ate attributes, and a high-level overview of every assessment. Next, this extracted textual data was sent to a parsing service offered by EMSI-Burning Glass Technology (EBG) (i.e. the curriculum parser tool) through API calls for skill tagging. EBG provides a taxonomy of more than 33,000 skills that are curated from job advertisement data. For each API call, the curriculum parser uses NLP to extract a list of skills which are probabilistically correlated to the subject information. This method returned skill lists for 2,747 subjects, resulting in a grand total of 138,455 skill tags. The occupational data used in this pilot study includes a relatively small set of job advertisements posted during 2020 (N = 144k) that represents a total number of 612 occupations covering 78k unique job titles. The mapping of the job ads to the occupation titles and their underlying skills (1.4M skill tags) was carried out by EBG.

2.3 Finding skill gaps between courses and the occupations they target

The procedure used to identify skills gap between curricula and job market is as follows:

- Step 1: Calculate the importance of skills for each subject
- Step 2: Calculate the importance of skills for each job ad
- Step 3: Calculate the pair-wise co-occurrence of skills for each subject
- Step 4: Calculate the pair-wise co-occurrence of skills for each job ad
- Step 5: Calculate the averaged importance of the skills associated with the job ads of each occupation
- Step 6: Calculate the averaged importance of the skills associated with the subjects of each course
- Step 7: Compute the pairwise similarity matrix of all courses and all occupations

For details about the calculations themselves, and how the RCA was implemented, the paper by Dawson et al. [8] should be consulted.

3 Results

Having used the RCA to weight the relative importance of skills, and constructed a similarity matrix, we can now work to identify skills gaps between the occupations targeted by various courses, and the skills that those courses teach. In this section we will demonstrate how these methods might be used in an institutional setting to extract actionable insights capable of informing curriculum development.

3.1 The RCA downgrades common skills

Firstly, we note that the RCA can help us to reduce the relative importance of very general skills. For example, at UTS ‘Creativity’ is returned by the EBG tagger 1,496 times across all courses that return at least one skill (see Table 1 for more examples). While possessing these general skills is *expected*, having them on a resume is unlikely to *distinguish* graduates in the job market. The RCA scoring method downgrades common skills with lower scores. Cross-checking these skills with the O*NET categorization of skills confirms that they tend to belong to the basic skill category. On the other side, skills with a high RCA score were not present in the basic skills category and so represent more *specialized* skills that distinguish individuals with respect to specific jobs. This in-

Table 1: Highly common skills in UTS curricula, with their counts across the 2,747 subjects, and the % column giving the relative frequency.

Skill	Count	%
Research	2368	86%
Teamwork / Collaboration	1788	65%
Writing	1647	59%
Creativity	1496	54%

dicates that the RCA is largely behaving as expected in its ranking of skills. It is important to note that some analyses might not want to downgrade common skills in this manner, in which case a different weighting method could be used.

3.2 Skill gaps across a collection of courses

With the methods described in Section 2 it is now possible to explore how various courses offered by UTS align with the occupations that they are attempting to prepare their students for. We have selected 10 courses which aim to prepare their students for professional careers (and so should align well to the needs of the job market), and examined their curriculum descriptions to extract target occupations (e.g. “The course prepares students to participate in a variety of emerging careers with the growth of data science — *Data Scientist, Data Engineer...*”). We also selected a small number of occupations not being targeted by any course in our sample. We then performed the analysis represented by Steps 1 to 7 to calculate the average similarity between the bag of skills returned for each course and each of the selected occupations. The results of this analysis are presented in Figure 1. According to this heatmap, the group of Information Technology courses show a relatively small skills gap for the IT related occupations, and a correspondingly high skills gap for the occupations that they are not claiming to prepare the students for. For example, these courses perform fairly poor in preparing graduates for pharmacy related occupations. On the other side, it is evident that the pharmaceutical occupations in fact show a small skills gap with the Master of Pharmacy. One interesting finding of this presentation is the fact that some courses in fact represent a low skills gap with some occupations that they are not targeting. For instance, the Master of Forensic Sciences shows a relatively small skills gap with *Data Scientist* occupation. This is likely due to a strong emphasis upon analytical thinking and some data analysis skills which are used to provide insights into the elements of a crime. This brings another application of the proposed method; to identify potential alternative career pathways for students

Figure 1: A heat map, representing the skills gap between 50 selected occupations and 10 courses offered at UTS.

beyond their chosen enrollment if they are dissatisfied with their existing pathway. We reserve the examination of such applications of our method for future work.

The hierarchical clustering of the occupations has successfully identified two major clusters, one including IT related occupations, and a second cluster that covers a number sub-clusters representing the other occupation categories chosen (i.e. pharmaceutical, finance, design, language, and forensic). Note in particular, that the occupations to the far right of Figure 1 show a high skill gap. This is a good sign, as they were the occupations chosen which are not targeted by any of the courses we chose to investigate. Given that the similarity calculation ranges from 0 to 1, these results are surprisingly good for two reasons. First, there are 6,684 skills in the occupation space (extremely unique skills are removed) and 3,467 skills in the curriculum space. The fact that there is such overlap between the courses and their intended occupations is a sign that the courses are indeed doing a good job in preparing their students with the skills required in the labor market. Second, as mentioned in Section 2, the occupational data used for this study includes the job advertisements of only one year (2020). This negatively impacts the results of our analysis because it reduces the accuracy of the RCA scores (as a job ad with an unusual skill profile can have a disproportionate influence over the form an occupation takes). Furthermore, the small sample means that some of the skills taught in the course that are in fact required for a given occupation are not identified in the job ads that we had access to. We expect our results to improve with access to a larger job ad dataset.

4 Discussion and Conclusions

Returning to our original research question (in Section 1), this paper has presented a new method that shows clear promise for identifying skill gaps between the content taught by an institution and the job market that it is targeting. The methods proposed in this paper are based on the assumption that relevant textual data can be represented as

a bag of skills. Keeping that notion in mind, our methods can be used in other scenarios as well. For example, this same method could potentially be used when developing a new course or subject to identify significant overlaps in the skills covered by two existing subjects, which may indicate that resources could be more effectively allocated towards the teaching of new content instead. In the same vein, this technique could be adopted for the automated identification of existing competencies, which could be used to identify students who are enrolling in a subject that is unlikely to add much value to their current skill set. While the potential applications of the method presented here are broad, it currently has some limitations. By far the most concerning centers upon the notion of *skillifying*¹ curriculum, occupations, or even a person’s resume or portfolio. We admit that this approach necessarily entails a highly simplified representation of each of these complex entities, and may be critiqued for this reason. However, we feel that the potential utility of the approach in supporting institutions to improve the employability of their graduates justifies this simplification. We believe that RCA can be used for recommending subjects/courses that minimize the skill gaps of each individual with respect to occupation goals that they specify in an interface. Such an interface could also be used to support students in identifying *alternative* occupation goals that they have not yet considered. We reserve these intriguing possibilities for future work.

In conclusion, this paper has provided a proof of concept method for mapping between the skills sought in a local job market, and the skills taught by an institution, an advance that will help to improve student employability in a rapidly changing workforce.

ABSTRACT

Knowledge Tracing (KT), the task of tracing students' knowledge state, has attracted attention in the field of artificial intelligence. Recently, many researchers have proposed KT methods using deep learning to predict student performance on unknown tasks based on learning history data. Especially, the latest DeepIRT reportedly has high predictive accuracy and parameter interpretability. Nevertheless, some room remains for improvement of its prediction accuracy because it does not optimize the degree of forgetting of past data. Specifically, although its forgetting parameters are optimized solely using current input data, it should use both current input and past data to optimize them. Therefore, for better parameter estimation to improve accuracy, this study proposes a new DeepIRT that optimizes the degree of forgetting of past data. The proposed method has a hypernetwork to balance both the current and the past data in memory, which stores a student's knowledge states. Results of experiments demonstrate that the proposed method improves the prediction accuracy compared to earlier KT methods.

Deep Learning, Hypernetwork, Item Response Theory, Knowledge Tracing

1. INTRODUCTION

Recently, with the development of online education [24, 25, 26], Knowledge Tracing (KT) has attracted broad attention for helping students to learn effectively by presenting optimal problems and a teacher's support. [3, 7, 10, 15, 16, 17, 28, 29, 33, 34, 35]. Important tasks of KT are tracing the student's evolving knowledge state and discovering concepts that the student has not mastered based on the student's past learning history data. Furthermore, accurate prediction of a student's performance (correct or incorrect response to an unknown item) is important for adaptive learning. Although KT methods have been proposed as probabilistic

approaches [3, 7, 28, 29, 34] and deep-learning-based approaches [17, 28, 29, 33, 35], the latter have been studied more actively in recent years because they reportedly have high prediction accuracies.

Various deep-learning-based approaches have been proposed to improve the prediction accuracy of a student's performance [1, 20, 21, 32]. Most recently, Ghosh et al. (2020) proposed attentive knowledge tracing (AKT) [5], which incorporates a forgetting function of past data to attention mechanisms: the Transformer method [27]. In addition, AKT optimizes the parameters to weight the data necessary for student performance prediction from past learning data. Therefore, AKT has the best performance for predicting a student's responses among earlier KT methods. However, the interpretability of the parameters is limited because it cannot express a student's ability transition of each skill [5, 14, 22].

On the other hand, to express a student's the knowledge state transition for deep-learning-based approaches, Zhang proposed the dynamic key-value memory network (DKVMN) [35]. DKVMN traces the knowledge state transition using a Memory-Augmented Neural Network and attention mechanisms. It can estimate the relations between underlying skills and items addressed by students. In addition, DKVMN has a memory updating component to allow forgetting and updating of the latent variable memory, which stores the students' knowledge states in the learning process [35]. For interpretability of the parameters, the memory updating component in DKVMN is more effective than the forgetting function of AKT because it updates the current latent variable memory, which stores the students' skills and abilities, using only the immediately preceding values.

To improve the interpretability of the parameters of DKVMN, DeepIRT was proposed by combining DKVMN with an Item Response Theory (IRT) [2, 11, 30] module [33]. It includes the students' ability parameters and the items' difficulty parameters. However, it was insufficient to improve the interpretability because a student's ability of DeepIRT depends on each item characteristic. To resolve this shortcoming, Tsutsumi et al. proposed DeepIRT methods with independent redundant student and item networks [22, 23]. They can learn the student's ability and item difficulty independently to avoid impairing the predictive accuracy. For DeepIRT [23], a student's ability is constant throughout a learning process because it is structured for test theory.

E. Tsutsumi, Y. Guo, and M. Ueno. DeepIRT with a hypernetwork to optimize the degree of forgetting of past data. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 543–548, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

Therefore, it can not be applied to KT. To apply DeepIRT to KT, DeepIRT [22] was proposed using architecture of DKVMN. In DeepIRT [22], a student network employs memory network architecture to reflect dynamic changes of student abilities as DKVMN does. Because the student’s ability parameters of the DeepIRT [22] are independent of each item characteristic, it has higher interpretability than the earlier method has [33]. Furthermore, the DeepIRT [22] can express a student’s ability transition for each skill by estimating relations among the multidimensional skills. Consequently, the DeepIRT provides high interpretability without impairing the predictive accuracy.

However, room for improvement of prediction accuracy of the DeepIRT remains [22] because it does not optimize the degree of forgetting the past data. Specifically, in DKVMN and DeepIRT methods, the forgetting parameters which control the degree of forgetting the past data are optimized from only the current input data: the student’s latest response to an item. As a result, it might degrade the prediction accuracy of the DeepIRT because the value memory insufficiently reflects the past learning history data. Namely, it might be difficult to reflect the past data accurately in a long learning process. It should use not only the current input data but also past data to optimize the forgetting parameters.

In this study, we propose the new DeepIRT with a hypernetwork to optimize the forgetting parameters. The hypernetwork [4, 6, 8, 9, 12, 13, 19, 31] balances both current and the past data in the latent variable memory, which stores a student’s knowledge state data. Before the model updates the latent variable memory, it optimizes not only the weights of the forgetting parameters but also the past latent variable memory. Experiments were conducted to compare the performances of the proposed method and those of the earlier KT methods. The results demonstrate that the proposed method improves the prediction accuracy of the DeepIRT [22]. They also indicate the proposed method as effective, especially for tasks with a long-term learning process.

2. DKVMN AND DEEP-IRT METHODS

DKVMN and DeepIRT methods [22, 33, 35] have the same memory updating component to update and forget the students’ knowledge states in the learning process [35]. The value memory \mathbf{M}_t^v , which traces the process of student ability growth, is updated in this memory updating component. They use \mathbf{c}_j based on input \mathbf{q}_j , which reflects a latest student’s response data u_{tj} to item j at time t .

$$\mathbf{c}_j = \begin{cases} [\mathbf{0}, \mathbf{q}_j] & u_{tj} = 1 \\ [\mathbf{q}_j, \mathbf{0}] & u_{tj} = 0. \end{cases} \quad (1)$$

Here, $\mathbf{0}$ is a zero vector consisting of J zero values. They updated the value memory \mathbf{M}_t^v as

$$\mathbf{v}_t = \mathbf{W}^v \mathbf{c}_j + \boldsymbol{\tau}^v, \quad (2)$$

$$\mathbf{e}_t = \sigma(\mathbf{W}^e \mathbf{v}_t + \boldsymbol{\tau}^e), \quad (3)$$

$$\mathbf{a}_t = \tanh(\mathbf{W}^a \mathbf{v}_t + \boldsymbol{\tau}^a), \quad (4)$$

$$(5)$$

and

$$\tilde{\mathbf{M}}_{t+1,l}^v = \mathbf{M}_{t,l}^v \otimes (1 - w_{tl} \mathbf{e}_t) + w_{tl} \mathbf{a}_t^\top, \quad (6)$$

where \mathbf{W}^v , \mathbf{W}^e and \mathbf{W}^a are the weight matrices, and $\boldsymbol{\tau}^v$, $\boldsymbol{\tau}^e$ and $\boldsymbol{\tau}^a$ are the bias vectors. Furthermore, w_{tl} signifies the degree of strength of the relations between the underlying skill l and skill tags addressed by a student at time t . It is noteworthy that \mathbf{e}_t , and \mathbf{a}_t are forgetting parameters, which adjust the degrees of forgetting the past data and reflecting the current input data. \mathbf{e}_t influences how much the value memory forgets (remembers) the past ability. Additionally, \mathbf{a}_t controls how much the value memory reflects the current input data.

For the interpretability of the parameters, this memory updating component is more effective than the forgetting function of AKT because it updates the current latent variable memory which stores the student’s skills and abilities using only the immediately preceding values. However, the forgetting parameters are optimized only from current input data. It should use not only the current input data but also past data to optimize them. Additionally, the weights are fixed values and are not optimized for each time point. As a result, DKVMN and DeepIRT might degrade the prediction accuracies because of value memory $\mathbf{M}_{t,l}^v$ which only insufficiently reflects past learning history data. Especially, it might be difficult to reflect past data accurately in a long learning process.

3. PROPOSED METHOD

The preceding section described that the forgetting parameters of DeepIRT are not optimized using both current input data and past data. However, when using both current input data and past data, it is difficult to optimize the weight parameters directly because the number of parameters increases dynamically.

Recent studies in the field of Natural Language Processing (NLP) proposed the extension components to LSTM [18] in the form of mutual gating of the current input data and the previous output hidden variables [6]. These extension components are called hypernetworks. A hypernetwork supports the main recurrent neural network by optimizing the non-shared weights for each time point in the hidden layers [6]. In standard LSTM [18], the hidden variables change with time, but the weights used to update them are fixed values and are not optimized for each time point. To resolve this difficulty, various hypernetworks have been proposed to optimize the non-shared weights in the LSTM at each time point. [4, 6, 8, 9, 12, 13, 31]. Their results demonstrate that LSTM with a hypernetwork works better than the standard LSTM [18].

Melis et al. earlier proposed the ”Mogrifier component” which is a kind of hypernetwork for LSTM in the field of NLP [12]. Mogrifier also scales the weights and the hidden variables using not only the current inputs but also the output of the hidden variable at the previous point in time. They reported that the LSTM with Mogrifier component outperforms the other methods for a long input data length. Inspired by those studies, this study proposes a new hypernetwork that optimizes the degree of forgetting of past data in the DeepIRT [22] to improve prediction accuracy with the parameter interpretability. We incorporate the proposed hypernetwork in the memory updating component, which updates the latent variable \mathbf{M}_t^v , to avoid greatly increasing

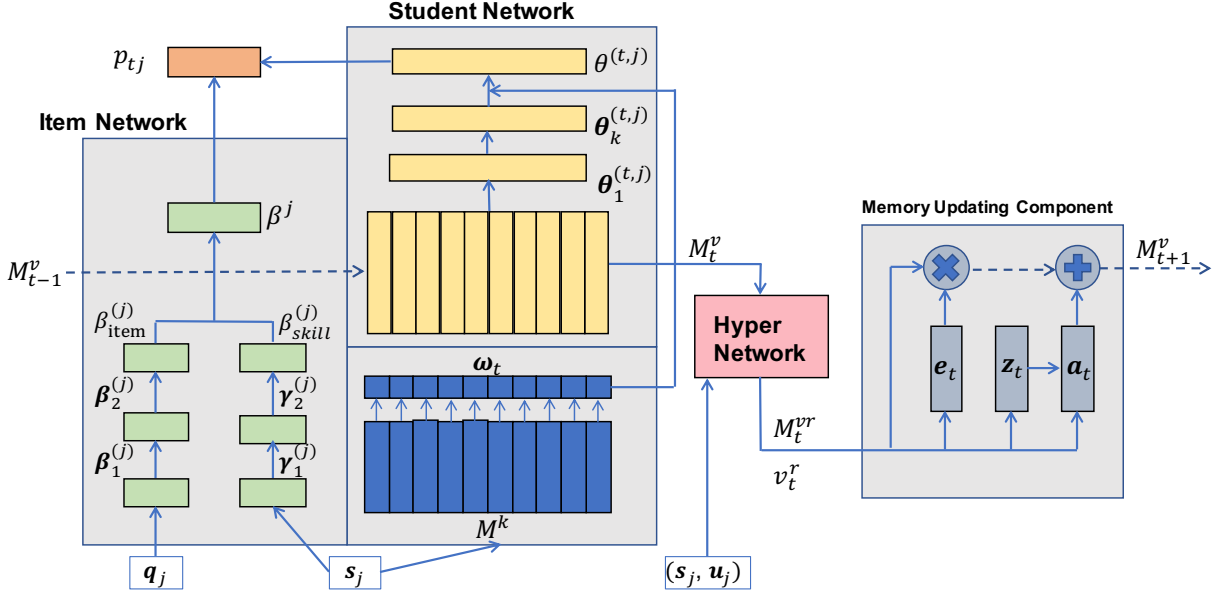

Figure 1: Network architecture of the proposed DeepIRT.

Figure 2: Proposed hypernetwork architecture.

number of parameters. Before the model updates the latent variable M_{t+1}^v , the proposed hypernetwork optimizes not only the weights of the forgetting parameters but also the past latent variable M_t^v . The proposed hypernetwork estimates the optimal forgetting parameters by balancing both the current input data and the past latent variable. In addition, the Mogrifier component [12] used constant values as the tuning parameters in the hypernetwork. For this study, we optimize the tuning parameters to adjust the hypernetwork for each dataset. No report of the relevant literature has described a study of the use of the hypernetworks for KT methods. Figure 1 presents the architecture of the proposed method. The right side of Figure 1 presents the hypernetworks and the memory updating component. The left side of Figure 1 shows the independent student and item networks.

3.1 Hypernetwork

To optimize the forgetting parameters at time t , the proposed hypernetwork balances the current input data and the past value memory M_t^v to store sufficient information of the learning history data before calculating the latent variables M_{t+1}^v . The proposed hypernetwork structure is located at the beginning of the Memory Updating Component on the right side of Figure 1 (shown in red).

Figure 2 shows the structure of the proposed hypernetwork. The inputs of the hypernetwork are the past value memory

M_t^v and current input data $(s_j, u_j) = s_j + u_j * S$ when a student responds to item j of skill s_j . Therein, $S \in \{1, 2, \dots, 2S\}$ represents the number of skills. The embedding vector of (s_j, u_j) denoted as $v_t \in \mathbb{R}^{d_v}$. Because of the repeating multiplications as shown in Figure 2, this hypernetwork balances current data v_t and past value memory M_t^v . For the proposed methods, we optimize the number of rounds r for each learning dataset.

3.2 Memory Updating Component

Next, we estimate the forgetting parameters e_t and a_t using the optimized v_t^r and M_t^{vr} in the hypernetwork. These forgetting parameters are important to update the latest value memory M_{t+1}^v optimally. The earlier memory updating component of DKVMN and DeepIRT methods calculates the forgetting parameters from v_t with only current input information in equation (3), (4). By contrast, we calculate them using the optimized current input data v_t^r and the past latent value M_t^{vr} . Therefore, the forgetting parameters e_t , and a_t are also estimated as optimizing the degree of forgetting of past data and as reflecting the current input data. Furthermore, the proposed method can capture the student knowledge state changes accurately because the latent knowledge state M_t^v has sufficient information of the past learning history data.

4. EXPERIMENTATION

4.1 Datasets and Experiment Setting

This section presents comparisons of the prediction accuracies of the proposed method with those of earlier methods (Tsutsumi et al. and AKT) [5, 22]. We use two standard benchmark datasets ASSISTments2009 and ASSISTments2017 collected from an online tutoring system. Table 1 presents the number of students (No. Students), the number of skills (No. Skills), the number of items (No. Items), the rate of correct responses (Rate Correct), and the aver-

Table 1: Summary of datasets

Dataset	No. students	No. skills	No. Items	Rate Correct	Learning length
ASSISTments2009	4151	111	26684	63.6%	52.1
ASSISTments2017	1709	102	3162	39.0%	551.0

Table 2: Prediction accuracies of students’ performances

Dataset	metrics	Tsutsumi et al.	AKT	Proposed
ASSISTments2009	AUC	80.70 +/- 0.56	82.20 +/- 0.25	81.57 +/- 0.39
	Acc	76.13 +/- 0.58	77.30 +/- 0.55	76.85 +/- 0.56
	Loss	0.54 +/- 0.10	0.49 +/- 0.10	0.53 +/- 0.13
ASSISTments2017	AUC	74.15 +/- 0.27	74.54 +/- 0.21	76.85 +/- 0.39
	Acc	68.73 +/- 0.11	69.83 +/- 0.15	71.08 +/- 0.50
	Loss	0.57 +/- 0.06	0.58 +/- 0.06	0.55 +/- 0.06
Average	AUC	77.42	78.37	79.21
	Acc	72.43	73.56	74.00
	Loss	0.56	0.54	0.54

age length of the items which students addressed (Learning length).

We used five-fold cross-validation to evaluate the prediction accuracies of the methods. The item parameters and hyper-parameters are trained by 70% of each dataset. Given the estimated parameters, the students’ abilities are estimated at each time using the remaining 30% of each dataset according to an earlier study [22]. We employ Adam optimization with a learning rate of 0.003 and batch-size 32. Additionally, 200 items was set as the upper limit of the input length according to the earlier studies [22, 33, 35]. For this study, we leverage three metrics for prediction accuracy: Accuracy (Acc) score, AUC score, and Loss score.

4.2 Prediction Accuracy

The respective values of Acc, AUC, and Loss for ASSISTments2009 and ASSISTments2017 datasets [5, 22] are presented in Table 2. We compared the performances of the proposed method with those of DeepIRT [22] and AKT for each dataset with item and skill tag inputs according to [5]. Additionally, this report describes the standard deviations across five test folds.

Results indicate that the proposed method, which optimizes the forgetting parameters, provides the best average scores for all metrics. Especially, the proposed method outperforms the Tsutsumi et al. [22] and AKT for ASSISTments2017. ASSISTments2017 has a long learning length. By contrast, the proposed method tends to have lower prediction accuracies for ASSISTments2009 with a shorter learning length than AKT has. Results suggest that the proposed hypernetwork functions effectively, especially for datasets with long learning lengths.

5. CONCLUSIONS

Recently, to express a student’s the knowledge state transition for deep-learning-based approaches, DKVMN and DeepIRT methods have been proposed. Tsutsumi et al. (2021) proposed a DeepIRT with independent redundant student and item networks [22]. It can learn the student’s ability and

item difficulty independently to avoid impairing the predictive accuracy. Furthermore, the DeepIRT [22] can express a student’s ability transition for each skill by estimating relations among the multidimensional skills. the DeepIRT [22] has a memory updating component to allow forgetting and updating of the latent variable memory, which stores the students’ knowledge states in the learning process. However, the forgetting parameters which control the degree of forgetting the past data are optimized from only the current input data. It might degrade the prediction accuracy of the DeepIRT because the value memory insufficiently reflects the past learning history data. It should use not only the current input data but also past data to optimize the forgetting parameters.

This study proposed a new DeepIRT with a hypernetwork that optimizes the degree of forgetting of the past data for parameter estimation to improve prediction accuracy with the parameter interpretability. In the proposed method, the hypernetwork balances the current input data and the past value memory to store sufficient information of the learning history data before calculating the latent variables. Specifically, it scales not only the weights of the forgetting parameters but also the hidden variables using the current inputs and the output of the hidden variable at the previous point in time.

Experiments conducted with the benchmark datasets demonstrated that the proposed method improves the prediction accuracies of the earlier KT methods. Especially, results showed that the proposed method is effective for tasks with a long-term learning process. As future work, we will evaluate the interpretability of the ability parameters of the proposed method by comparing the parameter estimates with those of the earlier DeepIRTs [22, 33]. Furthermore, we will clarify the mechanism of how the proposed hypernetwork functions to increase the predictive accuracy.

ABSTRACT

Two students in the same course working toward the same learning objectives may have very different strategies. However, on average, there are likely to be some patterns of student actions that are more common than others, especially when students are implementing typical self-regulated learning strategies. In this paper, we focus on distinguishing between students' typical actions and unusual, anomalous sequences of actions. We define anomalous activities as unexpected activities given a student's preceding activities. We distinguish these anomalies by training a self-supervised neural network to determine how predictable activities happen (the complement of which are anomalies). A random forest model trained to predict course grades from anomaly-based features showed that anomalous actions were significant predictors of course grade (mean Pearson's $r = .399$ across 7 courses). We also explore whether humans regard the anomalous activities labeled by the model as anomalies by asking people to label 20 example sequences. We further discuss the implications of our method and how detecting and understanding anomalies could potentially help improve students' learning experiences.

Keywords

Anomalies, Human understanding of anomalies, Log activities

1. INTRODUCTION

Online education systems can provide personalized learning experiences by understanding students' learning behavior automatically, given rich data that can be collected through such systems [18, 6, 12, 33]. Most research in this area focuses on investigating specific, theory-driven phenomena via data analytics and employs data-driven approaches to understand typical learning behaviors (the most frequent actions, most commonly studied resources, etc.) [33, 44, 23] and prediction tasks (grade/dropout prediction, test recommendation, etc.) [6, 25, 32, 41, 35]. These approaches, while

valuable, rarely consider the role of *anomalous* behaviors, which are also important to understand. For example, existing work has shown that some anomalous behaviors positively correlate with high course grade [17]. Much remains to be discovered regarding anomalous actions, how to determine which kinds of activities are anomalous activities, and how humans perceive anomalies. In this paper, we define students' activities in terms of typical (i.e., predictable) activities and anomalous activities (i.e., unpredictable activities), and describe a method for uncovering these anomalies. In addition, we investigate whether human experts' perceptions of anomalies align with anomalies identified by the proposed method, and explore how humans distinguish anomalous versus typical student activities.

We focus on data from log files [5], which accumulate a great deal of interaction information to understand anomalies in student learning behaviors. Due to the large amount of data in log files, it is difficult to glean insights from these manually. Thus, researchers have devised methods like behavior mining to extract insights computationally [20, 31]. However, behavior-based inferences mainly rely on handcrafted features [40, 43, 36] (e.g., number of occurrences of specific activities), which usually capture frequent or expected activities. Conversely, there may be anomalous activities that relate to learning as well, which are—by definition—unexpected and thus difficult to discover. In this paper, we propose and evaluate a generalizable approach to reveal anomalous activities by examining the prediction errors of neural networks.

Analyzing anomalies requires defining them, which may be difficult. Manual examination and inference based on expert knowledge is one possible approach for discovering specific constructs in data [30]. However, defining and determining anomalies is time-consuming and constrained to the limits of expert knowledge. In statistics and data mining, anomalous activities refer to data deviating from patterns exhibited by the majority of data [13, 29]. In this perspective, anomalous activities are those where, given a sequence of activities, the activities that followed are unexpected—similar to definitions for time series data [26, 42]. Anomalies in this definition indicate deviations from predictable learning strategies [14], and thus may be the result of deviations from common learning strategies or from the ways in which instructors expect students to go through course materials. Consequently, a method to discover students' anomalous learning behaviors might inspire changes to our understanding

of e-learning strategies and could eventually help refine the design of learning experiences.

We approach this problem by training a self-supervised neural network to learn typical activity sequences, then detect anomalies based on the prediction errors. We demonstrate one aspect of the usefulness of our method by exploring the correlation between students' anomalous actions and students' learning outcomes. We further contribute to this problem by understanding how humans perceive anomalous activities and whether those perceptions are aligned with proposed approach.

2. RELATED WORK

In this section, we first discuss the concept of anomalies and provide an overview of applications of anomalies to highlight the potential for work in this area with educational data (section 2.1). We then investigate existing research on log data from learning management systems (section 2.2) to show the importance of behavioral data and how our approach contributes to related work in this area.

2.1 Anomalies

Anomalies are generally understood as rare data that do not conform to preconceptions or expectations derived from the majority of data [7]. Anomalies can be identified with statistical and machine learning techniques, and in various types of data, such as images and time series data [34, 3, 37, 26, 42]. However, in the context of students' behavioral sequences, anomalies are relatively poorly understood.

In image and video data (outside of educational contexts), anomalies refer to a set of features that are not expected, which provides context for how anomalies are defined and detected in general. For time series data, the data are linearly ordered and the definition of anomalies may differ as a result. A particular data value could be an anomaly in a specific context, and might be considered typical (not anomalous) in other contexts. Malhotra et al. [26] and Zhang et al. [42] leveraged prediction errors as an indication of anomalies.

We are aware of only one study that focused on anomalies in education-related sequential data [37]. They considered response time as an indicator of anomalous learning. After plotting the sequence of response times, the authors derived a posterior predictive distribution and regarded the learners as anomalous when they had an unusually high or low response time. However, time spent is not the only way in which actions might be anomalous; moreover, unusually high or low response times might actually be expected for some students when considered in the context of their previous behaviors.

An alternative way to distinguish anomaly versus normal actions is to analyze them in the context of a student's sequence of behaviors, which is the approach we take in this paper.

2.2 Data Mining in Log Activities

In recent years, there has been an increasing interest in analyzing log activities from e-learning environments. Re-

searchers have done a large number of tasks that try to understand students' behaviors, academic performance, and learning processes [10, 1, 28, 38, 39].

Much of the work [9, 44] on data-driven discovery in education focuses on extracting frequent sequential patterns that are common and thus may characterize the behaviors of students from a specific group or across an entire dataset. In contrast, our focus is on behaviors that distinguish students from their peers. Some existing works [30, 15, 19] build behavior models that incorporate relationships between past activities and current activities, or past state and current state, as we do in this study. Other works that rely on log files have explored connections between students' actions and high-level learning information. One research direction is to detect students' learning behaviors or learning preferences [25, 32, 41] as evident in logged activity data, with the goal of enabling personalization of learning experiences after identifying students' needs and preferences.

The methods discussed above do not directly examine anomalies; they rely on extracting features from log files to discover connections between those features and student outcomes or states, or to explore properties of the learning domain and task itself. However, these studies do show that the behavioral data reflects various states of students, and is thus a promising area for further exploration, such as with respect to anomalous behaviors.

3. METHOD

In this section, we describe the data used in our study and present the methods used to answer each of the research questions stated in the Introduction.

3.1 Dataset

We analyzed the Open University Learning Analytics Dataset (OULAD) [24] in our experiments. The data included in OULAD were collected from 2013 to 2014. The dataset contains information about 22 sections of 7 different courses (labeled *A* through *G*), including 32,593 students and their aggregated interactions with an LMS in terms of per-day counts of different types of actions.

We combined multiple sections of the same courses assuming that different sections of each course should be relatively similar. Based on the frequency of each activity, we observed that some activities rarely happened and appeared to be less meaningful for understanding student behaviors. In this work, we aim to detect anomalous activities in a given context instead of mining activities that happen rarely. We decided to group extremely uncommon interaction activities to simplify analysis and interpretation, though exploring the extremely rare events is one possible area for future work. Thus, we chose a threshold (i.e., less than twice per student on average) and grouped all interaction activities less frequent than the threshold into an "other" category. More information regarding specific actions can be found in existing work with this dataset (e.g., Figures 2 and 4 in [24], Table 2 in [21]).

3.2 Anomaly Detection

As discussed above, an "anomaly", generally speaking, refers to an unusual event. In our task, we formalized "typical"

events as predictable activities given a previous action sequence. In contrast, anomalies are students' activities that do not conform with predictions. Anomaly detection included two steps: (1) use machine learning to model typical activities and (2) measure the model's prediction errors. In particular, we trained a self-supervised sequential neural network to model activity sequences, leaving poorly-predicted activities as anomalies.

Our prediction model consists of three layers (though in principle the model could be expanded for datasets with more complex inputs): (1) the encoding layer, which is used for representation generation; (2) a sequential layer (e.g., convolution, recurrent), which is used for feature extraction; and (3) a fully connected layer with sigmoid activation to predict the next step in the sequence. In our experiments, we split the dataset into train and test sets with a ratio of 9:1. We ran experiments on two models: one with a convolutional layer for feature extraction, as described above, and an alternative model based on long short-term memory (LSTM) instead. The model takes three sequential actions, predicts the following action, and convolves over time. We set the kernel width of the convolutional layer to 3 and the number of filters to 20. For the LSTM model, we used a similar configuration (i.e., 20 LSTM cells). We trained models for 50 epochs with batch size 32. We used Adam as the optimizer [22] with a .004 learning rate for all seven courses after tuning the rate from .001 to .01 on course *A*.

To compute prediction error, we calculated the difference between actual actions and predicted actions for each timestamp. For each student, we computed the L2 loss (mean squared difference) between predicted actions and actual actions of each timestamp in the test set as an indicator of how well at each point a student conformed to expected behaviors. Thus, for a student activity sequence of length l , the error between actual and predicted action sequences can be represented by an l -length sequence, which has d dimensions (one for each action type).

3.3 Correlation with Grade

A common approach for predicting students' outcomes is to engineer features from students' activities that are believed to have some relationship to outcomes [4]. Analogously, we expected that a student's activity typicality (anomalous versus typical actions) directly relates to their learning outcomes if anomalous behaviors are evidence of adapting behaviors (e.g., via self-evaluation) or the opposite. We tested this hypothesis by calculating correlations between anomaly loss features and students' outcomes.

To model the relationship between activity typicality and student's outcomes, we represented each student with a d -dimensional vector where each element in the vector is the aggregated error for a specific action. That is, we defined *anomaly loss* as the aggregated error for each possible action for each student. We computed anomaly loss by aggregating error from anomaly detection at the student level by calculating the mean for each possible action. We further determined which actions were most important by training random forest regression with 25 trees to predict students' outcomes from the anomaly loss. During whole process, we conducted experiments only on the test set in the dataset

we used to model students' activities. We further split the test set into train and test subsets randomly in a 2:1 ratio, ensuring that data from each student appeared in only one subset or the other. The usefulness of anomaly loss for each action can then be calculated from the feature importance values of the random forest regressor.

3.4 Human Perceptions of Anomalies

Anomaly detection is mostly rooted in the statistics and machine learning communities [2, 7, 14]. Whether or not the anomalies detected by the proposed approach align with human intuition is still unclear. Thus, we conducted a small survey in which we asked four people with data mining experience to make their own assessments of anomalous student behaviors. We selected 10 sequences that were representative from the top 5% of most anomalous sequences, and 10 sequences from the 5% most typical. We presented 20 sequences (half typical activities, half anomalous activities), descriptions of the types of activities, and asked the participants (i.e., "coders") to determine whether the activities that happened on day 4 were typical or anomalous given three previous days of activities. After they finished coding the activities, we asked participants to provide insight into their coding strategy and their perceptions of what an anomaly is. Specifically, we asked them to describe how they perceive anomalies versus typical activities.

4. RESULTS AND DISCUSSION

4.1 Behavioral Prediction Models

The losses of CNN and LSTM models indicated that they worked approximately equally (mean of loss of LSTM was 1.3% higher; details can be found in the Appendix) well for feature extraction and the behavioral prediction task. We focused on the CNN model alone in the remainder of analyses for the sake of simplicity, since the two models were similarly accurate.

4.2 Correlation with Grade

In this section, we present the results of the analysis comparing anomalies and grade.

For all courses, predicted grade—from a random forest model with anomaly-based features—had a substantial correlation (mean $r = .399$, $SD = .073$) with actual grade. Correlations ranged from $r = .295$ (for course *D*) to $.494$ (for course *G*) with all p -values less than .05, indicating that correlations were positive across courses; even the lowest correlation indicated a moderate relationship between course grades and predictions made based on anomalies. Thus, we conclude that anomalies are important to investigate since they relate to students' academic outcomes.

To further explore which types of anomalous actions were most related to students' course grades, we analyzed feature importance of the random forest model. We used course *A* as an example. Feature importances in Table 1 show that the top five most important actions were *exam*, *other*, *oucontent*, *resource*, and *gap*. These actions were not necessarily the most common, yet still important because of their role in learning. Anomalous exam-related actions, in particular, explained over half of the model's feature importance (which sums to 1 in a random forest). Other important anomalous

actions may relate to self-regulated learning behavior; for example, *gap*-related anomalies may indicate irregular course participation.

Table 1: Importance for each feature in random forest grade prediction. Top five important actions shown in bold. Detailed information of actions can be found in existing work with this dataset (e.g., Figure 2 and 4 in [24], Table 2 in [21])

4.3 Results of Anomaly Detection

Self-supervised neural networks, such as the model we trained in this study, learn the conditional probability distribution of possible elements in a sequence [16, 27, 11]. In our anomaly detection framework in particular, the model learns the probability of each activity occurring given activities in the preceding three days. We provided example sequences of activities labeled by the proposed method in Appendix Table 4 in appendix. The criteria the model learns for predicting activities may be complex, but Appendix Table 4 does illustrate some reasonable high-level patterns learned by the model. For example, if the activities that occurred on day 4 were not consistent with preceding activities (either students performed many more or fewer than the previous activity pattern), they were tagged as anomalous. In contrast, if the activities on day 4 appeared in the previous days once or more, then they were usually labeled as typical. The conditional probability of an activity is just one way of defining anomalies, however, and may not align with human perceptions of what anomalies are. Thus, we also explored human perceptions of anomalies, as described next.

4.4 Results of Human Perception

For each pair of four human coders, we calculated Cohen’s kappa coefficient to measure their inter-rater agreement [8], as shown in Table 2.

Table 2: Kappa coefficients among machine learning and human coders of anomalous vs. typical sequences.

	Model	Coder 1	Coder 2	Coder 3
Coder 1	.00			
Coder 2	.60	.00		
Coder 3	.00	-.20	-.20	
Coder 4	.40	.20	.42	-.20

Inter-rater agreement results show that coder 2 and coder 4 agreed somewhat with each other and with the model: the kappa coefficient between coder 2 and the model was .60, between coder 4 and model it was .40, and between coder 2 and coder 4 kappa was .42. Conversely, both coder 1 and coder 3 had close to zero agreement with others: the mean kappa coefficients between coder 1, coder 3 and others

were .00 and -.13 respectively. Similarly, kappa coefficients among coder 1, coder 3, and the model were -.07, on average, indicating that coder 1 and coder 3 also did not agree with each other or with the model.

Coders’ perceptions of anomalies largely aligned with whether they agreed with each other and with the model: coder 2 and coder 4 determined anomalies from a more statistical perspective, while coder 1 and coder 3 mostly determined anomalies subjectively (they imagined whether or not the sequences were consistent with their own behaviors). In their descriptions of anomalies, they mentioned that if students had different activities (either fewer or much more activities) on day 4 than what happened on day 1 to day 3, they considered the activities on day 4 to be anomalous. For example, as coder 2 said:

Coder 2: The first [criterion I used] is if the activities included many more than what I expected to be there from the past three days. For example, if on days 1-3 the user only went to the Homepage plus one other place, and on day 4 the user went to many different places, I considered that anomalous.

Conversely, coder 1 suggested that if a student did not use the discussion forum on day 1 to day 3 but used it on day 4, then the activities on day 4 are anomalies. In addition, coder 1 thought if a student only watches content to prepare for an exam, then the exam happening on day 4 is an anomaly. Coder 3 decided the typicality of activities by linking them to his/her own experience. Coder 3 thought that classes rarely require a consistent effort on the same activities throughout any given week:

Coder 3: If activity types appear to be too consistent in Days 1-3, I became doubtful that any activity in Day 4 would be a typical activity. From my experience taking college courses, classes rarely require a consistent effort on the same types of activities throughout any given week, so too much consistency made me more likely to believe that the activities on Day 4 were anomalous.

5. CONCLUSIONS

Our goal in this study was to more deeply understand students’ behavior in web-based learning systems, specifically in terms of anomaly detection. We formally defined anomalies as unexpected activities given preceding activities and demonstrated that these anomalies are significantly related to student outcomes. We only tested our method with a selection of the previous three days’ activities as context for the next day’s activities prediction. However, larger fixed sequence intervals could be of interest. We further investigated if anomalies detected by our method aligned with human perceptions of anomalies, finding that the method indeed aligns with some conceptions of what anomalies are, though further research is needed to explore alternative conceptions. Ultimately, anomaly detection may lead to improvements in student modeling, activity recommendations, and even modifications of course materials and learning environments as researchers and teachers rely on methods like these to identify and address critical moments in learning processes.

ABSTRACT

Item response theory models the probability of correct student responses based on two interacting parameters: student ability and item difficulty. Whenever we estimate student ability, students have a legitimate interest in knowing how certain the estimate is. Confidence intervals are a natural measure of uncertainty. Unfortunately, computing confidence intervals can be computationally demanding. In this paper, we show that confidence intervals can be expressed as the solution to a feature relevance optimization problem. We use this insight to develop a novel solver for confidence intervals and thus achieve speedups by 4-50x while retaining near-indistinguishable results to the state-of-the-art approach.

Keywords

item response theory, confidence intervals, relevance intervals, approximation

1. INTRODUCTION

Item response theory (IRT) is a well-established method to model the responses of students on a test [1, 5, 8]. The basic version models the probability of student i to answer correctly on item j as $p_{i,j} = 1/(1 + \exp[b_j - \theta_i])$, where θ_i is a parameter representing the ability of student i , and b_j is a parameter representing the difficulty of item j . If a student's ability exceeds the item's difficulty, the success probability is larger than 0.5, and vice versa. Numerous extensions have been developed over the years, such as parameters for item discrimination (two-parameter IRT), base success chance due to random guessing (three-parameter IRT) [1, 5], IRT for multiple skills [10], performance factor analysis, which describes the increased success chance for repeated attempts [12], or combinations with machine learning [11, 13].

Whenever we use IRT to estimate student ability, students have a legitimate interest in making sure that our model does

not underestimate them (in line with the European Union's concept of a right to explanation [6, 9]). Accordingly, it is important that we not only estimate each student's ability, but also our uncertainty. We can quantify uncertainty in IRT models via confidence intervals [3, 4]. Roughly speaking, an α -confidence interval describes a range of possible parameter values such that the 'true' value is outside the range with probability at most α . For example, Wald's method assumes that parameters are Gaussian-distributed and uses the Gaussian's standard deviation to estimate confidence intervals [3]. While this is efficient, the Gaussian approximation assumes symmetry of the distribution and is only valid for large numbers of items in the test [4]. This is often unrealistic, which is why Wald's method tends to provide inaccurate confidence intervals in practice [4]. Doebler et al. have reacted by providing more exact methods under the assumption of constant item parameters but the resulting confidence intervals are disconnected regions [4], which are challenging to interpret.

More recently, Chalmers et al. [3] suggested the likelihood profile method, which is based on a likelihood ratio test. In particular, we look for a parameter range in which the log-likelihood is at least the optimal log-likelihood minus half the $1 - \alpha$ -quantile of the χ^2 -distribution with one degree of freedom. Because this method does not assume symmetry and works on the 'true' likelihood, it improves the accuracy of confidence intervals considerably. However, the computation requires a nested optimization scheme for every single parameter, which is computationally demanding, especially for large numbers of students.

In this paper, we provide a new perspective by showing that likelihood profile confidence intervals are equivalent to feature relevance intervals, which can be found via an optimization problem [7]. Second, we utilize this theoretical insight to develop a novel solver for confidence intervals which is considerably faster (by factors of 4-50x), while the resulting confidence intervals are almost indistinguishable from direct computation. We evaluate our proposed solver on a range of synthetic experimental conditions from 30-500 students and tests with 10 or 20 items. The experimental code can be found at https://github.com/bpaassen/ability_bounds.

2. METHOD

Our goal is to develop a faster solver for confidence bounds for ability parameters of IRT models via the likelihood profile technique [3]. For an illustration of the technique, con-

Figure 1: Illustration of the optimal NLL we can achieve for a certain value of θ_i in a single-student, single-item setup with $C = 1$ and $y_{1,1} = 1$. The dashed line shows the loss bound for $\alpha = .05$, the solid lines mark the corresponding confidence interval

sider Fig. 1. The blue curve illustrates the best negative log-likelihood (NLL) ℓ we can achieve when fixing the ability parameter θ_i to the value on the x axis. The likelihood profile technique now asks for the values θ_i^- and θ_i^+ , such that the NLL is exactly $\ell^* + \frac{1}{2}\chi_\alpha^{2,-1}$, where ℓ^* is the overall minimum NLL and $\chi_\alpha^{2,-1}$ is the $1 - \alpha$ quantile of the χ^2 distribution with one degree of freedom. Our α confidence interval is, then, given as $[\theta_i^-, \theta_i^+]$.

More precisely, the NLL of an IRT model on a dataset with m students and n items is given as

$$\begin{aligned} \ell(\vec{\theta}, \vec{b}) = & \sum_{i=1}^m \sum_{j=1}^n -y_{i,j} \cdot \log[p_{i,j}] - (1 - y_{i,j}) \cdot \log[1 - p_{i,j}] \\ & + \frac{1}{2C} \cdot (\|\vec{\theta}\|^2 + \|\vec{b}\|^2), \end{aligned} \quad (1)$$

where $y_{i,j}$ is 1 if student i answered correctly on item j and is 0, otherwise, $p_{i,j} = 1/(1 + \exp[b_j - \theta_i])$, and C is the variance of a Gaussian prior on the ability parameters $\vec{\theta}$ and item parameters \vec{b} [1] (chapter 7).

Now, let $\vec{\theta}_{-i}$ denote the vector $\vec{\theta}$ without its i th element and let $\ell_i(\theta_i) := \min_{\vec{\theta}_{-i}, \vec{b}} \ell(\vec{\theta}, \vec{b})$. In other words, $\ell_i(\theta_i)$ is the minimum NLL value we can achieve if we hold θ_i fixed but optimize all other parameters. Then, the likelihood profile method solves the equation $\ell_i(\theta_i) = \ell^* + \frac{1}{2}\chi_\alpha^{2,-1}$, where $\ell^* = \min_{\vec{\theta}, \vec{b}} \ell(\vec{\theta}, \vec{b})$. Because ℓ is convex in θ_i , this equation has exactly two solutions, which correspond to our interval bounds. The drawback of the likelihood profile method is its computational demand. For each student i , we need to solve a nested optimization problem, where the outer optimization searches for a solution to the equation $\ell_i(\theta_i) = \ell^* + \frac{1}{2}\chi_\alpha^{2,-1}$, and the inner optimization computes $\ell_i(\theta_i)$ for each value of θ_i probed by the outer optimization. We look for a way to speed up this computation.

Our key inspiration is the concept of feature relevance intervals (FRI) proposed by Göpfert et al. [7]. The FRI for some parameter θ is defined as the interval between the minimum and maximum value that still retains a loss of at most $(1 - \delta)$ times the optimal loss, where δ is a user-defined hy-

perparameter. More precisely, given some loss function ℓ of some parameter vector $\vec{\theta}$ and some specific parameter θ_i , the FRI for θ_i is computed by solving the following minimization/maximization problem:

$$\min_{\vec{\theta}} / \max_{\vec{\theta}} \theta_i \quad \text{s.t.} \quad \ell(\vec{\theta}) \leq \ell^* \cdot (1 + \delta). \quad (2)$$

Note that this concept is more general than confidence intervals and is mostly intended for classifiers in machine learning [7]. However, for IRT, confidence intervals via the likelihood profile method and FRIs happen to be equivalent.

THEOREM 1. *Let $\ell^* = \min_{\vec{\theta}, \vec{b}} \ell(\vec{\theta}, \vec{b})$ for the NLL (1) and some $C > 0$. Then, for any $\alpha \in (0, 1)$ and any $i \in \{1, \dots, m\}$, it holds: Problem (3) is convex with a global optimum $\vec{\theta}^\pm, \vec{b}^\pm$, such that $\ell(\vec{\theta}^\pm, \vec{b}^\pm) = \ell_i(\theta_i^\pm) = \ell^* + \frac{1}{2}\chi_\alpha^{2,-1}$.*

$$\min_{\vec{\theta}, \vec{b}} / \max_{\vec{\theta}, \vec{b}} \theta_i \quad \text{s.t.} \quad \ell(\vec{\theta}, \vec{b}) \leq \ell^* + \frac{1}{2}\chi_\alpha^{2,-1}. \quad (3)$$

PROOF. As a notational shorthand, let $L_\alpha := \ell^* + \frac{1}{2}\chi_\alpha^{2,-1}$. Note that the objective function of (3) is linear and hence convex. Now, consider the feasible set $\mathcal{X} = \{(\vec{\theta}, \vec{b}) | \ell(\vec{\theta}, \vec{b}) \leq L_\alpha\}$. Let $x, y \in \mathcal{X}$ and let $z_\gamma = \gamma \cdot x + (1 - \gamma) \cdot y$ for some $\gamma \in [0, 1]$, that is, z_γ is on the connecting line between x and y . Then, it must hold: $\ell(z_\gamma) \leq \gamma \cdot \ell(x) + (1 - \gamma) \cdot \ell(y)$, because ℓ is convex with respect to $\vec{\theta}$ and \vec{b} . Further, because $x, y \in \mathcal{X}$, $\ell(x) \leq L_\alpha$ and $\ell(y) \leq L_\alpha$. Therefore, $\ell(z_\gamma) \leq L_\alpha$, implying that $z_\gamma \in \mathcal{X}$. Hence, \mathcal{X} is convex and (3) is convex.

Next, note that, for any $\alpha \in (0, 1)$, $\chi_\alpha^{2,-1}$ is strictly larger zero. Therefore, the feasible set \mathcal{X} is not empty (it contains at least the minimizer of ℓ). In turn, problem (3) must have a optimum $(\vec{\theta}^\pm, \vec{b}^\pm)$ with $\ell(\vec{\theta}^\pm, \vec{b}^\pm) = L_\alpha$ because the objective function is strictly increasing.

Finally, we need to show that $\ell_i(\theta_i^\pm) = L_\alpha$. Assume this is not the case. If $\ell_i(\theta_i^\pm) > L_\alpha$, then $\min_{\vec{\theta}_{-i}, \vec{b}} \ell(\vec{\theta}, \vec{b}) > \ell(\vec{\theta}^\pm, \vec{b}^\pm)$, which is a contradiction. If $\ell_i(\theta_i^\pm) < L_\alpha$, we need to inspect the behavior of ℓ_i in more detail. Let (θ_i^*, b^*) be the solution to the unconstrained problem $\min_{\vec{\theta}, \vec{b}} \ell(\vec{\theta}, \vec{b})$. Then, we know that ℓ_i attains its minimum at θ_i^* with $\ell_i(\theta_i^*) = \ell^*$. Further, because ℓ_i is defined as the component-wise minimum of a convex function, it is convex itself [2] (p. 87). In turn, we know that for any $\theta_i > \theta_i^*$, ℓ_i is increasing and for any $\theta_i < \theta_i^*$, ℓ_i is decreasing. Because $C > 0$, it is also guaranteed that $\ell_i(\theta_i)$ exceeds L_α for sufficiently large/small θ_i , e.g., $\ell_i(\pm\sqrt{2 \cdot C \cdot L_\alpha}) > \frac{1}{2C} \sqrt{2 \cdot C \cdot L_\alpha}^2 = L_\alpha$. Now, consider the minimization version of (3). In that case, we certainly have $\theta_i^- \leq \theta_i^*$, otherwise θ_i^- would not be minimal. Now, because $\ell_i(\theta_i^-) < L_\alpha$, because ℓ_i is decreasing for all values $\theta_i < \theta_i^*$, and because ℓ_i is continuous, there must exist some value $\theta_i < \theta_i^-$ with $\ell_i(\theta_i^-) < \ell_i(\theta_i) \leq L_\alpha$. Therefore, $(\vec{\theta}^-, \vec{b}^-)$ is not a solution for the minimization version of (3), which is a contradiction. The argument for the maximization version is analogous. \square

Fig. 1 provides a graphical intuition for the proof: We can find the two solutions to $\ell_i(\theta_i) = \ell^* + \frac{1}{2}\chi_\alpha^{2,-1}$ by starting at the minimum θ_i^* of ℓ and then decreasing/increasing θ_i

as much as possible while maintaining a loss that is at most $\ell^* + \frac{1}{2}\chi_\alpha^{2,-1}$. To do so, we automatically need to adjust all other parameters to allow for as much slack as possible to increase θ_i .

Alternating optimization solver. The key insight for our solver is that problem (3) becomes much more efficient if we *only* optimize over θ_i and not over any remaining parameters. In particular, we can re-write the NLL (1) as:

$$\begin{aligned} \tilde{\ell}_i(\theta_i) &= \sum_{j=1}^n -y_{i,j} \cdot \log[p_{i,j}] - (1 - y_{i,j}) \cdot \log[1 - p_{i,j}] \\ &\quad + \frac{1}{2C} \cdot \theta_i^2 + \ell_{-i}, \end{aligned} \quad (4)$$

where ℓ_{-i} is a constant term that does not depend on θ_i . Computing $\tilde{\ell}_i$ only requires $\mathcal{O}(n)$ computations, whereas the full NLL (1) requires $\mathcal{O}(m \cdot n)$. Overall, we obtain the simplified problem:

$$\min_{\theta_i} \pm\theta_i \quad \text{s.t.} \quad \tilde{\ell}_i(\theta_i) \leq \ell^* + \frac{1}{2}\chi_\alpha^{2,-1}. \quad (5)$$

By extension of Theorem 1, solving (5) is equivalent to solving the equation $\tilde{\ell}_i(\theta_i) = \ell^* + \frac{1}{2}\chi_\alpha^{2,-1}$, which we can do efficiently via standard nonlinear equation solvers.

Importantly, our solution of (5) will be sub-optimal according to the original problem (3) because $\tilde{\ell}_i$ only approximates ℓ_i . Therefore, we update $\tilde{\ell}_i$ by keeping θ_i fixed and minimizing over all other parameters $\vec{\theta}_{-i}$ and \vec{b} . Then, we can solve (5) again, and so forth, until convergence. This is our proposed alternating optimization (AO) solver.

Figure 2 shows an illustration of the algorithm. To infer the upper bound θ_i^+ , we start at $\theta_{0,i}^+ = \theta_i^*$, i.e. the optimal value according to the NLL. We obtain the next estimate $\theta_{1,i}^+$ by solving the $-\theta_i$ version of (5) with respect to the current surrogate NLL $\tilde{\ell}_{0,i}^+$. Then, we update all other parameters $\vec{\theta}_{-i}$ and \vec{b} by minimizing the NLL (1), yielding a new surrogate $\tilde{\ell}_{1,i}^+$. Solving (5) again yields the next estimate $\theta_{2,i}^+$. In this example, $\theta_{2,i}^+$ would already be indistinguishable from the optimal θ_i^+ according to (3) because $\tilde{\ell}_{1,i}^+$ and ℓ_i strongly overlap. In general, we can prove that $\theta_{t,i}^+$ converges to θ_i^+ .

THEOREM 2. *Let $\theta_{0,i}^\pm = \theta_i^*$, where $(\vec{\theta}^*, \vec{b}^*)$ minimizes the NLL $\ell(\vec{\theta}, \vec{b})$. Let $\tilde{\ell}_{t,i}^\pm$ be the surrogate NLL (4) for parameters $\min_{\vec{\theta}_{-i}, \vec{b}} \ell(\vec{\theta}, \vec{b})$ for fixed $\theta_i = \theta_{t,i}^\pm$, and let $\theta_{t+1,i}^\pm$ be the solutions of the \mp versions of (5) for $\tilde{\ell}_i = \tilde{\ell}_{t,i}^\pm$. Then, for $C > 0$ and $t \rightarrow \infty$, $\theta_{t,i}^\pm$ converge to solutions of the minimization/maximization version of (3).*

PROOF. *As a notational shorthand, let $L_\alpha := \ell^* + \frac{1}{2}\chi_\alpha^{2,-1}$. For simplicity, we only consider $\theta_{t,i}^+$ here; the proof for $\theta_{t,i}^-$ is analogous. First, observe that, for all t , we have $\tilde{\ell}_{t,i}^+(\theta_{t,i}^+) = \ell_i(\theta_{t,i}^+)$ by construction, and we have $\tilde{\ell}_{t,i}^+(\theta_{t+1,i}^+) = L_\alpha$, otherwise $\theta_{t+1,i}^+$ would not be a solution to (5). Further, by definition, we have $\tilde{\ell}_{t,i}^+(\theta_i) \geq \ell_i(\theta_i)$ for all t and all $\theta_i \in \mathbb{R}$. Therefore, we obtain $\tilde{\ell}_{t,i}^+(\theta_{t,i}^+) = \ell_i(\theta_{t,i}^+) \leq \tilde{\ell}_{t-1,i}^+(\theta_{t,i}^+) = L_\alpha$.*

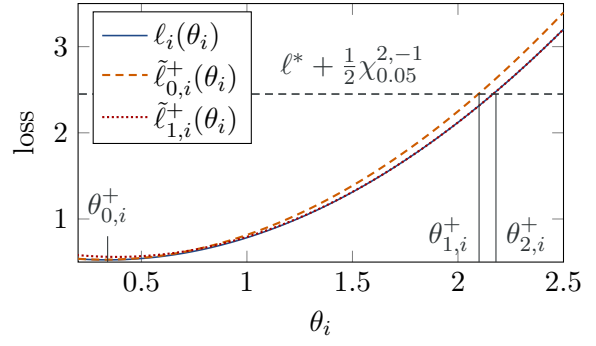

Figure 2: Illustration of the alternating optimization algorithm. We start with the optimum value for $\theta_{0,i}^+ = \theta_i^*$, then maximize θ_i via (5), yielding $\theta_{1,i}^+$, then update $\tilde{\ell}_i$, then maximize θ_i via (5) again, and so forth.

Accordingly, whenever we solve (5) in step $t + 1$, $\theta_{t,i}^+$ is a feasible initial point. Therefore, $\theta_{t+1,i}^+ \geq \theta_{t,i}^+$.

Whenever $\theta_{t+1,i}^+ = \theta_{t,i}^+$, we have $\tilde{\ell}_{t+1,i}^+ = \tilde{\ell}_{t,i}^+$ and, thus, $\theta_{t,i}^+ = \theta_{t+1,i}^+ = \theta_{t+2,i}^+ = \dots$, that is, we have a fixed point. Further, we have $\ell_i(\theta_{t+1,i}^+) = \tilde{\ell}_{t+1,i}^+(\theta_{t+1,i}^+) = \tilde{\ell}_{t+1,i}^+(\theta_{t,i}^+) = L_\alpha$, which is a solution to the maximization version of (3). Before the fixed point, the sequence $\theta_{0,i}^+, \theta_{1,i}^+, \dots$ is strictly increasing. Since ℓ_i is convex with a minimum at $\theta_{0,i}^+$, the sequence $\ell_i(\theta_{0,i}^+), \ell_i(\theta_{1,i}^+), \dots$ is also increasing. For $C > 0$, it would eventually grow beyond bounds due to the regularization term, but since it is upper-bounded by L_α , it must converge to L_α and, hence, $\theta_{t,i}^+$ must converge to θ_i^+ . \square

While Theorem 2 only holds in the limit, very few steps t suffice for a close-to-optimal solution in practice (e.g., Figure 2). We investigate this issue in more detail in our experiments.

3. EXPERIMENTS

In our experiments, we simulate synthetic data from a ground-truth IRT model with ability and difficulties sampled from a standard normal distribution. We varied the number of students m in the range $\{30, 50, 100, 500\}$ and the number of items n in the range $\{10, 20\}$ (similar to the protocol of [3]). For each model, we repeated the sampling 10 times to assess variation. In each repeat, we computed confidence intervals for θ_i at $\alpha = 0.05$ via Wald’s method, the likelihood profile-method via solving $\ell_i(\theta_i) = \ell^* + \frac{1}{2}\chi_\alpha^{2,-1}$ for each i (LP), a log-barrier solver (barrier) for (3), and our proposed alternating optimization scheme (Theorem 2) for $t = 1$ (AO(1)), $t = 2$ (AO(2)), and $t = 3$ (AO(3)) steps. All experimental code is available at https://github.com/bpaassen/ability_bounds.

Coverage. Table 1 shows the coverage rates of all methods, that is, the rate at which the ground truth θ_i value was included in the confidence interval $[\theta_i^-, \theta_i^+]$ [3]. For $\alpha = 0.05$, the coverage rate should be as close as possible to 0.95. We observe that Wald’s method selects too large confidence intervals, yielding rates close to 100%. The barrier method

Table 1: Coverage rates of all methods across experimental conditions

m	n	Wald	LP	barrier	AO(1)	AO(2)	AO(3)
30	10	0.983 ± 0.022	0.943 ± 0.054	0.910 ± 0.056	0.943 ± 0.054	0.943 ± 0.054	0.943 ± 0.054
30	20	1.000 ± 0.000	0.943 ± 0.021	0.083 ± 0.050	0.940 ± 0.025	0.943 ± 0.021	0.943 ± 0.021

50	20	0.998 ± 0.006	0.942 ± 0.039	0.098 ± 0.039	0.938 ± 0.040	0.942 ± 0.039	0.942 ± 0.039
100	10	0.998 ± 0.004	0.934 ± 0.028	0.892 ± 0.029	0.933 ± 0.027	0.934 ± 0.028	0.934 ± 0.028
100	20	0.999 ± 0.003	0.937 ± 0.030	0.059 ± 0.012	0.933 ± 0.031	0.937 ± 0.030	0.937 ± 0.030
500	10	0.998 ± 0.002	0.940 ± 0.011	0.898 ± 0.015	0.939 ± 0.010	0.940 ± 0.011	0.940 ± 0.011
500	20	1.000 ± 0.001	0.949 ± 0.008	0.097 ± 0.016	0.948 ± 0.008	0.949 ± 0.008	0.949 ± 0.008

Figure 3: Log-Log plots for the runtime in seconds versus m for $n = 10$ (top) and $n = 20$ (bottom). Dotted, gray lines show linear functions at .1, 1, 10, and 100ms per student.

selects smaller confidence intervals, yielding rates around 90% for $n = 10$ items. If we choose $n = 20$ items, the barrier method becomes numerically unstable and the coverage rates degrade (smaller 10%). The likelihood profile (LP) method consistently achieves rates between 92% and 95% and thus is closest to the desired value of 95%. Alternating optimization achieves indistinguishable results to LP at 3 significant digits for $t \geq 2$ (AO(2) and AO(3)).

Runtime. Figure 3 displays the time it took to compute confidence intervals for all students in every experimental settings in log-log plots. Dotted, gray lines are linear reference functions at .1, 1, 10, and 100ms per student. Using linear fits, we find that Wald’s method is fastest (at about .3ms per student), followed by AO(1) (about .8ms per student), barrier (about 4ms per student), AO(2) (about 9ms per student), AO(3) (about 12ms per student), and finally LP (about 37ms per student). Accordingly, AO(1) is roughly 50x faster than LP, and AO(2) is roughly 4x faster.

4. DISCUSSION AND CONCLUSION

In this paper, we introduced a new solver for confidence intervals on item response theory parameters via the likelihood profile method. In particular, we found that our

alternating optimization solver was 4-50 times faster than the existing solver while achieving almost indistinguishable results. For anyone who seeks to compute confidence intervals, this should provide massive speedups in practice. More generally, though, we hope that our new solver can help the community to respond to an emerging need in educational data mining: more and more, policy makers and the general public expect machine learning models to provide explanations for their decisions. This is exemplified by recent policy initiatives in the European Union for a right to explanation and a risk-based approach to regulate artificial intelligence. Grading student ability—like in item response theory—will likely be under increasing scrutiny in the years to come. As such, we believe that it is crucial to quantify a model’s uncertainty precisely, which our solver can help to do.

We also provide a key theoretical insight in our paper: Traditionally, confidence intervals express the range of parameter values which is likely to contain the ‘true’ value. We showed that the likelihood profile method for confidence intervals can also be interpreted as an optimization problem: We try to find the minimum/maximum ability value for a student which is still consistent with a high likelihood of the data. This interpretation provides a new way to explain an ability estimate: The upper bound of our confidence interval is the highest possible grade we can give to a student while still being consistent with the responses they provided.

Beyond this paper, there remains ample room for future work. Our evaluation has only covered synthetic data to validate the runtime advantage and the closeness to existing methods. Future work could investigate how large confidence intervals tend to be in practical scenarios. Further, our experiments indicated that the size of our confidence is still larger than it would need to be to cover the ‘true’ ability value. Future work could try to find new methods to compute confidence intervals which are more precise. In particular, it may be promising to investigate combinations with recently proposed models for variational item response theory [14].

ABSTRACT

Research on tailored gamification has shifted from analysing single students' characteristics (e.g. gender or behavioural profiles) to multiple characteristics and how they are influenced by gamification (e.g. context and system log usage). Yet, few studies have been conducted that are concerned with culture, which influences many of the students' characteristics and, consequently, their learning performance. In order to provide a better gamified experience, it is important to understand culture and how it impacts on students' perceived importance of gamification elements, so these elements can be adapted to specific cultures. To this end, we conducted an exploratory study using Association Rule Mining, to explore how the cultural landscape (country) influences the students' behaviour and perceived importance of gamification elements in educational environments. We collected and analysed data ($N = 1296$) from two different countries, Brazil ($N = 428$) and the United States ($N = 868$) and identified significant differences between the perceived importance of some gamification elements.

Keywords

gamification, association rules, culture, personalisation

1. INTRODUCTION

Personalised gamification in learning environments has become a trend in the past few years [7, 6]. This field of study focuses on enhancing existing gamification approaches with

user-centred and personalised design, tailored to the specific characteristics of the user, which will have an impact on their perceived satisfaction, engagement, and motivation, when using a gamified system [4]. Tailored gamification engaged the interest of researchers and educational professionals, due to facilitating positive effects associated with it, such as motivation and performance increase [12].

Recent studies focused on the use of personalised approaches using student demographics (e.g. gender) [21], gamer profiles (e.g. using the HEXAD [22] model), and gaming preferences (e.g. users' favourite game genres or elements) [14] as part of the gamification design.

Whilst these recent studies demonstrated that personalised gamification tends to have a positive influence on students' motivation and performance, there is still no consensus on what kind of personalisation and which attributes should be considered, since most studies focus only on single factors [16]. Literature on personalised gamification points to a lack of studies that deal with other learners' characteristics that can also influence their perception and interaction with gamification; one such important characteristic being *culture* [6, 13].

Culture is not a trivial concept to define; according to [18], culture is an evolving cognitive structure, which influences the behaviour of members of a given group. Features included in the schema of this structure are those that influence and are influenced by the geographical location of an individual and educational contexts they are exposed to [17]. It is this aspect of 'culture' that we will seek to investigate within the rest of this paper. Recently, culture's importance to gamification has come to the fore [2, 24, 19]. In spite of this surge in interest, according to [19], most existing gamification studies that address education and culture are focused on language learning, rather than on understanding how culture can impact on gamification design.

Based on what has been exposed, this paper aims to answer the following research question "Does culture impact on the importance of gamification elements?". We answer this research question, by conducting a relatively large and representative¹ quantitative study, analysing the perceived importance of gamification elements in two different countries (United States and Brazil). Our results provide empirical evidence on the differences between the perceived importance of gamification elements for these two different countries, which can guide designers when considering national culture as a set of variables² in gamification design for learning environments, and also guide researchers to conduct new research in this field. In summary, our main contributions are new insights on which game elements for education are preferred in different countries.

2. METHODS

Considering our main research question, we designed an initial sub-research question to identify if a certain gamification element is more important in a country than in another (here, Brazil versus US). We use <gamification element> for any element from the Taxonomy of Gamification Elements for Education (TGEE) proposed by [20], while the 'country' refers to data collected from people living in a given country.

We opted for the TGEE [20] due to it being the first classification created and evaluated for educational purposes. TGEE is composed of 21 gamification elements, alongside its synonyms, descriptions, and examples of use. These elements are classified in 5 categories that deal with students' performance, sociability, personal information, and experience, and the environment ecosystem.

Through analysing the perceived importance of gamification elements in different countries, we can infer how the culture can influence the design of personalised gamified applications for education. To conduct this research, first we used inferential statistics, to test our assumption that the elements' perceived importance differs, depending on the country of residence. To do so, we used the Mann-Whitney U test (due to the non-parametric and independent nature of our data [11]) and Cliff's delta, to understand to what extent perceptions differ (i.e., the effect size) [10]. Following this we conduct an exploratory analysis, using unsupervised learning algorithms and descriptive/inferential statistics to provide inferences that can be explored deeply in future studies. The data-driven pipeline consists of data collection, filtering, and analysis, further explained in the respective sections.

To collect our data, we relied on the survey method, due to its low cost and other benefits (e.g. speed of obtaining answers) [8]. The survey used in this study was designed in Google forms and consists of two parts. The first collects self-reported demographic information about the respondents, such as gender, country (of residence) and some information regarding their 'gamer' status, such as: years

¹According to Sample Size calculator, our sample is representative for both US and Brazil. Link: <https://www.checkmarket.com/sample-size-calculator/>

²It is important to note that culture itself cannot be defined in one single variable (e.g. country), but a set of characteristics from that might be associated with the place of origin, social group, etc..

playing games, hours per week spent playing, favourite game genres and favourite setting (single or multiplayer games). Whilst it is known that games and gamification are not the same, however, recent studies [15] demonstrated that gaming characteristics of users do influence their gamification acceptance. Previous literature also showed that students' player profile might additionally influence their performance when using gamified learning environments. Based on these premises, we collect the participants' gaming culture information, to establish how it influences the perceived importance of the gamification elements. The second part of the survey consists of 21 gamification elements that were proposed for educational contexts, where we asked what the respondents' perceived importance for each of the 21 gamification elements was, on a Likert scale [9] from 1 to 5, where 1 meant "not important at all" and 5 "extremely important".

The recruitment of respondents occurred via (1) Amazon Mechanical Turk, demonstrated to be an effective platform to obtain a representative sample of answers especially in the US [3], and (2) social networks, which allow us to reach a broad audience and can also be useful tools for survey recruitment [3], social networks were used mainly to collect data from Brazil. We left the survey open for answers for 3 months. The first page of the survey contained the informed consent form³, which the participant needed to agree to, in order to participate in the study, as well as the information regarding the study's objectives, as suggested in [5].

After preparing our dataset, we used descriptive statistics and ARM to explore it. Descriptive statistics allow us to understand the significant differences between countries, which in addition can support us in answering. ARM consists of verifying the associations between the data, by presenting *if-then-else* clauses that are explained using a given set of metrics. It is mainly used in market-basket analysis, to identify possible combinations of elements [1]. In this work, we will consider support (related to the frequency of a given item), confidence (related to the strength of the clause based on its frequency), and lift (which measures the independence of the items in the clause) as the main metrics for ARM.

3. RESULTS AND DISCUSSIONS

In this section, we present the results of our analyses using the given dataset. Initially, our raw data consisted of 1952 answers; after applying our filters, as described in the previous section, we obtained a total of 1296 respondents who live in Brazil ($n = 428$; 33%) or the US ($n = 868$; 67%). Considering the country distribution and genders (Table 1), 428 are from Brazil (33%) and 868 from the US (67%). Among the respondents, 447 identify themselves as female (34.5%), 839 as male (64.7%), nine as non-binary (0.7%) and one person preferred not to disclose (0.1%).

Considering their age and time spent on games distribution: the minimum age (in years) is 16, with maximum age

³The consent allows us to analyse and publish the answers of the respondents. The data collected within this study is in accordance with the General Data Protection Regulation (GDPR⁴) and any kind of personal information was removed prior to the analysis. This research was also approved by an ethical committee 42598620.0.0000.5464 at University of Sao Paulo.

Table 1: Gender distribution

Gender distribution	Brazil		US		Total
	N	%	N	%	
Female	81	18.93	366	42.17	447
Male	344	80.37	495	57.03	839
Non-Binary	3	0.70	6	0.69	9
Prefer not to disclose	0	0	1	0.12	1
Total	428	100	868	100	1296

77. The medium age of the population is 29.7 with a standard deviation of 10. Considering the experience and gaming preferences of our population, they had an average of 18.7 years of playing games ($SD = 8.2$), and an average of 14 hours per week ($SD = 13.8$). The top 3 favourite game genres were RPG (499 answers, 38.5%), adventure (259 answers, 20%) and strategy (186 answers, 14.4%).

The favourite setting (Table 2) of the respondents was single player games (898 answers, 69.3%), followed by multiplayer games (398, 30.7%). In Brazil, the top 3 favourite game genres were RPG ($N = 182$, 42.5%), followed by Adventure ($N = 66$, 15.4%), and Strategy ($N = 65$, 15.2%). As for the US, they considered RPG ($N = 317$, 36.5%), followed again by Adventure ($N = 193$, 22.24%), and Strategy ($N = 121$, 13.94%).

Table 2: Favourite setting distribution

Favourite setting	Brazil		US		Total
	N	%	N	%	
Multiplayer	137	32,009	261	30,069	398
Singleplayer	291	67,991	607	69,931	898
Total	428	100	868	100	1296

When applying our sub-research question formula to each of the elements, we can see in Table 3 that only 6 elements showed a significant difference ($p < 0.05$, after corrected with False discovery rate (FDR)). We also applied Cliff’s Delta to measure the effect size (since this delta can be used to measure the effect size of different size populations) and obtained small effect size results on the same 6 elements [23].

Considering the results seen in Table 3, we can observe that 6 elements (Cooperation, Novelty, Stats, Sensation, Narrative, and Storytelling) had a significant difference in the hypothesis tests ($p < 0.05$), and a small effect-size (up to 0.3). In practice, this means that each of the analysed countries consider these elements to a different degree of importance. The low effect-size indicates that these element differences may pose a significant impact when tied with other elements considering the respondents’ country; this must be confirmed with empirical studies using these elements.

As for the Association Rules, when mining all the rules that contain the variable country, we found 937 rules. In this work, we considered only rules that contained a gamification element and that satisfies the following conditions: (A) *confidence* > 0.8 ; and (B) *lift* > 1.1 , similar as seen in [21].

Considering our conditions, we found 44 rules for condition (A); and 295 for condition (B). When considering the in-

tersection between condition A and B, we found 40 rules ($A \cap B = 40$). The strongest rule (rule 3275, confidence = 0,93; lift = 1,99) that was mined was associating Brazil with Objective, Storytelling, and Narrative. The following rules also associated Brazil with different gamification elements as Progression (rule 3279), Sensation (rule 3270) and characteristics as favourite setting as single player (rule 3278). The same set of gamification elements (Narrative, Storytelling, Progression, and Objectives) were also associated with the United States. The major difference was in the Sensation element that was found in the strongest rules associated with Brazil (Table 4).

4. CONCLUSIONS AND FUTURE WORKS

This paper presented a data-driven work focusing at exploring cultural differences between Brazil and the US regarding their perceived preferences on gamification elements. We found significant and interesting associations and groups of gamification elements that can be used in educational environments (both virtual and non-virtual). These can also be used as input for adaptive gamification environments as a new set of variables that can be grouped by the country of origin of the student.

In summary, we provide as the main contributions of our work the first empirical evidence on the impact of culture in the perceived importance of gamification elements, comparing Brazil and the US, as well as providing new strategies based on respondents’ country of origin and others easy-to-obtain characteristics that can be used in adaptive gamified learning environments.

In future works, we intend to expand the research by applying other unsupervised algorithms, and investigating other sub-cultures within these countries and identify different and similar patterns. We also intend to expand the concept of culture and not associate it only with a country, but also including the region the respondent was raised and live nowadays, as well as other variables that can be related to their education level, or gaming preferences that might have an influence on their perceived importance of gamification elements. Another future work is related to the implementation of these strategies in a real educational environment. Finally, it would be interesting to also analyse other countries and see the differences and similarities between patterns.

5. ACKNOWLEDGMENTS

This research was partially funded by the following organizations: Brazilian National Council for Scientific and Technological Development (CNPq)—processes 141859/2019-9, 163932/2020-4, 308458/2020-6, and 308513/2020-7; Coordination for the Improvement of Higher Education Personnel (CAPES)—Finance Code 001; and São Paulo State Research Support Foundation (FAPESP)—processes 2018/15917-0 and 2013/07375-0. ABSTRACT

The number of unfilled jobs in Science, Technology, Engineering and Mathematics (STEM) is predicted to rise while young people’s interest in STEM careers and education is declining. Efforts to understand this decline have identified some potentially contributing factors based on statistical correlation analysis. However, these correlations can sometimes have relatively low effect-sizes. In these cases, Machine Learning (ML) techniques may provide an alternative by uncovering more complex patterns that provide stronger predictive accuracy. In this pilot study of Irish school children aged 9-13, supervised ML techniques were applied to model interest in pursuing education and careers in STEM fields. Despite the rather low coefficients from Pearson Correlation, the ML techniques were able to predict an individual’s interest in STEM careers and education with accuracies of 72.79% and 79.88% respectively. Our results suggest that ML techniques could be an important tool in understanding young people’s interest in STEM careers and education by providing models that derive more complex relationships.

Keywords

STEM Attitudes, Machine Learning, Educational Data Mining, STEM Interest in Ireland

1. INTRODUCTION

The importance of Science, Technology, Engineering and Mathematics (STEM) skills is increasing, both in our everyday lives and in the demands on our future workforce [5]. Meanwhile, current educational systems are unable to keep up with this increasing demand; STEM courses tend to suffer from high drop-out rates [17] and only around half of STEM students go on to pursue STEM careers [3]. Coupled with a decrease in young people’s interest in STEM [1, 6, 7], concerns have been raised about the increasing skill-gap; the STEM Education Policy Statement 2017–2026 from the Irish Department of Further and Higher Education, Research, Innovation and Science [5] highlights both the economic and personal consequences in a world that relies on modern technologies.

An important part of addressing this skill shortage is to understand the underlying factors that drive young people’s interest in STEM fields. Previous studies have employed statistical techniques to identify correlated attributes, including the student’s gender, grades and school experience [4], their self-efficacy scores [11, 20] and affective stereotypical values about STEM major choices [20]; external factors included parents’ education and STEM knowledge [9, 20], as well as their teacher’s knowledge about STEM [20].

While traditional statistical techniques can provide valuable insights, these techniques are not always sufficient to establish strong correlations, e.g. the Pearson Correlation coefficient for individual attributes may be relatively low in relation to the target variable. Supervised Machine Learning (ML) techniques may offer a solution to this, by modelling complex patterns in the data through more advanced mapping functions that predict the outcome variable.

In this pilot study, five traditional ML algorithms – Logistic Regression, k -Nearest Neighbour, Decision Trees, naïve Bayes and Support Vector Machines (SVM) – were applied to predict interest in STEM careers and education among Irish school children aged 9-13. Further, an epilogue experiment was carried out using a Neural Network (Deep Learning) model, to assess whether this may offer additional benefits over the traditional ML techniques.

The code for the experiments is made publicly available online:

2. DATASET

The data used in this study consist of a sub-set of answers collected during 2020 through an online survey directed at Irish primary school children. Participants were recruited from a random selection of primary schools on the Irish government’s list of national schools. Consent was obtained from parents by providing a consent form via email, to comply with the COVID-19 stay-at-home orders at the time; the filled-out forms were collected by teachers and either emailed back as scanned copies or posted as hard copies.

From the survey’s 48 questions, two yes/no questions were selected as target variables: “*I would like to study STEM in the future*” and “*I am interested in a career in STEM*” (referred to as Career in STEM and Study STEM). 36 of the remaining 46 questions were considered as potential independent variables. (These 38 questions, along with their answer types, are listed in Table 3 in the

Appendix.) Out of the 309 participants who filled out the survey, 255 (82.5%) answered all 38 questions of interest. Future surveys will include validation to prevent missing data, and introduce options such as “Don’t know” or “Not applicable” for all relevant questions. For this study, incomplete instances were not included in the analysis. Gender balance and target variable class balances were measured before and after to ensure no bias was introduced with respect to these factors. Proportions remained highly similar, with 40.1% female before and 40.8% after, with interest in Career in STEM changing from 49.5% positive to 49.4%, and Study STEM changing from 69.6% positive to 70.2%.

2.1 Data Preparation

Two datasets were constructed, each including one of the two target variables (Careers in STEM and Study STEM) along with a subset of the 36 potential independent attributes. The two subsets of the independent variables were selected based on statistical correlation between each attribute and each of the target variables. The reasoning behind this, was to reduce the number of noisy attributes. This initial sub-selection can work well even when the correlation magnitude is relatively low as it still helps to filter out those with very low or no correlation. In this study, Pearson Correlation (PC) and Multiple Regression Analysis (MRA) were employed, which are typical techniques for this purpose. Both techniques were applied independently, so that if two different sets of attributes were identified, each set could be used for developing a separate model. Cut-off values for attribute selection were determined by visually examining bar charts of the ordered absolute coefficients for PC and MRA respectively; the selected cut-off values were based on attribute grouping and the elbow method. Future work will include a more comprehensive analysis of the attribute selection step by including additional considerations, such as p -values.

For the Career in STEM dataset, the selected cut-off values for PC and MRA were 0.2 and 10.00 respectively. Both methods produced the same ten attributes (although the order was different):

- Age
- County
- Do you have family in STEM?
- I am good at projects involving Science Technology Engineering and Maths.
- I would like to participate in more after-school programs in Science Technology.
- Confident to problem solve.
- Confident to do science tasks.
- Homework in Science Technology Engineering and Maths is easy.
- Science Technology Engineering and Math is important.
- On average, how long, per day, do you spend using technology at home?

For Study STEM, PC and MRA both produced the same set of 8 attributes with a threshold of 0.21 and 10.73 respectively:

- Age
- Confident to problem solve.
- Confident to do science tasks.
- Confident to use technology in schoolwork.
- I am good at projects involving Science Technology Engineering and Maths.

- Homework in Science Technology Engineering and Maths is easy.
- I would like to participate in more after-school programs in Science Technology.
- Science Technology Engineering and Math is important.

The cut-off point for the Study STEM data was more ambiguous than for the Career in STEM data. To avoid omitting two potentially beneficial borderline attributes, two separate datasets were constructed: Study STEM A which only includes the top 8 attributes, and Study STEM B which includes two additional attributes based on lowering the thresholds for PC and MRA to 0.18 and 7.83 respectively. These attributes were:

- Do you have family in STEM?
- I am good at using technology and completing coding tasks.

Following the attribute selection process, each selected attribute was assessed for outliers by examining the range and spread of values using standard deviation. No significant outliers or unexpected values were identified.

3. MACHINE LEARNING TECHNIQUES

The Machine Learning (ML) investigations of this study were implemented in Python 3.7, using the Scikit-learn¹ v1.0.2 library for the traditional ML algorithms, and TensorFlow² v2.1 for the epilogue Deep Learning experiment. All code was run on a PC with an Intel Core i9 CPU, 32GB RAM and NVIDIA RTX 2070 Super GPU with 8GB RAM. The following sections briefly discuss each algorithm and how they make predictions about a binary class label.

3.1 Logistic Regression

Logistic Regression (LR) is used to predict the binary class label of a data point by estimating the probability of the positive class based on a set of attributes, without having to meet requirements regarding normal distribution or homogeneity of variance [2]. LR can model non-linear relationship between one or more attributes and the class label, according to the following equations:

$$t_x = \sum_{i=1}^N x_i w_i, \quad P(x) = \frac{1}{1 + e^{-t_x}}$$

where w_i are the learned model weights, x_i is a single attribute and N is the number of attributes. $P(x)$ denotes the probability of the positive class, with $P(x) \geq 0.5$ resulting in a positive prediction.

3.2 k-Nearest Neighbour

k -Nearest Neighbour (k -NN) is used to predict the class label for a new data point based on the class label of known data points that have similar attributes to the new data point. The model selects the k closest neighbours (based on a chosen distance metric) and predicts the class label by majority voting [10, 14]. In this study, a value of $k=3$ was used along with the Euclidean distance.

3.3 Naïve Bayes

Naïve Bayes is based on the Bayes Theorem, which is given by $P(Y|X) = P(X|Y) \cdot \frac{P(Y)}{P(X)}$. This assumes the interdependence between all attributes in the term $P(X|Y)$ whose calculation becomes intractable in practice. Hence, a simplified version, known as naïve

¹ <https://scikit-learn.org/>

² <https://www.tensorflow.org/>

Bayes, is often used where $P(X)$ is assumed to be constant and the attributes are assumed to be conditionally independent. In practice, it has been shown to provide strong predictive performance even when this assumption is violated [13, 14]. For a binary classification task, the probability of the positive class is given by $P(y) = P(Y) \cdot \prod_{i=1}^M P(x_i|Y)$ where $P(Y)$ is the prior probability of class y .

3.4 Decision Trees

Decision Trees provide class predictions through a tree-like flowchart where the next branch is selected based on the value of a single attribute. The cut-off points for the attribute values of these branches are decided based on the optimal splitting of the training data into class labels. Once a leaf-node is reached (i.e. no further branching), a class label is assigned based on the majority class of the training data points that were routed to that node [10, 14]. In this study, binary branching was used based on a measure called GINI Gain which aims to reduce the GINI Impurity calculated by $\sum_{i=1}^c p(y_i) \cdot (1 - p(y_i))$ where $p(y_i)$ denotes the probability of each class label.

3.5 Support Vector Machines

Support Vector Machines (SVM) is a class of algorithms that generates a discriminant function to separate the data points belonging to each class label. The SVM used in this study is a linear SVM that uses Sequential Minimal Optimization [16]. This algorithm is grounded in principles of the optimal hyperplane from statistical learning theory [19]. The optimal hyperplane is found by maximising the perpendicular distance between the closest vector to the hyperplane and the hyperplane itself [8]. Given a dataset $(x_1, y_1), \dots, (x_n, y_n) \in X \times \{\pm 1\}$ where each x_i has been sampled from some space X , the optimal hyperplane can be found by solving the dual-form Lagrangian, which is subject to the constraints $\alpha_i \geq \forall_i$ and $\sum_{i=1}^m \alpha_i y_i = 0$:

$$W(\alpha) = \sum_{i=1}^m \alpha_i - \frac{1}{2} \sum_{i,j=1}^m \alpha_i \alpha_j y_i y_j (x_i \cdot x_j)$$

4. EVALUATION AND METRICS

To promote generalisable model results, 10-fold cross-validation (10FCV) is considered the gold standard validation techniques for these ML algorithms [10]. 10FCV randomly splits the dataset into (as near as possible) equally sized folds; any number of folds can be chosen, with 10 being the typical number. Training is performed on data from all folds except one which is left for evaluation (i.e. the unseen data), and this process is repeated until the algorithm has been trained and evaluated on each fold. The result from each fold's evaluation are averaged to obtain the final result. Thus, all data is considered for evaluation, while at the same time ensuring that test data is never seen during training. This reduces the risk of both under- and overfitting to the data [10].

The metrics used for this study were *sensitivity*, *specificity*, and *accuracy*, each relating to predictions about two mutually exclusive classes, where “yes” is *positive* class, and “no” the *negative* class. True Positives (TP) are correct predictions of the positive class, while True Negatives (TN) are correct predictions of the negative class. Likewise, False Positives (FP) are incorrect predictions of the positive class, while False Negatives (FN) are incorrect predictions of the negative class. Accuracy refers to the proportion of correct predictions (for both the positive and the negative class) in relation to the total number of predictions. Sensitivity refers to the proportion of correctly predicted positive instances TP , in relation to the total number of positive instances $TP + FN$ in the data. High

sensitivity indicates that most of the positive cases are likely found, so if a negative case is predicted, it is highly likely that it is indeed negative. Specificity refers to the proportion of correctly predicted negative instances TN , in relation to the total number of negative instances $TN + FP$ in the data. High specificity means most of the negative cases are likely caught; thus, any positive predictions are highly likely to indeed be positive.

5. RESULTS

5.1 Career in STEM

As shown in Table 1, the highest accuracy was achieved by the SVM model, followed by Logistic Regression (LR), naïve Bayes (nB), Decision Trees (DT) and k-NN. An ANOVA test was carried out, showing statistically significant ($p < .001$) differences between the accuracies with $F(5,255) = 215.8951$. Standard deviation was calculated after applying the binomial distribution formula.

Table 1. Results for the five traditional ML algorithms on predicting an individual's interest in a STEM career

Algorithm	Accuracy	Sensitivity	Specificity
Logistic Regression	71.84%	72%	72%
SVM	72.79%	75%	70%
k-NN	59.15%	58%	60%
Decision Tree	60.02%	60%	63%
Naïve Bayes	71.50%	81%	63%

There is a clear gap in accuracy between the best three models (all above 70%) and the worst two (accuracy around 60%). A possible explanation is the difference in algorithm types; the top three are known for better handling of higher dimensional data with noisy attributes. While steps were taken during the data preparation phase to reduce the number of attributes and lower the risk of noisy data (see sections 2.1), the results indicate that this is an issue that should still be considered during the model design phase.

Sensitivity and specificity followed a similar trend with respect to performance ranking. LR was the best-balanced prediction model with 72% in both sensitivity and specificity. Meanwhile nB was the most imbalanced with 81% sensitivity and 63% specificity, indicating a strong bias towards making positive predictions.

5.2 Study STEM

For the Study STEM target variable, results are reported for both the Study STEM A and Study STEM B datasets (described in section 2.1). Table 2 shows that for STEM A, naïve Bayes (nB) gave the best accuracy, followed by SVM, Logistic Regression (LR), k-NN and Decision Tree (DT); for Study STEM B, the order was the same except for LR and SVM switching places.

ANOVA tests showed statistically significant ($p < .001$) differences between the model accuracies for both datasets, with $F(5,255) = 257.2687$ for Study STEM A and $F(5,255) = 257.4049$, for Study STEM B. The standard deviation was calculated after applying the binomial distribution formula.

The top three models in terms of accuracy, on both datasets, are the same as for predicting Career in STEM (see section 5.1). However, the differences are less pronounced for Study STEM, and the sensitivity and specificity metrics do not show the same clear pattern.

Interestingly, the sensitivity-specificity balances among the top three performers show the opposite relationship from the results on Career in STEM. Overall, the accuracy levels on this task were higher while the balance of nearly all models were worse, mainly due to low levels of specificity; this is not unexpected considering the class-imbalance for the Study STEM target variable, with 70.2% of cases belonging to the positive class, in contrast to the more well-balanced Career in STEM target where the positive class constituted 49.4% of the cases. Only the nB model performed well on specificity for this task, with 70.77% on the Study STEM B data.

Table 2. Results for the five traditional ML algorithms on the Study STEM A and Study STEM B datasets

Algorithm	Accuracy	Sensitivity	Specificity
Logistic Regression	A: 76.74 % B: 76.84 %	A: 88.12 % B: 87.50 %	A: 49.23 % B: 50.77 %
SVM	A: 77.25 % B: 76.82 %	A: 88.12 % B: 87.50 %	A: 50.77 % B: 50.77 %
k-NN	A: 74.11 % B: 73.70 %	A: 85.62 % B: 84.38 %	A: 46.15 % B: 47.69 %
Decision Tree	A: 73.16 % B: 72.35 %	A: 81.88 % B: 78.12 %	A: 50.77 % B: 50.77 %
Naïve Bayes	A: 78.50 % B: 79.88 %	A: 85.62 % B: 83.75 %	A: 61.54 % B: 70.77 %

The results are similar between Study STEM A and Study STEM B, with the exception of the increase in specificity for the nB mode. This, again, highlights the influence that the model selection can have on the outcome. Furthermore, depending on the application of the model, there may also be a preference for better sensitivity or specificity (or indeed a balance between the two) as well as the preference for a simpler model with fewer attributes.

5.3 Deep Learning Epilogue Experiment

Finally, a small epilogue experiment was carried out with a Neural Network model consisting of two layers with 1000 and 8000 Rectified Linear Units (ReLU) [15] respectively, along with a single sigmoid output unit, outputting a value between zero and one; a cut-off point of ≥ 0.5 is used to predict the positive class label. The network was trained with the backpropagation algorithm, using the binary cross-entropy function to calculate the network error.

Each dataset was split into a training and test set, with 66% and 34% using random selection. Training was performed iteratively through repeated exposure of the training set, where one pass through the data is called an epoch. Accuracy was measured on both the training and test set after each epoch.

Figure 1. Accuracy at each epoch for Career in STEM (above), Study STEM A (bottom left) and Study STEM B (bottom right). Upper (blue) lines show performance on training data, while bottom (orange) lines show performance on test data.

In Figure 1, the upper lines represent the accuracy on the training set, with the lower lines representing the accuracy on the test set. As is common for this type of model, these accuracies diverge once the network becomes overfitted to the training set. Future experiments will employ techniques for mitigating this, including reducing the number of model weights and implementing early stopping on an additional validation set. The best preliminary results are found at around epoch 80 for the Career in STEM model where the accuracy is near 70% which is roughly on par with the top three traditional algorithms. For the Study STEM, the best test results are found around epochs 8 and 10 respectively, with around 80% accuracy for Study STEM B, and slightly lower on Study STEM A, which again is on par with the traditional ML results.

6. DISCUSSION

The ML algorithms were all able to predict the target variable to some extent. The best accuracies achieved were 72.79% for predicting an interest in a career in STEM and 79.88% for studying STEM. A simple baseline that always predicts the most common class would have accuracies of 50.6% and 70.2% respectively. Thus, while the accuracy for the Study STEM task was higher, the improvement over baseline performance was greater for the Career in STEM task; the latter showed an improvement of 22.19 percentage points or a 43.85% relative increase in predictive performance.

The more advanced algorithms performed better than the simpler models, possibly suggesting that the underlying patterns were too complex to be explained by individual attribute contributions. On the other hand, complexity of interpretation increases along with the complexity of the model. To improve the practical usefulness of applying ML models to this problem, future work will consider various interpretation methods, including advanced techniques such as LIME [18] and SHAP [12] that offers a interpretability for the overall results as well as for individual predictions.

7. CONCLUSION AND FUTURE WORK

This pilot study has demonstrated the potential benefit of Machine Learning (ML) algorithms to model young people’s interest in pursuing STEM careers and education. The more advanced techniques (Logistic Regression, Support Vector Machines and naïve Bayes) achieved higher accuracy levels than the simpler ones (k-Nearest Neighbour and Decision Trees), suggesting that the advanced algorithms may have an advantage in modelling the complex interplay between contributing factors. Future work will aim to distil practically useful insights about these relationships by leveraging existing techniques for interpreting the outcome of ML models. Additionally, we intend to apply these methods on datasets from longitudinal studies to predict changes in interest in STEM after introducing STEM-promoting activities and interventions.

We wish to emphasise that our long-term goal is to use ML algorithms to identify underlying factors that influence interest in STEM careers and further education, to address the predicted skill-gap, and to inform strategies towards more equitable access to STEM jobs. The methods presented here, while predictive in nature, are not intended to be used as prescriptive tools to encourage or discourage individual students of partaking in the STEM field. Even well-intended applications of such nature would need to carefully consider potential consequences, to avoid furthering existing biases and inequities.

ABSTRACT

At present, the educational data mining community lacks many tools needed for ensuring equitable ability estimation for Neurodivergent (ND) learners. On one hand, most learner models are susceptible to under-estimating ND ability since confounding contexts cannot be held accountable (*e.g.* consider dyslexia and text-heavy assessments), and on the other, few (if any) existing datasets are suited for appraising model and data bias in ND contexts. In this paper we attempt to model the relationships between context (delivery and response types) and performance of ND students with zero-inflated learner models. This approach facilitates simulation of several expected ND behavioural traits, provides equitable ability estimates across all student groups from generated datasets, increases interpretability confidence, and can significantly increase the quality of learning opportunities for ND students. Our approach consistently out-performs baselines in our experiments and can also be applied to many other learner modelling frameworks.

Neurodiversity, Zero-Inflated Models, Learner Models, Item Response Theory, Data Simulation

1. INTRODUCTION

In the UK, it is estimated that 15% of the population are ND, having neurological functions that differ from what is considered typical [22]. Neurodiversity covers the range of differences in individual brain function and behavioural traits, regarded as part of normal variation in the human population [37]. Each Neurodivergent Condition (NDC) uniquely affects how information is absorbed, processed, and communicated [30, 4]. Our objective is to adapt Learner Models (LMs) for the individual requirements of a number of NDCs

in learning environments, focusing specifically on dyslexia, dyscalculia and Sensory Processing Disorder (SPD) (with prevalences of 10%, 6% and 5-15% respectively [7, 36, 9]).

Achievement gaps due to NDCs occur early in life and persist through adolescence into adulthood [8]. In many cases, impeded learning opportunities for ND students result from unsuitable learning contexts or lack of adequate student support rather than intrinsically low student ability [29]. However, as learning begins to move further into the digital space [14, 34], LMs, which are statistical models of student attainment, will use historic performance to estimate student ability. Owing to a legacy of potentially poor learning contexts, the ability of ND students tends to be underestimated by LMs since they are not equipped to distinguish between context- and ability-based explanations of performance. Without deliberate effort, therefore, it is very likely that LMs will become biased and offer inequitable recommendations for ND students. On the other hand, opportunities to quell these achievement gaps before they grow are at hand in smart learning environments if LMs are empowered to reason about alternative explanations of performance.

LM research is highly active in the Educational Data Mining (EDM) community. State-of-the-art approaches include deep neural networks [33, 11, 28], and nonparametric Bayesian methods [15]. We find that the literature is sparse for inclusive LMs applied to ND populations, and we were unable to find many bespoke models or datasets (real or synthetic) even in recent literature reviews [1, 21]. Kohli *et. al.* [16] introduced an approach for identifying dyslexic students based on historic patterns of behaviour and artificial neural networks. Mejia *et. al.* [26] approached the task by estimating learner's cognitive deficit specifically for students with dyslexia or reading difficulties. Ensuring the equity of LM is an important area of research, and learning interfaces can be improved by offering multiple assessment Delivery and Response Type (DRT) [29]. Other works have elaborated further on scores and metrics for ethical and equitable recommendation systems with broad stakeholders, including dyslexic students [25]. Equity is also explored along explainability and interpretability axes. Some classical LMs are readily interpretable and offer intuitive explanations of datasets [31, 24], though caution must be exercised to avoid over-interpreting models [13].

ND students face at least two additional hurdles than Neurotypical (NT) students in learning environments: 1) their ability is inaccurately modelled due to LMs shortcomings; and 2) choosing the most suitable learning context for them to express their true ability is rarely considered. Furthermore, the EDM community currently lacks datasets and simulation tools for developing LMs and assessing equity for NDC contexts. We address these three limitations in this work, by motivating and defining equitable LMs for ND students (Sec 2), defining a simulation environment (Sec 2.2), and demonstrating strong performance in our results and conclusions (Secs 3 and 4).

2. METHODS

Due to a lack of available datasets that include ND students, we explore equitable estimation in simulations. Our model combines the use of Zero-Inflated Models (ZIMs) [17] and Item Response Theory (IRT) [2, 20]. Our assumption is that DRT choices will affect the quality of learning opportunities for ND students, with unsuitable DRT resulting in lower Learning Quality Factor (LQF). Without considering the suitability of DRTs for students, LMs risk recommending low-quality learning opportunities and mis-interpreting poor performance on these as an indication of low student ability. The model and simulation procedure proposed is designed to be used to identify the best DRTs for each student, and prevent underestimation of abilities.

2.1 IRT-based Zero-Inflated Learner Model

Our proposed approach, Zero-inflated Learner Models (ZILMs), shown in Eqn (1), builds on the assumption that there are two explicit explanations of zeros: 1) low ability relative to difficulty (low p); and 2) low LQF (high π). With this formulation, a zero from a student with high ability with in an unsuitable DRT can be explained by the poor LQF since π has high responsibility for the outcome [3].

$$Pr(Y = y) = \begin{cases} \pi + (1 - \pi) \cdot (1 - p) & \text{if } y = 0 \\ (1 - \pi) \cdot p & \text{if } y = 1 \end{cases} \quad (1)$$

In our setting, p is based on IRT, and π (which reflects LQFs) is parameterised by item, NDC and DRT features (*c.f.* Sec 2.2), resulting in IRT-based ZILM (IRT-ZILM).

IRT was chosen as the base LM in IRT-ZILM over alternative options as: 1) IRT is well-understood and simple to interpret; 2) Bayesian Knowledge Tracing (BKT) is known to have over- and under-estimation problems [6, 18] that may muddle our understanding of equity for ND students; 3) several technical hurdles need to be overcome to incorporate our approach into BKT; and 4) although Deep Knowledge Tracing (DKT) [33] models can probably learn latent representations that correlate to DRT preferences, this is at the expense of control and interpretation of the effects.

2.2 Simulations

In the simulated dataset, we assume that the ability of ND and NT students are drawn from the same distribution, meaning that ability and NDCs are independent. The NDCs considered in this initial work are dyslexia, dyscalculia, and SPD. These chosen conditions reflect a wide range of effects from different delivery and response types, but this work could be applied to others.

Table 1: Description of parameter distributions used to generate synthetic dataset. Each parameter was randomly assigned from distributions. Users are given an intrinsic ability and the possibility of one or more ND conditions. Items are assigned a difficulty, discrimination, guessing, subject, content type, information density, delivery type and response type. Information density describes how much information is provided—0.1 represents only a few words, 1 is a large block of text—designed to reflect how clearly an item is presented.

Parameter	Value (Range)	Probability
Ability	$(-\infty, \infty)$	$\mathcal{N}(0, 1)$
ND condition	Dyslexia, Dyscalculia, SPD	0.1, 0.06, 0.11
Difficulty	$(-2, 2)$	uniform
Discrimination	$(0.5, 4)$	uniform
Guessing	$(0, 0.15)$	uniform
Subject	Maths, English	0.5, 0.5
Content type	Letter, Digit, Both	M: 0.1, 0.5, 0.6, E: 1, 0, 0
No. attempts	20	fixed
Info. density	$(0.1, 1)$	$\mathcal{N}(0.35, 0.15)$
Delivery type	Read, Listen, Both	0.3, 0.3, 0.4
Response type	Written, Speak, Click Picture,	0.4, 0.2, 0.2, 0.2
	Click Read	

Datasets are created based on the parameters outlined in Table 1. These features contribute to the estimation of LQFs and the probability a user will respond to an item. For example, a dyslexic user’s learning quality is impacted by delivery types involving reading letters, and response types involving reading letters to click the correct answer(s) or writing an answer that includes letters. A dyscalculic user is affected by delivery and response types involving digits. And someone with SPD is impacted when the delivery involves both reading and listening with either letters and/or digits, as this can cause sensory overload [29].

Collectively, these features are used to describe the suitability of DRT to a variety of NDCs, which we now relate back to Eqn (1). If a poorly chosen DRT is selected for a ND student, this will result in poor learning opportunities due

Figure 1: This image shows that LQFs can make the perceived ability of an affected student much lower than their true unobserved ability. \diamond shows a student’s true ability, \circ shows the impact of low LQFs, and \square shows the perceived ability if LQF is not considered.

Figure 2: Comparison of attempt outcomes for each NDC (dyslexia: upper left; dyscalculia: upper right; SPD: lower left; all: lower right) when a single delivery type is used for all items (R and L correspond to ‘read’ and ‘listen’ respectively).

to a low LQF (*i.e.* large π). However, if a suitable DRT is selected for a student, the suitability is reflected in higher LQFs. Synthesising datasets that adapt to DRTs and NDCs requires specification of the weight vectors to adapt π to context (*e.g.* ‘reading’ should increase π / reduce LQF for dyslexic but not for dyscalculic students). Although specification of weight vectors is a subjective process, it allows us to express our intuition and instincts about the influential pathways. These are fully described in our implementation¹.

The effect of LQFs on an item’s characteristic curve can be seen in Fig 1. As the LQF decreases, the upper asymptote is reduced, indicating that their opportunity to learn from the interaction is compromised. With this, we interpret LQF as a measure of the contextual inequity.

3. RESULTS AND DISCUSSION

There are four main questions we want to explore in this work: 1) how much are ND users learning opportunities impacted by poor DRTs; 2) is it possible to identify users with potential NDC based on their performance on items with a range of DRTs; 3) is it possible to estimate user true abilities, accounting for any poor performance due to other factors; and 4) can student learning quality and success be improved through active selection of DRTs?

3.1 How are ND users impacted?

Fig 2 shows how ND student performance is affected if a learning environment only delivers information in a single format. Across the full neurodiverse population, the mean performance is approximately the same for all learning material formats. There are also no observable differences in performance for users with dyscalculia. However, for users with dyslexia or SPD there are noticeable differences. For users with dyslexia, they answer 6–11% more attempts correctly and are able to attempt 9–15% more items when the item has a listening component. For users with SPD, they answer an item correctly, and are able to attempt, 19–24% more attempts when the item is only delivered in one format compared to multiple formats. The probability of a

¹github.com/niall-twomey/zero-inflated-learner-models

user succeeding at an item is can be drastically effected by a poor learning quality.

3.2 Can NDCs be identified from interactions?

To investigate if users with a potential NDCs can be identified from the interactions, we have compared individuals mean performance in different subjects and on items with different delivery types (Fig 3). When Maths and English are compared (Fig 3 left), dyscalculic users have attempted more English items than Maths (large spike on ‘Not answered’). Additionally, when Maths is attempted, there is a lower success rate than in English (dip in ‘Correct’). Their performance in terms of ‘Incorrect’ counts in English and Maths are equivalent. However, this tally is achieved with 30% fewer attempts, indicating poor performance in Maths, further illustrating the effect of their NDC (*i.e.* 10/20 *vs.* 5/15). The most noticeable effects between read *vs.* listen DRT (Fig 3 middle) are seen by a clear increase in number of not answered items and decrease in the number of correct answers for ‘dyslexia’ and ‘dyslexia & SPD’ students. SPD students are unaffected by these DRTs. Comparing the ‘read & listen’ and ‘read’ delivery types (Fig 3 right), there are features seen with the dyslexia users, as above, but the SPD users now show a significant difference in performance, with large increases on ‘not answered’ and decreases on ‘correct’. So, by comparing individual students’ performance in different subjects and DRTs, it’s possible to identify the ND students and their condition. In practices, these comparisons could be used to identify what contexts a student may be struggling with, and additional support they may need.

3.3 Can a user’s true ability be estimated?

One aspect of ensuring each user gets suitable learning material is understanding their true ability. Fig 4 compares the performance of classical IRT and our IRT-ZILM model for parameter recovery. With IRT, most of the ability values are under-estimated, particularly for students with 1 or 2 NDCs (Fig 4a). Under-estimated ability makes sense given our expected inflated zero counts. However, the bias of under-estimated ability for ND students is concerning given that ND and NT abilities were drawn from the same distribution. On the other hand, IRT-ZILM is a much better estimator of true abilities (Fig 4b). Additionally, there is no obvious gap in ability estimates for students with NDCs compared to NT students. Table 2 summarises the predictive accuracy of the considered models. Although the performance of all models is approximately equivalent (only small gains for our approach) the lack of distorted recovered parameters may indicate stronger reliability of IRT-ZILM.

Table 3 summarise parameter estimation using Pearson and Spearman correlation coefficients, and have included linear KTM [39] (using contextual features) as another baseline. KTM, like IRT also under-estimates ND ability, and IRT-ZILM is a significantly better estimator of the true parameters.

3.4 Can learning quality be improved?

We explore the effect of actively selecting DRTs to improve LQFs and the number of successful learning attempts for ND students in Table 4. The table shows the potential that selecting the most suitable DRT can have on learning quality, with large lifts on students with 1 or 2 NDCs.

Figure 3: Performance differences for selected students across subject- and NDC-oriented contexts. Bar chart colour indicates NDCs. Large positive and negative values in the bar charts indicates that a group has been affected by the context. While every NDC is affected (indicated in parentheses in subfigure captions), no significant effects present for NT students.

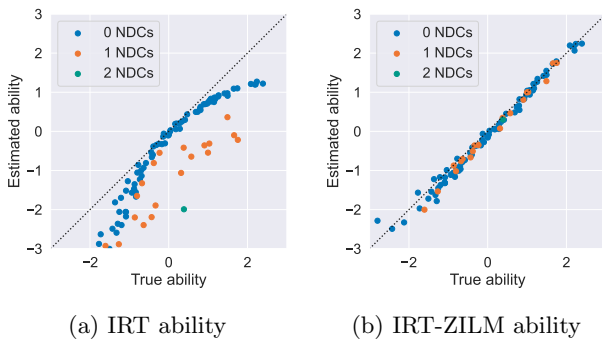

Figure 4: Scatter plots of true vs. estimated ability parameters from IRT and IRT-ZILM. Perfect estimation will place all points on diagonal. IRT is biased against ND students, while IRT-ZILM parameter estimation is very reliable.

Table 2: Predictive test metrics. Similar performance obtained with all models, though IRT-ZILM is slightly more performant than baselines.

Metric	IRT	KTM	IRT-ZILM
Accuracy	0.734	0.742	0.753
F1	0.559	0.567	0.583
NLL	0.513	0.499	0.494
Brier Score	0.170	0.166	0.163

3.5 How can this model be applied?

As already discussed, comparing user interactions in different contexts can identify students who may need additional support in specific areas. Often, high achieving ND students needs can be overlooked since their performance doesn't tend to require interventions. With IRT-ZILM, support/adaptions can be put in place early to enable them to reach their full potential since this model is less susceptible to the biases of traditional LMs. IRT-ZILM can be used to better estimate a students true ability, by adapting it to contexts and underestimating their DRTs preferences. This can help identify and explain causes for underperforming students. By understanding which DRTs a student struggles to engage with, alternative items can be provided to

Table 3: Pearson and Spearman correlation coefficients between true and recovered parameters. Values of 1 indicate perfect matches. IRT-ZILM parameter estimation is the most accurate across both metrics for all parameters.

	Pearson			Spearman		
	IRT	KTM	IRT-ZILM	IRT	KTM	IRT-ZILM
Ab	0.839	0.955	0.993	0.929	0.966	0.996
Diff	0.394	0.686	0.953	0.413	0.707	0.954
Disc	0.270	0.544	0.932	0.234	0.610	0.942

Table 4: Increase (and decrease) of learning opportunities obtained with active (and adversarial) DRT selection.

	1 NDC	2 NDCs
Baseline	0.391	0.123
Lift	1.432 ↑	1.898 ↑
Drop	0.248 ↓	0.014 ↓

help them reach their full potential. These insights can also be used by teachers to explore if the DRTs of their content can be expanded to create an accessible learning environment for all. Education traditionally has taken a one size fits all approach. By harnessing models that incorporate contextual understanding, learning can be tailored to each student, reaching many of those who may previously have felt dejected in learning, as their needs weren't being met.

4. CONCLUSIONS

Our application of zero-inflated models in learning contexts offers a rich simulation environment of neurodivergent conditions in question answering settings, unbiased evaluations of neurodivergent learners, encourages increased learning quality, and more reliably recovers unbiased ability parameters. On the basis of our successful results we believe that further study and exploration of zero-inflated learner models can yield an inclusive framework for equitable, explainable, and reliable learner models in diverse educational data mining contexts. Future work will expand on the experimentation to new contexts, and the model to new domains.

Appendix

This section gives supplementary details of our proposed model, see Sec 2.1.

Delivery and Response Weakening

We adapt learner models for NDCs by taking inspiration from techniques used in Weakly Supervised Machine Learning (WSML) [41]. Our approach is to model the interplay between item DRTs and NDCs. Let a binary random variable be drawn from a Bernoulli distribution, $y \sim \text{Ber}(p)$, and let us assume that a label flipping process acts upon y and this results in observations of the corrupted labels, \tilde{y} . The mixing matrix, M , is defined as follows:

$$\begin{pmatrix} 1 - q_0 & q_1 \\ q_0 & 1 - q_1 \end{pmatrix} = \begin{pmatrix} Pr(\tilde{Y} = 1|Y = 1) & Pr(\tilde{Y} = 1|Y = 0) \\ Pr(\tilde{Y} = 0|Y = 1) & Pr(\tilde{Y} = 0|Y = 0) \end{pmatrix}$$

The q_{ij} variables can be selected using prior knowledge and assumptions on the data distributions [27, 32]. In our setting, we are interested particularly in the contexts when learning of ND students is being sabotaged by the environment, *i.e.* q_0 . We therefore model q_0 (previously introduced as a global parameter) and parameterise it with ND, LQF and interaction features.

IRT-based Zero-Inflated Learner Model

Our IRT-ZILM merges LMs and ZILM as follows:

$$Pr(Y = y | \mathbf{x}) = \begin{cases} \pi(\mathbf{x}_\pi) + (1 - \pi(\mathbf{x}_\pi))(1 - p(\mathbf{x}_p)) & \text{if } y = 0 \\ (1 - \pi(\mathbf{x}_\pi))p(\mathbf{x}_p) & \text{if } y = 1 \end{cases}$$

where π and p from Eqn (1) are now functions leveraging ND/LQF/content features (\mathbf{x}_π) and LM/collaborative features (\mathbf{x}_p).

By separating the functional contribution of confounders (π) and ability (p) in IRT-ZILM, we hope to unambiguously decouple these aspects from each other and improve interpretability and explainability. The model is learnt by gradient descent of negative log likelihood of the training data to optimise all parameters. In WSML it is common to learn in a two-step process, for example, by iteratively fixing and optimising IRT and weak label weights [32].

ZIMs have been used to account for excess zeros in many counting tasks using Poisson and negative binomial models [17, 40, 38, 23], and in learning analytics as statistical counting models in self-regulated learning [12]. An important property of statistical models is identifiability as it allows for the precise estimation of the values of its parameters [10, Sec 4.5]. Parallel theoretical analysis has considered identifiability of the counting model parameters [35] and the mixture components [19]. It is worth noting that IRT also suffers from identifiability problems (*c.f.* [5, p.6] and [10, Sec 14.]) but using priors or regularisation can alleviate these.

As far as we are aware, this is the first work to incorporate ZIM in this manner. Choosing IRT as the base LM in IRT-ZILM over alternative options is motivated for several reasons. Firstly, IRT is well-understood and simple to interpret, and using this model as a platform to demonstrate new properties of equity in this early work carries the same benefits. Secondly, BKT is known to have over- and under-estimation problems [6, 18] which may muddle our under-

standing of equity for ND students. Additionally, several technical hurdles need to be overcome, notably adaptation for contextualised individualisation in mixed graphs. Finally, although DKT [33] models can probably learn latent representations that correlate to DRT preferences, this is at the expense of control and interpretation of the effects.

Extra Results

Fig 5 shows this effect for four user/item pairs. For example, the first student should be 60% (orange) successful on this item, however, their LQF is 0.25 (blue), so their success rate drops to 15% (green). Therefore, LQF can be interpreted as a measure of the contextual inequity in these settings.

Although the purpose of this research is to provide equitable estimates of student ability and to provide enabling technology that selects the most appropriate DRT for students, we note that we may also identify students that need additional support in specific areas by recognising potentially unidentified NDCs. We can approach this by creating two models: let \mathcal{M}_0 be the model for a student’s reported NDC state (the ‘null’ model), and let \mathcal{M}_1 be a model trained on data assuming an alternative NDC state (the ‘alternative’ model). Since we have already shown that metrics and likelihood is improved with IRT-ZILM, a statistical hypothesis test can be performed on both likelihoods to determine whether the null or alternative NDC offers a better explanation of data. We leave further elaboration of this approach as future work since it is outside the scope of our direct objectives.

Figure 5: IRT predictions (f) combining with complementary LQFs (π) producing IRT-ZILM predictions (p).

Figure 6: Scatter plots of true *vs.* estimated difficulty parameters from IRT and IRT-ZILM. Perfect estimation will place all points on diagonal. Estimation from IRT-ZILM is significantly more accurate than IRT.

Equity and Fairness of Bayesian Knowledge Tracing

ABSTRACT

We consider the equity and fairness of curricula derived from Knowledge Tracing models. We begin by defining a unifying notion of an equitable tutoring system as a system that achieves maximum possible knowledge in minimal time for each student interacting with it. Realizing perfect equity requires tutoring systems that can provide individualized curricula per student. In particular, we investigate the design of equitable tutoring systems that derive their curricula from Knowledge Tracing models. We first show that the classical Bayesian Knowledge Tracing (BKT) model and their derived curricula can fall short of achieving equitable tutoring. To overcome this issue, we then propose a novel model, Bayesian-Bayesian Knowledge Tracing (B²KT), that naturally allows online individualization. We demonstrate that curricula derived from our model are more effective and equitable than those derived from existing models. Furthermore, we highlight that improving models with a focus on the fairness of next-step predictions can be insufficient to develop equitable tutoring systems.

Keywords

equity & fairness, knowledge tracing, intelligent tutoring

1. INTRODUCTION

In recent years Massive Open Online Courses (MOOCs) and online educational platforms have gained significant importance. They hold the opportunity of providing education at scale and making education accessible to a larger part of the world's population. To facilitate learning in online education and enable customized learning paths for all students, intelligent tutoring systems can be employed while limiting the amount of manual work necessary for each student [11].

In that context, moving education from an offline setting to an online setting, has the potential to promote *Inclusion, Diversity, Equity, and Accessibility (IDEA)*. In particular, by reducing personnel efforts for tutoring, there is the opportunity to include students with diverse backgrounds and

skills, and, importantly, to support their learning equitably. To achieve this, an intelligent tutoring system must be able to adapt to the specific characteristics of each student.

While individualized tutoring has been studied in the community for many years, we consider individualization with a focus on equitable and fair tutoring in this paper. We start by providing a unifying definition of an equitable tutoring system. Our definition is based on the ethical principles of *beneficence* (“do the best”) and *non-maleficence* (“do not harm”) which are commonly adopted in bioethics and medical applications [1]. These principles dictates that we should provide tutoring which maximizes the achieved knowledge while minimizing a student's efforts. In particular we focus on modifying Bayesian Knowledge Tracing (BKT) [2] to better realize these ethical principles. To this end, we propose the Bayesian-Bayesian Knowledge Tracing (B²KT) model and demonstrate its advantages for equitable tutoring in several experiments. Furthermore, we investigate the relation of the commonly considered AUC score concerning the derived tutoring policies, finding that even if a BKT model appears fair in terms of the AUC score, the derived tutoring policies can be inequitable.

In summary, we make the following contributions: *(i)* We propose a unifying definition of equitable tutoring motivated by ethical principles. *(ii)* We propose the B²KT model which allows for effective individualization and demonstrate its benefits concerning equitable tutoring. *(iii)* We highlight that focusing on equity in terms of AUC can be insufficient to ensure equitable tutoring in terms of our definition.

An longer version of this paper with additional experimental results and extended discussion is available [15].

2. RELATED WORK

Fairness in online education and BKT. Several works have considered fairness in data-driven educational systems and intelligent tutoring, e.g., [7, 4, 17, 8]. In [7], the authors discussed implications of using data-driven predictive models for supporting education on fairness. They identified sources of bias and discrimination in “the process of developing and deploying these systems”, and discussed high-level possibilities to improve fairness of systems in the “action step”. In [8, 17], it was investigated how different data sources can provide helpful information to predict students' success in education. Key insights were that different data sources can help to make better predictions but have different characteristics in whether they over- or underestimate students' success [17], and that such predictions can include gender and

racial bias in some fairness measures which can be partly alleviated through post-hoc adjustments [8]. In [4] fairness in the context of BKT was studied, and it was found that tutoring policies basing on inaccurate BKT models can be inequitable, when considering the difference in learning success for different subpopulations as a measure of unfairness. Related work also considers adopting a Bayesian perspective for realizing fair decision rules under model uncertainty [3] and fairness in the context of non-i.i.d. data [19].

Individualization in BKT. Several papers have studied individualization of BKT models per student, e.g., [9, 10, 18]. In [10] the *prior per student* model was introduced which uses a student-specific parameter characterizing the students’ individual knowledge. [18] considered individualization through defining student and skill specific parameters which are fitted through gradient descent.

Instructional policies. Key for achieving equity according to our definition are instructional policies which stop practicing a skill at the right time. This problem has for instance been considered in [6, 12]. Further related work has investigated approaches leveraging deep models for creating policies to quickly assess students’ knowledge [16] and using reinforcement learning for optimizing tutoring policies [14, 5].

3. BACKGROUND & NOTATION

Bayesian Knowledge Tracing. Bayesian knowledge tracing (BKT) [2] is a model characterizing the skill acquisition process of students. For a single skill, it can be understood as a standard hidden Markov model in which the binary (latent) state encodes the mastery of the skill, and the binary observations indicate whether a practicing opportunity of the skill was solved correctly. Upon practicing a not yet mastered skill, the student acquires the skill with probability $p(T)$. Once a skill is mastered, it remains mastered. If a student has mastered the skill practiced by an exercise, they solve this exercise correctly with probability $1 - p(S)$. If a student has not mastered the skill, it guesses the correct answer with probability $p(G)$. At the beginning, a student has already mastered the skill with probability $p(L_0)$.

Notation. We consider the interaction of students $s \in \mathcal{S}$ with an intelligent tutoring system. The interaction history up to time t is denoted as $\mathcal{D}_t^s = \{(z_1, c_1), (z_2, c_2), \dots, (z_t, c_t)\}$, where $z_{t'} \in \mathcal{Z}$ is the skill practiced through an exercise at time t' , $c_{t'} \in \{0, 1\}$ is an indicator of whether the exercise was solved correctly, and \mathcal{Z} is the set of skills. In the context of BKT, we refer to the random variables (RVs) indicating whether skill $i \in \mathcal{Z}$ is mastered at time t as Z_t^i and to the RVs indicating whether an exercise practicing that skill would be solved correctly as C_t^i . Sometimes we add another superscript s to indicate the student the RVs correspond to. Upper-case terms like Z_t^i denote RVs and their lower-case counterparts like z_t^i denote particular instantiations.

4. EQUITABLE TUTORING

In this section, we provide a definition of equity in intelligent tutoring and discuss its operationalization.

4.1 Definition

We consider a tutoring setting in which a total of K skills ought to be taught to a set of students \mathcal{S} by an intelligent tutoring system employing a tutoring policy $\pi: \mathcal{H} \rightarrow \mathcal{I} \cup \{\top\}$. This policy maps histories $h \in \mathcal{H}$ consisting of observations

of a student’s learning process to an exercise $e \in \mathcal{I}$ to be practiced next or to a stop-action \top , which ends the teaching process. Each student can have different learning characteristics. Every tutoring policy π has an expected stopping time $T^s(\pi)$, i.e., the expected time of executing the stop action, and an expected knowledge $L^s(\pi)$ acquired by the end of the teaching process, i.e., $L^s(\pi)$ is the expected number of mastered skills upon executing the stop action.

Our notion of equity is based on the ethical principles of *beneficence* and *non-maleficence*. We understand them to translate into the objective of maximizing a student’s knowledge using as little of the student’s resources as possible, i.e., performing a minimal number of exercises:

Definition 1. Consider a tutoring system employing a tutoring policy π . The policy π is equitable for student s iff

$$T^s(\pi) = \min_{\pi', L^s(\pi')=K} T^s(\pi') \quad \text{and} \quad L^s(\pi) = K.$$

A tutoring system is equitable if its tutoring policy is equitable for all students $s \in \mathcal{S}$.

Thus, informally, a tutoring system is equitable if it can teach all K skills in the minimal amount of time possible to any student. Note that our notion of equity is strongly related to that introduced in [4] (cf. discussion below). In the above definition, we implicitly assume that all students can master all K skills.¹ Importantly, a tutoring system can only be equitable if it is adaptive to the students which are interacting with it. In particular, it has to individualize the assignment of exercises and needs to carefully select the “stop action”, in order to achieve equity. The above definition describes an idealized notion of equity which in general cannot be achieved as the tutoring policy would have to teach using the optimal policy right from the beginning. Nevertheless, we can compare tutoring policies π in the spirit of the above definition. In particular, given two tutoring policies π and π' which both teach the same number of skills, we consider the policy π to be *more equitable* as compared to π' if for all students $s \in \mathcal{S}$ it holds that $T^s(\pi) \leq T^s(\pi')$.

We note that our notion of equity is strongly related to that introduced in [4]. In [4], the authors “assume that an equitable outcome is when students from different demographics reach the same level of knowledge after receiving instruction”. The desideratum of achieving knowledge fast is later also added to their notion of equity whereas in our case it is a fundamental constituent. Furthermore, our interest extends to downstream implications of such a definition of equity, namely the individualization of knowledge tracing.

Theoretical Implications. Our definition of equity leads to the following (probably obvious) but important observation:

Observation 1. A tutoring system for a population of students with different learning characteristics can only be equitable if its tutoring policy is adaptive to the students.

Thus, we note that if the tutoring policy is derived deterministically from a non-adaptive, initially incorrect, model of the students, the tutoring system will in general not be equitable. Achieving equity would require basing a policy on rich side information in order to employ an optimal tutoring policy for each student right from the beginning. But such rich side information might not be available.

¹Our definition can be easily generalized to account for an individual student’s maximal achievable knowledge.

Figure 1: Graphical model of B²KT. The acquisition and application of the K skills depends on $p(L_0)$, $p(S)$, $p(G)$, $p(T)$.

4.2 Operationalization

Tutoring policies are often either simple fixed strategies or derived from a model, e.g., a BKT model, such that each knowledge component is repeatedly exercised until it is mastered with a certain probability. But tutoring policies based on incorrect or non-adaptive models can result in a student not acquiring all skills or suggest to perform too many practicing opportunities. Thus the following two general directions are important for building equitable tutoring systems: (i) **Using side information.** Any available side information about a student should be used to individualize the underlying models. In the context of classical BKT models, the side information could be used to make an initial guess about the key parameters of the model ($p(L_0), p(S), p(G), p(T)$). (ii) **Online adaptation.** Even when using side information, a model is likely not perfectly individualized to all students. To further adjust the models in such cases, online adaption of the models during interaction seems promising.

5. PROPOSED APPROACH: B²KT

In this section, we propose a Bayesian variant of the classical BKT model which enables online adaption to student’s parameters from which individualized — potentially more equitable — policies can be derived, cf. Figure 1.

We assume that each student s has its own learning dynamics, described by student-specific parameters θ^s . If the learning dynamics can be described using a BKT model, $\theta^s = (p(L_0^s), p(T^s), p(S^s), p(G^s))$. We assume these learning dynamics to apply for the acquisition of *all* skills. In practice, we don’t know these parameters and need to infer them. To this end, we take a Bayesian approach, and we assume a set of possible parameters Θ such that $\theta^s \in \Theta$ and a prior distribution $p_0(\theta^s)$. Based on t observations of a student’s practicing exercises collected in \mathcal{D}_t , we can compute the probability that a student has mastered a specific skill and base tutoring policies thereon. As we don’t know θ^s , this requires marginalizing out the (unknown) parameters θ^s . In this way the different possible parameters and their influence for predicting the knowledge state get re-weighted according to the available data. In particular, we compute

$$p(Z_t^{s,i} | \mathcal{D}_t) = \int_{\theta \in \Theta} \underbrace{p(Z_t^{s,i} | \theta, \mathcal{D}_t)}_{=:(\#1)} \underbrace{p(\theta | \mathcal{D}_t)}_{=:(\#2)} d\theta, \quad (1)$$

where $Z_t^{s,i}$ is a random variable indicating whether skill i is mastered at time t by student s . For only a few possible parameters θ , the above equation can be solved exactly by enumeration and by observing that both terms (#1) and

Figure 2: Equity gap vs number of excess learning opportunities. B²KT becomes more equitable as more skills are taught.

(#2) can be computed efficiently by the following recursion:

$$\begin{aligned} \alpha_0^\theta(l) &= p(Z_0^{s,i} = l | \theta) = p(L_0)^l (1 - p(L_0))^{1-l} \\ \alpha_{t+1}^\theta(l) &= p(Z_{t+1}^{s,i} = l, \mathbf{c}_{t+1}^i) \\ &= \sum_{z_t^{s,i}} p(\mathbf{c}_{t+1}^i | Z_{t+1}^{s,i} = l) p(Z_{t+1}^{s,i} = l | Z_t^{s,i} = z_t^{s,i}) \alpha_t(z_t^{s,i}) \end{aligned}$$

Here \mathbf{c}_t^i collects all observations with respect to practicing the i th skill up to time t , and $c_{t'}^i$ is the t' th entry of \mathbf{c}_t^i . Then

$$\begin{aligned} (\#1) &= p(Z_t^{s,i} = 1 | \theta, \mathcal{D}_t) = \frac{\alpha_t^\theta(1)}{\alpha_t^\theta(0) + \alpha_t^\theta(1)}, \text{ and} \\ (\#2) &= p(\Theta = \theta | \mathcal{D}_t) = \frac{p_0(\theta) \cdot (\alpha_t^\theta(0) + \alpha_t^\theta(1))}{\sum_{\theta' \in \Theta} p_0(\theta') \cdot (\alpha_t^{\theta'}(0) + \alpha_t^{\theta'}(1))}. \end{aligned}$$

6. EXPERIMENTS

We perform experiments on synthetic data and consider settings in which the learning rate $p(T^s)$ is assumed to be unknown. This is motivated by previous work which has identified the learning rate as a key parameter for improving BKT based models [18]. In all presented results we denote the average stopping time of a policy for a population of students by T_{stop} and the average number of acquired skills by % skills. We consider THRESHOLD(τ) curricula based on knowledge tracing models. These curricula repeatedly exercise a skill until it is mastered with a probability of at least τ under the model. We consider the following models: (i) BKT: the classical BKT models with fixed parameters; (ii) B²KT: the proposed Bayesian-BKT model.

Students with different learning behaviors. We study the equity of tutoring policies when the students are sampled uniformly from two groups, each containing students with learning dynamics described by a ground truth BKT model. In particular, we build on the experimental setup from [4] where there is a group of slow learners (BKT slow) and fast learners (BKT fast). In [4], the authors also fitted a BKT model to interaction data from students from both groups; we refer to the corresponding BKT model as BKT mixed. The parameters of the considered models are as follows:

	$p(L_0^s)$	$p(S^s)$	$p(G^s)$	$p(T^s)$
BKT slow	0.0	0.2	0.2	0.05
BKT fast	0.0	0.2	0.2	0.3
BKT mixed	0.071	0.203	0.209	0.096

We considered the interaction with 400 students, 200 from the slow and the fast group, respectively, and we compared the performance of THRESHOLD(0.95) tutoring policies based on these models for different numbers of skills that ought to be taught in Table 1. We observe that in the case of mismatch of the student properties and the BKT models used

Table 1: Equity trade-offs of curricula derived from different models/parameterizations.

THRESHOLD(0.95)	1 skill				5 skills				20 skills			
	slow learners		fast learners		slow learners		fast learners		slow learners		fast learners	
	% skills	T_{stop}	% skills	T_{stop}	% skills	T_{stop}	% skills	T_{stop}	% skills	T_{stop}	% skills	T_{stop}
BKT slow	97.00	24.14	99.50	9.49	97.20	122.80	99.90	66.00	97.55	492.64	99.90	183.84
BKT fast	61.00	13.85	97.50	5.96	62.60	71.98	96.10	29.81	64.20	288.76	97.23	120.59
BKT mixed	95.00	23.51	100.00	8.33	95.40	113.67	99.90	40.93	94.53	466.55	99.68	169.86
B ² KT	94.50	24.04	100.00	7.88	97.70	120.87	98.40	32.61	96.68	493.00	96.66	120.05

for the threshold policy, either only a small fraction of the skills (clearly below 95 %) is acquired or that more than necessary time is spent exercising. The mismatch issue is alleviated in the case of the B²KT model (assuming a uniform prior over both types of students), in particular for a larger number of skills. Intuitively this is because, in the case of multiple skills, the model has more opportunities to learn about the students’ characteristics and leverage this knowledge in later tutoring. This fact is also illustrated in Figure 2 in which we reproduce and extend an experiment from [4] in which we compare the “equity gap” (the difference in the percentage of skills mastered by fast and slow students, respectively) to the number of excess learning opportunities. Importantly, B²KT becomes more equitable as more skills are taught.

Out-of-distribution generalization. We test whether B²KT can help with aspects relevant to *inclusion and diversity*. In particular, we consider a stylized mismatch setting in which a tutoring system interacts with students who have a learning behavior not considered when building the system. In addition to the previous two types of students, we assume a third type of learner (BKT med) with the following parameters: $p(L_0^s) = 0.0, p(S^s) = 0.2, p(G^s) = 0.2, p(T^s) = 0.18$. We considered THRESHOLD(0.95) policies based on BKT models of slow and fast learners and the B²KT model with a uniform prior over slow and fast learners. Our results are presented in Table 2. We observe that the performance of the policies derived from the B²KT model have comparable performance to those derived from the true model (although the true model has zero posterior probability) whereas other models yield policies worse in terms of stopping at the right time or teaching the right amount of skills. This property of B²KT can be helpful for promoting inclusion, e.g., when interacting with students who were underrepresented in the data used for building an intelligent tutoring system.

Fair next step predictions do not necessarily imply equitable tutoring. We show empirically that models which might appear to be fair when looking at their AUCs for different groups of students do not necessarily yield equitable tutoring policies. In particular, we again focus on a student population consisting of two groups of students:

	$p(L_0^s)$	$p(S^s)$	$p(G^s)$	$p(T^s)$
Group 1	0.0	0.1	0.4	0.1
Group 2	0.0	0.1	0.2	0.3

We generated data of 400 students (50% from group 1 and group 2, respectively) in a setting with 20 skills and 1000 random exercises from a BKT model. The true model of group 1’s students achieved an AUC of 0.7393 for group 1’s students, while the true model of group 2’s students achieved an AUC of 0.6710 for group 2’s students.

Looking only at the AUC, the two models appear rather inequitable (there is no group parity). Thus it might appear

sensible to aim to use a BKT model for tutoring which has comparable AUCs for both groups in order to promote equity. For instance, a BKT model using parameters $p(L_0) = 0, p(S) = 0.4, p(G) = 0.1, p(T) = 0.65$ achieves an AUC of 0.6719 on group 1’s students and of 0.6733 on group 2’s students, respectively. That is, the AUCs on the two groups are approximately equal. However, when looking at the different models with respect to their tutoring performance using a THRESHOLD(0.95)-policy, we observe a very different picture, cf. Table 3. In particular, the fraction of skills taught differs significantly between the two groups: In group 1 only 28.68% of the skills are acquired by the students on average while in group 2 74.70% of the skills are acquired. This finding is closely related to the observation that models with greatly different characteristics can have similar AUCs [13].

Table 2: Out-of-distribution generalization.

THRESHOLD(0.95)	1 skill		5 skills		20 skills	
	BKT med		BKT med		BKT med	
	% skills	T_{stop}	% skills	T_{stop}	% skills	T_{stop}
BKT slow	99.50	11.28	99.55	56.45	99.59	225.25
BKT fast	90.75	7.61	91.55	37.59	91.70	151.36
BKT mixed	99.50	10.46	99.00	51.71	99.21	211.29
BKT med	98.25	8.82	97.35	45.59	97.84	184.20
B ² KT	98.75	10.33	97.50	48.80	94.19	168.36

Table 3: Fairness in terms of similar AUCs on different groups does not imply fairness in terms of the derived curricula.

group	group fair wrt AUC			true model wrt group		
	AUC	% skills	T_{stop}	AUC	% skills	T_{stop}
group 1	0.6719	28.68	61	0.7393	96.13	308
group 2	0.6733	74.70	64	0.6710	96.35	105

7. CONCLUSION

We considered the equity and fairness of curricula derived from knowledge tracing models, and provided a unifying definition of equitable tutoring systems. Our definition is, in many practical settings, not realizable but suggests that the individualization of tutoring policies to students is key for realizing equity. We proposed the B²KT model, a Bayesian variant of the classical BKT model, and demonstrated in various experiments that it can be beneficial for realizing equitable tutoring systems and promoting IDEA more generally. Furthermore, we highlighted that improving and evaluating models with the main focus on next-step predictions can be insufficient to develop equitable tutoring systems.

ABSTRACT

Several studies adopt different approaches to examining how economic, racial, and gender circumstances influence student performance in large-scale entrance exams, such as the National High School Exam (ENEM). Using a methodology based on Item Response Theory, ENEM's exam attempts to assess, for each item (question), the curve (function) that relates the participants' abilities to their probabilities of correctly answering the item, which is assumed to hold whichever subgroup, a fundamental premise of IRT called invariance. This work analyzes whether the ENEM 2019 test presented similar curves for subpopulations defined by gender, race, and income, regardless of the participant's actual abilities. Our approach is to analyze the properties of the observed curve for each group and then perform a non-parametric ranking test to compare the equity of each item (question) for each analyzed characteristic. We found that the "Languages and Codes" questions consistently favored male, white, and high-income participants. At the same time, the other three sets of questions (Mathematics, Natural Sciences, and Human Sciences) were considerably more egalitarian.

Higher education entrance exams, Grading equity, Item Response Theory, Educational Data Mining

1. INTRODUCTION

The Brazilian National High School Exam (ENEM, for its initials in Portuguese) is one of the most extensive entrance exams globally, having over 5 million participants registered in 2019 [11]. The exam has several functions; on an individual scale, it serves as an admission test to access the federal universities (through the Unified Selection System or SISU) and access to the federal scholarship programs (University for All Program or ProUni). On a collective scale, this exam allows a comparison between schools and municipalities, and it also serves as an indicator for national public

educational policies at the national level [10]. Several studies investigated how sensible characteristics such as income, race, gender, and locality, affect the participants' score [13, 20, 19]. However, most studies use the grade obtained as a direct indicator of the participants' ability without investigating whether exams' grading methodologies are unfairly favoring or disfavoring specific subpopulations.

Since 2009, ENEM's participants' grades have been assigned using Item Response Theory (IRT) methods, which consider the difficulty of each participant's correct questions [7] to assign the grades, in contrast to the Classical Test Theory, where only the number of correct answers matter [4]. IRT creates a probability function that gives, for each question, the probability of a correct answer given the participant's ability. Moreover, the primary assumption of IRT theory is that such function does not vary independently of subgroups of students [7, 16]. This assumption means that, given two groups based on a specific characteristic (*e.g.*, men and women), we expect the proportion of correct answers for a particular question and grade to be similar in both groups. If that is not the case for several questions in a test, the method will end up a sub or super estimating a group's grade, causing inequality between the groups.

We investigate ENEM's 2019 edition to evaluate whether the invariant assumption holds for gender, race, and income level characteristics. For such, we use the assigned grades and participant's answers given by ENEM's IRT evaluation to approximate the Item Characteristic Curves (ICCs)—which are functions of the probability of correct answer given the participant score. We compare the standard deviation of the observed Area Under Curve (AUC) for each group based on a characteristic (such as men and women for the gender). If a group has a bigger AUC than another group, their participants have a more significant overall probability of correctly answering the question, independently of their true abilities. Therefore, questions showing a high AUC standard deviation for a particular characteristic may favor a group. Following the first analysis, we perform a non-parametric ranking test to check if the behavior found in the questions is statistically consistent in the whole test.

Thus, this paper uses statistical analysis to evaluate whether or not the ICC's estimation of IRT theory might favor particular groups. The contributions of our analysis reside in these aspects: (1) Analyzing whether the question estimations *per se* discriminate towards certain groups instead of

evaluating the grades themselves. (2) Using robust non-parametric statistical tests to determine if these differences are consistently privileging a specific group.

2. DATA

We used ENEM’s most recent microdata from 2019, composed of four objective tests, each containing 45 multiple choice questions and an essay. The tests evaluate the knowledge areas: Mathematics, Languages and Codes, Human Sciences, and Natural Sciences. The Languages and Codes test consists of five foreign language questions, where the participant chooses whether to be evaluated in English or Spanish, and the remaining 40 questions are in Portuguese. Each participant must take all of the tests.

The National Institute of Educational Studies and Research Anísio Teixeira (INEP), responsible for the ENEM, made available the microdata per participant. These data are anonymized and contain the scores obtained, each participant’s answers, registration data (such as city, age, and school), and a non-mandatory socioeconomic questionnaire about (self-declared) race, family income, and parent’s education and profession. We analyze three group characteristics obtained from the questionnaire:

Race: There are five options in addition to “undeclared”: white, black, brown, yellow (Asian), and indigenous. We analyzed only the first three (white, black, and brown), as the others have few participants.

Income: Family income is defined as monthly minimum wages (MW), and the possible range goes from zero to twenty or more MW. Based on Neri et al. (2020) [14], we separate the participants into low (less than 1/2 MW per capita), middle (between 1/2 and 2 MW per capita), and high-income (more than two MW per capita) classes.

Gender: The exam’s registration only allowed for “Female” and “Male” to be mandatory in its selection. Therefore, we do not have information about other gender minorities.

Group	Exam	Foreign Language	
		English	Spanish
White	463,431	307,657	174,199
Black	125,489	65,503	66,069
Pardo	502,996	244,485	281,473
Low Income	660,222	305,442	389,535
Medium Income	390,670	259,454	144,957
High Income	97,881	83,409	16,223
Women	666,905	350,375	347,461
Men	481,868	297,930	203,254
Total	1,148,773	648,305	550,715

Table 1: Number of participants in each group which were regular graduates in 2019 and answered the questions about Race, Gender, and Income Level. Each participant can choose to take the Foreign Language questions in English or Spanish.

As the parameters of the grading methodology used by ENEM are estimated using only the responses of students who are regular graduates in that particular year, our analysis will

use data from such students who answered the questions of gender, race, and income. Table 1 summarizes the number of analyzed participants in each subgroup divided by the different characteristics.

3. ENEM SCORE ESTIMATION

The method used to obtain the ENEM participants’ score is from the Item Response Theory (IRT) [8], which models the probability of a participant responding correctly to an *item* (or *question*) as a function of its parameters and the participant’s *ability* (or *proficiency*). Several increasing monotonic functions are used to model such a relationship such as the Rasch model [15], and the one and two-parameter logistic models [12, 2]. We employed ENEM’s three-parameter logistic function [2], that is the probability of a correct answer by participant j to item i (event $U_{ij} = 1$) given the proficiency parameter θ_j and item parameters a_i , b_i , and c_i :

$$P(U_{ij} = 1 | \theta_j, a_i, b_i, c_i) = c_i + (1 - c_i) \frac{1}{1 + e^{-a_i(\theta_j - b_i)}}, \quad (1)$$

The relationship between $P(U_{ij} = 1 | \theta_j)$ and the parameters a , b , and c is called the *Item Characteristic Curve* (ICC). Figure 1 illustrates an example of this curve.

Figure 1: Example of an Item Characteristic Curve (ICC).

Both the item parameters and the participants scores are estimated simultaneously using the participants answers. The scores are estimated, given the item parameters, using the *Expected a Posteriori* (EAP) method with an *a priori* probability function, which is the same for all participants. The *a priori* distribution has mean and variance corresponding to the mean and variance of regular graduating participants in 2009, defined as 500 and 100 points, respectively. More information is available in the participant guides [8, 9] and their bibliographic references [1, 3, 7].

Invariance: Item Response Theory starts from the premise that, for a given question, a single function maps an examinee’s ability to his probability of answering it correctly. Therefore, if the model is well specified, all populations’ parameters are the same. This premise implies the property called *invariance of item and ability parameters*, which is the primary distinction between IRT and classical test theory [7]. Under invariance, we have that the parameters that

characterize an item do not depend on the participants' ability distribution and that the participant ability parameter does not depend on the set of test items.

In practice, invariance does not occur in the strict sense, even when the model is correctly specified [7]. Nevertheless, it is essential to determine the "degree" to which invariance holds. Next, we present how we examine the invariance of the items concerning the subpopulations defined by gender, race, and income.

4. METHODOLOGY

We use the concept of Item Characteristic Curves to compare the performance of each analyzed group in each question. The advantage of such comparison is that it allows us to disregard distinct distributions of scores as we analyze the probability of a correct answer *given* the participant score. For such, we analyze the *observed* ICCs, which were constructed considering the proportion of participants who answered the item correctly for different score ranges.

4.1 AUICC Inspection

Under invariance, we expect the relationship between the participants' scores and the probability of correctly answering a specific question (*i.e.*, the item characteristic curve) to be similar to all groups. Therefore, the area under the item characteristic curve of a specific question should be near equal to all groups. We calculated how different the observed AUICC is for each group of a specific characteristic with the following steps:

1. **Observed ICC:** For each question and subpopulation, the observed ICC was the proportion of participants who answered correctly given their score range.

2. **Item AUICC:** To compare the difficulties of each question, we calculated the area under the item characteristic curve for each subpopulation and the total population. The AUICC can be interpreted as: if a group has a higher AUICC for a question, then it has a higher probability of answering it correctly regardless of possible abilities; therefore, the item is less difficult for that group. Figure 2 shows the Item AUICC calculation.

3. **AUICC discrepancy:** Lastly, we estimated the discrepancy of difficulty for each item and each analyzed characteristic (gender, race, and income) by taking the standard deviation of AUICC for the groups and normalized this value by dividing by the AUICC found for the total population. This normalized value indicates whether inequality seems to hold for this item (small values) or not (bigger values).

4.2 Invariance Checking

The item-by-item AUICC comparison indicates potentially troubling questions. However, to show if there is a consistent difference among the social/gender groups, we performed a non-parametric Friedman ranking test [6, 18] (as implemented in [17]). We performed this test for each exam to see if there are statistical differences among the groups considering a set of items' AUICCs for each social/gender group. For a fixed exam and characteristic, the test procedure involves ranking the groups' AUICC for each question and

Figure 2: Illustration of the Observed ICC for a given question. The light blue bars represent the proportion of correct answers given by the participants given a grade range. The AUICC is the sum of the area of the bars.

then comparing the ranks obtained for each group. Therefore, if we have n questions and k groups, the Friedman test determines if any of the k groups ranked consistently higher or lower than the others.

For the combination of tests and features whose null hypothesis was rejected by the Friedman test, we determine the one-by-one comparisons through a Finner post-hoc test [5] using the pivot quantities obtained by the previous test. Friedman test checks the hypothesis all groups are equal. If rejected Finner post-hoc test distinguish how each group performs compared to the others.

5. RESULTS

5.1 AUICC Inspection

We performed the Observed ICC analysis to all selected characteristics and the Mathematics (MT), Languages and Codes (LC), Human Sciences (HS), and Natural Sciences (NS) tests. The proportion of corrected answers was calculated for sets of participants' scores with a bin size of 15. For the Languages and Codes test (LC), we separated the questions based on the idiom (Portuguese, English, and Spanish). Every participant takes the Portuguese questions but can choose whether to take English or Spanish as the foreign language questions.

The results are summarized in Figure 3, where for each exam, we have a heatmap where each row of squares indicates which characteristic was analyzed, and the squares in the same columns correspond to the same question. The color of the squares denotes the value of Area discrepancy for that question in the given characteristic, where the darker tones are equivalent to the greater discrepancy, and the symbol indicates which group had the highest area. The color scale is the same for all exams. Therefore, if a particular row contains several dark squares, it indicates that the corresponding exam may be unequal for that given characteristic. If the symbols on the squares are mainly the same, such a given group is more frequently favored in such an exam.

Visually, we can see that a few questions have high diffi-

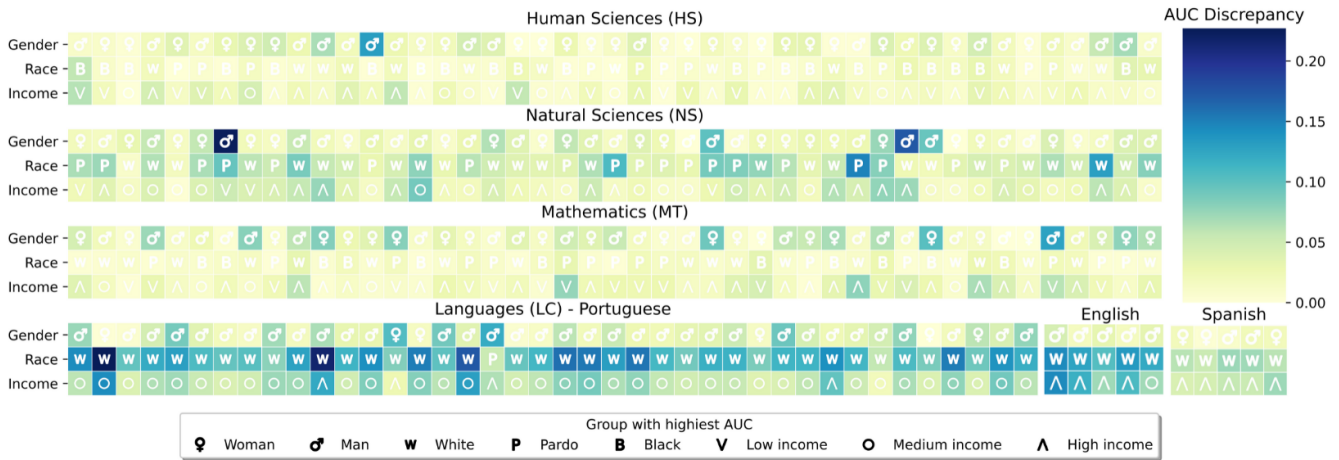

Figure 3: Heatmap of the Area discrepancy based on the Observed ICC. The color of each square indicates the value of Area discrepancy and the symbol indicates the group with the highest area. As the importance of the indicated grows with the discrepancy, the symbols' visibility also grows with the color.

culty discrepancy for the HS, NS, and MT tests. However, the group with the highest area in such questions varies significantly. For instance, in MT and NS, the most discrepant questions are almost equally divided between *man* and *woman*, being the group with the highest area. However, the LC test behaved quite differently. For the race characteristic, almost all of the questions presented high difficulty discrepancy, with the *white* group being dominant as the race with the highest area. Meanwhile, the income groups did not show a consistent dominance of a specific group for the question in Portuguese. However, they did show a strong dominance of the *high* income group in the foreign language questions, mainly in English. This result indicates that the first three tests are egalitarian for gender, race, and income, while the LC test, principally the foreign language questions, is not.

5.2 Invariance Checking

To assess whether the behavior observed in the visual comparison is consistent, we performed the Friedman and Finner tests with the AUICCs. Agreeing with the first experiment, the Human Sciences (HS) and Mathematics (MT) tests did not show a consistent favoring or disfavoring for any group, having a p-value greater than 0.05 in the Friedman test. Meanwhile, the Languages and Codes questions in Portuguese and in English showed a relevant difference among *men* and *women*, with *women* having a lower AUICC rank.

Regarding the Race characteristic, the Natural Sciences (NS) test showed lower AUICC for *black* participants than *white* and *pardo* participants. The Portuguese questions in the LC exam showed similar behavior to the NS test, with the only difference being that the *pardo* participants had a lower AUICC rank than the *white* ones. In both foreign languages questions (English and Spanish), the *black* participants showed a lower AUICC rank than *white*. Lastly, for the Income characteristic, the *low-income* group ranked lower than the *high-income* for NS and also LC in all languages. For the NS test, the *low-income* also ranked lower in AUICC than the *medium-income* participants.

6. CONCLUSIONS

This paper investigated whether the 2019 edition of the Brazilian National High School Exam (ENEM) presented any consistent favor or disfavor for groups based on Gender, Race, and Income Level. Our methodology assessed if the invariance property of Item Response Theory (IRT) holds for Item Characteristic Curves (ICC) estimated for each group given its participants' assigned grades and answers. In our first analysis, we visually compared the overall difficulty of each question and for each group. Then, in our second analysis, we tested if any of the exams were consistently unequal for any group. We found that the Human Sciences and Mathematics questions did not favor or disfavor any group. Meanwhile, the Natural Sciences test was consistently easier for *white* and *pardo* participants in detriment of *black* ones and easier for *high-* and *medium-income* in detriment of *low-income*.

The "Languages and Codes" exam was consistently unequal, with different ICC's (that assigns questions difficulty) behavior for native and foreign language questions. Portuguese questions were overall harder for *women* than *men*, primarily due to the first group having a higher chance of correctly guessing the questions. They were also harder for *black* and *pardo* participants than *white* ones and harder for *low-income* than *medium-* and *high-income*. Foreign language questions also showed inequality, with the English questions favoring *men* in detriment to *women* and both English and Spanish questions favoring *white* participants in detriment of *black* and *high-income* in detriment of *low-income*.

This research also cataloged means of improving IRT: (1) using the analysis of this work to evaluate and possibly reformulate the exam; (2) using data mining methods called multi-task learning to create particular models for each group; (3) using imbalance-robust data mining methods to avoid ICC's bias towards favored groups; and (4) using multi-objective optimization to take into consideration multiple goals (fit the data and keep the model fair). We believe this research contributes to reaching fairer IRT-based tests with the analysis and those future directions.

A deep dive into microphone hardware for recording collaborative group work

Mariah Bradford, Paige Hansen, Ross Beveridge, Nikhil Krishnaswamy, Nathaniel Blanchard

Colorado State University
mbrad@colostate.edu

ABSTRACT

Classroom environments are challenging for artificially intelligent agents primarily because classroom noise dilutes the interpretability and usefulness of gathered data. This problem is exacerbated when groups of students participate in collaborative problem solving (CPS). Here, we examine how well six popular microphones capture audio from individual groups. A primary usage of audio data is automatic speech recognition (ASR), therefore we evaluate our recordings by examining the accuracy of downstream ASR using the Google Cloud Platform. We simultaneously captured the audio of all microphones for 11 unique groups of three participants first reading a prepared script, and then participating in a collaborative problem solving exercise. We vary participants, noise conditions, and speech contexts. Transcribed speech was evaluated using word error rate (WER). We find that scripted speech is transcribed with a surprisingly high degree of accuracy across groups (average WER = 0.114, SD = 0.044). However, the CPS task was much more difficult (average WER = 0.570, SD = 0.143). We found most microphones were robust to background noise below a certain threshold, but the AT-Cardioid and ProCon microphones were more robust to higher noise levels. Finally, an analysis of errors revealed that most errors were due to the ASR missing words/phrases, rather than mistranscribing them. We conclude with recommendations based on our observations.

1. INTRODUCTION

The ubiquity of technology and computers in the classroom has provided unparalleled opportunities to uncover new insights about how people learn in an increasingly digital environment. Successful analysis of learning settings and outcomes — whether through traditional data mining and information extraction, general machine learning, or targeted applications of artificial intelligence (such as intelligent agents in the classroom) — must be able to handle multiple human inputs like structured questions and answers, free-form text, and, importantly, naturalistic human speech that grounds so much of education.

Over the years, various works have assessed the feasibility of utilizing automatic speech recognition (ASR) systems in various environments [1, 4, 6, 7, 8] — of particular note, in 2015, Blanchard et al. [4] evaluated state-of-the-art speech recognition technology on teachers wearing high-quality headset microphones in classrooms, reporting an average word error rate (WER) of 0.44. While [4] found a wide range of ASR performance across major platforms, modern ASR performance is now largely consistent [6]; thus, the primary focus of our work is on which hardware should be used to collect the data to be processed, from real classroom environments. This work highlights budget and performance trade-offs for researchers and practitioners to consider when deploying hardware for studying group work or collaborative problem solving (CPS) [10].

For our evaluation, we simultaneously recorded group audio from multiple microphones. Groups participated in discussion under various conditions that simulate a classroom environment. We then used automatic speech recognition (ASR) to generate separate transcripts from the audio streams of each microphone and used word error rate as our primary metric for evaluating hardware performance. Finally, we took a deep dive into specific errors in the automatic transcription under various conditions to better anticipate how a downstream system might be influenced by said errors. The result is, to our knowledge, a novel assessment of audio sensor hardware for recording collaborative problem solving in a classroom-based data mining system.

2. METHODOLOGY

2.1 Recording setup

We evaluated six microphones: an Audio-Technica ATR2100x-USB (AT-ATR), an Audio-Technica U891Rb Cardioid Condenser Boundary Microphone (AT-Cardioid), an Audio-Technica U891RbO Omnidirectional Condenser Boundary Microphone (AT-Omni), a Blue-Yeti, an MXL AC-404 ProCon (Pro-Con), and a Saramonic SmartMic. Microphones were selected to represent a range of technologies and price points. We assumed that, in a real-world context, one microphone would be used for a single group.

The Blue-Yeti was set to medium-low gain and omnidirectional recording, which are empirically-derived settings motivated by the manufacturer guidelines to maximize the volume of the recording while minimizing clipping. The AT-Cardioid, AT-Omni, and AT-ATR were plugged into a mixer, with the gain set following the same procedure as the Blue-Yeti. The Saramonic was plugged into an auxiliary port (AUX). All other microphones were plugged in with USB. Microphones were all placed on one table five feet from participants. Participant and microphone locations were marked to ensure consistency across groups. Using Adobe Audition, all microphones were synchronously recorded on separate tracks.

Table 1 breaks down our participant demographics. Participants were all students in the Computer Science Department at Colorado State University, all over the age of 18. 26 participants considered English as their first language. Other first languages in the participant pool included Gujarati, Korean, Spanish, Turkish, and Urdu. Providing demographic information was optional and recorded anonymously. Participant groups were recruited by request and all personal information was de-identified.

Table 1: Demographics

Gender	Male	20
	Female	12
	Nonbinary	1
Native Language	English	26
	Non-English	5
	Bilingual	2
Age	18-24	28
	25-31	5

Data was gathered in two types of tests: 1) a prespecified, scripted recording, and 2) a collaborative problem solving task, which are described in Section 2.2 and Section 2.3. In each session, participants sat facing toward the microphone array, and performed both tasks (script first, followed by collaborative task). Each test contained variant noise conditions and was run with 11 ($N = 33$) collaborative triads. Groups were split into two conditions: a “noise” condition where generic “classroom noise” was played at 50% volume from a speaker 10 feet away from the microphone array, and a condition without background noise. The “classroom noise” was pre-recorded classroom sounds including indeterminate chatter. The speaker used was a JBL Bluetooth Flip4 with two 8W amplifiers, corresponding to a maximum 12 dB amplification of the source audio, which was intended

to simulate ambient background noise of an average classroom.

Across all microphones, 7:50:34 total hours of audio were recorded. Specifically, the noise condition constituted 3:40:05 hours of audio, with the remaining 4:10:29 comprising the non-noise condition. Additionally, the scripted task comprised 2:22:38 hours of recording, while the collaborative task constituted 5:27:56 hours of recording.

Each recording from each microphone was separately processed through Google Cloud Automatic Speech Recognition (ASR). Word error rate (WER) was calculated for the full session. The prewritten script served as the ground truth transcript for the scripted portion of the experiment. For the collaborative tasks, transcripts were manually transcribed by researchers, with a lead researcher subsequently verifying the correctness of all the transcripts.

2.2 Group Script Reading Task

In this condition, the participants read a specified script where each participant played a distinct “role” (teacher, student 1, or student 2). The script was a transcription of a real classroom interaction involving two students and a teacher with no overlapping speech.

2.3 Fibonacci Weights Collaborative Problem Solving Task

The Fibonacci Weights exercise is a collaborative problem solving (CPS) group activity where the participants work together to determine the relative weights of five differently colored cubes. The masses of each cube correspond to the Fibonacci sequence. The participants are given a scale, a 10g calibration weight, the cubes, and a worksheet on which to log the weight of each cube when it is determined. The task invites CPS, leading to explicit and implicit coordination, free-form utterances, and overlapping speech.

2.4 Evaluation Metric

We evaluate microphone performance based on ASR performance for word error rate (WER), given by:

$$WER = \frac{S + D + I}{N} = \frac{S + D + I}{H + S + D}$$

where S = the number of substitutions, D = the number of deletions, I = the number of insertions, N = the number of words in the ground truth transcript, and H = the number of successes.

3. RESULTS

3.1 Cross-Task Performance

Figure 1 shows the word error rate (WER) distribution for each microphone across both tasks. A high-level analysis shows that results were relatively consistent across all microphones, with the average WER for every microphone all within 1 standard deviation. The AT-Cardioid showed the best performance, with an average WER of 0.319 ($\sigma = 0.235$). The worst-performing microphone was the Blue-Yeti, with an average WER of 0.365 ($\sigma = 0.278$).

Table 2 provides statistics describing the performance of each microphone across all groups in the script reading task.

Figure 1: Box-and-whisker plot showing word error rate for each microphone across all groups in the collaborative problem solving task.

Table 2: Descriptive statistics of WER across microphones in the script reading task.

Microphone	μ WER	σ
AT-ATR	0.115	0.051
AT-Cardioid	0.112	0.050
AT-Omni	0.112	0.042
Blue-Yeti	0.117	0.040
ProCon	0.120	0.051
Saramonic	0.107	0.035
All	0.114	0.044

Table 3 provides the same in the collaborative problem solving (Fibonacci Weights) exercise.

In the script reading task, all recordings resulted in a low WER within a very small numerical window of each other, with a low standard deviation across groups. The scripted nature of the task allow for clean turn taking, and a review of the recordings confirm there is little to no overlapping speech during the reading of the script. However, this is not how speech in group work typically manifests. Rather, there are overlaps, incomplete sentences, interruptions, etc. Speakers mumble, speak fast, and rely on implicit communication strategies that are not captured in audio recordings, and therefore on information that is not captured in an automatic speech recognition (ASR) platform’s underlying language model. Put simply, if a typical speech recognition algorithm encounters actual audio as captured in group work, we can expect the WER to be much higher.

Table 3: Descriptive statistics of WER across microphones in the Fibonacci Weights Task.

Microphone	μ WER	σ
AT-ATR	0.577	0.151
AT-Cardioid	0.527	0.137
AT-Omni	0.530	0.128
Blue-Yeti	0.613	0.157
ProCon	0.602	0.150
Saramonic	0.581	0.151
All	0.570	0.143

In the collaborative problem solving task, which contains free-form speech with many overlapping utterances and some disfluencies, we also find that all microphones performed comparably. The clear difference in performance between

the scripted condition and collaborative problem solving condition implies free-form speech (e.g., contains natural interruptions, overlaps, sentence fragments, disfluencies, etc.) was the primary difference in ASR performance. In Section 3.2 we quantify these effects. While the Saramonic was (marginally) the best-performing microphone in the scripted condition, but the AT-Cardioid and AT-Omni produced the lowest mean WER for the Fibonacci Weights recordings.

3.2 Word-Level Analysis

Increased word error rates can be due to three primary factors: *deletions*, where a word in the ground truth transcript is omitted; *insertions*, where an additional word not in the ground truth transcript is added; and *substitutions*, where one word in the ground truth transcript is swapped for a different word.

The majority of errors from the ASR were deletions, while substitution and insertion rates stay relatively stable across both tasks. The most commonly deleted words were relatively constant across microphones. This likely means that the deletions were not due to the quality of the recording, but rather the ASR model itself.

A qualitative analysis of the most frequently deleted words exposes the commonality of such terms in the collaborative problem solving task. For instance, the most commonly deleted word weighted by frequency is the demonstrative pronoun “this”. “This” was dropped 41% of the time and correctly transcribed 53% of the time. In the collaborative problem solving activity we can expect this word to be used frequently, which contributes to the high weighted deletion rate. Likewise, other most commonly deleted words, weighted by frequency, include common particles like “so” or “oh,” and acknowledgments like “yeah” or “okay.” However, some words that in context are important and contentful, such as “10” or “20” (referring to the masses of the weights), are also frequently deleted. See supplemental material for the complete analysis of these commonly missed words.

3.3 Ablation of noise

Classroom environments are by nature noisy [5, 9]. Thus, we ran additional experiments where we increase the noise testing, we had four groups of two participants read the prepared script from Section 2.2 multiple times. With each trial we increased the level of the background noise played by the speaker (a 10% increase was equivalent to a 1.6W increase in speaker power). The net effect of this trial was to control for participants (vocal profile) and ground truth transcript (speech content), while varying background noise level.

Figure 2 shows the results of the noise ablation test. The effect of background noise up to 50% (9 dB) was negligible across all microphones, confirming the results in Section 3.1. When the background noise level is greater than 50% (9 dB), we see the word error rate start to increase significantly with each 10% increase in background noise. With the background noise played at maximum speaker volume, with certain microphones (e.g., Blue-Yeti, Saramonic), we see word error rates start to approach the word error rates demonstrated in the free-form Fibonacci Weight collaborative task, even though the participants in this experiment

Figure 2: WER vs. background noise volume.

Table 4: Cost of microphones

Microphone	Cost
Chromebook*	\$0.00
Saramonic	\$25.00
AT-ATR	\$99.00
ProCon	\$99.95
Blue-Yeti	\$129.99
AT-Cardioid	\$319.00
AT-Omni	\$319.00

*Baseline microphone

were reading the “well-behaved” prepared script. When the speaker is at maximum volume, this condition should better approximate the noise conditions of a real classroom [5, 9].

3.3.1 Correlation with price

Figure 3: Microphone cost plotted against group mean WER in scripted, Fibonacci weights, and 100% noise ablation conditions.

Finally, Figure 3 shows the mean word error rates across groups in three of the conditions: the script reading, the collaborative task and the noise ablation test session where noise was set to 100%. Together, these three plots show that there is no clear relationship between the cost of the microphone hardware and the ASR performance over associated recordings. Note, the Chromebook served as a “zero dollar” baseline because all other microphones required a laptop to connect to; the microphone integrated with a laptop that students already have access to would entail zero dollars in additional purchases for an in-class recording system.

4. LIMITATIONS AND DISCUSSION

We assessed the quality of a number of microphones by considering how downstream tasks like automatic speech recognition (ASR) performed. At a high level, we found microphones were largely comparable; however, diving deeper, even when the speech is canonically well-behaved the influence of background noise causes dramatic differences in word error rate across microphones at different rates. We found that in the most extreme noise cases, the AT-Cardioid and the ProCon were the most robust to noise, with word error rates (WER) below 0.2 (the no-noise baseline performance was about 0.1). Our overall pick is the ProCon, because it too is highly robust to noise, the price is a third of the AT-Cardioid, and WER is arguably comparable.

Independent of the microphone hardware, off-the-shelf automatic speech recognition performs well (WER less than 0.2) when the recorded speech is canonically well-behaved (e.g., few overlaps, disfluencies, simultaneous speech). However, when participating in group work, there *are* explicit overlaps, disfluencies, and simultaneous speech. Indeed, the presence of these may indicate healthy, productive, educational group dynamics. Still, when recorded speech contains these artifacts, word error rate soars to surprising levels, not dissimilar to the word error rates reported by Blanchard et al. [4] in their study of live teacher speech. Interestingly, they also evaluated scripted and unscripted speech, and found scripted speech error rates were similar to unscripted. Our results showcase that the technology driving automatic speech recognition has improved substantially, since scripted speech is now transcribed with a far lower WER — just not for the kind of naturalistic speech used in collaborative group-work.

There are several limitations of our study. First, we did not verify our conclusions with alternative ASRs (e.g., solutions from Microsoft or Amazon). Several microphones have settings like gain which we hand-tuned, but could be further experimented with. There are, of course, a plethora of microphones we did not include in our test. Finally, we have done our best to replicate classroom environments in a lab setting, but, for now, our evaluation is limited to the lab.

Since most of the word error rate is due to deleted words, a future analysis should consider if it matters if those words are dropped. Taking the transcribed text and evaluating the performance of a further downstream task such as abstract meaning representation (AMR) parsing [2, 3, 11] on it, and on the ground truth transcript, would demonstrate if the dropped words are resulting in significant lost information. However, downstream tasks are likely much more context/project dependent, and being able to predict possible errors in the transcription by understanding limitations of the data gathering process can aid in appropriately designing the downstream tasks by, for example, accounting for the likelihood of missing stop words.

be	think	it's	think	think	like
oh	be	oh	be	it's	it's
think	it's	be	like	oh	oh

Since substitution and insertion rates stay relatively stable across both tasks, it seems clear that in the free-from collaborative problem solving task, the nature of the speech captured in the recordings leads to more deletions. Therefore it becomes more important to understand the nature of the high deletion rates in the collaborative problem solving task. Are there differences in the precise words that are deleted from the recordings made by each microphone? Are these words, when deleted, ones that are likely to have a negative effect on the performance of downstream analysis tasks using the transcription, e.g., parsing or classification?

Table 5 shows the top 20 most frequently deleted words for each microphone, weighted by the overall occurrence of that word in the ground truth, human-generated transcript. Data here was taken from recordings of the collaborative problem solving task only, to analyze the nature of the words being dropped in a group work environment.

Words w are ranked according to $\sum_{t \in T} D_t(w) \times \frac{\sum_{t \in T} C_t(w)}{\sum_{t \in T} N_t}$, where t is a transcript $\in T$ the set of all transcripts, $D_t(w)$ is the number of times w was deleted in transcript t , $C_t(w)$ is the total count of w in the ground truth transcript t , and N_t is the total number of words in the ground truth transcript t . Since this was the free-form activity and each ground truth transcript was different for each group performing the activity, we sum counts over all transcripts.

The most commonly deleted words were relatively constant across microphones. This likely means that the deletions were not due to the quality of the recording, but rather the ASR model itself. In fact, the only words that appear in the top 20 most deleted words that do *not* appear in the top-20 list for every microphone are “it’s,” which did not appear in the top 20 of the Blue-Yeti, “think,” which did not appear in the top 20 of the Saramonic, and “like,” which *only* appeared

in the top 20 of the Saramonic and Blue-Yeti.

A qualitative analysis of the most frequently deleted words exposes the commonality of such terms in the collaborative problem solving task. For instance, the most commonly deleted word weighted by frequency is the demonstrative pronoun “this”. “This” was dropped 41% of the time and correctly transcribed 53% of the time. In the collaborative problem solving activity we can expect this word to be used frequently, which contributes to the high weighted deletion rate. Another commonly deleted word is “one,” a common continuation of “this” as in the bigram “this one,” as might be used to refer to an object in a situated context. Likewise, other most commonly deleted words, weighted by frequency, include common particles like “so” or “oh,” and acknowledgments like “yeah” or “okay.” However, some words that in context are important and contentful, such as “10” or “20” (referring to the masses of the weights), are also frequently deleted.

In reality, most of the deleted words are stop words, indicating that downstream processes should be robust. However, there are some task specific content words that may impede downstream tasks.

Linguistic Profiles of Students Interacting with Conversation-Based Assessment Systems

Carol M. Forsyth, Jesse R. Sparks, Jonathan Steinberg & Laura McCulla
Educational Testing Service
[cforsyth,jsparks,jsteinberg,lmcculla]@ets.org

ABSTRACT

Conversation-based assessment systems allow for students to display evidence of their knowledge during natural language conversations with artificial agents. In the current study, 235 middle-school students from diverse backgrounds interacted with a conversation-based assessment system designed to measure scientific inquiry. There were two versions of the conversations where the initial question was manipulated to examine the relationship between question-framing and conversational discourse. We analyzed the human input during these conversations post-hoc using LIWC to discover linguistic profiles of students that may be related to the type of question asked as well as overall task performance. Furthermore, we compared these linguistic profiles to human ratings as a validity check and to inform our interpretation. Results indicated four separate profiles determined by linguistic features that indeed align to human scores and performance in directions consistent with the effects of question framing. These results offer important implications for improved detection of types of student learners based on linguistic features that do not differ by diverse student characteristics and for designing conversation-based assessments.

Conversation-based Assessment, Computational Linguistics, Artificial Agents, Question-Framing

1. INTRODUCTION

1.1 Conversation-Based Assessment

Conversation-based assessments (CBAs) are interactive formative assessment systems with natural language conversations between humans and two or more artificial agents designed to capture evidence of a student's knowledge, skills, and abilities (KSAs) [36]. CBAs leverage previous research on digital learning environments with similar artificial agents or "talking heads" [5, 10, 19, 20, 23,35], artificial intelligence and technology enhanced assessments [4, 6, 26] to create environments where students take actions, answer questions, and participate in conversations to display their

KSAs. CBAs include other components of simulated, scenario-based, and game-based environments [30, 31, 35] in addition to conversations.

Learning environments with natural language conversations have aided increasing student motivation and deep learning as students converse with artificial agents [1, 2, 21]. Several types of adaptive conversations have been created to accomplish this goal [17, 18] but we will focus on AutoTutor [13] as it greatly influenced the creation of CBAs. AutoTutor is an Intelligent Tutoring System where students have natural language tutorial conversations with an artificial agent; this system shows learning gains comparable to expert tutors in dozens of experiments across multiple domains [13]. Perhaps the "secret sauce" is the adaptive scaffolding moves, which are based on extensive analysis of expert tutor and student interactions [13,15] which include providing hints or broad clues, prompts requiring single word or phrase answers, and assertions as part of the scaffolding framework with associated natural language processing (NLP), which is beyond this paper to discuss [see 13].

CBAs augment the original conversational framework while utilizing the associated NLP of AutoTutor to create more constrained conversations for gathering evidence of KSAs which is necessary for assessment, where less information can be given to the student than in a tutorial dialogue. CBA conversations are designed to elicit information from students that may be difficult to elicit via other means such as multiple-choice or open-ended items. An important issue for CBA design is the impact of question framing in eliciting information from students.

1.2 Question Framing

The need to capture evidence of student knowledge has spurred research in question-asking for decades [3, 8, 15, 22]. This research has yielded multiple taxonomies of questions that seek to elicit student knowledge with respect to both mental representations and cognitive processes [12, 14, 27, 28, 29]. For example, Bloom's taxonomy [3] is well-known for capturing depth of understanding [7]. Specifically, multiple-choice questions provide evidence of shallow or factual understanding while open-ended questions require a deeper conceptual understanding to provide sufficient answers.

Formulating main questions to initiate a conversation with an artificial agent that may require multiple turns to elicit evidence from students is quite different from formulating a single question asked with a constructed response item. Therefore, we drew from a detailed taxonomy [15] to consider specific types of questions that may help elicit information and inform cognitive processing [14,

15]. This taxonomy includes 16 question types at varying levels of depth. Within a CBA task, however, constraints including the target constructs, context, and scenario narrow the possibilities of questions that are appropriate for assessment (e.g., comparison and justification questions). Notably, research shows that tasks requiring students to generate justifications for their responses, such as constructing arguments, can sometimes lead to better learning than comprehension tasks [11]. Therefore, we investigated student responses to two separate types of question framing in a CBA task for science inquiry that prompted students to make a comparison between two artifacts (i.e., observation notes collected from simulated data), contrasting an approach where students were asked to *make a selection and explain their choice* (comparison-framing) with one in which students are asked to *justify whether or not they agree with a choice made by a virtual agent* (argumentation-framing) [34]. Previous research suggests that this manipulation had an impact on CBA conversation performance with the argumentation-framing condition making better selections but showing poorer explanations than the comparison-framing condition [33].

Previous research on CBAs suggests that additional computational linguistic analysis beyond the NLP algorithms needed to operate the system can provide fine-grained insights on how students respond [9]. Furthermore, CBAs offer an opportunity to explore methods for inferring information about students' experiences from their responses in ways that may have implications for equity issues in assessment, given the wide range of responses that can be accepted and awarded credit. Thus, in this study we analyzed responses from a diverse sample with a bottom-up approach using linguistic features and associated profiles, contextualized them within question framing conditions, and compared these profiles based on human scoring and on task performance.

2. METHODS

2.1 Participants

In total, 235 middle school students were recruited from one rural (35%) and one urban (65%) school, yielding quite a diverse sample. Specifically, the sample was 48% female and 52% male, 34% free/reduced price lunch eligible, and 79% White, 9% Black/African American, 4% Hispanic/Latino, and 8% other. The experiment was approved by an IRB and all personally identifiable information was removed from the data.

2.2 Tasks and Measures

2.2.1 Conversation-Based Assessment Weather Task

The Weather CBA task [32, 34] is an innovative, computer-based task that engages students in simulated science inquiry around the topic of thunderstorms, including data collection, analysis and prediction, and justification of reasoning in the context of conversations with two virtual agents: Art, a virtual peer working on the task alongside the student, and Dr. Garcia, a scientist and authority figure guiding the students. Students place weather stations to collect simulated data on an impending thunderstorm, take notes from the data, and in a conversation-based item are presented with two of the notes (one of their notes, and one "created" by the virtual peer). Students are asked to explain which note should be kept for making predictions about the likelihood of a thunderstorm. Students should choose the note summarizing data across multiple weather stations (i.e., more data yields a better prediction).

Students were randomly assigned to one of two question framing conditions, which included different main questions posed to the student [34]. In both conditions, students were presented with the two notes and were asked to indicate which note should be kept for

making predictions later. In the comparison-framing condition, the main question is posed as "Please look carefully at and compare these two notes. Which one do you think we should keep for making predictions later and why?" whereas in the alternate argumentation-framing condition, the question is posed as "Please look carefully at and compare these two notes. I think we should keep [your note/my note] for making predictions later. Do you agree with me? Why or why not?" In this argumentation-framing condition, the peer always pointed students to the "better" note summarizing data from multiple stations. Thus, the conversations included adaptivity based on the student's responses to the simulation components and their linguistic input.

2.2.2 Overall Task Performance

The Weather CBA task includes a combination of more traditional item types (multiple choice, constructed response) and technology-enhanced items (drag-and-drop, simulation items), in addition to simulated conversations characteristic of CBAs, with a maximum total score of 29 points.

2.2.3 Human Scores for Conversations

Responses were dichotomously scored by human raters along multiple dimensions (see Table 1), with a maximum of five possible points per conversation. Responses were scored both for the correctness of students' conclusions and the quality of the supporting reasoning, summed to create a single score for the entire response to the conversation (across all conversational turns). Raters were trained by a scoring leader to score these responses using a well-defined rubric. After two raters independently rated each category as 0 or 1, inter-rater reliability was examined. Initial inspection of the data revealed that there was an unequal cell distribution which can skew kappa results, so we only report percent agreement by dimension: Note Choice (93%); Immediate (90%); Relevant (82%); Sufficient (84%); and Aligned with Note Choice (88%).

Table 1. Dimensions of Human Scores and Definitions

Dimension	Definition
Note Choice	Students choose the note with more complete data represented (observations from multiple weather stations).
Reasoning: Immediate	Students provide reasoning immediately, within the first turn of the conversation.
Reasoning: Relevant	Students mention features related to the notes and the data they contain (e.g., weather stations, water vapor, instability).
Reasoning: Sufficient	Students mention that one note has more data than the other note.
Reasoning: Aligned with Note Choice	Students provide reasoning that is consistent with their choice of note.

2.2.4 LIWC

Linguistic Inquiry and Word Count (LIWC) is a computational linguistic tool that primarily uses a bag of words approach which identifies words in a given text and compares it to categories of words corresponding to parts of speech or at times broader constructs such as affect [24]. Overall, there are currently over 90 features that have shown to predict outcomes such as college GPA [25] to relationship longevity [16]. The system is available for research or for real time use, with an available API (<https://www.receptiviti.com/liwc>). In this study, we used a licensed desktop version of LIWC2015 [24] for post-hoc analysis of

the student contributions to the conversations with the artificial agents in the CBA task.

3. ANALYSES AND RESULTS

We began by analyzing all text with LIWC2015. Next, we inspected the data by question framing condition for sparseness (i.e., more than 95% of features with 0's), such that sparse features were removed. We also removed two outliers with an over-abundance of exclamation marks which were unique to these two students only (<1% of data lost). Next, we conducted a k-means cluster analysis on the remaining 34 features for 233 students. The results yielded four unique profiles discovered with a bottom-up approach. We interpreted the clusters via several methods including inspecting final cluster center means across features, qualitative analysis, and relationships to external variables including student demographics, question framing condition, human scoring of the conversations, and overall task performance.

3.1 Profiles

In total, 34 features were entered into a k-means clustering algorithm, which converged after 9 iterations. The results yielded 26 features with significant cluster centers (see Appendix A). The four clusters were titled Shallow Performers, One-Turn Wonders, Low Performers, and High Performers, with each described below.

3.1.1 Shallow Performers

The first profile was entitled “shallow performers” as these students were likely to give the correct answer to the question in terms of note choice (i.e., were above chance at picking the note that included more data) but did not provide good reasoning for their answers. The linguistic profile of these students as indicated in Appendix A included relatively higher levels of emotional tone ($M=67$, $SD=38$), positive emotions ($M=8$, $SD=9$), affect ($M=9$, $SD=9$) and the highest amount of dictionary words ($M=90$, $SD=8$), which is reverse coded indicating more words that are not in the dictionary, as well as a low word count ($M=14$, $SD=8$) compared to the other profiles. Qualitative analysis indicated that this group produced several responses in which students appeared to be implying that the peer agent is “smart” (e.g., argumentation-framing: “i do [agree] because you have good ideas. _ I do, because you have good ideas and you sound smart.”; comparison-framing: “We should keep Art’s. Art’s notes have more vocabulary and are more descriptive_ I don’t know. Maybe because you are smarter.”). This illustrates positive emotional tone with words such as “good” and “smart/smarter”. The argumentation-framing responses earned credit for agreeing with peer’s note choice but little credit for their explanations; comparison-framing responses were just above chance (60%) in note choice and also had quite poor reasoning.

3.1.2 One-Turn Wonders

Overall, these students provided “immediate” reasoning on the first turn of the conversation, but the likelihood of this reasoning being relevant was around chance levels; the reasoning was only rarely sufficient and aligned to note choice, although comparison-framing condition students scored slightly higher. Argumentation-framing condition responses were overwhelmingly likely to make the correct note choice, while comparison-framing responses were at chance levels. As seen in Appendix A, these students had the highest mean level of affect ($M=10$, $SD=8$), positive emotions ($M=10$, $SD=8$) and words per sentence ($M=17$, $SD=11$). From qualitative analysis, we saw that the first response included apparently longer sentences, consistent with providing immediate reasoning on turn one, and often used the word “better” (positive affect). An example argumentation-framing response is “Yes, you have a very good

note. (I guess) _ It has a bunch of good information on it.”. The student includes reasoning in the first turn (i.e., yes followed by attempted justification); with prompting, they provide additional detail (“good information”) but no relevant reasoning. An example comparison-framing response is: “I personally think my notes are better because i did notes for each seperate weather station. _ I had more hours to predict what happen and i wrote seperate notes for each weather station.” This illustrates higher words per sentence and an attempt to provide immediate reasoning, but the note choice and reasoning are entirely incorrect. It appears these students understand the need to provide reasoning to support their note choice, but this reasoning was not relevant or sufficient.

3.1.3 Low Performers

These students performed poorly on all aspects of the task and human scores, with note choice at chance levels. Their linguistic profile as seen in Appendix A, showed a relatively low level of words per sentence ($M=12$, $SD=8$) which could indicate minimal attempts to provide a viable answer. These responses had high levels of personal pronouns ($M=18$, $SD=10$), perhaps an artifact of requiring students to say “my note” when choosing their own note. Qualitative analysis indicated that comparison-framing students often incorrectly chose “my note”, and argumentation-framing students sometimes disagreed with Art. Their reasoning was more relevant than the shallow performers, but it was similarly insufficient and misaligned to note choice (although somewhat better for comparison-framing). This group also had more off-task responses, perhaps indicating disengagement. An example argumentation-framing response is “No because i did not give a water vaper percent _ no because i did not give a vaper number _ i did not give an exact answer”, showing relevant but insufficient reasoning and incorrect note choice. A comparison-framing response with incorrect note choice and poor reasoning is “mine because im an actual person _ because im an actual person and not a computer program”.

3.1.4 High Performers

These students performed relatively well on all human scores. As seen in Appendix A, these students had relatively high levels of words per sentence ($M=15$, $SD=12$) and analytical thinking ($M=43$, $SD=30$) which makes sense given the science inquiry task context. An example response is “yes because my note shows that there are no cold fronts _ There are no cold fronts” which includes the correct note choice, immediate reasoning on the first turn, and relevant (but not sufficient) reasoning (i.e., mentioning cold fronts) aligned with the note choice. Therefore, these students appear more likely to draw on relevant evidence within the task (above chance levels), with comparison-framing students especially likely to provide correct responses with more relevant reasoning.

3.2 Relationships to External Variables

Profiles were compared to external variables. Specifically, we examine how features correlate with question-framing conditions and overall performance (see Appendix B), followed by analyses of the relationship between profiles to demographics. Relationships between profiles and question-framing conditions, human scores, and overall performance, were examined using a Kruskal-Wallis method with Monte Carlo simulation across 10,000 samples.

3.2.1 Profiles and Demographics

We conducted chi-square analyses between demographic variables and the four profiles. We discovered no significant differences leading us to interpret that profile membership was indeed diverse.

3.2.2 Profiles and Question-Framing Condition

There was a significant difference between profile membership and question-framing condition, ($X^2(3,233) = 8.07, p = .04, \text{partial } \eta^2 = .035$). The Monte Carlo simulation for significance with 10,000 samples revealed a significance level of $p = .04$ (lower bound $p = .038$, upper bound $p = .049$). Mean ranks indicate that the Shallow Performers had the highest number of cases in the argumentation-framing condition (130.34) and the High Performers had the lowest (101.60). Although this may simply be an artifact of random assignment, it makes sense as students in the comparison-framing condition performed better overall. The other two profiles of One-Turn Wonders and Low Performers were in the middle with slightly higher mean ranks for the former over the latter (123.91 and 116.36, respectively).

3.2.3 Profiles and Human Scores

3.2.2.1. Note Selection

A significant relationship was discovered between the profiles and human scores for note selection ($X^2(3,233) = 10.106, p = .02, \text{partial } \eta^2 = .046$). The Monte Carlo simulation for significance with 10,000 samples revealed a significance level of $p = .02$ (lower bound $p = .014$, upper bound $p = .020$). The mean ranks suggest the highest scores for the Shallow Performers (129.38) and the lowest for the Low Performers (98.51) with the One-Turn Wonders and High Performers having virtually equivalent mean ranks (121.59 and 121.98, respectively). These results are consistent with the fact that argumentation-framing students were overwhelmingly likely (~90%) to make correct note selections in both the Shallow and Low Performing profiles, vs. 50-70% for comparison-framing.

3.2.2.2. Immediate Reasoning

A non-significant relationship was not discovered between the four profiles and Immediate ($X^2(3,233) = 4.267, p = .234, \text{partial } \eta^2 = .018$). Patterns revealed that One-Turn Wonders had the highest overall mean (126.64) though essentially similar to that for High Performers (122.21), but substantively different from both Shallow Performers (111.73) and Low Performers (108.51).

3.2.2.3. Relevant Reasoning

A significant relationship was discovered between the four profiles and relevant reasoning ($X^2(3,233) = 20.896, p < .001, \text{partial } \eta^2 = .089$). The Monte Carlo simulation for significance with 10,000 samples revealed a significance level of $p < .001$, (lower bound $p = .000$, upper bound $p = .001$). Mean ranks indicate that High Performers performed the best (142.19), whereas the Shallow Performers performed the worst (92.48). Not surprisingly, the One-Turn Wonders and Low Performers fell in the middle, with One-Turn Wonders showing higher scores (122.00 and 107.19, respectively). Relevant reasoning was most likely for High Performers and One-Turn Wonders in the comparison-framing condition.

3.2.2.4. Sufficient Reasoning

A significant relationship was discovered for the four profiles and sufficient reasoning ($X^2(3,233) = 13.974, p = .003, \text{partial } \eta^2 = .061$). The Monte Carlo simulation for significance with 10,000 samples revealed a significance level of $p = .003$, (lower bound $p = .001$, upper bound $p = .004$). Mean ranks were highest for the High Performers (133.71) and lowest for the Shallow Performers (98.63) with One-Turn Wonders having higher scores than the Low Performers (124.38 and 109.05, respectively).

3.2.2.5. Supports Note Choice

A significant relationship was discovered for the four profiles and supporting note choice ($X^2(3,233) = 18.304, p = .001, \text{partial } \eta^2 = .084$). The Monte Carlo simulation for significance with 10,000 samples revealed a significance level of $p < .001$, (lower bound $p = .000$, upper bound $p = .001$). Once again, mean ranks revealed High Performers had the highest score (139.99) and Shallow Performers had the lowest score (103.99). The One-Turn Wonders and Low Performers fell in the middle with higher scores for the One-Turn Wonders (115.21 and 105.44, respectively).

3.2.4 Profiles and Overall Task Performance

A significant relationship was discovered for the four profiles and overall CBA task performance ($X^2(3,233) = 11.332, p = .010, \text{partial } \eta^2 = .048$). The Monte Carlo simulation for significance with 10,000 samples revealed a significance level of $p < .001$, (lower bound $p = .007$, upper bound $p = .012$). Mean ranks indicate the highest score for the High Performers (134.79) and the lowest for the Shallow Performers (98.41) with One-Turn Wonders still outperforming Low Performers (126.94, 106.16, respectively).

3.3 Results and Conclusions

We discovered four profiles of students based on linguistic features identified with the computational linguistic tool LIWC. The resulting profiles consisted of Shallow Performers, One-Turn Wonders, Low Performers, and High Performers. The Shallow Performers had higher levels of emotional tone, especially positive affect words, but fewer dictionary words. The One-Turn Wonders were characterized by high positive affect words and high words per sentence, reflected in their longer attempted justifications for their choices. The Low Performers showed low words per sentence and high levels of personal pronouns, in part reflecting the design of the task, but also reflecting generally shorter responses with poorer quality of reasoning. Finally, the High Performers had relatively high levels of words per sentence and analytical thinking which has predicted GPA in previous studies [25]. These four profiles were then validated by external measures that revealed patterns in expected directions.

Given the IDEA conference theme and our diverse sample, we compared key demographic measures including school location, race/ethnicity, free/reduced price lunch status, and other factors to the four profiles and found no significant differences. This indicates that these linguistic profiles did not show different demographic composition even though these factors did relate to overall task performance in prior research [32]. The implications are that linguistic profiles may be a manner of detection and intervention that transcend demographics and therefore may enable greater inclusion during the learning experience. That said, we do acknowledge that our sample was predominantly White (about 80%) despite the large variation in other key variables. We also acknowledge the relatively small sample size and plan to attempt to replicate these findings on a larger data set from this same CBA task in future work.

In sum, these findings can guide the creation and augmentation of novel CBAs to support personalized learning based on students' interactions with the system, transcending demographic differences. The methodology employed may also inform other researchers' attempts to discover ways to adapt and personalize other learning and assessment environments based on students' use of language.

Does chronology matter? Sequential vs contextual approaches to knowledge tracing

ABSTRACT

Deep learning architectures such as RNN and pure-attention based models have shown state-of-the-art performance in modeling student performance, yet the sources of the predictive power of such models remain an open question. In this paper, we investigate the predictive power of aspects of LSTM and pure attention-based architectures that model sequentiality. We design a knowledge tracing model based on a general transformer encoder architecture to explore the predictive power of sequentiality for attention-based models. For the LSTM-based Deep Knowledge Tracing model, we manipulate the state transition coefficient matrix to turn sequential modeling on and off. All models are evaluated on four public tutoring datasets from ASSISTments and Cognitive Tutor. Experimental results show that DKT and pure-attention based models are overall insensitive towards removing major sequential signals by disabling their sequential modeling parts but with the attention-based model about four times more sensitive. Lastly, we shed light on benefits and challenges of sequential modeling in student performance prediction.

Keywords

Knowledge tracing, DKT, BKT, Cognitive Tutor, ASSISTments, KDD Cup, Contextual embedding, Self-attention

1. INTRODUCTION

Bayesian and Deep Knowledge Tracing models use machine learning architectures with explicit representation of time slices that capture sequentiality. A new generation of models have emerged based on self-attention that have outperformed both BKT and DKT on the knowledge tracing task [9, 11, 19, 17, 7]. Interestingly, the transformer-based architecture that these models rely on has relatively weak modeling of the concept of a time-slice and subsequently of sequence. This prompts us to ask the question of what role sequentiality plays in the predictive performance of the latest generations of neural knowledge tracing models. Some

of the better performing self-attention models adopt a combination of transformer and LSTM architectures, raising the question of if the LSTM is superior for capturing sequence-based signals. To investigate the role of sequentiality in the predictive power of the RNN-based DKT and transformer-based self-attention, or "contextual" models, we design experiments that compare two variants of each model; the original, a version in which time-components of the architecture are systematically disabled. Using four public datasets, we report each model's sensitivity to removing signals of sequence. Our major contributions in this work are:

1. A simple, yet theoretically effective way of disabling attention-based models' sequential modeling components.
2. A novel way of insulating DKT's sequential modeling components to study its sequential modeling ability.
3. We find that DKT and BertKT are exceptionally robust to losing sequential modeling components in terms of performance.

2. RELATED WORK

For studying sequence effects for student performance prediction, Ding and Larson [4] showed that relative ordering of skills have negative effects on the performance of DKT. Kim et al. [10] studied DKT's behavior by conducting a series of perturbation experiments on Monotonicity, Robustness and Convergence etc. Work prior to DKT has also studied sequencing effects, Pardos and Heffernan [13] used a modification of the BKT model to capture learning rates of ordered item pairs, finding that while statistically separable learning rates could be fit, this extra modeling of order did not significantly improve performance prediction accuracy.

Pure-attention based models such as Transformer [18] and Bidirectional Encoder Representations from Transformers (BERT) [3] were first introduced in the NLP field and achieved state of the art performance on major NLP tasks. These models, compared to LSTM predecessors, have the added advantage of enabling parallel training for computational efficiency [18] [2] and being better able to capture long term dependencies. Adapting these strengths to the knowledge tracing task, Self Attentive Knowledge Tracing (SAKT) [12] introduces the earlier attention-based models to solve student performance prediction. SAINT+ [14], which leverages various input features embeddings to assist tutoring on massive online learning platforms, and AKT [7] further improves

the attention-based architecture by introducing monotonic attention and context-aware distance measure.

Hybrid sequential-contextual models have shown success. *Last Query transformer RNN model* [9] LSTM-SAKT [11] and MUSE [19] utilize the combination of transformer encoder and LSTM/GRU and achieved top-5 performance in a Kaggle AIED Prediction Challenge 2020¹.

3. METHODOLOGY

3.1 Problem Restatement

Our study on sequential effects is based on the task of student performance prediction. We define this task as follows.

Definition 1. Given a student s 's past interactive sequence from time step 1 to $t - 1$ that contains problem marked by required skill ids $X_{t-1}^{(s)}$ and their correctness of responses $Y_{t-1}^{(s)}$, performance prediction of problem x of student s at time step t is defined as:

$$\hat{y}_t^{(s)} = f(X_{t-1}^{(s)}, Y_{t-1}^{(s)}, x_t^{(s)})$$

where $X_{t-1}^{(s)} = \{x_i^{(s)} \in \mathbb{Z}^+ | 1 \leq i \leq t - 1, i \in \mathbb{Z}^+\}$ and $Y_{t-1}^{(s)} = \{y_i^{(s)} \in \mathbb{Z}^+ | 1 \leq i \leq t - 1, i \in \mathbb{Z}^+\}$

3.2 The BertKT Architecture

To study the positional effect of transformer family of models, we design a simple, general architecture named **Bidirectional encoder representations from transformers for Knowledge Tracing**, or **BertKT**. We design this model instead of utilizing previously proposed models for several reasons:

1. It does not contain redundant structures other than transformer encoder layers and an output layer for our downstream task. This helps us isolate the impact of sequential effects for attention-based models.
2. It adopts the most widely used sine-cosine positional encoding with easy enabling/disabling, which facilitates generalization of our results.
3. This architecture is flexible due to its simplicity to accommodate additional settings for future research.

In this work, we conduct student performance prediction in an auto-regressive fashion supported by an upper-triangular attention masks. We do not utilize the bi-directionality here, but such functionality could be enabled for future use such as for bi-directional pre-training tasks. Thus, we keep here the naming convention "bi-directional" as is.

3.2.1 Knowledge and Positional Encoding

In transformer models, scaled-dot-product self-attention which runs in $O(n^2)$ [18]. Thus we adopt word embedding [1] in stead of one-hot encoding in the field of NLP to obtain a

¹<https://www.kaggle.com/c/riiid-test-answer-prediction>

Figure 1: BertKT Architecture Visualization. The shaded part is the self-attention based encoding method.

learnable knowledge encoding with higher computational efficiency. In this work, we only use skill and responses as input features. Embeddings of such features are element-wise-summed together to form a unified representation named combined embedding.

The transformer model is permutation-invariant [18, 5] without positional encoding, making it suffer from not being able to capture original sequence order. A wide varieties of positional encodings are introduced for better performance or interpretability[8, 7]. To study the effect of positionality in this type of model, we completely remove the sine-cosine positional encoding of our model introduced in section 3.2 and compare the model's performance with the baseline model (positional encoding on).

3.2.2 BertKT encoder

In section 3.2.1, we have introduced our element-wise-summed embedding. On top of that, we add a canonical transformer encoder to form the integrated BertKT Architecture. For computation flow, the skill embedding layer and the response embedding layer first take in skill ids and responses to compute their raw embeddings. These two embeddings together with positional encoding are summed element-wise to form a combined embedding. Secondly, the combined embedding goes through BertKT encoder to learn rich contextualized representations. Such contextualized embedding is further processed by linear output layers followed by sigmoid/softmax activation to output response predictions. The entire BertKT architecture can be viewed in Figure 1.

3.3 Manipulations of Sequential Factors

We manipulate the model structures to control the intensity of sequential signals learned in the hidden space. In terms of naming, we add the prefix *static-* to the resulting models with sequential signals modeling disabled.

3.3.1 Static BertKT

In this section, we describe a modification to BertKT's positional encoding to explore sequential influences of the pro-

duced hidden space on the models’ performance. Specifically, we remove completely the sine-cosine positional encoding of BertKT and name it static-BertKT. For any position i in a sequence ranging from $1, \dots, n$ attending to other items, the model can not distinguish the order of those items even if they are manually arranged in the correct order. This is because all other items are treated the same when computing attention regardless of their position. In such a sense, disabling the positional encoding is equivalent to disabling the exclusive indication for the model to capture explicit positionality. We compare the performance of BertKT and static BertKT in section 6.1.

3.3.2 Static DKT

In this section, we describe our modification to the sequential LSTM structures in DKT to observe performance changes due to effectively disabling weights associated with sequentiality modeling.

Static DKT Experiment

For DKT and all its variants we utilize in this work we employ an LSTM as the core computational structure. The formula for a canonical LSTM structure is as follows.

$$f_t = \sigma(W_f x_t + U_f h_{t-1} + b_f) \quad (1)$$

$$i_t = \sigma(W_i x_t + U_i h_{t-1} + b_i) \quad (2)$$

$$o_t = \sigma(W_o x_t + U_o h_{t-1} + b_o) \quad (3)$$

$$\tilde{c}_t = \tanh(W_c x_t + U_c h_{t-1} + b_c) \quad (4)$$

$$c_t = f_t \circ c_{t-1} + i_t \circ \tilde{c}_t \quad (5)$$

$$h_t = o_t \circ \tanh(c_t) \quad (6)$$

where

$x_t \in \mathbb{R}^d$: input vector of time step t

$f_t \in (0, 1)^h$: forget gate

$i_t \in (0, 1)^h$: input gate

$o_t \in (0, 1)^h$: output gate

$h_t \in (-1, 1)^h$: hidden state vector of time step t

$\tilde{c}_t \in (-1, 1)^h$: cell input

$c_t \in \mathbb{R}^h$: cell state

$W \in \mathbb{R}^{h \times d}$, $U \in \mathbb{R}^{h \times h}$ and $b \in \mathbb{R}^h$: learnable weight and bias; d and h are the dimension of input features and that of hidden states.

Concretely, the hidden state of time step $t + 1$ is dependent on that of t , the current input item at $t + 1$, but not on any future time step ranging from $[t + 2, \dots, T]$, where T is the ending time step. Here we would like to disable the sequential, hidden-state transitioning dynamics to compare results with the original DKT model. Concretely, we set each of $U_f, U_i, U_o, U_c \in \mathbb{R}^{h \times h}$ to an identity matrix $I \in \mathbb{R}^{h \times h}$. Obviously for any hidden state h , an identity matrix multiplication equal to no transformation exerted at all. Also the h could be combined with the bias term b . However, we still keep matrix U here for 2 reasons:

1. For the completeness of math formulation as this is a special case of the dynamic LSTM with learnable U .
2. In terms of implementation, U could be changed easily from a placeholder to other values for future research experiments.

Table 1: Model names and the corresponding explanations

Model/Setting	-
BertKT	baseline BertKT
static-BertKT	BertKT with positional encoding removed
DKT	baseline DKT
static-DKT	DKT with static hidden state update matrix

In the end, we have the following *static-LSTM* as the new component of the corresponding DKT model we refer to as static-DKT.

$$f_t = \sigma(W_f x_t + I h_{t-1} + b_f) \quad (7)$$

$$i_t = \sigma(W_i x_t + I h_{t-1} + b_i) \quad (8)$$

$$o_t = \sigma(W_o x_t + I h_{t-1} + b_o) \quad (9)$$

$$\tilde{c}_t = \tanh(W_c x_t + I h_{t-1} + b_c) \quad (10)$$

$$c_t = f_t \circ c_{t-1} + i_t \circ \tilde{c}_t \quad (11)$$

$$h_t = o_t \circ \tanh(c_t) \quad (12)$$

where each gate update function remains the same but the explicit hidden state update is disabled.

Note that we do not hamper the sequential update format of cell state c and hidden state h , as they are part of the nature of a classic LSTM model. The hidden state is still sequentially updated but only implicitly through W_f , W_i , W_c and W_o . In summary, this experiment is to explore to what extent that sequential modeling factor of DKT contributes to its total predictive power in terms of evaluations metrics we introduce in section 5.2.

4. COMPARISON MODELS

In this section, we provide a reference table 1 to summarize the name of each model and their corresponding settings.

5. EXPERIMENTAL SETUP

5.1 Datasets

We evaluate the performance of BertKT and other comparison models based on four benchmark datasets: ASSISTments 2009-2010² [6], ASSISTments 2012-2013³, Cognitive Tutor Bridge to Algebra 2006-2007⁴ and Cognitive Tutor Bridge to Algebra 2008-2009⁵ [15]. Among these benchmarks, ASSISTments datasets are collected from ASSISTments online tutoring system primarily for secondary school mathematics. Cognitive Tutor (now MATHia) is an intelligent tutoring system and the datasets we used are from its Algebra curricula. The two Cognitive Tutor datasets we use were used as the official development/competition dataset for the KDD Cup 2010 Challenge [16].

For all the above datasets, we follow a series of conventional pre-processing procedures such as removing all problems not

associated with a concept/skill and using correct on first attempt responses only.

5.2 Models and Evaluation Metrics

We compare BertKT and DKT with their sequentiality-weakened counterparts. Differences and features of these model have been discussed in section 4; We evaluate each model across four metrics: BCE (Binary cross entropy loss), AUC (Area under the receiver operating characteristic curve), ACC (Accuracy as the proportion of correct classification with threshold 0.5) and RMSE (Root-mean-square error).

5.3 Training and Testing

We take out 20% of the entire data as the development set to conduct hyper-parameter tuning. For training and testing, We perform student-level k -fold cross validation (with $k = 5$) on each model, meaning each student will appear exclusively in training, validation or test set. In each phase of the cross validation, 60% of the dataset is used as the training set, 20% as the validation set to perform early stopping, and the rest 20% as the test set.

We fix a sequence length of 100 for computational efficiency with longer sequences split to subsequences of length 100 and trailing subsequence padded. We use Adam optimizer to update parameters for all models trained on two NVIDIA GeForce RTX 2080 Ti (11 GB) or TITAN Xp GPU (12 GB). All models are implemented using PyTorch with fixed random seeds for reproducibility.

6. EXPERIMENTAL RESULTS

In this section, we compare evaluations results of BertKT and DKT with their variants introduced in section 3. We report evaluation metrics per each model per metrics defined in section 5.2 as well as the relative percentage increase of these metrics between comparison models. Models with the best metrics are in bold. Specifically, we report the percentage increase by the "performance increase/decrease", meaning that increase in {BCE, RMSE} is marked by "-" and that increase in {AUC, ACC} is marked by "+". Decrease means the opposite way.

6.1 BertKT Model Results

Table 2 shows the evaluations metrics for BertKT and static-BertKT. The best performances by metric are in bold. We

have explained the meanings of these variant models in table 1. Overall, the baseline BertKT performs better, with 10 bolded cells, than its sequentially disrupted variants. However, the percentage performance differences averaged over the four dataset benchmarks of static-BertKT from BertKT are -0.64%, -0.19%, -0.02%, -0.24% for BCE, AUC, ACC and RMSE, respectively ('+' indicates a performance improvement for the metric, while '-' represents a performance decrease). This suggests that BertKT is insensitive towards sequential permutation even without positional encoding.

6.2 DKT Model Results

In this section, we compare in table 3 DKT with its sequentially weakened counterpart, namely, DKT and static-DKT. Naming conventions have been introduced in table 1 in section 4.

Surprisingly, the static-DKT model was the best performing model on all datasets for all but one metric of one dataset (ASSISTments 2009-AUC). The average percentage performance differences averaged over the four dataset benchmarks of static-DKT from DKT are +0.13%, +0.04%, +0.07%, +0.09% for BCE, AUC, ACC and RMSE, respectively ('+' indicates a performance improvement for the metric, while '-' represents a performance decrease). Even after disabling weights associated with time-slice transitions, the model performs closely to the baseline model and even with a slight increase. This suggests that the embedding weights for input X W_f , W_i , W_o and W_c are still sufficient to capture signals that support the model's original performance.

Across the four metrics and four datasets, DKT improves 0.08% due to a static hidden state transition, while the performance of BertKT decreases by 0.27% due to no positional encoding (static). The average percentage performance loss of BertKT due to being static is -4.3340x larger than that of DKT. This suggests BertKT's positional encoding is more sensitive in modeling the sequence order than DKT in terms of performance.

7. CONCLUSIONS AND DISCUSSION

While our motivating observation was that transformer-based models have weaker explicit modeling of time than LSTM-based models, we find that BertKT is more dependent on its positional encoding than DKT is on its time-slice transition weights. Such sensitivity may be an indication that there is room for improvement for positional encodings to better leverage input sequence order. This improvement is perhaps seen in the performance of AKT [7], which outperforms DKT and employs additional modeling of sequentiality in the form of imposed monotonicity of attention weights with respect to time.

Our results raise the question of why DKT is not negatively affected by disabling its transition weights. Potentially, the temporal signal is being pushed down into the embedding W . Is student growth better captured in the interactions between input embeddings than it is by a generalized recurrent hidden state transition? This may speak to the powerful but simple assumption of the original knowledge tracing model, that learning is a function of *opportunity count*, growth rate, and prior.

Algorithmic unfairness mitigation in student models: When fairer methods lead to unintended results

Frank Stinar

fstinar2@illinois.edu

Nigel Bosch
University of Illinois Urbana–Champaign
pnb@illinois.edu

ABSTRACT

Systematically unfair education systems lead to different levels of learning for students from different demographic groups, which, in the context of AI-driven education, has inspired work on mitigating unfairness in machine learning methods. However, unfairness mitigation methods may lead to unintended consequences for classrooms and students. We examined preprocessing and postprocessing unfairness mitigation algorithms in the context of a large dataset, the State of Texas Assessments of Academic Readiness (STAAR) outcome data, to investigate these issues. We evaluated each unfairness mitigation algorithm across multiple machine learning models using different definitions of fairness. We then evaluated how unfairness mitigation impacts classifications of students across different combinations of machine learning models, unfairness mitigation methods, and definitions of fairness. On average, unfairness mitigation methods led to a 22% improvement in fairness. When examining the impacts of unfairness mitigation methods on predictions, we found that these methods led to models that can and did overgeneralize groups. Consequently, predictions made by such models may not reach the intended audiences. We discuss the implications for AI-driven interventions and student support.

Keywords

Machine learning, Unfairness mitigation, Fairness, Data science applications in education

1. INTRODUCTION

Student assessment has been plagued with biases against students from different demographic groups [2]. Various fairness metrics have been designed to evaluate the severity of biases [27], including biases in automatic assessments powered by machine learning [13]. Researchers have explored methods for mitigating such biases [3, 16, 21], including for assessment-related tasks such as student grade prediction [18]. However, the implications of applying unfairness mit-

igation methods to educational datasets are currently not well understood. In this paper, we explore unfairness mitigation on the State of Texas Assessments of Academic Readiness (STAAR) dataset [25], including examples of what impacts might be felt by students when models are optimized for different definitions of fairness.

The influx of data stemming from education contexts has allowed computational methods to be used for understanding education [4]. Alongside the creation of computer-based assessment methods, researchers have also analyzed current assessment data with machine learning and other computational methods [17]. These forms of analysis allowed researchers to uncover new biases towards different demographic groups in education and assessment methods [3]. Moreover, newer methods do not necessarily fix the biases present in traditional assessments [21]. However, the newer methods are needed when dealing with complex (e.g., nonlinear, multimodal) educational datasets—as are new methods to address biases present in computational analyses [7, 8].

Biases in the field of education have differing definitions, differing impacts, and can come from different places within educational and social systems [3]. In the study presented in this paper we are unable to disentangle the systemic biases present in assessment systems, as is often the case with educational data that concerns specific contexts, learning environments, or topics. Instead, we focused on biases in statistical measurements and biases present in the machine learning models. In particular, we investigate how unfairness mitigation methods and machine learning models impact student representations in data (and predictions), and if the biases found in these methods are analogous to biases in assessments—which may come from the assessments themselves or from systemic biases. In this paper, we explore these issues by addressing two research questions:

Research Question 1 (RQ1): Do demographic differences in standardized assessment scores correspond to biases in machine learning models? Standardized tests often contain biases [21]. Machine learning models have been shown to exacerbate biases that are present in training data [5]. RQ1 therefore examines the link between test score differences (including biases) and the biases that are found in machine learning models trained on closely related data from the same students. By comparing the biases that machine learning models elicit and the biases present in standardized test data, we are able to disentangle some of the sources of bias

F. Stinar and N. Bosch. Algorithmic unfairness mitigation in student models: When fairer methods lead to unintended results. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 606–611, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

<https://doi.org/10.5281/zenodo.6853135>

that occur in data-driven assessment, and thereby inform future work on mitigating such biases. In alignment with previous work [3], we expect that biases present in standardized assessments and machine learning models will not perfectly align. If the biases do not align, differences between them indicate that new biases may be introduced—or, ideally, that there are opportunities for reducing such biases.

Research Question 2 (RQ2): What are the implications of machine learning unfairness mitigation methods when applied to student test score prediction? Researching this provides insight into the real-world implications for applying fairness metric optimization to human-based datasets. These implications can provide insight into the types of interventions that could take place in learning environments, because applying machine learning (or even expert-created) models to the real world without substantively examining the possible impacts can lead to dire consequences [1, 5].

By answering these two RQs, we tie test score biases and machine learning biases together through unfairness mitigation strategies and examine the implications of applying these strategies in education. By comparing the outputs of unfairness-mitigated machine learning models with the actual biases present in standardized tests we found a relationship between the two. Then, we showed how learning environments and students are impacted from applying fairness processes. Next, we address related research to position our work in the space of educational data mining and AI fairness research.

2. RELATED WORK

We focus on work related to fair AI methods and fair AI used within educational data mining. For a more general overview, see Fischer et al. [12]; we discuss fair AI, specifically, in the remainder of this section.

We first discuss fairness research being done in AI, regardless of domain. Many different research approaches have differing definitions of fairness and what fair AI looks like. For example, Hu et al. increased fairness in part through comparing differing groups positive predictive rates [16]; others have examined several different statistical definitions of fairness [6], which can even be contradictory with each other [11]. Work has also been done to *explain* many of the definitions of fairness that are used in fair AI research [26], independent of domain.

There is an increasing body of work in the field of educational data mining that uses fair AI, including the impact caused by algorithmic bias in education systems [3, 20]. This research being done in educational data mining with fair AI methods shows the growing use of machine learning in education research, complementing existing work in related topics like fair assessment (e.g., [21, 2]). These publications represent how biases are seen within different data mining avenues.

Using similar connections made in previous work between fair AI methods and educational data mining, we harness machine learning models and unfairness mitigation methods to examine performance differences between demographic groups in standardized tests.

Table 1: Breakdown of Demographic Groups

Demographic Identifier	# Occurrences	% Sample
Female	672,545	17.7%
Male	670,664	17.6%
Economic disadvantage	648,716	17.1%
Hispanic	554,697	14.6%
White	440,972	11.6%
Special education	315,072	8.3%
African American	240,901	6.3%
Asian	125,308	3.3%
Two or more races	80,817	2.1%
Pacific Islander	1,273	0.03%
American Indian	1,050	0.02%

3. METHODS

We used the assessment database from the STAAR Texas Education Agency dataset. These data were collected from the Teaching Trust (a now defunct leadership development group with the goal of eliminating opportunity gaps for students) between 2012 and 2019 [25]. This dataset has information from over 5 million students, which is approximately 10% of the public school students in the United States. The data include at most one demographic identifier per student—e.g., a student’s race or gender might be included, but not both. Table 1 contains the breakdown of demographic-related information in the dataset.

3.1 Machine Learning Models

The three machine learning models we used were the logistic regression, random forest, and extremely randomized trees models. We used 5-fold cross validation and tuned hyperparameters via grid search. We trained all models using `scikit-learn` [22]. The logistic regression used the default hyperparameters from `scikit-learn` (i.e., a small L_2 regularization penalty). The random forest and extremely randomized trees models underwent hyperparameter tuning for the maximum depth of trees and the proportion of features samples for each tree.

3.2 Model Evaluation

For each of the machine learning models we used four unfairness mitigation methods (described in more detail below): disparate impact preprocessing, reweighing, equalized odds postprocessing, and calibrated equalized odds postprocessing. We evaluated each of these model/method combinations in terms of accuracy measured via area under the receiver operating characteristic curve (AUC) and four unfairness metrics: statistical parity difference, disparate impact ratio, average odds difference, and equal opportunity difference (described in the Appendix).

3.3 Unfairness Mitigation Algorithms

We implemented unfairness mitigation algorithms with the AIF360 Python library [7].

3.3.1 Disparate Impact Preprocessing

Disparate impact preprocessing compares the label (passing the STAAR test) base rate across groups. The algorithm

takes this rate and edits features of the original data so that it is impossible to tell which group an individual belongs to.

3.3.2 Reweighting

The reweighting algorithm adds weight to each example during model training based upon the proportion of students in different demographic groups and outcome (e.g., positive vs. negative class) groups. The equation for the weight is given in Equation 1.

$$w_{positive/group1} = \frac{(N_{group1})(N_{positive})}{(N_{all})(N_{positive/group1})} \quad (1)$$

3.3.3 Equalized Odds Postprocessing

Equalized odds postprocessing works to optimize the equalized odds fairness metric by changing predicted labels as needed to satisfy the metric. Specifically, the algorithm solves a linear program for probabilities. From these probabilities, classification labels are given [15]. An equalized odds predictor is made for this program from predicting on equalized odds incentive measurements for all classes.

3.3.4 Calibrated Equalized Odds Postprocessing

Calibrated equalized odds postprocessing follows a similar process to equalized odds postprocessing; however, it optimizes for equalized odds over a calibrated model output. Calibrated output is found when probability predictions align with the actual probability of observing the predicted outcomes [23].

4. RESULTS

We describe our results with respect to the two research questions outlined in the Introduction.

4.1 RQ1: Machine Learning Bias compared to Assessment Bias

RQ1 asks if biases found in machine learning models are analogous to the biases present in the STAAR assessment. Table 2 contains the values of accuracy and fairness metrics found after applying unfairness mitigation algorithms.

On average we observed a 22% improvement in fairness metric evaluation. However, different unfairness mitigation methods led to different trends in results. We found the disparate impact preprocessing method had the smallest impact, on average, across all fairness metrics. However, disparate impact preprocessing yielded the highest accuracy for each model, perhaps because it impacted the models the least. For both the random forest and extremely randomized trees models, reweighting unfairness mitigation led to the fairest predictions across all fairness metrics. We found that for some unfairness mitigation methods, especially equalized odds and calibrated equalized odds, the predictions were so influenced that the accuracy was no better than chance level (i.e., $AUC \leq .500$).

4.2 RQ2: Unfairness Mitigation Implications

We answered RQ2 by analyzing each unfairness mitigation algorithm's impact on the STAAR data or models being used. The disparate impact preprocessing algorithm removed distinctions between groups in the dataset itself. The

disparate impact removal process preserves within-group ranking of singular data points; however, group membership of singular data points are changed so it is not possible to discern what groups individuals belong to. The reweighting algorithm adds weights to different data points based on frequency of group membership to remove bias. Equalized odds postprocessing and calibrated equalized odds postprocessing do not edit the original dataset. Instead, they change output labels of singular data points with the objective of maximizing the equalized odds of the classifications. Each algorithm thus impacts either the student data itself or the process used to classify students as passing or failing the assessment, the implications of which need to be understood to determine whether such methods are procedurally fair—that is, whether the process by which decisions are made is fair, not just the fairness of the decisions themselves [9, 6, 14].

We found that using these unfairness mitigation algorithms resulted in unintended consequences for how students were computationally represented. For example, after disparate impact preprocessing, students who originally belonged to one group were now considered part of a different group for training. In the case of STAAR data, if the data were bimodal, with each group having their own pattern of demographic identifiers, students would be represented in data with different demographic identifiers than they actually have.

The impacts of each unfairness mitigation method are seen in the manipulation of the STAAR data. For example, some individuals in the “Female” demographic group were now in the “Asian” demographic group after disparate impact preprocessing; the algorithm preserved the within-group ranking of individuals, but changed group membership in unintended ways. This may have created a more fair model in terms of predictions, but while ignoring or confusing the systemic education problem present in the data.

In contrast, the two equalized odds based algorithms effectively changed whether or not students in the training data passed or failed the assessment. This may be less drastic than shifting students' demographic identifiers; however, decisions made upon this unfairness mitigation are imperfect if they obfuscate the problem of unequal learning.

Finally, the reweighting algorithm introduces weights to students for fairer classification. This method does not change the students' features, and thus might be considered a more faithful representation of students. However, weighting students may cause unintended effects as demographic group and assessment score combinations become more impactful to classification of others. This is especially true for students from smaller groups, who may find their characteristics or behaviors become far more important to a model's decisions than is desirable.

5. DISCUSSION

Our first research question predicted that demographic differences in test scores do correspond to biases seen in machine learning models trained on those data. Our results show that there were similarities between the biases present; however, models can further propagate biases present in the

Table 2: Fairness metric calculations. The *No Model* row represents the metrics calculated on the original dataset (for metrics that could be calculated from outcome labels in the dataset) for comparison to the rest of the algorithms.

Model	Unfairness Mitigation	AUC	Stat Parity Diff	Disp Imp Ratio	Avg Odds Diff	EqOpp Diff
No Model	None	–	-.172	.766	–	–
LogReg	None	.579	.113	1.419	.124	.162

Extra-Trees	Calibrated Equalized Odds	.445	-.665	0.235	-.668	-.597

data when trained on unfairness-mitigated data. This aligns with other research on biases present in education [24].

Different types of biases can be measured in our machine learning models that can not be measured within STAAR. Models might include biases that are separate from biases present in the test scores, indicating that machine learning models may exacerbate biases already present in data or even introduce new biases. Additionally, putting assessment data into a machine learning pipeline with unfairness mitigation can lead to negative implications as theorized by RQ2.

Our expectation for RQ2 was that applying unfairness mitigation strategies would lead to unintended real-world consequences for students. Indeed, unfairness mitigation strategies manipulated data in ways that could be perceived as unfair, especially with respect to procedural fairness. We investigated this by examining how unfairness mitigation impacted the STAAR data and the classifications made. RQ2 results show if one is planning to administer data-driven interventions in education, applying unfairness mitigation will likely overgeneralize groups. Thus, students who require intervention may not receive it and students who do not need intervention may receive one, not because of model inaccuracies necessarily but because of unfairness mitigation strategies. For example, if students with differing amount of background knowledge are misrepresented, learning outcomes could be negatively impacted [19]. This imprecision of groups that comes with unfairness mitigation can lead to unintended consequences when applied to real-world applications. Thus, unfairness mitigation methods must be applied with caution.

5.1 Limitations and Future Work

The study in this paper explored one prediction task, which—though representative of a large proportion of U.S. students—

is not representative of all assessments nor any of the other educational outcomes and constructs of possible interest. Similarly, we examined a few machine learning models with a selection of preprocessing and postprocessing unfairness mitigation algorithms. We focused on methods that are common in (or well suited to) education data contexts, but the space of possible models and unfairness mitigation algorithms is far larger. Thus, future work would benefit from working with other educational datasets, machine learning models, and unfairness mitigation algorithms to further examine how these methods can impact the representations of students in data analysis. Finally, a nearly insurmountable limitation of this work is that we are unable to disentangle the systemic biases that lead to different amounts of learning (e.g., structural racism and classism) versus the assessment biases (e.g., lack of cultural responsiveness) and algorithmic biases that contribute to biased measurement. We are unable to resolve this problem, but we do evaluate the alignment of these biases in this paper, and suggest that future work with quasi-experimental analyses may be one possible route to address this limitation.

5.2 Conclusion

Education is plagued with unfairness for differing demographic groups [10]. Unfairness mitigation methods have potential to reduce unfairness in data-driven assessment and student support, but when applied to educational datasets these methods may lead to unintended negative consequences. We explored machine learning pipelines with unfairness mitigation methods applied, and examined how these methods would affect the representations of individual students. We expect that these findings will guide the selection of unfairness mitigation methods in future work, and hope that with our findings in mind, when decisions are made from models based on educational data, less harm is done to students from a lack of caution when choosing models and algorithm.

APPENDIX

A. FAIRNESS METRICS

We measured fairness according to four quantitative definitions, detailed below. The combination of these metrics allowed us to holistically judge the impact of the unfairness mitigation algorithms on the machine learning models.

A.1 Statistical Parity Difference

The statistical parity difference metric compares the difference between the groups' probability of being predicted to pass the assessment. A value of 0 indicates both groups were predicted to pass the assessment with equal probability. A positive value means one group is predicted to pass the assessment more, a negative value means the other group is predicted to pass the assessment more.

$$SP = P(\hat{Y} = 1|D = group2) - P(\hat{Y} = 1|D = group1) \quad (2)$$

A.2 Disparate Impact Ratio

Disparate impact ratio is the ratio of the differing groups being predicted to pass the assessment. A value of 1 indicates that both groups are predicted to pass the assessment with equal probability. A value greater than 1 indicates that one group is predicted to pass the assessment more than the other group, while a value less than 1 indicates the opposite.

$$DI = \frac{P(\hat{Y} = 1|D = group2)}{P(\hat{Y} = 1|D = group1)} \quad (3)$$

A.3 Average Odds Difference

Average odds difference measures the average of the difference in the false positive rate and the true positive rate for the differing groups. A value of 0 indicates an equality of odds. A value of -1 or 1 indicates maximum possible inequality.

$$AO = \frac{(FPR_{group2} - FPR_{group1}) + (TPR_{group2} - TPR_{group1})}{2} \quad (4)$$

A.4 Equal Opportunity Difference

The equal opportunity difference metric compares the difference in true positive rates between the two groups. A value of 0 indicates equality between groups. A value of -1 or 1 indicates high inequality.

$$EO = TPR_{group2} - TPR_{group1} \quad (5)$$

The Impact of Semester Gaps on Student Grades

Gary M. Weiss, Joseph J. Denham, and Daniel D. Leeds

gaweiss@fordham.edu, jdenham2@fordham.edu, dleeds@fordham.edu

ABSTRACT

College students have great flexibility in choosing when they take specific courses. These choices sometimes are constrained by prerequisite requirements, which determines the order in which pairs of courses may be taken. However, even in these cases the student can choose the number of semesters, or gap, between the pairs of courses. In this paper we study the impact that this gap has on student learning, as measured by course grades. Our methodology accounts for differences in instructor grading policies and in student ability as measured by overall grade point average. Our results can be used to inform course selection and advising strategies. Our study is applied to eight years of undergraduate course data that spans all departments in a large university. Due to space limitations, in this paper we focus our analysis on the semester gaps in Computer Science courses and in Spanish courses. Our results do not show a consistent negative impact on increasing semester gaps between all pairs of courses in a department; however, a negative impact is shown when the gap increases between courses that have a particularly strong relationship and overlapping content.

Course sequencing, Student performance, Educational Data Mining

1. INTRODUCTION

Undergraduate college students have considerable flexibility in when they can take specific courses. Course sequencing is typically determined by certain courses being deemed as prerequisites for others. However, even in such cases, there is no requirement that the prerequisite must be taken in the prior semester. Thus there may be a “gap” between when the two courses are taken. A gap may also exist between courses that have no prerequisite relationship. In this study we compute, for all possible course pairs, the impact that this gap has on the course that is taken second. We ignore course pairs with an insufficient number of students in common and focus our analysis on course pairs with a clear connection and overlapping topics.

Our study is based on course grade data from Fordham University, a large university [2] with approximately 15,000 undergraduate and graduate students. As discussed in detail in Section 2, we account for some important factors that could distort our results, such as whether a particular instructor is an easy or hard grader, and whether a course section happens to have a stronger or weaker set of students, based on student overall grade point average (GPA). We introduce a general set of metrics that can be used to assess the

G. Weiss, J. Denham, and D. Leeds. The impact of semester gaps on student grades. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 612–615, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

<https://doi.org/10.5281/zenodo.6853153>

impact of semester gaps. Our findings indicate that when courses are very strongly related and cover overlapping topics, that an increasing semester gap degrades student performance. However, our results do not show this pattern over the broader set of courses, even if the courses are offered by the same department. The information that we compute can be used to inform the course selection process and to improve departmental advising strategies.

Our study is a special case of the more general work on course sequencing, especially the work on course sequencing as it impacts student grades. Work on the more general area of course sequencing is quite limited and has often been restricted to a single discipline, such as communications [5] or psychology [1]. A prior study of ours did span all academic disciplines in a university, and compared student grades between pairs of courses when the courses are taken in the two possible orderings [3]. Our current study is similar in that we also study only course pairs, but rather than comparing the two sequential orderings, we evaluate the impact of the number of semesters between the courses.

2. COURSE-GRADE DATA SET

The initial data set includes course enrollment and grade data for each undergraduate student in the university. Each individual record corresponds to a specific student taking a specific course (identified by the course department, course number and title, section number, and semester and year) and also has the earned student grade in the course. Grades are represented using a 4-point scale, where a 0 represents an “F” and 4.0 represents an “A.” Our ability to identify individual course sections is important because, as discussed in Section 3.2, student grades are normalized at the section level to account for differences in instructor grading schemes. The data set contains 473,527 records that cover 24,969 students. Due to strict privacy laws, we are unable to share our data set even though the student identifiers have been anonymized.

Our study is focused on student grades as well as the timing between courses. Before proceeding, we need to acknowledge that the course gaps have additional implications. For example, if a large gap exists, then the student will be more advanced in their education (and age) when taking the second course. This by itself can impact student learning. Similarly, the courses that tend to have larger gaps are more likely to have a higher course level, designated by the first digit of the course number (where 1000 represents a first year freshman course and 4000 represents a fourth year senior class). However, this numbering is only a rough guideline and there are even cases where a freshman takes a 4000 level course.

Table 1 shows how “Student Year” and “Course Level” impact a grade, as these factors can influence grade patterns tied to semester gaps. Table 1 shows the average grade by student year (freshman to senior) for each course level and then averaged over all course levels. The final column shows that the average grade increases monotonically with student year; the final row shows that the average grade also increases monotonically with course level. The

number of students in each student year that take courses at a particular course level varies greatly. We track these numbers, although they are not included in Table 1, and use them to compute the displayed averages, which are weighted by the number of students corresponding to each entry. If our results show that an increasing gap degrades student performance, this effect would run counter to the general trend of higher grades as one advances in one's college career.

Table 1. Average grade by year and course level

Student Year	Course Level				Average
	1000	2000	3000	4000	
Freshman	3.108	3.271	3.034	3.209	3.120
Sophomore	3.189	3.281	3.215	3.244	3.222
Junior	3.167	3.310	3.278	3.305	3.261
Senior	3.182	3.342	3.327	3.385	3.320
Average	3.136	3.301	3.271	3.364	

3. CALCULATING GAP PERFORMANCE

In this section we describe how gap performance is measured. Our methodology and the associated metrics incorporate two types of grade normalization, discussed below.

3.1 Basic Methodology

We measure gap performance for potentially every pair of undergraduate courses. For each pair (Course A, Course B), we consider both orderings (i.e., placing Course A first and then placing Course B first). For each ordering, we further partition the students based on the number of semesters between the pair of courses. If the number of students in a partition associated with a particular gap size is at least *gap-threshold*, we calculate the average grade of the students in the second course. If the number of students is below this threshold, the partition is omitted since any average grade may not be reliable. We then compare average grades for different gap lengths to detect the relative impact of larger semester gaps.

For this study we omit summer courses and consider only fall and spring semester courses – we consider the gap between a fall 2014 and spring 2015 course to be the same as the gap between a spring 2015 and fall 2015 course. We do this because summer courses are taken with relative infrequency, and because summer courses compress the material from a fifteen week fall or spring semester into a five week summer session. This compressed schedule, even though it may maintain the number of lecture hours, is likely to have a deleterious impact on student learning. We consider courses taken in consecutive semesters to have a gap of 1 (i.e., one semester difference), although we recognize it might be more natural to consider this as a gap of 0. However, using our scheme courses taken in the same semester can be represented with a gap of 0; we ignore such cases from our present analysis but may consider them in the future. Taking courses simultaneously is very different from taking courses sequentially, and merits a separate analysis.

3.2 Normalizations

We normalize our student grades to account for two confounding factors. We first normalize grades at the course section level to account for instructors that are easy versus harsh graders; we then normalize for student ability, as measured by the student's grades across all of their courses (i.e., their GPA). We apply these sequentially, so we never normalize only for student ability. We refer to the resulting normalized student grades as *instructor* normalized and *compound* (instructor and student ability) normalized grades. In order to provide more succinct names and table headings, and to reflect that these normalizations are applied sequentially, we refer

to these as *Level 1* and *Level 2* normalizations. These two levels of normalization have been used in several of our labs other studies, including the previously discussed study on the impact of course pair orderings on student grades [3].

The Level 1 instructor normalization takes the raw student grades in an individual course section and applies z-score normalization. This will account for instructors who assign grades with higher, or lower, overall means, so that these factors do not obscure the semester gap effects. Equation 1 describes the normalization process. In this equation, $L1_i$ represents the L1 instructor normalized grade of student i in the course section, x_i represents the initial grade of the student, μ represents the mean grade of the course section, and σ represents the standard deviation of the course section grades.

$$L1_i = (x_i - \mu) / \sigma \quad (1)$$

The next normalization accounts for student ability. That is, a particular section may contain students who are stronger-than-usual overall. While such affects may be expected to average out, they nonetheless could distort our results. We measure student ability by the student's grades in all of their courses. We could try to do better by using a student's major GPA for major courses, humanities GPA for humanities courses, and so on, but we do not want to overly complicate the calculations. This step takes the normalized scores produced by Equation 1 and then applies another round of z-score normalization, as described by Equation 2. In this equation, $L2_i$ represents the Level 2 compound normalized grade of student i in the course section, $L1_i$ represents the L1 instructor normalized grade of student i , μ_i represents the mean instructor normalized grade across all courses taken by student i (i.e., instructor normalized GPA), and σ_i represents the standard deviation of this student's instructor normalized grades.

$$L2_i = (L1_i - \mu_i) / \sigma_i \quad (2)$$

These steps are done at the course section level. These values are then aggregated over all course sections for each course. These are the values that we report in our results as long as there are a sufficient number of values (i.e., students). As mentioned in Section 3.1, our metrics are based on the students who take the second course a specific number of semesters after the first course. We refer to the metrics computed over these partitions of student grades as the L1 gap and L2 gap metrics, where each of these metrics in turn is associated with a specific gap length (e.g., we can talk about the L1 gap=1 value versus the L1 gap=2 value). In our discussion we prioritize the L2 gap metric over the L1 gap metric.

3.3 Example Gap Performance Entry

An example is provided in Table 2 to provide a better understanding of the metrics that were just introduced. The table includes just a single entry, which corresponds to "Introductory Biology I" followed by "General Chemistry 1." In our dataset there are a total of 1301 students who took these two courses in this sequence. The number of students who took it with a gap of 1 and a gap of 2 is not provided in the table but is above *gap-thresh* (the results in Section 4 use *gap-thresh*=40 unless otherwise specified). Table 2 only includes the Level 2 results. The value for students taking "Gen Chem 1" in the semester right after taking "Intro Bio 1" is 0.519, while the value for those waiting an extra semester (so they take it the same semester in the following year) is -0.362. Since the value decreases, the delay hurts student performance. The difference between these values (gap 1 minus gap 2) is 0.881 and is denoted as the L2 difference (L2 Diff). We generally do not show the gap values past a gap of 2 because there are often insufficient numbers of students to satisfy *gap-thresh*. For this reason we focus on the

difference between a gap of 1 and 2, although we provide one example with a larger gap in Table 3. As we accumulate additional student data, we may be able to extend our analyses to look at larger gap lengths.

Table 2. Sample course gap table entry

Course 1	Course 2	Corr.	Students	Level 2 Gap		L2 Diff (gap 1-2)
				1	2	
Intro Biol	Gen Chem1	0.64	1301	0.519	-0.362	0.881

We tend to focus our analyses on courses that are normally taken closely together—if this is not the case then the courses are most likely not highly linked, and a delay is less likely to matter. Table 2 specifies the Pearson correlation (Corr.) between the student grades in the two courses. This correlation, which is computed independent of order, tends to identify courses that are highly related/linked. The link may not be causal—it could just be that the courses utilize similar skills so that students who perform well in one perform well in another. But we do feel that a high grade correlation is a necessary, but not sufficient, condition for two courses to have their grades causally linked—and hence have the possibility of a semester gap having a substantial influence on student performance. Thus we can use grade correlation to help guide our search for courses to focus our attention on. This use of grade correlation was studied in one of our prior studies [4], which suggested that a grade correlation of 0.5 or higher suggests that courses are linked.

Table 3 includes the only entry in this paper with a gap length greater than 2. The example involves “General Chemistry 1” followed by “General Chemistry 2.” This example was selected by sorting all of our results by decreasing levels of grade correlation and then selecting the first entry. Note that the performance degrades when the gap transitions from 1 to 2. This trend does not continue to a gap length of 3, but student performance at gap length of 3 is still below that of gap length of 1. The entries for gap length of 3 may be less reliable since they involve fewer students, although they still exceed the *gap-threshold* of 40.

Table 3. Course gap entry for GenChem1 → GenChem2

Metric	Corr.	Students	Gap Length		
			1	2	3
L1	0.730	1328	-0.040	-0.753	-0.615
L2	0.730	1328	-0.337	-1.012	-0.689

4. MAIN RESULTS

This section covers our main results. Section 4.1 take a detailed look at Computer Science courses and then Section 4.2 looks at Spanish courses. We study Computer Science courses because all of the authors of this study are affiliated with a Computer Science department. Foreign language courses were selected since our intuition is that courses in a foreign language will be heavily sequenced and the performance in one course will impact the performance of subsequent courses; Spanish courses were selected because Spanish is the most popular foreign language studied in our university.

4.1 Computer Science Results

In this section we take a detailed look at the course gap results for Computer Science (CS) courses. In order to provide a fair analysis, all course pairs that satisfy a *gap-threshold* of 40 are displayed in Table 4.

Before analyzing the results, it is important to understand the relationship between CS courses, since the gap values are not as likely to be meaningful for courses that are not highly related. Thus we

first highlight the course pairs where the courses cover the same topic(s), although perhaps at different levels. In these cases the first course will be an *essential* prerequisite for the second course. Our introductory programming sequence is CS1→CS2→Data Structures, and each course builds on the prior ones and utilizes the same programming language. While other courses may be related by a prerequisite, the prerequisite may not be as essential. For example, Databases has CS1 as a prerequisite, but mainly just to ensure that the student has had a general exposure to programming. The only other course pair in Table 4 that may share an “essential” relationship is “Data Structures” and “Algorithms,” although there are substantial differences, as the first course has a heavy programming component, while the second course generally does not.

Table 4. Computer Science course gap table

Course 1	Course 2	L1 Diff	L2 Diff	Corr.	Stdnts	L1 gap		L2 gap	
						1	2	1	2
CS1	CS2	.250	.308	.568	582	.052	-.198	.078	-.730
CS2	DataStruct	.301	.357	.549	351	.072	-.229	.063	-.293
Databases	DataComm	.044	.346	.526	170	.000	-.044	.452	.107
Databases	OS	-.017	.069	.520	187	.146	.163	.188	.118
CS1	Databases	.116	.024	.443	274	-.193	-.309	-.087	-.111
CS2	Databases	-.029	-.009	.469	238	.069	.098	.304	.313
DiscMath	CS1	-.196	-.137	.382	300	-.320	-.125	-.160	-.024
DataStruct	Algrthms	-.163	-.346	.526	232	.011	.174	-.131	.215
DataStruct	OS	-.168	-.353	.550	226	-.114	.054	-.284	.069
DataStruct	TOC	-.143	-.412	.460	251	-.149	-.006	-.402	.010
CS1	CompOrg	-.292	-.446	.410	268	-.238	.053	-.151	.296
CS2	CompOrg	-.239	-.533	.463	256	.101	.340	.166	.699
CS2	DataMining	-.129	-.821	.492	212	-.070	.059	-.176	.646

The key observation from Table 4 is that the gap between CS1 and CS2, and the gap between CS2 and Data Structures, has a large L2 difference—and in fact they have the two largest positive differences. The same pattern is also observed with the L1 normalized differences. The grade correlation between students who take CS1 and CS2 (0.568), and CS2 and Data Structures (0.549), is quite high, and in fact are higher than for just about all other course pairs. This further supports the strong relationship between these pairs of courses. In other cases, when the grade correlation is high it could just be that the courses rely on similar student abilities and there is no causal link. Nonetheless, we generally would expect a relationship between grade correlation and L2 Difference, even if some of the relationships are not causal. The scatter plot and associated trendline in Figure 1 demonstrates that there is such a relationship, and the Pearson correlation coefficient between these two measures of 0.459 confirms this (this is considered to be a moderate positive correlation).

Figure 1. Grade correlation versus L2 diff (Computer Science)

The remaining entries in Table 4 do not support the hypothesis that a larger gap will yield poorer performance, since in many cases the L1 and L2 differences are negative. This suggests that the gap has no substantive negative impact on student learning in those cases. Often negative differences are associated with first-courses intended to be taken early in the major (CS1, CS2, and Data Structures) and second-courses intended to be taken in the middle years of the major with relatively few official prerequisites. Perhaps the gap poses a benefit in these cases by allowing the students time to reflect and grow through partially-tangential academic experiences before joining the second course. It should be noted that we already advise students to take our introductory programming sequence CS1 → CS2 → Data Structures as quickly as possible, but our universities' large liberal-arts core curriculum, which includes well over a dozen courses, sometimes interferes with this advice.

4.2 Spanish Results

The next discipline/department that we look at is Spanish, for the reasons provided earlier. Students who do not major in a science are all required to take a substantial amount of a foreign language—beyond the placement credits that most students receive. Our university catalog reveals the following prerequisite structure for the Spanish courses that appear in Table 5:

Spanish 1 → Spanish 2 → Language and Literature → Approaches to Literature → Latin America: Literature and Culture

The first two courses in the sequence are standard intermediate-level courses that focus on language fundamentals such as reading, writing, listening, and speaking. They do require two introductory Spanish courses, but most students receive placement credit for those based on their high school foreign language requirement. The Spanish Language and Literature course introduces Spanish literature, but a key focus in the course is using these topics to review the language fundamentals. The last two courses assume language competence and the focus goes beyond language fundamentals. Based on this background, one would expect that “Spanish 1” and “Spanish 2” would have the strongest relationship, followed by “Spanish 2” and “Language & Literature.”

Table 5. Spanish course gap table

Course 1	Course 2	L1	L2	Corr.	Stdnts	L1 gap		L2 gap	
		Diff	Diff			1	2	1	2
Spanish1	Spanish2	.686	.420	.663	2348	.001	-.685	-.036	-.456
Spanish2	Lang&Lit	.471	.232	.640	2472	-.023	-.494	-.236	-.468
ApprToLit	LatinAmerica	-.111	.151	.592	166	-.092	.019	-.451	-.602
Spanish1	Lang&Lit	-.317	-.246	.583	2020	-.395	-.078	-.580	-.334
Lang&Lit	ApprToLit	-.113	-.397	.390	496	.009	.122	-.747	-.350

The data in Table 5 agrees with the expectation that the courses that are most related will most negatively impacted by an extra semester gap. Those courses also have the highest grade correlation, which further suggests a close relationship.

5. CONCLUSION

This paper introduced a methodology for evaluating the impact of semester gaps between courses on student performance. Performance is measured based on student grades and two levels of normalization are used to account for differences in instructor grading policies and in student ability. This methodology was applied to eight years of undergraduate course data. This initial study focused on the impact of semester gaps on Computer Science courses and on Spanish courses; the former was selected to utilize the

domain knowledge of the authors while the latter was selected due to the expected strong impact between introductory foreign language courses. In both cases a longer gap did not consistently degrade student performance. This may be explained by the fact that even within a given discipline, the knowledge gained in one course may not necessarily have a strong impact on the performance in the other course. However, for both Computer Science and Spanish, the courses with the clearest direct connections *did* show a degradation in performance with a longer gap. In these two cases the courses with the largest such degradation were introductory courses where both pairs of courses *share the same name*, but with a different suffix (i.e., “Computer Science 1” and “Computer Science 2” and “Intermediate Spanish 1” and “Intermediate Spanish 2”). We believe that this connection is not accidental and that performance in highly related courses suffer from degradation in retained knowledge over time, as measured in the present work. We further note that if two courses have no meaningful link in grades, a larger gap should lead to *improved* performance in the second course based on our results in Table 1, which show that students earn higher grades the further along they are in their academic career. Our work has the potential to improve academic advising in that an advisor, or an automated tool, could warn students when a delay is most likely to lead to degraded performance.

This study has several limitations that will be addressed in future work. Although our university is considered a large university by the Carnegie classification [2] since it has more than 10,000 degree seeking students across all levels, we often found that the number of students taking pairs of related courses was often quite modest, and the number quickly diminished with the number of intervening semesters. Our immediate plan is to obtain several years of additional data, since our data is currently three years old. Longer term, we hope to obtain data from another university, or to lend our analysis tool to other researchers, who can apply it to their university data. We also plan to form higher level hypotheses about the role of time between courses, and combine it with domain knowledge across many disciplines, so that we can generate more reliable conclusions. For example, if we had a list of the two most highly related courses in each academic major, we could compare the impact of gap length on these collective pairs of courses.

ABSTRACT

Educational institutions rely on instructor assessment to determine course assignments, which instructors to retain or promote, and whom to provide with additional assistance or training. Instructor assessment is most commonly based on student surveys or peer evaluation—which are both subject to the evaluator’s personal biases. This study describes an assessment method based on future student grade performance, which has the potential to avoid these biases. This study is based on eight years of undergraduate course-grade data from over 24,000 students in a large metropolitan university. The methodology introduced in this paper accounts for confounding factors, such as diverse instructor grading policies and varying student abilities. Top and bottom performing instructors are identified for each course.

Keywords

Instructor effectiveness, instructor evaluation, data mining, educational data mining, grade analysis, data analysis.

1. INTRODUCTION

Assessing instructor effectiveness is important for determining which instructors to retain or promote, optimal assignment of courses, and providing additional mentorship or training to weak instructors [3, 8]. It is also often a key factor in tenure decisions. In a university, these assessments are typically done through student surveys or peer evaluations based on classroom observations [8]. Both of these methods are subject to the biases of the evaluators, which may be impacted by instructor gender and race, and may not measure student learning [1, 2, 5, 7]. The justification for using student surveys is derived from several studies in which positive correlations are found between student evaluations and instructor effectiveness as measured through exams at the end of each course. However, a recent meta-analysis conducted on thirty-two of these studies shows that there is no such positive correlation for the studies containing the most course sections, indicating earlier conclusions were due to a lack of data and providing argument against the use of student evaluations to measure instructor effectiveness [7]. These studies also measure instructor effectiveness using the grades for the course being taught. Given that the exams and grades are usually designed by the instructor, this yields another potential source of bias; our methods avoid this bias by relying on students’ performance in future courses. Peer evaluations are most likely subject to similar biases.

The method introduced in this paper assesses instructors by quantifying their impact on future student grade performance. If students with a given instructor perform better (worse) in future courses than students who have a different instructor, then the instructor is ranked favorably (unfavorably). Our study only assumes basic course-grade data is available, and does not account for all potential confounding factors, such as the time of day of the class or class size [9]. However, we do account for grade-related factors such as instructor grading leniency and student ability as measured by grade-point average. We have developed a publicly available Python-based software tool that implements our methodology and generates the instructor effectiveness metrics [6].

Our study identifies instructors who appear to be much more or less effective than other instructors based on their student’s future performance. Our analysis first focuses on two case studies, assessing instructors of “Spanish 1” and “Computer Science 2” based on future performance in “Spanish 2” and “Data Structures,” respectively. We then identify the best instructors in the university based on the teaching of a single course, and then identify the top-10 and bottom-10 instructors based on the performance over all courses each instructor teaches, with future student performance measured on all future courses taken within a single department. We discuss several interesting patterns across these results.

2. STUDENT COURSE-GRADE DATA SET

The work presented in this paper is based on eight years of undergraduate course-grade data from Fordham University. Each record in the dataset represents a student earning a grade in a specific course section and includes the following fields: student identifier, instructor ID, course name, course number, course department, course term (semester and year), and student grade using a 0.0 (F) - 4.0 (A) scale. Table 1 provides key dataset statistics. In order to enhance privacy, student identifiers were remapped and data for course sections with fewer than five students were omitted. Even with such measures, due to federal regulations we are not permitted to publicly share the dataset.

Table 1. Summary Dataset Statistics

Feature	Unique Values
Record Number	442,230
Student ID (SID)	24,654
Instructor ID (IID)	2,195
Course Name & Number	2,505
Course Section	21,504

Demographic information was not included in the data set as it could facilitate de-anonymization. We therefore characterize the population using university statistics for the middle year of the data: gender distribution is 60% female and 40% male, and the racial/ethnic breakdown is 55% White, 14% Hispanic, 11% Asian, 7% International, 4% Black, and 9% other. The majority of students are between the ages of 17 and 22.

3. MEASURING INSTRUCTOR BENEFIT

This section describes the methodology used to calculate instructor benefit and introduces our three instructor benefit metrics. This methodology is implemented in a publicly available Python-based software tool developed by our research group [6], which enables other researchers to apply our research to other student grade datasets. The steps used to generate our results are summarized in Figure 1 and described in subsequent subsections.

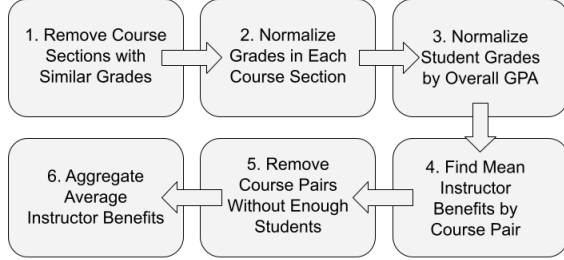

Figure 1. Overview of Data Processing Steps

3.1 Remove Sections with Too Similar Grades

Differences in instructor effectiveness can only be measured if there is reasonable variance in the grades assigned to students. Thus we remove the data associated with course sections with very low grade variance. Step 1 computes the standard deviation of the grades in every course section and eliminates sections where the standard deviation is below $MinSD$. The distribution of grade standard-deviation values at the section level is provided in the Appendix, and Section 4 specifies the $MinSD$ value of 0.2 that is used throughout this study.

3.2 Normalize Grades in each Section

To account for different instructor grading schemes, we employ z-score normalization for each course section. The Level-1 normalized score, defined below, tells us how many standard deviations away from the course section mean a student scores.

$$L1_{SID}^{CrsSec} = \frac{G_{SID}^{CrsSec} - \mu_{CrsSec}}{\sigma_{CrsSec}}$$

In this formula, $L1_{SID}^{CrsSec}$ is the normalized course grade for student SID in the specified course section $CrsSec$, G_{SID}^{CrsSec} is the original grade for student SID in $CrsSec$, and μ_{CrsSec} and σ_{CrsSec} are the mean and standard deviation of the grades in $CrsSec$. Instructor benefits calculated using this Level-1 normalized grade are referred to as L1 Instructor Benefits. Instructor benefits calculated using the unnormalized grades are referred to as Grade Benefits (although they can be viewed as Level-0 Instructor Benefits).

3.3 Normalize Grades by Overall Performance

Student performance is not just dependent on the effectiveness of the instructor but also depends on a student's abilities. We therefore employ a second level of grade normalization that is based on the student's overall performance in all of their courses (i.e., GPA). Without this normalization, an instructor that coincidentally is assigned high-performing students will appear to perform better than an instructor that is assigned weaker students. This Level-2 normalization is defined by the formula below and L2 Instructor Benefits are calculated using these values.

$$L2_{SID}^{CrsSec} = \frac{L1_{SID}^{CrsSec} - \mu_{SID}^{norm}}{\sigma_{SID}^{norm}}$$

In this formula, $L2_{SID}^{CrsSec}$ is the Level-2 normalized grade of student SID in course section $CrsSec$, $L1_{SID}^{CrsSec}$ is the Level-1 normalized score from the prior step, and μ_{SID}^{norm} and σ_{SID}^{norm} are the mean and standard deviation of student SID 's L1-normalized grades across all courses.

3.4 Find Instructor Benefit by Course Pair

We next consider every ordered course pair, $C1 \rightarrow C2$, where course $C1$ is taken prior to course $C2$. Assume that the instructor for $C1$ has an instructor ID, IID . The instructor benefit associated with instructor IID teaching $C1$ based on $C2$ performance is computed using the $C2$ grades for those students who previously had instructor IID for $C1$. The type of $C2$ grade (unnormalized, L1-normalized, L2-normalized) determines the type of Instructor Benefit (Grade, L1, L2). The calculations just described are aggregated over all sections for a given course. More formally, $IB_{IID}^{C1 \rightarrow C2}$ is the instructor benefit (IB) for students taking $C2$ after taking $C1$ with instructor IID .

$$IB_{IID}^{C1 \rightarrow C2} = \langle GRADE_{SID \in (C1, IID)}^{CrsSec \in (C2)} \rangle$$

In this formula, $CrsSec \in (C2)$ is any course section of course $C2$, $SID \in (C1, IID)$ is every student who took course $C1$ with instructor IID , and $\langle x \rangle$ is the average of all values in x .

$IB_{IID}^{C1 \rightarrow C2}$ is computed for all ordered course pairs $\langle C1, C2 \rangle$ and for every $C1$ instructor, as long as at least 80% of the students who complete both courses take $C1$ first. This restriction ensures that we only evaluate instructor effectiveness between courses that are taken in the expected order. In Section 3.6, we discuss aggregating the instructor effectiveness metrics for each instructor teaching $C1$ over all $C2$ courses, and then again over all $C1$ courses for each instructor. However, we believe that these higher level metrics are less meaningful, since each $C1$ course is often best evaluated on a single $C2$ course (e.g., Spanish 1 is best evaluated using performance in Spanish 2). For this reason most of the results in Section 5 are at course-pair level. When the most appropriate future course is not clear based on domain knowledge, the choice can be guided by looking at the course pairs with the highest pairwise grade correlation, as described in one of our recent studies [4].

3.5 Remove Course Pairs with Few Students

Instructor effectiveness is computed for pairs $C1 \rightarrow C2$. For the resulting instructor effectiveness metrics to be reliable, the instructor will need to have taught at least $MinStudents$ in $C1$ who subsequently completed $C2$. However, since this is a comparative statistic, we also require that there are $MinStudents$ who completed $C1$ with *other* instructors and then completed $C2$ (hence if $MinStudents = 50$ there must be at least 100 students that took $C1$ and then completed $C2$). Section 4 explores how the $MinStudents$ threshold impacts the number of available course pairs.

3.6 Aggregate Average Instructor Benefits

Course-pair level instructor benefit metrics are aggregated to yield higher level views of instructor performance. The instructor benefit values for each $\langle C1, C2 \rangle$ course pair are first aggregated over the set of $C2$; restrictions on $C1$ and $C2$ may be applied. The results in Section 5.3 are at the instructor level but are aggregated over all $C1$ courses taught by instructor IID in a single department and measured on future performance over classes in another department (i.e., $AIB_{IID}^{D1 \rightarrow D2}$). This aggregation formula, which is provided below, also weights the courses by the number of students.

$$AIB_{IID}^{D1 \rightarrow D2} = \frac{1}{\sum_{C1 \in CX_{IID}} |\{S \in CX_{IID}\}|} \sum_{\substack{(C1 \in D1) \\ (C2 \in D2)}} IB_{IID}^{C1 \rightarrow C2} |\{S \in IB_{IID}^{C1 \rightarrow C2}\}|$$

The computation is performed across all relevant course pairs in the department $C1 \rightarrow C2$, where $IB_{IID}^{C1 \rightarrow C2}$ is an instructor benefit from $C1$ to $C2$, $|\{S \in IB_{IID}^{C1 \rightarrow C2}\}|$ is the number of students who took the instructor in that particular course pairing, and $\sum_{CX, IID} |\{S \in CX_{IID}\}|$ is the number of students who took a course with instructor IID (summed over all possible courses CX). The formula above can be used to find, amongst other things, the instructor effectiveness scores for a Computer Science instructor when evaluated on future Math classes, as well as when evaluated on future Computer Science classes (i.e., when $D1 = D2$).

4. Threshold Sensitivity Analysis

We selected appropriate thresholds for $MinSD$, the minimum standard deviation of section grades, and $MinStudents$, the minimum number of students in each course pair. The Appendix provides additional relevant information related to the selection of these thresholds. We select $MinSD=0.2$, retaining most (20,904 of 21,504) course sections while ensuring some variability in student grades, and $MinStudents=50$, to keep a large number of course pairs while maintaining reliability of the instructor benefit metrics.

5. RESULTS

This section provides our instructor benefit results. Section 5.1 and Section 5.2 provide results at the course-pair level, while Section 5.3 identifies the top and bottom performing instructors based on their performance across all courses in a department. Grade Benefit, Level-1 Benefit, and Level-2 Benefit metrics are all provided, with a focus on Level-2 Instructor Benefits.

5.1 Section Level Course-Pair Results

This section provides results at the course-pair level. Due to space limitations we can only provide instructor benefit results for instructors teaching Spanish 1 based on future student performance in Spanish 2 and for instructors teaching Computer Science 2 (CS2) based on future performance in Data Structures. We include the Spanish courses because they are popular and Computer Science courses because they are offered by our home department and there is great interest in Computer Science education. In both cases, the course pairs are part of a common introductory sequence, and the second course directly follows the first course.

Table 2. Instructor Benefit for Spanish 1 \rightarrow Spanish 2

Instructor ID	Sections Taught	Total # Students		Instructor Benefit		
		Spanish 1	Spanish 2	Grade	Level 1	Level 2
F980	22	381	325	-0.024	0.016	0.050
F494	17	367	295	-0.189	-0.091	-0.090
F787	12	217	166	-0.154	-0.079	-0.210
F424	11	231	191	-0.278	-0.259	-0.146
F425	11	213	171	0.034	-0.076	-0.097
F819	10	201	176	0.050	0.124	0.233
F883	9	154	129	0.030	-0.039	0.065
F719	8	179	134	0.090	0.076	0.147
F890	7	172	138	-0.097	-0.009	-0.282
F541	7	86	67	0.061	0.045	-0.219
All	189	3485	2644	-0.088	-0.092	-0.073

The results for the Spanish classes are summarized in Table 2. Sections where fewer than five students continue to Spanish 2 are excluded to allow section-level instructor benefit values to be reliable for statistical analyses. Due to space limitations, instructors with fewer than seven sections are not listed but are included in the summary statistics in the last row.

Our analysis focuses on Level 2 instructor benefit because it accounts for the two confounding factors discussed earlier, but Figure 2 shows that the three metrics are generally correlated, and

the Pearson correlation coefficient (ρ) using the 189 section level values confirms this with $\rho=0.74$ between the Grade and Level-1 metric and $\rho=0.76$ between the Level-1 and Level-2 metric.

Figure 2. Instructor Benefit Metrics for Spanish 1 Instructors

Table 2 and Figure 2 show that there are substantial differences in the Level-2 values since they vary from +0.233 to -0.282. Small differences in instructor ability may be hard to distinguish, so in this initial study, we focus on cases with the largest differences and where the values are based on many students. Given this, we conclude that instructor F819 is highly effective, while F890, F541, and F787 are least effective. A two-sample unequal variance t-test at the section level for Instructor F819 (+0.283) and F787 (-0.210) yields $p=0.0156$ for the one-tailed distribution and $p=0.0312$ for the two-tailed distribution. These p-values suggest that the differences are statistically significant, although this is partially due to comparing instructors at the two extremes. More students would make more refined assessments possible.

Table 3 provides analogous results for the <CS2, Data Structures> course pair. Instructor data is limited because the CS major was not heavily populated in the timeframe considered (2010 to 2018). The table includes all instructors that taught three or more sections of CS2 (the bottom two instructors did not meet our preferred $MinStudents$ threshold of 50). Based on the level 2 instructor benefit, two instructors are strongly positive and two moderately negative. A t-test on the first two instructors in Table 3 yields p-values of 0.00030 (1-tail) and 0.0003 (2-tail).

Table 3. Instructor Benefit for CS2 \rightarrow Data Structures

Instructor ID	Sections Taught	Total # Students		Instructor Benefit		
		CS2	DataStr.	Grade	Level 1	Level 2
F212	12	293	158	-0.304	-0.226	-0.189
F177	4	92	62	0.237	0.151	0.396
F589	3	56	36	-0.329	-0.177	-0.228
F653	3	35	33	-0.385	-0.042	0.400
All	32	697	410	-0.227	-0.145	-0.054

The section level results suggest that it is possible to distinguish between high and low-performing instructors when using future student performance in a single highly related course. It may be difficult to reliably assess less extreme differences, but universities with larger classes or higher teaching loads should be better able to perform more refined assessments.

5.2 Global Course-Pair Instructor Results

Table 4 provides the best Level 2 Instructor Benefit results at the course-pair level. The course pairs are restricted to the same department or between departments that share major requirements, since it is best to measure instructor effectiveness using related courses. The results are based on $MinSD=0.2$ and $MinStudents=50$. Each entry in Table 4 corresponds to a single instructor. Course names are abbreviated using department codes and course numbers, but the full names are provided in our discussion.

Table 4. Top 6 Instructor Course Pairs by Level 2 Benefit

Course1	Course2	Grade Benefit	Level 1 Benefit	Level 2 Benefit
Chem 211	Bio 342	0.11	0.09	1.50
Econ 220	Econ 332	0.53	0.50	1.12
Phys 140	Chem 121	0.24	0.43	0.79
Chem 121	Chem 212	0.14	0.22	0.76
NatSci 304	NatSci 321	0.44	0.48	0.75
Comm 112	Comm 242	0.41	0.38	0.72

The courses pairs that appear in Table 4 exhibit a strong relationship between Course 1 and Course 2. For example, the first row involves “Organic Chemistry Lab” and “Biochemistry,” while the two Natural Science courses correspond to “Organic Chemistry I Lab” and “Organic Chemistry II.” Our belief is that the instructor associated with each entry is a very effective instructor, although, as discussed in Section 6, we cannot validate this. The Grade and L1 Benefit values are rarely as high as the L2 Benefit values, which indicates that the second round of normalization has a substantial impact. Note that students who take Econ 220, with the instructor represented by that entry, obtain a grade that is, on average, 0.53 higher than otherwise expected; this corresponds to a difference of more than a half letter grade.

5.3 Department Level Instructor Results

This section describes the aggregate effectiveness of an instructor ($AIB_{ID}^{D1 \rightarrow D2}$, as defined in Section 3.6.) based on all courses that instructor teaches in one department, measured by student success in future courses in one (potentially different) department. We consider these results to be less meaningful than results on course-pairs selected for mutual relevance. Nonetheless, some interesting high level observations arise. The results in Table 5 include the top and bottom performing instructors using $MinStudents=50$ and $MinSD=0.2$. Each entry corresponds to a single instructor.

Table 5. Top and Bottom 10 Instructors by Level 2 Benefit

Course 1 Department	Course 2 Department	Instructor Benefit		
		Grade	Level 1	Level 2
Top 10 Instructors				
Political Sci.	Natural Science	0.317 ⁽⁸⁾	0.340 ⁽⁵⁾	0.588
Mathematics	Mathematics	0.033	0.242 ⁽⁸⁾	0.570

Natural Science	Natural Science	-0.475 ⁽¹⁾	-0.372 ⁽³⁾	-0.416
Chemistry	Biology	-0.342 ⁽⁸⁾	-0.443 ⁽¹⁾	-0.415
Comp. Science	Physics	0.304	-0.185	-0.411
Mathematics	Natural Science	0.085	-0.042	-0.406

The instructor benefits in Table 5 indicate that there is a substantial difference between the top and bottom performing instructors. Many unnormalized grade differences are about 0.3, representing one-third of a letter grade difference. The values for the three effectiveness metrics appear correlated. To verify this we computed

the Pearson correlation ρ between all three pairs of metrics, with the following results: $\rho(\text{Grade, Level 1}) = 0.977$, $\rho(\text{Grade, Level 2}) = 0.990$, $\rho(\text{Level 1, Level 2}) = 0.989$. These correlations are higher than in the prior section, showing a difference through aggregation over many sections and courses. For comparison, when the Grade or Level 1 benefit metric appears in the top-10 or bottom-10 for the listed instructor entry, we provide the rank in parentheses as a superscript (e.g., the instructor in the first row of data has the third highest Level-1 Benefit). The ranks are not needed for Level 2 Benefits since they are already in rank order.

We generally would expect that instructor effectiveness in a course will have the biggest impact on other courses in the same discipline. Many of the entries do involve the same department or related departments, but quite a few do not. There is much more agreement between the departments for the bottom 10 instructors, seeming to indicate weak instructors fail to convey field-specific concepts for future use, while strong instructors may convey broader skills useful across disciplines. We note that STEM (Science, Technology, Engineering, and Math) instructors account for 80% of the bottom performing instructors but only 40% of the top performing instructors, which is plausible given that STEM graduate programs generally provide little pedagogy instruction.

6. CONCLUSION

Bias in student and peer evaluations of instructor effectiveness have been widely observed [1, 2, 5, 7], supporting the need for more objective assessment methods. This study presents an alternative method for instructor evaluation based on student performance in future courses. Our study accounts for instructor grading leniency and overall student ability; these factors impact assessment, but all three metrics are nonetheless highly correlated.

Instructor assessment appears most appropriate at the course level and provides most insight when considering future performance in a single, highly related course. We focused on instructor performance for Spanish 1 and CS2, based on future student performance in Spanish 2 and Data Structures, respectively. In both cases, instructor benefit varied substantially and the Level 2 instructor benefit for instructors at these two extremes differed with reasonable levels of statistical confidence. Our methodology distinguishes between instructors and identifies high and low performing instructors. Evaluation of single instructors across courses was less clear, but revealed patterns, such as the weakest instructors often being associated with STEM disciplines.

The methodology and metrics described in this paper are calculated from traditional student course-grade data using a publicly available Python-based tool developed by our research group [6]. This tool can be used by other researchers and practitioners to extend our analysis to other educational institutions. We plan to improve the tool’s documentation and usability in the near future.

There are numerous areas for further work. Increasing the size of our data set would substantially strengthen future analysis, especially within our Computer Science department. Effects of instructor rank, title, years of experience, gender, and race also would be valuable to study. Furthermore, we aim to identify further discipline-based patterns, such as differences in instructor effectiveness distributions across departments.

The most fundamental limitation of this work relates to validation. Currently we only perform limited validation across course sections. Additional validation will inherently be limited since there is no way to assess the “ground truth.” Still, we aim to measure the relationship with weaker metrics like student survey results.

APPENDIX

This appendix provides additional information related to the two thresholds that were discussed in Section 4. The relevant underlying data distributions are shown, which inform the choice of specific threshold values.

Figure 3 shows the distribution of the standard deviation values for grades at the course section level. There are quite a few sections

with grade standard deviation near zero, most likely due to small project-based courses, where instructors often assign grades of “A”. As discussed in Section 3.1, sections with grade standard deviations below *MinSD* are removed since student performance cannot be effectively measured in such cases. Threshold values of 0.1, 0.2, 0.3, 0.4, and 0.5, were evaluated before a *MinSD* value of 0.2 was selected; that value was selected because it ensures a reasonable level of variance in the course grades while retaining most of the course sections.

Figure 3. Distribution of Section Grade Standard Deviations

Figure 4 shows how the number of course pairs vary, in log scale, based on the number of students in the course pair. This number is based on the students in the first course in the pair taught by a particular instructor. The figure is used to help select the *MinStudents* threshold defined in Section 3.5, which removes course pairs with too few students. Most pairings have less than 100 students, even though course pairs are aggregated over all relevant course sections; this occurs because many course pairs involve disparate courses in different disciplines. Our results are based on *MinStudents*=50. A larger threshold would increase the reliability of our instructor benefit scores but eliminate too many course pairs.

Figure 4. Number of Students in Course Pairs by Instructor

Modeling study duration considering course enrollments and student diversity

niels.seidel@fernuni-hagen.de

ABSTRACT

Students are self-determined to choose degree programs and courses at their own pace. However, this variety of choices can lead to a long duration of study, especially in part-time distance learning. Hence, this paper aims to explore data on course enrollments of students pursuing bachelor's and master's degrees in Computer Science and Mathematics at a European distance-based German university to uncover predictors for study duration. Distance students have highly diverse backgrounds, which might also be represented in their enrollment behavior and duration of study. Thus, it is vital to analyze this behavior to identify bottlenecks and adjust instructions. We employed a Multiple Regression Analysis with a Genetic Algorithm for model selection to uncover predictors that lengthen or shorten the study duration. For model selection, we considered demographic data, modes of study, enrollment behaviors, and individual courses. We used the method to find predictors within the data of 1898 students who graduated in at least one of the five study programs offered by the Faculty of Mathematics and Computer Science between 1999 and 2019. The enrollment behavior strongly predicts the duration of study compared to demographic and study-behavior predictors. Individual courses are good predictors for specific study programs.

Keywords

course enrollment, study duration, multiple linear regression

1. INTRODUCTION

In accordance with the Humboldtian model of higher education, students are self-determined to choose degree programs and courses at their own pace. However, this variety of choices can lead to a long duration of study, especially in part-time distance learning. At many universities, a long duration of study was not seen as a problem as long as sufficient capacity was available. In the OECD countries, the proportion of young people between 25 and 34 years of age with a university degree rose by a total of 14 percentage points

between 2000 and 2013 [27]. In Germany for instance, the number of students increased by 1,146,262 (63%) between 1998/99 and 2021/22¹. At the same time, the capacities for teaching did not increase at the same level. In this paper, we take a look at the duration of study as a driver for high student number.

Study programs are designed so that students graduate within a defined amount of time. If students exceed this regular period of study, it has consequences for the students, the teachers, and the respective faculty. Additional semesters cost a student time and effort to repeat courses and exams. This can also be accompanied by financial costs for tuition fees and a late entry into professional life or a higher career level. In addition, there are psychological burdens. For instructors, longer study durations mean an increase in the amount of supervision required due to the need to retake courses and exams. This is apparent in the supervision ratio which is defined as the number of students per teacher. From a faculty perspective, long-term students need to be considered for capacity planning. Just like the number of new program enrollments, the number of graduations is part of the target agreements or key performance indicators considered by the university management and ultimately the federal or state ministries of education. Today, higher educational organizations are placed in a very highly competitive environment. The analysis, presentation, and data mining is one approach to tackle challenges in the organization of study programs.

The causes of protracted studies are not necessarily due to a lack of motivation, performance, or effort on the part of students. Behavioral factors in the choice of one or more courses of study, as well as the distribution of the workload over the semesters, can have a major influence on the time to degree. Past studies have shown that differences in enrollment behavior are related to student diversity factors [2]. The manifestations of these factors vary by country/culture, university type, institution, and program respective subject domain. Further factors for a long study duration are under the influence of teachers. Repetition of courses and exams can be an indicator of high difficulty, but also of inadequate instructional design or exams with low pass rates. Thus, it is vital to analyze enrollment behavior to identify bottlenecks and adjust instructions. Other reasons for a slowed down study progress result from organizational bottlenecks, such

N. Seidel. Modeling study duration considering course enrollments and student diversity. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 621–628, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

¹See <https://www.datenportal.bmbf.de/portal/de/K254.html> (accessed 2022/05/08).

as overfilled courses, missing or too late reexaminations, annual instead of semesterly course offers and examinations.

Hence, this paper aims to explore data on course enrollments of students pursuing bachelor's and master's degrees in Computer Science and Mathematics at a German distance-based university to uncover predictors for study duration. Our study aims at providing initial insights into enrollment processes of German distance learning students. In particular, we are going to focus on one research question (RQ): *(RQ1) What predictors significantly influence the duration of study?* To answer this question we employed a Multiple Linear Regression Analysis with a Genetic Algorithm for model selection to uncover predictors that lengthen or shorten the study duration. For model selection, we considered demographic data, modes of study, enrollment behaviors, and individual courses. We used the method to find predictors within the data of 1898 students who graduated in at least one of the five study programs offered by the Faculty of Mathematics and Computer Science between 1999 and 2019.

Identifying predictors associated with time to graduation can help educators design better degree plans, and students make informed decisions about future enrollments. Distance students have highly diverse backgrounds, which might also be represented in their enrollment behavior and duration of study. Thus, it is vital to analyze this behavior to identify bottlenecks and adjust instructions.

2. RELATED WORKS

There exist various studies focusing on enrollment data. In this section, we provide an overview of the background and intent for the analysis of these data and shed a light on the data and methods used.

Most of the research on enrollment data relates to educational institutions in the Anglo-American world. Among the cited literature in this paper, only two papers refer to African [34, 13] and three to European institutions of higher education [7, 33, 3]. The majority of the works come from traditional universities compared to distance learning universities as referred by [33] or MOOCs [31].

The intentions for analyzing enrollment data range from descriptive analysis, prediction to the preparation of interventions. [33] identify factors contributing to students continuing for the duration of their distance learning studies and completing their degree. The motivation for enrollment to computer science degree programs has been explored by Duncan et al. [15]. Age, gender, and demographic trends in motivation (goals, opportunities, and assurance of goal achievement) for enrollment have been analyzed and significant motivation differences regarding gender and age have been reported. Sahami et al. [30] explored the phenomena of performance decline using the computer science enrollments data from Stanford University and found that despite increased enrollments, student performance remains stable. Analysis is conducted on different scales such as courses [7], study programs [35, 34] and faculties [35, 34]. [24] and [9] for instance, analyzed changes in the enrollment and study progress before and after policy changes. [35] focuses on students' experiences of guidance in relation to their study progress and perceptions of their learning outcomes. The impact of co-enrollment was studied by [8] and [37]. The prediction of dropout (e.g. [10, 22, 7]), study performance

(e.g. [11, 14, 17, 25, 29, 38, 39]), and future enrollments (e.g. [20, 23, 36]) gained a lot of attention in the last years. Prediction of time to degree were employed by [18] and [21]. [6] identify potential predictors of academic success including the time to graduation for Ph.D. students. Age, sex, employment institution, mentor experience, and tuition subsidy had no influence on the time to graduation and completion rate. [35] predicted slow study progress from self-report data using Binary Logistic Regression. [24] identified factors affecting time to bachelor's degree attainment. Dahdouh et al. used association rules mining over course enrollments for recommendations of further study paths [12]. The rules are used for recommending suitable courses to students based on their behavior and preferences. [7] investigated bottlenecks of learning progress in order to support the student advisory services, while [28] make use of enrollment data to prepare re-enrollment campaigns.

Data collected from university information systems has been proved to be the source of helpful information (e.g. [24, 9, 4]) for improving study processes and educational decisions. However, due to a strong data protection culture, some European universities tend to interpret the European data protection regulations (GDPR) very strictly. Even within institutions researchers do not get access to personal data and are also not allowed to link anonymized data. Student performance data such as grades are considered particularly sensitive. Another common source for investigating enrollment behavior comes various forms of self-reports including surveys (e.g. [26, 29, 13, 13, 31, 19]). The used variables cover a broad range that reflects cultural and institutional conditions. For example, the housing situation was studied in countries where campus universities are found [5].

Subgroups including their intersections have been rarely considered [35, 3, 2]. [3] for instance, identified differences in study success and early dropout between minority and majority students in economics which can be attributed to differences in high school education, but not on academic and social integration. [2] considered dimensions underpinning students' study philosophy towards teaching, learning, and study for different groupings and subgroup interactions (e.g. age, sex, ethnicity, study discipline, academic performance). The definition of student profiles [7, 13] is an approach coming from social science which can be helpful to distinguish and explain patterns of subgroups.

The analytical methods used for enrollment analyses include frequent item mining [1, 12], sequence mining [1, 9], Clustering [34], Social Network Analysis [37], Latent Profile Analysis [13], and Linear/Logistic Regression [24, 35, 34, 6]. For example, Elbadrawy et al. [16] used sequence mining via the so-called Universal discriminating Pattern Mining framework capable of mining enrollment patterns from groups of low and high-performing students to enable educators for better degree planning. [26] applied an investment theory to predict the degree of commitment. The application of a Multiple Linear Regression by [5] and [24] underlines its advantages with regard to traceability, explainability, and the possibility of deriving interventions.

3. METHODS

3.1 Data

The data set contains 1489 bachelor students and 1014 master's students who enrolled in 1999 to 2016 and finished the degree until 2019. The collected data include student en-

rollments to courses during their studies, information about completion of the degree, and a list of courses required to complete the degree. In addition, the enrollment data do not contain information on whether a student finished a course successfully since different departments carry out the oral and written examinations at the Faculty. University data protection rules restrict the use and analysis of the exam results. By enrolling in the program, students gave their consent to the processing of the data used in this analysis. To further ensure data privacy the unique identifiers of the students have been pseudonymized in order to prevent linking with other datasets and to prohibit the identification of individual students. However, the identification of individuals cannot be ruled out, the data set will only be provided on request instead of being published.

The available data includes demographic data as well as information on the enrolled programs and courses. From this information, four diversity dimensions will be categorized with regard to (i) demographics, (ii) study behavior, (iii) enrollment behavior, and (iv) course impact. While the first three categories are related to the students, the latter refers to organizational and didactical aspects mainly influenced by the responsible teachers.

The demographic data available contains the age at program admission, gender, and the completion of previous bachelor's or master's degrees. The age ranges between 14 and 69 in all study programs. Detailed demographic information per program are listed in Tab. 1.

From the program enrollment data, we derive study behavior information. Students at the Faculty of Mathematics and Computer Science can enroll in up to three programs at the same time. These programs are prioritized by the student (cf. Program priority). For each program, students can decide whether to study full-time or part-time which has an effect on the expected study duration. The duration of study in part-time study is half as long as the full-time duration. Furthermore, Master's programs distinguish consecutive study after completing a related bachelor's degree and non-consecutive study. A second degree is stated if a student already achieved a degree on the same level (e.g. a second bachelor's degree). Listener status describes the opportunity to join a program as a guest or listener without the obligation to achieve a degree.

The enrollment behavior is described by the number and variety of course enrollments per semester and in total. For the first three semesters first-time and re-enrollments are counted separately (e.g. *Enrollments 1st semester*, *Repetitions 2nd semester*). For the number of unique courses, we distinguish between courses offered at the Faculty (*Different Faculty courses*) and those offered at another faculty (*Different other courses*). Semesters without any enrollments are described as *semesters off*.

Furthermore, 25% of the most frequently enrolled course have been dummy-coded for each student representing the fourth diversity dimension.

3.2 Multiple Linear Regression

For each study program, the student data was represented in a Learner Profile including the before mentioned data about the demographics, study behavior, and enrollment behavior as well the binary information about the most frequently enrolled courses.

Outliers regarding the total number of different enrolled courses, the total course repetitions, and the repeating enrollments have been removed. Values above the mean plus three times the standard deviation have been considered as outliers. Finally, 884 B.Sc. and 1014 M.Sc students remained in the dataset.

The mentioned variables have been selected from the Learner Profile and used to produce model formulas. These formulas are passed to a fitting function. The variables in the formula correspond to the data in the Learner Profile. The duration of study was defined as the dependent variable. The remaining variables were used as independent variables in the formulas. By default, an intercept is included in all models. Due to the initial use of a large number of variables, it is necessary to find a simpler model based on fewer variables. Instead of trying all candidates for a suitable model with an unapplicable brute force approach, the candidate set is explored by a Genetic Algorithm (GA). A GA can readily find the best models without fitting all possible models. For the GA the formula is encoded as a sequence of binary values. This sequence forms a population that will undergo an evolution by adapting certain bits to form a new generation. The genetic algorithm keeps track of a population of models and their size. Asexual reproduction, sexual reproduction from parental generations, and immigration are the three methods used to create the next generation of models.

As decision criterion the Akaike Information Criterion (AIC) is used. It is defined by

$$AIC = -2l(\hat{\beta}_M, \sigma^2) + 2|M + 1| \quad (1)$$

with $l(\hat{\beta}_M, \sigma^2)$ as the maximum value of the log-likelihood and M as the number of variables present in the current model. On the one hand, one can see that the AIC value is negatively directed, which is why the goal of model selection is to minimize this value. On the other hand, a high number of variables is penalized. Thus, a too complex model is prevented. The models are fitted to every generation by using the AIC values to calculate each model's fitness, w . The i th model's fitness is calculated as follows:

$$w_i = \exp(-(AIC_i - AIC_{best})) \quad (2)$$

where AIC_{best} is the best AIC in the current population of models. Lower AIC means higher fitness. Inference was aided by point and interval (95% CI) estimates, the goodness of fit measures, AIC, and p values.

In order to measure and compare the goodness of a fitted model we compute the Cragg-Uhler *Pseudo-R*². *Pseudo-R*² is defined as one minus the ratio of the residual deviance and the intercept (null deviance):

$$R^2 = 1 - \frac{ResidualDeviance}{NullDeviance} \quad (3)$$

R^2 describes the deviation of the current model between 0 and 1, whereas 0 means total deviation and 1 a complete congruence.

4. RESULTS AND DISCUSSION

Appendix A.1 provides an overview of the fitted models and the number of predictors with regard to the four categories of diversity dimensions. Except for the B.Sc. CS the values for R indicate a good model fit. For the smaller number of graduates in the M.Sc. in Mathematics a very good was

Table 1: Demographic information about the students who graduated in the Computer Science (CS) and Mathematics programs

Program name	B.Sc. CS	M.Sc. Practical CS	M.Sc. CS	B.Sc. Mathematics	M.Sc. Mathematics
Time range	1999-2019	2003-2019	2003-2019	2000-2018	2003-2018
N (mean \pm sd)					
Women	454	16	120	130	9
Men	634	153	690	180	33
Total	686	169	803	198	42
Age at admission (years mean \pm sd)					
Women	31.77 \pm 6.14	31.56 \pm 5.39	32.53 \pm 7.84	28.39 \pm 7.88	31.78 \pm 10.44
Men	30.44 \pm 6.24	29.86 \pm 5.42	31.61 \pm 6.82	30.79 \pm 7.88	30.45 \pm 7.93
Total	30.69 \pm 6.23	30.02 \pm 5.42	31.74 \pm 6.98	30.29 \pm 7.89	30.74 \pm 8.41
Time to degree (semesters mean \pm sd)					
Women	14.15 \pm 6.19	10.19 \pm 4.81	5.58 \pm 3.31	11.06 \pm 3.7	5.89 \pm 1.05
Men	11.89 \pm 6.18	8.5 \pm 3.82	5.89 \pm 3.56	10.22 \pm 4.83	7.91 \pm 3.74
Total	12.31 \pm 6.24	8.66 \pm 3.94	5.85 \pm 3.52	10.4 \pm 4.61	7.48 \pm 3.44

achieved. The AIC and BIC measures are not suitable to make comparisons between the programs but relate to the model complexity. The model of the bachelor of CS appears to be the most complex with 29 predictors. Here again, the M.Sc. in Mathematics stands out with simpler model of 8 predictors.

The four diversity dimensions have a different influence on the models. In general, it can be said that demographic factors and study behavior predicting the study duration less than the enrollment behavior. The effect of individual courses depend on the study program.

The fitted linear regression models for predicting variables influencing the duration of study in each of the five study programs are presented in the Appendix A.2. The size of the coefficients expresses the number of semesters by which the study is extended or, if negative, shortened. For example, if a student takes 3 courses in the Bachelor CS in the 3rd semester, the duration of study is shortened by 3 times -0.38, i.e. by 1.14 semesters. Binary represented values like gender or taking a certain course correspond to factor 1. As stated before, age has no significant impact on study duration. Note, that the coefficient for the age is multiplied by the number of years. As a result, this apparently small coefficient may predict the study duration of elderly students. Also the gender impact is comparatively small, but recognizable with opposite direction in the CS bachelors and Practical CS masters' programs. For the same two programs the existence of a past degree predicts the time to degree. While the length of study for students in the Bachelor CS is shortened by the experience gained in another program, the length of study is lengthened for students in the Master Practical CS. Studying in multiple programs at the same time can be beneficial for the overall study duration. This can be explained by the fact that examination credits from one study program can be credited in the thematically related study programs of the faculty. Thus, a successfully completed examination can be used in several study programs. However, for the M.Sc. CS additional activities on other programs is at the expense of the duration of study. The enrollment to courses of other faculties extends the time needed for completion.

As expected, the total course repetition and the variety of chosen Mathematics-related or CS-related course strongly predict study duration. A single semester off lengthens the study duration by more than one semester.

5. SUMMARY AND OUTLOOK

In this paper, we explored data on course enrollments of students pursuing bachelor's and master's degrees in Computer Science and Mathematics at a European distance-based German university to uncover predictors for study duration. We tried to consider the highly diverse backgrounds of distance-learning students that are represented in a restricted and pseudonymized dataset consisting only of information on current and past study programs and enrolled courses. From this information, Learner Profiles have been created. These profiles contained measures that are potentially suitable for describing influencing factors for the duration of study. Instead of predicting the time of study completion for future cohorts, we used them to describe and analyze the past student (and teacher) behavior. We find it is vital to analyze this behavior to identify bottlenecks and adjust instructions as well as the organization of study programs.

We employed a Multiple Regression Analysis with a Genetic Algorithm for model selection to uncover predictors that lengthen or shorten the study duration. For the models, we considered demographic data, study behavior, enrollment behaviors, and individual courses. We used the method to find predictors within the data of 1898 students who graduated in at least one of the five study programs offered by the Faculty of Mathematics and Computer Science between 1999 and 2019. With regard to RQ1 the enrollment behavior strongly predicts the duration of study compared to demographic and study-behavior predictors. Individual courses are good predictors for specific study programs.

As a next step, we want to identify changes in the fitted models over time. The considered time range of almost 20 years included many changes of regulations, tuition fees, and teaching staff. Similar to the work of [24] and [9] we want to trace predictors over time in order to recognize relevant trends for teachers and faculty managers. With this regard, we also would like to continue our past research about student course recommenders [32].

ABSTRACT

University students have a great deal of freedom in deciding the order in which to take their courses. In this paper we apply the Apriori-based Generalized Sequential Pattern (GSP) algorithm to undergraduate course data from a large university in order to identify frequent course sequences. Course sequencing results are primarily generated at the department level, with a special focus on Computer Science courses. This paper also introduces the course sequence flow diagram, which compactly represents a large amount of course sequencing information in an intuitive visual form. Our results and associated flow diagrams can help to answer a variety of important questions, such as: what course sequences are most common, how are courses between different departments ordered, and when are courses taken in an order that may contradict the advice given by academic advisors? In this paper we show that this form of descriptive data mining can identify standard core curriculum and pre-health sequences of study, as well as computer science courses that are either artificially pushed to the end of a student's program of study or taken earlier than would be recommended.

Keywords

Sequence mining, association analysis, course sequencing, educational data mining.

1. INTRODUCTION

The order in which university students take their courses is only partially constrained by course prerequisites and university policies. However, course sequencing is important since it impacts student learning and can impact student grades. This was demonstrated by one of our research group's recent studies that looked at pairs of courses taken in both possible orderings and showed that the different orderings produced different grade performance [4]. Other work has looked at the sequences that courses in specific disciplines, such as communications [7] and psychology [2], are taken in, and assessed how these impact student learning. Some work looks more generally at course selection and how it impacts student grades [5] or time to graduation [6].

Prior work focuses mainly on assessing the impact of specific course sequences rather than on identifying or characterizing course sequences. This paper focuses on the descriptive data mining task of identifying common course sequences and how to best represent this information. These sequences are of intrinsic value, providing insight into how our curricula operate in practice. They

can identify course prerequisite structures and interrelationships between departments. They can also expose courses taken in an unexpected, and perhaps inadvisable, order. These insights can be used to modify and improve academic advising and inform curricular changes, such as by modifying course prerequisites.

In this paper we use the Apriori-based Generalized Sequential Pattern (GSP) algorithm [9] to identify frequent k -sequences, where a k -sequence contains k courses taken in a specific sequential order. We apply this method to courses at the department level and in some cases across departments. We show how these frequent k -sequences can be used to form a course sequence flow diagram that encapsulates the knowledge of many sequential patterns in a simple and useful visual form. We then show how the flow diagrams and associated results can be used to gain useful academic insights, which can inform academic advising and perhaps even changes to the curricula (e.g., modifications to prerequisites or course numbering). Our most detailed analysis focuses on the Computer Science department, building off our familiarity with our home department.

In Section 2 we describe the Apriori and GSP algorithms. Section 3 describes the course-enrollment data set provided by our university and the steps necessary to transform this data into the student-level course sequences suitable for mining by the GSP algorithm. In Section 4 we present our results in the form of frequent k -sequences, introduce the course sequence flow diagram, and extract insights from these results by utilizing our curricular domain knowledge. Section 5 provides our broader conclusions, study limitations, and plans for future work.

2. SEQUENCE MINING

This paper extracts common course sequences from undergraduate course enrollment data. It relies on the generalized sequential pattern mining framework [9], which is an extension to the Apriori association rule mining algorithm that takes ordering into account. Whereas Apriori generates a set of frequent itemsets, GSP generates a set of frequent sequences, and, in the context of this study, a set of frequent course sequences. Minimum support is used analogously to its use in Apriori, so a specific sequence is considered frequent if it occurs in more than *minsup* sequences. We briefly introduce the well-known Apriori algorithm and then describe the GSP algorithm as an extension to Apriori.

The Apriori association rule mining algorithm [1] was developed to provide retailers with information about what items are usually purchased in the same transaction. Formally, let $I = \{I_1, I_2, I_3, \dots, I_d\}$ be the distinct items and let $T = \{T_1, T_2, T_3, \dots, T_n\}$ be the set of customer transactions, where each T_i contains a subset of items in I . A k -itemset X is a collection of exactly k items:

$$X = \{X_1, X_2, X_3, \dots, X_k\}, \text{ where } X_i \in I \ \forall i, \text{ and } |X| < d.$$

Given a set of transactions T , the *support* of a k -itemset is the fraction of the transactions T that contain all of the k items in the k -itemset (e.g., if $k=2$ and the items are *milk* and *cereal*, then

support is the fraction of transactions that contain *milk* and *cereal*). Association rule algorithms like Apriori [1] and FP-growth [3] identify all *frequent k*-itemsets. These algorithms also include a second step that generates association rules from the itemsets, but our study does not need to generate rules, only frequent sequences, so we focus only on the first step.

The GSP algorithm [9] is a modest extension of the Apriori algorithm. The extension involves making the Apriori algorithm sensitive to the order of items (i.e., courses) in each transaction. There are two extensions that need to be made to the Apriori algorithm. The first is to extend the candidate generation phase to generate ordered itemsets and the second is to account for item ordering when computing the support for an itemset (i.e., sequence).

3. METHODOLOGY

This section describes our initial data set, how we transform this data into a form suitable for the GSP algorithm, and the impact of the *minsup* threshold on the resulting course sequences.

3.1 Initial Course-Enrollment Data Set

This study is based on eight years of undergraduate course enrollment data from Fordham University. Each entry in the initial data set represents the enrollment of a specific student in a course section, along with their grade in the course and the semester and year that they took the course. To preserve privacy the student identifiers were mapped to new, but consistent, values and course sections with fewer than five students were dropped. The data set contains 473,527 records that collectively cover 24,969 distinct students. For the purpose of this study all sections of the same course are considered equivalent. Even with these privacy protections we cannot share the course-enrollment data, due to strict privacy laws.

3.2 Student Course-Sequence Data Set

The initial data is not in the format expected by the GSP algorithm since it expects each entry to include an ordered sequence of courses. Thus we transform the initial data set into a student course-sequence data set by separating the courses for each student and then ordering these courses chronologically. Courses that are taken during the same semester are ordered lexicographically using the course identifier. Below is a sample course sequence record, which starts with the student-ID and is followed by five courses:

S245632: CS1000, CS2000, HIST1200, CS3462, CS2250

3.3 Applying GSP to Course-Sequence Data

When we run the GSP algorithm on course-sequence data at the departmental level, we restrict the data to only include sequences that contain students who take one or more courses from that department. This improves the algorithm's running time without impacting the generated frequent *k*-sequences; however, it impacts *minsup*, if expressed as a fraction, since the denominator used to calculate support is reduced. To address this, and also account for the fact that different departments have different numbers of students (i.e., sequences), we express *minsup* as a minimum support count (an integer) rather than a minimum support (a fraction).

The GSP algorithm can be applied directly to the student course-sequence data set, where each entry corresponds to the ordered courses taken by one student. If *minsup* is set too low, the number of frequent sequences will explode exponentially, which will radically impact the running time of the algorithm and lead to an unwieldy number of frequent sequences. Experiments in Section 4 vary *minsup* to assess its impact on running time and on the number of frequent sequences.

4. RESULTS

This section includes our main results. Section 4.1 provides department level information about the number of frequent *k*-sequences generated by the GSP algorithm, while Section 4.2 provides information on the running time of the algorithm. Section 4.3 examines the frequent sequences for the Computer Science (CS) department, introduces our course sequence flow diagram, and uses this diagram to provide insights into the sequencing of CS courses. The section concludes by analyzing some non-CS course sequences.

4.1 Summary Department Level Results

This section provides summary results of running the GSP algorithm on courses from individual STEM departments, combined Biology and Chemistry courses, and all undergraduate courses. By varying the number of courses considered we demonstrate its impact on the number of frequent sequences and running time. Table 1 shows the number of *k*-sequences generated for these groupings, for various values of *k* and *minsup*. Two entries are provided for each *minsup* value: one without pruning and one with pruning. The pruned results remove any frequent *k*-sequence contained (i.e., with the courses in the same relative order) within a larger frequent sequence, since this information can be considered redundant. Pruned entries have a "*" next to the *minsup* value. When generating frequent sequences from all undergraduate courses, much larger *minsup* values are employed to keep the running time manageable and to avoid generating more sequences than could be analyzed.

Table 1. Department-level results for the GSP algorithm

Department	<i>minsup</i>	Number of <i>k</i> -sequences (<i>k</i> from 2 to 9)							
		2	3	4	5	6	7	8	9

	1000*	105	238	148	6				

* frequent *k*-sequences that appear in frequent *k*+1 sequences are pruned

Table 1 shows that the number of k -sequences varies greatly by department. This variation is due in part to the varying number of students, and student majors, in each department, as well as the amount of sequencing in the curriculum. The largest k -sequence for each department varies from 4 to 10 (Natural Science has one 10-sequence for $\text{minsup}=25$ that did not fit in the table). The number of k -sequences is also dramatically impacted by the minsup value, which indicates that care must be chosen in selecting this value. Adding additional courses can also have a large impact, as can be seen by comparing the individual Biology and Chemistry department entries with the combined Bio+Chem entry. The number of entries when using all courses would be enormous if we did not increase the minsup threshold by a factor of 10. The number of sequences that are pruned is more substantial for smaller sequences—a pruned itemset has a cascading effect as it trickles down to the lower levels (i.e., lower k values).

4.2 Run-time Complexity

The running time of the GSP algorithm is affected by the number of items (distinct courses), the number of sequences to mine, and the number of items (i.e., courses) in each sequence. While worst case performance is exponential in the number of items/courses, the performance is generally much better, depending on the minsup value. If minsup is sufficiently low, the complexity can even be linear in the number of sequences. The time to generate the frequent course sequences for the same nine department groups appearing in Table 1, when run on a MacBook Air laptop with an 8-core 3.2GHz processor, is displayed in Figure 1. To make the figure easy to read the legend is ordered to match the running times associated with each department. Since the y-axis uses a log-scale, the running time is not actually linear. In order to keep the running time manageable, minsup starts at 500 when mining all courses—but as shown in Table 1, this still yields a much longer running time.

Figure 1. Impact of minimum support on running time

4.3 Detailed Analysis of Computer Science

This section looks into the detailed results for the CS department. In Section 4.3.1 we introduce our course sequence flow diagrams, which are capable of representing the information from a large number of frequent sequences in compact visual form. In Section 4.3.2 we then use this diagram to better understand how students sequence their CS courses.

4.3.1 Course Sequence Flow Diagram

Many of the results for the department are summarized in Figure 2, which embodies the information within all twenty-three Computer Science 5-sequences (the 5-sequences are listed in Appendix Table 2). We focus on these since there is only one 6-sequence and no larger sequences (see Table 1). Our course sequence flow diagram constitutes a substantial improvement upon previously existing sequencing visualization methods, such as Sankey diagrams [8]. We

believe that our course sequence flow diagram is a significant contribution, preserving information across multiple sequences while conveying this information clearly and compactly.

Figure 2 contains all eleven courses that are represented in the 23 5-sequences in Table 2. Each sequence in Table 2 has an index, and each node in the Figure 2 is labeled with the matching index, so the 23 5-sequences can be reconstructed from the diagram. For example, if you follow the flow of all nodes in Figure 2 that contain index 1, you will reconstruct the first sequence in Table 2 (DISC, CS1, CS2, DS, TOC). The diagram actually goes much further, however, presenting support information for each sequence. Each of the 23 sequences has its own support; when sequences overlap, the corresponding supports are added together in the current flow diagram. Thus, we can determine the combined support associated with any edge in the diagram based on the summed supports assigned to that edge. Appendix Table 3 provides the underlying information about each pair of courses across the extracted sequences. To avoid overcrowding the diagram with information, we encode the support sum from each edge through varying thicknesses. The thickness level listed in Table 3 and utilized in Figure 2 is computed as follows:

$$\text{Thickness} = \lfloor 2 * \log_{10} \Sigma \text{Support} \rfloor$$

4.3.2 Specific Insights into CS Based on Results

Figure 2 provides a succinct high level view of the flow of courses, which enables us to learn about how students sequence their courses. Given our experience with the undergraduate CS curriculum, we are able to verify known patterns in course sequences (first three bullet items) and glean new and potentially useful insights (last three bullet items). We summarize some of these as follows:

- The diagram recognizes the key prerequisite relationships including our introductory programming sequences of CS1 → CS2 → Data Structures (DS). These courses are connected with the thickest edges.
- Computer Organization is often taken after CS2 and Data Structures, which is what we recommend, but it is not required (it can be taken after CS1).
- The nodes in Figure 2 are arranged into 6 vertical columns based on the edges and relative position of the courses within the frequent sequences. These reflect the general structure and course levels quite well. For example, Discrete Structures and CS1 are 1000 level courses, CS2 and Data Structures are 2000 level courses, the courses in the next column are all 3000 level courses, etc. A few notable exceptions are discussed next.
- The position of Data Mining (DM) is surprising. Its only prerequisite is CS1, while Theory of Computation (TOC) has many prerequisites—yet Data Mining is generally taken after Theory of Computation. This may be an artifact of our assigning Data Mining as a 4000 level course even though our faculty believe that level is not appropriate.
- Theory of Computation is almost always taken after Algorithms (ALG), even though both are 4000-level courses with no prerequisite relationship. The observed sequencing could be an artifact of scheduling but may be related to student belief that the algorithms course is essential for obtaining employment, including internships. Relevant 2-tuples show that ALG→TOC occurs 2.4 times as often as the reverse ordering.
- Database Systems (DB) is taken a bit later in the sequence than we would expect and perhaps recommend. It only requires CS1 but is taken after CS2 and Data Structures.

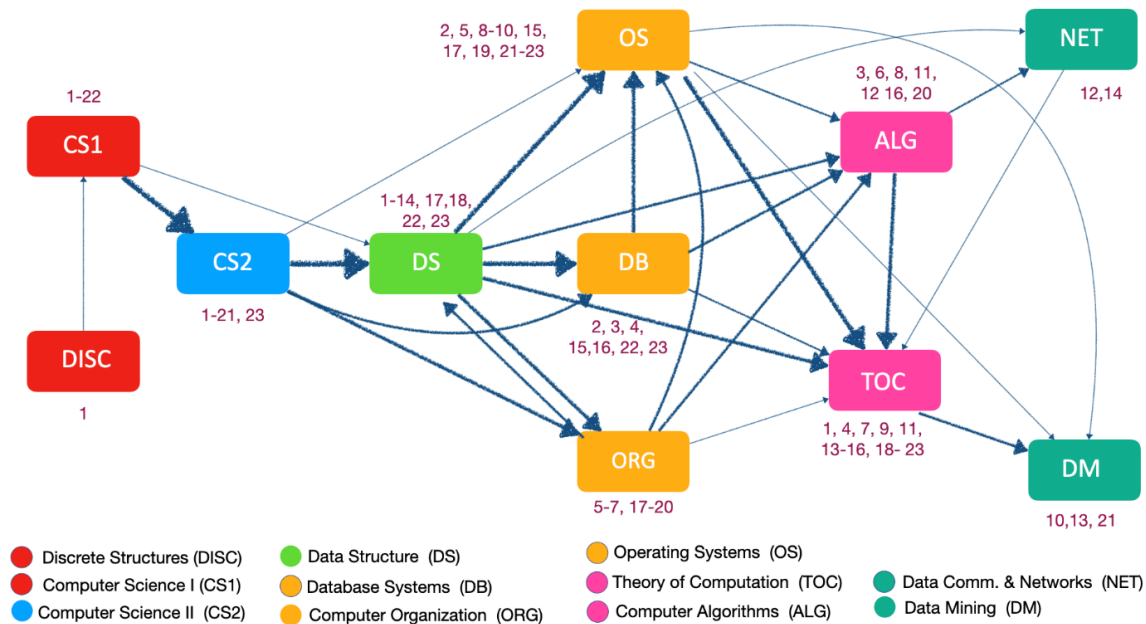

Figure 2. Course sequence flow diagram for Computer Science frequent 5-sequences (nodes labeled with indices from Table 2)

4.4 Analysis of Non-CS Departments

The dataset contains courses from dozens of departments. We lack the space and domain knowledge to analyze all of them, but we mine course sequences from several groupings of departments and provide a few observations. We start with the longest frequent sequences, which occur when courses from all departments are considered. With $minsup = 500$ we obtain five 9-sequences, all of which include only biology and chemistry courses, and four of the five sequences begin with the following eight courses:

IntroBio1+lab, GenChem1+lab, IntroBio2+lab, GenChem2+lab

Half of the courses above are lab courses which count as separate courses but probably should be excluded from the data set in order to find more meaningful sequences (we removed all lab courses for Computer Science only). Nonetheless the algorithm was able to identify a very common science sequence that is taken by students planning to go on to medical school. If we start to look at smaller k -sequences, such as when $k=5$, the sequences with the highest levels of support are dominated by courses that satisfy core requirements. In general we see that science courses are more tightly sequenced than other courses, although for shorter sequences the more popular core courses play a central role.

Due to their role in our university, we next present the results associated with core curriculum courses, which must be taken by all students, and span many departments. Below are the five 6-sequences that appear with $minsup = 1000$. These provide insight into the most common ways in which the core courses are taken:

IntroBio1+lab, GenChem1+lab, IntroBio2+lab
 MacroEcon, BusinessMath, MicroEcon, EngComp2, Business Calculus
 EngComp2, Philosophy1, Theology1, EngLit, Philosophy2
 EngComp2, Theology1, EngLit, Philosophy1, Philosophy2
 Phil1, EngComp2, Philosophy1, EngLit, Philosophy2
 Theology1, EngComp2, Philosophy1, EngLit, Philosophy2

The first two sequences are associated with science and business majors, respectively, who are directed to take those courses to fulfill their science, math, and social science core requirements; the last four are humanities courses taken by a wide range of students.

Given the Computer Science discipline has a close relationship with Mathematics, we also looked at the frequent sequences for the Math department. We were surprised to note that the last course in the sequence is very often Statistics, which we thought would be taken earlier, especially since courses with a higher number were sometimes taken first. But the department has the following long prerequisite sequence, which explains the observed behavior:

Calc1 \rightarrow Calc 2 \rightarrow Multivariable Calc \rightarrow Probability \rightarrow Statistics

5. CONCLUSION

This paper introduces GSP-based sequence mining for analyzing university course sequences. The method was applied to eight years of undergraduate course enrollment data and produced a large number of frequent k -sequences. Course sequences were generated for individual departments, several related departments, and across all departments. Our results show that it is possible to mine course sequences on a standard laptop given reasonable $minsup$ values.

We also developed a new course sequence flow diagram that visually captures many different common course sequences, while maintaining almost all of the low level information. We view the development of this diagram as a significant contribution since it is far superior to our prior efforts, and the Sankey diagrams [8] we generated using existing libraries. The course sequence flow diagram generated for Computer Science accurately represented well known course relationships and uncovered subtle sequencing issues. These insights can lead to improved advising and changes to our curriculum—for example, we can update course numbers to better reflect the role of the course, or to modify student behavior to better align with our sequencing intentions. Our analysis also provided insights into other course sequences and identified a long sequence taken by students in the pre-medical education track.

We believe that course sequencing mining can be a useful tool for academic advising and for better understanding how students sequence their courses. This work is an example of descriptive data mining and additional applications for this work will likely be discovered in time.

Table 3 shows CS1→CS2 and CS2→Data Structures have the two highest support sums; this is reflected in the edge-widths in Figure 2.

Employing Tree-based Algorithms to Predict Students' Self-Efficacy in PISA 2018

Bin Tan

Maria Cutumisu
University of Alberta
cutumisu@ualberta.ca

ABSTRACT

Self-efficacy is a critical psychological construct that has a substantial impact on students' learning experience and global well-being. Thus, the early identification of low self-efficacious learners is an important task for educators and researchers. This study uses machine learning (ML) approaches to model the self-efficacy of over 520,000 students based on their test performance and responses to survey questions in the Programme for International Student Assessment (PISA) 2018. Two tree-based ensemble learning models (random forest and XGBoost) were built using 64 predictors and evaluated using nested cross-validation with a grid search method. The results showed that, although both algorithms predicted self-efficacy accurately, XGBoost slightly outperformed Random Forest (RF). The findings also revealed that students' non-cognitive constructs such as meaning in life and the motivation for mastering tasks were the most important predictors. Theoretical contributions include the expansion of the body of literature on ML applications that predict students' self-efficacy and the potential advancement of theoretical models of self-efficacy. Practical contributions include the applications of tree-based algorithms to identify low self-efficacious individuals at scale, in a large international assessment. Implications include the development of systems that use ML algorithms to detect low self-efficacious learners and provide support for early interventions.

Keywords

Self-efficacy, large-scale assessment, PISA 2018, students' traits

1. INTRODUCTION

Self-efficacy represents individuals' general beliefs about their competencies of performing specific tasks or achieving goals [4]. Students' self-efficacy has been consistently associated with their learning achievement [3, 11, 14]. Students with higher self-efficacy, at all levels of competency, are more successful in school activities and use more effective learning strategies [21]. In addition, various empirical findings showed that self-efficacy is associated with academic engagement [25]. High self-efficacious students tend to report a higher level of academic aspirations, spend more time on homework, and gain more positive learning experiences [6]. Those students are more gratified and satisfied with their accomplishments [27]. Moreover, self-efficacy is highly linked to students' global well-being and life outcomes [11]. It has been

found that students with low self-efficacy are more likely to drop out of school, which jeopardizes their future employment prospects [5]. In addition, low self-efficacious students tend to suffer from many mental and behavioral problems such as depression [2], suicidal ideation and attempts [25], social avoidance [24], and addictive behaviors [23]. Thus, students' self-efficacy is an important topic for psychological and educational research. If students' self-efficacy can be screened and predicted, practitioners may be able to deliver early intervention to help low self-efficacious students improve their learning experience, global well-being, and life outcomes.

In this present study, two decision tree-based algorithms (RF and XGBoost) were trained based on over 520,000 students' test performance and responses to survey questions in PISA 2018. The proposed research questions (RQ) were:

- (1) Is it possible to use the RF and XGBoost algorithms to predict students' self-efficacy with a small error rate?
- (2) What are the most important predictors of self-efficacy in these models?

2. RELATED WORK

Self-efficacy has been increasingly used as a predictor in ML models. However, to date, despite the significance of self-efficacy for students' learning and life, there are very few studies that treated self-efficacy as the focal variable to be predicted. The first such study [17] used Naive Bayes and decision tree algorithms to generate two sets of classification models of self-efficacy (high vs. low). The first set of models were built based on the demographic factors of the students, whereas the other set of models added additional predictors that were obtained when students were exposed to an intelligent problem-solving tutoring system including biofeedback signals and recorded log data. The classification accuracy of the models ranged from 82.1% to 87.3%.

Later, a K-medoids clustering algorithm was employed to group similar students based on their gender, survey-reported self-efficacy, and collected natural language utterances during dialogue in an intelligent tutorial dialogue system [9]. Results revealed differences in the use of utterances between students with high and low self-efficacy. For example, students with high self-efficacy tend to use more confident utterances to express their understanding of the knowledge, compared to students with low self-efficacy who usually make less confident utterances.

Recent efforts have examined domain-specific self-efficacy. A study trained a K-nearest neighbor algorithm to classify 127 students' responses as low, middle, or high using a 21-item self-efficacy survey [1]. The optimal results of the model performance based on validation-set approach reached 92.3%. Another study applied a decision tree classifier to a dataset containing 1894

undergraduate students' survey data, obtaining the highest accuracy score of 82.58% [26].

3. METHODS

3.1 Data Source

The international large-scale dataset used in this study contained students' self-reported survey data and their test results of the OECD's PISA 2018. The dataset was publicly accessible at [20]. All students participating in PISA 2018 were included in this study regardless of their country of citizenship or origin. This constituted the original sample of 612,004 students from 74 countries and regions.

3.2 Tree-based Algorithms

We employed two tree-based algorithms to predict students' self-efficacy. Tree-based algorithms use a series of if-then rules to generate predictions. In each step of the series, the if-then rules separate data points into subsets according to a node where the prediction has the lowest error rate. By repeating the step, the split will eventually terminate when reaching the stopping criterion. Although singular tree models can be interpreted straightforwardly and work well with nonlinear relationships between predictors and the target variable, they usually have weaker predictive performance given that they are prone to overfitting, a situation where the supervised learning model fits too close to the training data to be able to generalize well and predict future data.

Tree-based ensemble learning methods are alternatives to singular decision trees by combining decision trees. The algorithms used in this study are RF and XGboost. RF is an ensemble learning algorithm developed based on two algorithms: decision tree and bootstrapping. Bootstrapping resamples data with replacement and it is used to repeatedly split the same dataset into bootstrapped samples based on which multiple decision trees can be built. Each of the trees built can generate a result. Then the algorithm makes the final decision by aggregating the results of all singular trees. In predicting the numerical values, the final result is calculated by averaging the results of all individual trees. The advantage of RF is that it is less prone to overfitting, which lifts the accuracy and stability of prediction to a much higher level.

XGBoost is another ensemble learning algorithm based on decision trees [7]. In contrast to RF, XGBoost employs boosting, a technique of correcting the errors of existing models by adding new models sequentially to predict the residuals of the existing model and, then, along with the existing model make another prediction. Through sequential iterations, each execution is completed on the same dataset and later models are improvements of prior models. Eventually, the errors will be gradually minimized; the algorithm stops when the model performance converges to a stable state.

3.3 Focal Variables

In this study, self-efficacy is the response or target variable (i.e., the variable to be predicted in the current supervised learning task). In the survey of PISA 2018, students' self-efficacy was measured by five items, namely, "I usually manage one way or another", "I feel proud that I have accomplished things", "I feel that I can handle many things at a time", "My belief in myself gets me through hard times", and "When I'm in a difficult situation, I can usually find my way out of it". Available responses were "Strongly disagree", "Disagree", "Agree", and "Strongly agree".

The predictors in the current study are the variables collected in the mandatory parts of students' self-reported questionnaire and their

test results in PISA 2018, classified as home factors, students' well-being, motivational factors, other non-cognitive constructs, school climate, teacher-related variables, personal experiences, as well as the PISA 2018 test performance [19]. Table 1 lists the predictors included and their dimensions. The reliability of students' self-reported scale scores was available in PISA technical reports [18]. All scales achieved at least an acceptable reliability.

Table 1: Predictors used in the tree-based models

Dimension	Variable name
Home factors	Home possessions
	Parents' professions and qualifications
	Parents' education backgrounds
	Parental support
School climate	Cooperation climate
	Disciplinary climate
	Competition climate
Teachers	Teacher support
	Teacher understanding
	Adaptive instruction
	Teacher feedback
	Teacher enthusiasm
Well-being	Teacher directed instruction
	Meaning in life
	Life satisfaction
	Positive affective states
	Lively
	Miserable
	Proud
	Afraid
	Sad
	Fear
Sacred	
Motivational factors	Learning interests
	Learning aspiration
	Value of school
	Motivation for mastering tasks
	Motivation for competition
Other non-cognitive constructs	Reading self-concept
	Fixed mindset
	Empathy
	Attitude toward bullying
	Sense of belonging
Personal experiences	Exposure to bullying
	Skipped class or being late
	The age of early childhood education
	The age of pre-primary education
	Grade repetition
PISA 2018 test performance	Reading performance
	Math performance
	Science performance
Other	Gender

3.4 Data Preprocessing

A two-stage method was adopted to deal with missing values. In the first step, the entire row of the data entry was excluded if there were missing data on any of the five items measuring self-efficacy. Listwise deletion was used because it does not introduce new errors to the outcome variable as replacing the missing data with other values. This step excluded 84,179 instances, so 527,825 instances remained. In the second step, the missing values of the predictors were replaced with their column medians.

First, the responses of reverse worded items were reverse coded. Second, if the predictor is a categorical variable and is not grouped

with other predictors (single-item scale), k-1 dummy variables (k is the number of categories) were created to replace the original categorical variable. Third, for multi-item scale response data (e.g., self-efficacy, measured by five items), a polytomous item response theory (IRT) model, the generalized partial credit model (GPCM) was used to transform the data to IRT scores ranging from negative to positive. In this way, self-efficacy scores became truly continuous data. This is a similar method that was adopted in the PISA 2018 Technical Report [18]. In order to facilitate meaningful interpretations, the IRT scores were linearly transformed using a formula: $X' = X \times 15 + 100$. The choice of multipliers for mean and standard deviation was arbitrary, just for the ease of interpretation (i.e., no negative self-efficacy scores). Such transformation does not alter the true comparative values of the measured constructs.

Upon the completion of data preprocessing, the dataset contained 64 individual predictors (including coded categorical variables) and one target variable (self-efficacy).

3.5 Model Training, Validating, and Testing

The *xgboost* and *scikit-learn* libraries in Python 3.7 were used to build the XGBoost and RF regressors. Model training, validating, and testing were conducted using the *scikit-learn* library. A nested cross-validation with grid search algorithm was used to obtain a robust and trustworthy estimation of the model tuning and performance [16]. As shown in Figure 1, the nested cross-validation algorithm has two layers: an outer three-fold cross-validation and an inner three-fold cross-validation. There was a total of nine distinct folds of inner cross-validation and three folds of outer cross-validation. The goal of the inner cross-validation was to find the hyperparameters yielding the best model performance, while the outer cross-validation was to test the generalizability of the tuned model performance to a new dataset.

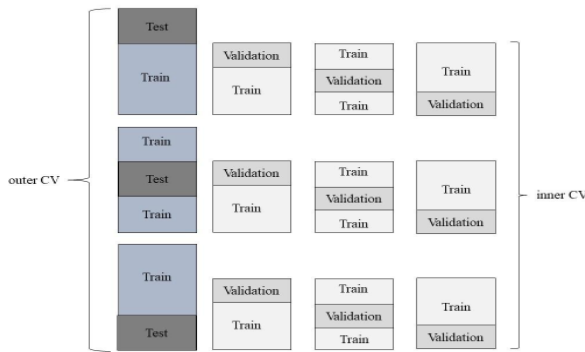

Figure 1: Nested cross-validation

Hyperparameters tuned for both RF and XGBoost regressors included the number of trees (*n_estimators*) and the maximum depth of the trees (*max_depth*). The maximum depth was selected in a range of 5 to 25, with a step of 5, whereas the number of trees could be 100, 150, or 200. Mean absolute error (MAE), Root mean square error (RMSE), and R^2 were used as evaluation metrics for both model validation and testing.

4. RESULTS

4.1 Descriptive Statistics of Self-Efficacy

The mean self-efficacy score of this sample was 99.99, ranging from 57.60 to 128.32, with a standard deviation of 13.28. Figure 2 shows the histogram of self-efficacy scores that indicates a

leptokurtic distribution. Thus, more students scored extremely high or low compared to a normal distribution.

Figure 2: The distribution of self-efficacy IRT scores

4.2 Evaluation Results

Table 2 shows the training, validation, and test accuracy, for each set of the RF and XGBoost models, respectively. On the test set, R^2 of both prediction models was at least 0.447, suggesting that the two tree-based learning models could explain nearly half of the variability in students' self-efficacy. With reference to the range and standard deviation of self-efficacy scores, the MAEs and RMSEs indicated that both trained models achieved reliable prediction results.

Table 2: Results of model performance in training

Model	Data	RMSE	MAE	R^2
RF	Training set	4.240	3.279	0.898
	Validation set	9.898	7.373	0.444
	Test set	9.878	7.354	0.447
XGBoost	Training set	<.001	<.001	1
	Validation set	10.760	8.030	0.344
	Test set	9.776	7.271	0.458

4.3 Relative Importance of Predictors

The importance of the 64 predictors of students' self-efficacy was ranked. Figure 3 and Figure 4 present the top ten predictors and their weight contribution to the predictive power for the two models. In the RF model, the motivation for mastering tasks appeared to be the most powerful predictor with a relative importance of 19.5%, followed by meaning of life (10.8%), reading self-concept (5.1%), learning aspiration (4.4%), motivation for competition (3.2%), positive emotions (3%), empathy (2.9%), always feel proud (2.5%), and fear (2.5%).

Figure 3: Relative predictor importance of the RF model

The ten most important predictors of the XGBoost model were the motivation for mastering tasks (14.5%), meaning in life (11.1%), proud (sometimes, always, rarely, and never; a total of 26.5%), motivation for competition (4%), learning aspiration (3.9%), positive emotions (3.2%), and reading self-concept (3.1%). These predictors contributed a total of 66.3% of the model prediction power. Notably, numerous variables were ranked in the top ten in both RF and XGBoost models, with motivation for task mastery and purpose in life maintaining the top two positions in both models. However, all the highly ranked predictors in both models appeared to be students' non-cognitive constructs including well-being and motivational factors. There were no variables of home factors, school climate, teachers, experience, and PISA 2018 test performance in the top 10 list.

Figure 4: Relative predictor importance of the XGBoost model

5. DISCUSSION

The present study employed the RF and XGBoost algorithms to predict students' self-efficacy. The results suggest that the two tree-based algorithms could predict students' self-efficacy with small error sizes based on their self-reported survey data and test data. The XGBoost model seems to slightly outperform the RF model with respect to all chosen evaluation metrics on the test data.

The results also revealed the most salient predictors of both ML models. According to the rank of the relative importance, the best predictors for both models appeared to be students' non-cognitive factors including well-being and motivation. This is consistent with theories and empirical evidence [2, 13, 22, 27] supporting the close relationships between one's self-efficacy and their other non-cognitive constructs. On the other hand, gender was not a very important predictor. This is in line with a previous meta-analysis which reveals only a slight difference in self-efficacy between genders [13]. A surprising finding, however, is that students' test performances in PISA 2018 did not strongly predict self-efficacy. In a number of previous studies, researchers often consider self-efficacy as one of the strongest predictors for academic achievement [10]. However, this study revealed that predicting self-efficacy based on academic achievement seemed to be less unsuccessful. Another finding that is beyond our expectation is that home factors including parents' education and qualifications and home possessions contribute poorly to the predictive power in both models. This contradicts other studies which suggest the strong associations between self-efficacy and socioeconomic status [12, 15]. In addition, teachers-related variables and factors of school climate were not highly ranked predictors. We attribute the relatively weak predictive power of these predictors to their indirect relationship with students' self-efficacy. Home factors, academic achievement, as well as school and teacher factors, usually shape

students' self-efficacy through other non-cognitive constructs. This also explains why the non-cognitive constructs are better predictors in the current models.

The present study has three major implications. First, it provides a successful example of predicting students' self-efficacy, expanding the body of literature on self-efficacy modeling. Second, it ranks the relative importance of predictors for students' self-efficacy, paving the way for future studies to further examine the relationships between self-efficacy and its best predictors. This may advance theories of self-efficacy as such expanding the model of how one's self-efficacy is formed. Third, it predicts and models students' self-efficacy at scale, using data from an international assessment. Because high self-efficacy is beneficial to students' motivation and learning experience [8], while low self-efficacy is associated with many mental and behavioral problems [24], early identification of low efficacious students is critical to students' educational careers and global well-being. This study suggests that it is feasible for education systems to use ML approaches to identify low self-efficacious students at scale.

A limitation of this study is that the family-level, school-level, and country-level factors used to predict students' self-efficacy are not exhaustive in the current ML models. Although our findings indicate that factors such as students' home factors and learning environment have a negligible effect on the model's performance, the current study was not able to examine a number of other potentially significant features. For example, parenting styles may be predictive of students' self-efficacy at the family level; at the school level, the predictive effect of geography, socioeconomic position, and school resources remains unknown. Another limitation is that the dataset mainly relied on students' self-reported questionnaires. Due to the subjective nature of self-reported data, the quality of students' responses may be subjectively biased. Finally, more tuning is needed for these models to address the overfitting issue inherent with tree-based models.

6. CONCLUSION AND FUTURE WORK

Noting that very limited ML research has been conducted to model students' self-efficacy, this study is the first to establish tree-based models that successfully predict students' self-efficacy at a large scale. This study also identified important predictors of students' self-efficacy, which helps to identify students with low self-efficacy and develop targeted programs to potentially improve self-efficacy. In responding to the limitations of the current studies, future studies can seek to use a more comprehensive feature set that includes more family level, school level, and country-level variables. In addition, for objective and real-time monitoring of self-efficacy, future studies may use other methods to gather objective, real-time indicators for predicting students' self-efficacy. In the future, other ML algorithms (e.g., lasso, deep learning) will be employed to tackle this task. Thus, applying ML approaches to predicting students' self-efficacy is feasible and constitutes an important undertaking.

ABSTRACT

Attendance reflects students' study motivation, and serves as an important indicator in educational management. A strong correlation has been found between attendance and academic performance. Due to the time varying nature of attendance and the challenge of collecting data automatically, few studies explored the longitudinal attendance of student subpopulations. In this paper, we introduce a new method combining Exponential Moving Average (EMA) and Kullback-Leibler Divergence (KLD) to identify longitudinal attendance patterns. We justify that KLD best preserves the structural difference between attendance distributions in student subpopulations. Using real-life data from a university, our result identifies the critical period when high and low academic performance students diverge in attendance, which calls for the attention of educators.

Keywords

longitude attendance data, exponential moving average, Kullback-Leibler divergence, behavior pattern

1. INTRODUCTION

Attendance is an important indicator in education. It interplays with many other factors, such as instructional quality, psychological status, and academic performance which lies in the essence of education. Many studies confirmed the correlation between attendance and attainment, using methods including hypothesis test [20], correlation analysis [1] and prediction [32, 33]. Furthermore, many studies identified positive relation between drop out and low attendance [12, 30]. These studies suggest that attention data provides valuable information in the early detection and assistance of students with low attendance. However, few studies considered associating longitudinal attendance data with academic performance.

Longitudinal attendance data reveals the dynamics between attendance and academic success, but is still under-researched. Though many educators are aware of the importance of attendance and have carried out certain attendance policy, the lack of

deep understanding of the interaction between attendance and academic success hinders the design and implementation of effective attendance policy. This is especially true for universities, where a mandatory attendance policy on every course at all time is usually not pervasive.

With the popularity of smart devices and the arrival of Internet of Things (IoT), longitudinal attendance data can be collected automatically and in a large scale. Techniques such as Bluetooth/Beacon [2, 31], face recognition [13] and Wi-Fi tracing [23, 34] have been applied to detect attendance automatically. [7] collected attendance data in an institution-wide fashion. The abundance of data makes it easier to study longitudinal attendance, and calls for new methods and in-depth analysis.

Traditionally longitudinal attendance data is assessed by simple statistics and line charts. The average attendance rate over a period of time (e.g., a week or a semester) is a widely adopted indicator of students' attendance. While being effective in many educational applications, a single average value is subject to noise in the period. For example, in attendance data collected using Wi-Fi tracing [7, 23, 34], the mal-function of some access points on campus can lead to inaccurate weekly attendance data for students. When studying the weekly attendance data in a time series, the fluctuation of data points can lead to wrong interpretation of the trend in attendance.

The comparison of the attendance for two student populations is another challenge. For example, it is interesting to compare the trends of attendance for students with top 25% and last 25% academic performance. However, the handy line chart of weekly average attendance rates does not fully reflect the structure inside each population.

Below we list the research questions of this study.

- 1) How to measure attendance dissimilarity from the fluctuating attendance time series between student subpopulations with different academic performance?
- 2) What can we learn from the divergence of attendance patterns for students with different academic performance?

For Question 1, when measuring the dissimilarity between two populations, in order to preserve as much information in the student populations as we can, we apply Kullback-Leibler divergence (KLD) on attendance data. KLD was first introduced in 1951 by Kullback and Leibler [18]. It was proposed as a measure of dissimilarity between statistical populations in terms of information. We will show below that comparing with other commonly used methods, KLD emphasizes more on inner struc-

tural divergence between the attendance data of student populations with different academic performance.

To deal with fluctuation, we propose to apply Exponential Moving Average (EMA) to smooth the time series in order to obtain trend and regional information. Moving average is a simple but widely adopted technique in time series analysis, and has been applied to process longitudinal data in many areas. Learning from the successful application of exponential moving average methods on implementing weekly stock index [9], we apply it on weekly attendance index calculation.

For Question 2, we propose the combination of Exponential Moving Average and KLD to detect critical periods when attendance patterns of students with top 25% and last 25% academic performance diverge dramatically.

In summary, the contributions of this study are as follows. We propose to apply the combination of Exponential Moving Average (EMA) and Kullback-Leibler divergence (KLD) to study longitudinal attendance data. So far as we know, there is no previous study that apply EMA or KLD on attendance data. We derive random subsamples to study moving average indexes and dissimilarity functions of student populations. Experiment results on attendance data shows that our method out-performs traditional methods. The application of our method on first year university students shows that the attendance of the top 25% and last 25% students on academic performance diverges during mid-term periods and holidays, which calls for the attention of university managements.

The rest of this paper is organized as follows. Section 2 describes the related studies. Section 3 introduces our method. Section 4 presents the results. Section 5 describes the limitations. Section 6 draws the conclusions.

2. RELATED STUDIES

The time variant nature of attendance contains rich details for student behaviors changes; however, before attendance data can be collected automatically, attendance is usually collected by sign-up sheets which have to be process manually and hinder the study of longitudinal attendance data. [6, 21] observed declines in student attendance over the duration of academic years. [12, 27] treated students' attendance as time series data and performed clustering. [32] studied the life-cycles of 48 students using multiple dimensions of data, including raw attendance data from GPS tracing and Wi-Fi tracing. Valuable information was collected from these results.

Critical period detection is often associated with time series analysis. [11] divided students into several bands according to their academic performance, plotted the cumulative credit time series of each student subpopulation and detected divergent critical points using unpaired t-test. [29] identified students' withdrawal routes by showing the proportion of students not submitting their assignments and found that only very few of them returning to submit the next ones. [4] researched into MOOC data, plotted students' activity time series and found activity peaks before each assessment due. None of these researches considered attendance time series. Using attendance records from high schools in New York, [16, 17] found weekly cycles and detected abnormal data points. The authors [15] then utilized the results to identify problems and provide suggestion for high school educators. These researches considered attendance, but did not associate it with academic performance.

Kullback-Leibler Divergence (KLD) is a popular method to calculate the difference between two populations. It has been justified as a sensitive dissimilarity measurement for probability distribution [35]. In the context of education, KLD is widely applied to detect test collusion by comparing unusual distribution of individual testing behavior to that of the whole test taker population [3, 19]. Besides, KLD was applied in [8, 26, 28] to classify students into groups by maximizing the divergence of certain quality between distributions of different subpopulations. [24] observed student's learning trajectory by calculating the difference between quizzes data collected before and after instructions. So far as we know, there is no previous study that applied KLD to attendance data of student populations.

Moving Average (MA) method is one of the most popular techniques in time series analysis. It's often used for the purpose to smooth and track the trend in longitudinal data [9]. Exponential Moving Average, as a variation of Moving Average, is widely used in many area, including finance [9, 10], sales analysis[14], weather forecasting[5] and education [25] (to predict enthusiasts in mathematics programs). So far as we know, no previous study has applied exponential moving average on attendance data.

3. METHOD

3.1 Data and Setup

Anonymous data of students' cumulative GPA (denoted as CGPA) and attendance data were retrieved from a university in China with approval from the university management. The data was collected from undergraduate students spanning over 3 semesters in 2018 and 2019, namely, Fall 2018, Spring 2019 and Fall 2019 (noted that academic year starts in a Fall semester). To protect privacy, student IDs were converted into hash code beforehand.

For most courses, students received letter grades from A to F. As an example, only 15 out of 426 courses taught in academic year 2018 are courses with P/F grades. These courses were mostly for internship or research methodology/seminar, which were seldom taken by undergraduates in their first two years of study. All courses with P/F grades were excluded in calculation.

Attendance data was collected using a Wi-Fi based method and was handled using method proposed in [23, 34]. Students' weekly attendance rate was calculated by taking the average of attendance within a week. For most courses, no mandatory attendance policy was established. The rest of courses that declared mandatory attendance policy were mostly university core courses which should be taken by all undergraduates.

3.2 Moving Average Index

In this subsection, we introduce exponential moving average methods to smooth the attendance curve.

Let a_t be the attendance rate at time t for student i , then we have $a_t \in [0, 1]$. Let $EMA_{i,t}$ be the corresponding index for student i at time t . Exponential moving average can be calculated using the formulas below.

Definition 1 Exponential Moving Average (EMA):

β stands for the weighting decay factor taken between 0 and 1. Commonly it's set to be $\beta = 2/(n + 1)$ with $n = 2$ in our experiment (see the appendix for details).

EMA assigns the highest weight for the most recent data. The weight for the earlier data points decay with time via recursive process. Therefore, the earliest data would never vanish in the process of gaining successive values.

3.3 Dissimilarity Measurement

In this subsection, we study the dissimilarity measurements between attendance data of two student populations. Ideally, we want to find a dissimilarity measurement that can best reflect inner structure divergence between the two concerned populations.

Definition 2 Mean Difference (MDF): Let $a_{i,t}$ be the attendance rate at time t for student i . Let P and Q be two distributions of $a_{i,t}$ at time t of two populations of students. The mean difference (MDF) of P and Q is calculated as below.

$$MDF(P, Q) = E(P) - E(Q)$$

MDF is the simplest way to measure difference between two population. However, this measurement ignores the inner structure of distributions.

Definition 3 Absolute Distance (AD) & Definition 4 Kullback-Leibler Divergence (KLD): We divide the domain of distributions P and Q into several attendance intervals and name these intervals $1, 2, \dots, n$. Then the probability of a student from distribution P or Q falling in a given interval is p_1, p_2, \dots, p_n or q_1, q_2, \dots, q_n . We calculate the absolute distance (AD) and KLD as follows.

$$AD(P, Q) = \sum_{j=1}^n |p_j - q_j|$$

$$KLD(P, Q) = \sum_{j=1}^n p_j \log \left(\frac{p_j}{q_j} \right)$$

Both AD and KLD consider the inner structures of the distributions [35]. However, KLD is more sensitive when detecting inner structure differences than absolute distance.

The difference between AD and KLD can be illustrated by an example as follows. Let A, B1, B2 be three student populations. Divide the domain evenly into 4 intervals based on the attendance rates of the students: last 25% quantile, 25% - 50%, 50% - 75%, top 25% quantile. Probability of the three populations fall into the above-mentioned intervals are listed below. For example, 0.25 represent 25% of the population.

A: [0.25, 0.25, 0.25, 0.25]

B1: [0.30, 0.30, 0.30, 0.10]

B2: [0.40, 0.25, 0.25, 0.10]

For A, the attendance rates of students are evenly distributed in the 4 intervals. B1 differs from A by moving 15% of the population from the top quarter to the other 3 intervals evenly. B2 differs from A by moving 15% of the population from the top quarter to the last quarter only. Therefore, A overall should be considered to have higher attendance than B1 and B1 higher than B2.

Calculate the dissimilarity between A and B1, A and B2 using AD and KLD respectively, we have

$$AD(A, B1) = AD(A, B2) = 0.3$$

$$KLD(A, B1) = 0.072, KLD(A, B2) = 0.096$$

$$KLD(A, B2) > KLD(A, B1)$$

In this example, AD cannot distinguish the difference between B1 and B2 in terms of the dissimilarity to A, while KLD correctly measures the dissimilarity order. It illustrates that KLD is more sensitive to inner structure differences than AD. MDF is not calculated in this example because we do not have the detailed distribution. In the result section, we will demonstrate the advantage of KLD over MDF and AD using random subsamples derived from real-life data.

4. RESULTS

4.1 Dissimilarity Measurement Selection

We make comparisons of dissimilarity measurements using large samples of random groups synthesized from our dataset. Though this experiment, we want to show that KLD can best illustrate the difference in attendance data between top students and other students.

Attendance data used is collected from students from Cohort 2018 in Fall 2018 and Spring 2019 semesters. We consider students' overall attendance rates in the academic year 2018-19. We use their first year CGPA as the measurement of academic performance.

There are 120 students whose academic performance are in top 10%. Therefore, we set the top 120 students as top 10% group and randomly generate 10000 groups, each of 120 randomly selected students from the whole student population.

We divide the whole student population evenly into 4 levels based on their overall attendance rates. In each level there are 25% of students from the whole population. we then calculate for each group, the portion of students in each level. For example, for top 10% group, its attendance rate distribution in the 4 levels (from low to high) is: [0.125, 0.242, 0.3, 0.333]

We perform the three candidate dissimilarity measurements between the 10000 groups and the top 10% group. Noted that for KL-divergence, the direction is from the top 10% group to the generated group. We then find out the 3 groups (named as KLD, AD, MDF) having the largest attendance dissimilarity via the 3 different measurements and rank the 3 groups' academic performance among the 10000 groups. Intuitively, the group with the largest difference from the top 10% group have the poorest academic performance.

Table 1. The rankings of different dissimilarity measurements

	Mean GPA	Mean GPA Rank	Last 10% Ratio	Last 10% Ratio Rank
Top 10%	3.77	10000	0	10000
KLD	3.02	1	14.17%	328
AD	3.14	2157	10.83%	2670
MDF	3.14	1714	10.00%	3759

The results are shown in Table 1. The rankings of mean GPA and the last 10% ratio indicate the academic performance of the chosen group among the 10000 groups (the higher the ranking the poorer the academic performance). We can see that the group detected by KLD has the highest mean GPA rank (last 1) among 10000 groups and the highest last 10% ratio rank (last 328) among the three dissimilarity measurements. Therefore, KLD is a good

dissimilarity measurement and we apply it for distribution comparison on attendance difference.

For more experiment of dissimilarity measurement selection, please see the appendix.

4.2 Exponential Moving Average and KLD

In this subsection, we compare the performance of two methods, KLD combined with EMA (denoted as EMA+KLD) and KLD combined with the raw attendance rates (denoted as RAW+KLD). The partition of data and the experiment setup are similar to those in section 4.1.

The results are shown in Table 2. The group detected by EMA combined with KLD has a higher mean GPA rank (last 24) and a higher last 10% ratio rank (last 276) than the group detected by Raw+KLD. Therefore, combining exponential moving average and KLD improves our ability to detect attendance divergence between student subpopulations of different academic performance.

Table 2. The rankings of two methods

	Mean GPA	Mean GPA Rank	Last 10% Ratio	Last 10% Ratio Rank
Top 10%	3.743	10000	0	10000
Raw+KLD	3.144	2085	9.65%	4801
EMA+KLD	3.063	24	14.91%	276

For more information of EMA, please see the appendix.

4.3 Critical Periods in Attendance Divergence

In this subsection, we discuss the longitudinal attendance divergence between top and last 25% students on CGPA. The data is collected from first year undergraduate students in Fall 2018 and Spring 2019.

Figure 1 shows the KLD time series calculated between attendance of top and last 25% students using weekly attendance indexes processed with EMA. Noted that for KLD, we calculated the distance in the direction from the top population to the last population. The top and last quarter students first diverge after the 3-days national holiday (Fall 2018 Week 4, the Mid-autumn festival). In the mid-term period, the difference enlarges again and the difference stays at about the same level till the end of the semester. At the beginning of Spring 2019 semester, the attendance difference is reduced but is restored to the level of the last term quickly.

Figure 1. KLD time series.

During the mid-term of Spring 2019, the difference is enlarged and stays at the same level till the end of the semester.

We conjecture several reasons behind the divergence of attendance rates. In the local culture, the 3-days national holiday (Mid-autumn festival) is the time when people travel to meet their loved ones. Since the holiday is close in time to another national holiday, some students may leave the university and do not return to the university till the end of the second holiday. This behavior could lead to low attendance rates among the last quarter students during the week after the Mid-autumn festival. The mid-term period significantly enlarges the difference and multiple factors can be behind the phenomenon. The last quarter students could be frustrated by the mid-term exams and give up their studies; Preparing the mid-term exams is stressful and some students did not relax properly after the exams and start skipping classes; Some students might be addicted to video games and persistently reduce their class attendance.

5. LIMITATIONS

Raw attendance rate data used in our research was collected using a Wi-Fi based method proposed in [23, 34]. The data can be biased because some students would close their Wi-Fi connections or even close their digital devices all together, leading to a false label of absence. To avoid the possible bias, students whose data having less than 50 Wi-Fi connection records in a week were excluded. Previous studies [7, 22, 33] show that attendance collected from Wi-Fi tracing has usable accuracy. EMA can help reducing the noise and fluctuations in the attendance data.

Privacy is an importance issue in research related to Wi-Fi tracing. In our study, we removed personal information from the data and encrypted the student ID with a hash code. Attendance data and CGPA data were connected using this hash code. The Wi-Fi data collection had a clear location boundary and data was collected only when the students are on campus. We did not collect website URLs or communication content. Given that the research can potentially improve the existing attendance policy, this study has been approved by the university management.

6. CONCLUSIONS

In this study, we identified the divergence of longitudinal attendance patterns between student subpopulations of different academic performance using the combination of Exponential Moving Average (EMA) and Kullback-Leibler Divergence (KLD).

We designed several experiments to prove the efficacy of EMA and KLD to process raw attendance data and measure dissimilarity between top and last student populations. We then combined EMA and KLD to analyse real-life attendance data from two student subpopulations of top and last academic performance. The resulting curves are intuitive and imply rapidly increasing attendance divergence during the mid-term periods and right after public holidays.

Through the visualized results generated using our proposed method, we address the importance of longitudinal attendance patterns on academic performance. Our result gave educator an example on how to measure longitudinal attendance and can potentially help institutes to optimize attendance policy.

APPENDIX

Attendance Index Comparison

Let $c_{i,t}$ denoted the index used (raw attendance data $a_{i,t}$ or EMA index $EMA_{i,t}$). In order to illustrate the advantage of EMA over raw data, we predict the attendance rate $a_{i,t}$ using the index $c_{i,t-1}, c_{i,t-2}$ from previous 2 weeks. We construct a model for each week, with the prediction model of each week reflects the properties of the week.

Definition 5 Weekly Prediction Model (WPM): For every week t , the attendance rate of t is predicted as:

$$a_{i,t} = w_{1,t}c_{i,t-1} + w_{2,t}c_{i,t-2} + \varepsilon_{i,t}$$

where $w_{1,t}, w_{2,t}$ are parameters to be estimated.

As we consider attendance rate could be a vibrate behavior influenced by the attendance rates of the previous 2 weeks (two points determine a line), we use the attendance rates of the 2 weeks before time t to predict attendance in week t . The decay factor β for EMA is therefore set to be $\frac{2}{3}$. Model used is linear regression and mean square error (MSE) are calculated for every week (every model) as the evaluation.

Fall terms in both 2018 and 2019 have 14 weeks. Because we used the indexes of previous 2 weeks as predictor, we start to train prediction models beginning from week 3. We then have in total 12 separate models for WPM in a semester.

We use attendance data of students from Cohort 2018 in Fall 2018 semester training set and attendance data of students from Cohort 2019 in Fall 2019 semester as test set.

Figure 2. Comparison of test set MSE between raw data and EMA for weekly prediction models.

Figure 2 shows the performance of weekly prediction models for test set data. The difference between original data and EMA (RAW-EMA) is plotted in the figure. A value above zero indicates that RAW has a larger error (worse) than EMA on that point. EMA performs equal to or better than raw data in all 12 models. We can then confirm that EMA can smooth the fluctuating time series and better reveal trend information.

Dissimilarity Selection on Real Data

In this subsection, we compare the performance of KLD over mean difference (MDF) and absolute distance (AD) using real-life attendance data.

To confirm the performance of dissimilarity measurements on real-life data, we apply the three methods on attendance data of

students from Cohort 2018 in week 8 and week 9 in the Fall 2018 semester. We compare the weekly attendance rate between students whose CGPA (measured after Fall 2018) are in the top 25% quantile (297 students) and last 25% quantile (298 students). Weekly attendance rates in a subpopulation are divided into 5 levels, as is illustrated in Figure 3. Larger inner structure difference is detected in week 9 than in week 8, especially for the lowest attendance category (<0.6).

Figure 3. Attendance distribution in Fall 2018 Week 8 & 9

The dissimilarity values between top and last 25% students calculated from the three measurements are shown in Table 3. KLD derives significantly more divergent result for the two weeks (Week 8 and 9), which is consistent with Figure 3. AD cannot detect the divergence order. As KLD could put more emphasis on their most different part, it is more suitable for attendance group comparison.

Table 3. Dissimilarity calculated for the two weeks.

Dissimilarity Measurement	Fall 2018 Week8	Fall 2018 Week9
MDF	0.073	0.083
AD	0.365	0.336
KLD	0.177	0.274

Improved Automated Essay Scoring using Gaussian Multi-Class SMOTE for Dataset Sampling

ABSTRACT

Automated Essay Scoring (AES) research efforts primarily focus on feature engineering and the building of machine learning models to attain higher consensus with human graders. In academic grading such as essay scoring, the scores will naturally result in a normal distribution, more commonly referred to as the bell curve. However, the datasets used do not always have such distribution and are often overlooked in most machine learning environments. This paper proposes a Gaussian Multi-Class Synthetic Minority Over-sampling Technique (GMC-SMOTE) for imbalanced datasets. The proposed GMC-SMOTE generates new synthetic data to complement the existing datasets to produce scores that are in a normal distribution. Using several labeled essay sets, some of which already have a substantial agreement between the machine learning model and human graders, learning from normal distribution datasets yields significant improvements. Improvements of 0.038 QWK score (5.8%) over the imbalanced dataset were observed. The experimental result has also shown that naturally occurring distribution in the automated essay scoring domain contributes to the most appropriate training dataset for machine learning purposes.

Boosting, Data Sampling, Gaussian Distribution, Data Pre-Processing, Automated Essay Scoring

1. INTRODUCTION

In an educational setting, essay compositions are commonly used to evaluate students' competence in articulation. The task to grade is labourious and is highly biased to the grader,

J. S. Tan, I. K. T. Tan, L. K. Soon, and H. F. Ong. Improved automated essay scoring using gaussian multi-class SMOTE for dataset sampling. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 647–651, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

<https://doi.org/10.5281/zenodo.6853024>

which causes the scoring to lack consistency in the essay scoring process [20]. For this reason, Automated Essay Scoring (AES) systems have been proposed and implemented to solve the traditional human scoring approach problem or act as a complementary mechanism. Research projects in AES have focused on feature engineering, and in the design of the scoring machine learning models to achieve higher agreement with human graders [19, 22]. In building the machine learning models, the quality of the dataset is of utmost importance. In the earlier research projects on AES, the distribution of the scoring in the datasets was not taken into consideration. The datasets for building the AES models are often imbalanced, as the scores assigned by human graders may not be appropriately distributed. A significant level of imbalance in multi-class datasets such as essay scoring datasets is a profound problem [21].

1.1 Dataset Distribution

To visualise the imbalanced dataset issue in essay scoring, the score distribution of a commonly used dataset for AES research is used. The dataset is from the Automated Student Assessment Prize (ASAP) competition¹. There are 8 datasets, where sets 1, 2, 7 and 8 are essays of the same genres were chosen and their score distribution is shown in Figure 1, the other sets are not selected as they are of the short letters genre.

Figure 1a and 1b have fewer classes compared to 1c and 1d. The agreement (accuracy) between the model and the ground truth in a multi-class classifier would generally be better with smaller classes. However, for Essay Set 7 (Figure 1c), the model built for it outperforms that of the smaller number of classes Essay Set 2 (Figure 1b) as shown in Table 1b and 1c. Also, it is observed that Figure 1c has a typical academic scoring distribution that has a Gaussian distribution with a median around the 60% mark. It can also be observed that for Figure 1d, the distribution of the scores does not reflect a Gaussian-like distribution with a trough around the 66% mark. As the scoring range for Figure 1d is larger (0 to 60), this would mean that the dataset quality

¹<https://www.kaggle.com/c/asap-aes>

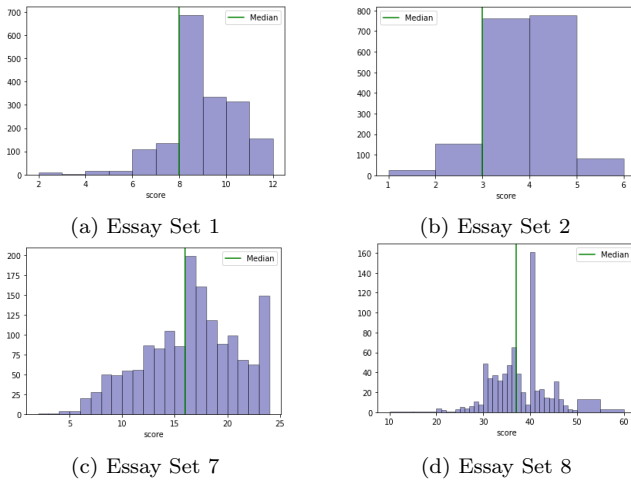

Figure 1: Histogram for ASAP essay sets 1, 2, 7 and 8.

is poor as there are insufficient data that will result in poor performance of the model by comparing the QWK score of Table 1d with 1a, 1b and 1c. Hence, an appropriate dataset distribution is important for training a model to have better performance.

In automated essay scoring, it is well known that the scoring of academic work such as essays normally falls within a Gaussian distribution curve with the median hovering around the 60 - 70 percentile. Motivated by the understanding that quality training dataset will improve the learned model [10, 3], we propose Gaussian distribution Multi-Class Synthetic Minority Oversampling Technique (GMC-SMOTE) to overcome the issues of imbalanced multi-class data for AES modelling. Instead of implementing SMOTE to provide a uniform distribution of the sampling, GMC-SMOTE is used to oversample the multi-class dataset into a Gaussian distribution. With the improved quality of the training set, the inherent bias of the dataset is kept in the training of the models. To evaluate GMC-SMOTE effectiveness, three type of train sets were generated. In addition, the evaluation was conducted using the same features and modelling algorithm, namely the Bayesian Linear Ridge Regression as proposed by Phandi et al. [19].

2. IMBALANCED DATASET HANDLING

2.1 Imbalanced Data Problem Trends

Researchers worked on the imbalanced data problem from two distinctive approaches; modifications on the attributes at the algorithmic level for the training model to fit the imbalanced data, or augmentation at the data level. These two approaches are summarised as follows.

2.1.1 Algorithmic level

Most of the imbalanced data solutions are targeted on the minority class due to the common high cost of misclassifications on a minority class [18]. Hence, numerous cost-sensitive learning approaches are introduced to balance the classes based on the ratio to each classes' costs [17]. The most popular approach of cost-sensitive learning is to assign different weights for each class in the training models that are based on the costs of misclassifications [8]. Other than

assigning weights, cost-sensitive learning can be done differently, such as changing the models' threshold based on its own misclassification costs [8]. However, in most real-world cases, the cost matrix is not easily identified.

2.1.2 Data level

Random undersampling (RU) and oversampling (RO) are the first few methods introduced to deal with imbalanced data. Both of the methods replicate random samples to reduce the imbalance ratio. However, the RU might eliminate some significant samples, and RO might cause the model to overfit. There are several extensions based on random undersampling and oversampling such as one-sided selection [15] and Edited Nearest Neighbour rule (ENN) [25]. Synthetic Minority Oversampling Technique (SMOTE) was introduced by Chawla et al. [6] to address the problem in random oversampling. Instead of randomly replicating the minority samples, SMOTE creates new minority class samples by using the interpolation between minority class samples' neighbourhood. Several extension and hybrid methods based on SMOTE were introduced such as Borderline-SMOTE, SMOTE with Tomek-links and SMOTE with ENN. Eventually, many extensions of SMOTE are proposed such as Borderline-SMOTE [11], ADASYN [13] and MWMOTE [2].

2.2 SMOTE and Multi-Class SMOTE variations

2.2.1 SMOTE

The SMOTE algorithm [6] records the interpolations between minority class instances within a defined neighbourhood to create new synthetic samples. To do so, SMOTE measures the difference between the selected feature vector and its nearest neighbour. SMOTE multiplies the calculated difference by a random number between 0 and 1, then adds it to the selected feature vector. For this reason, the synthetic sample will be at a random point between two specific feature vectors. This method effectively forces the decision making areas for minority class instances to become more generic. However, SMOTE cannot be applied to multi-class problems (such as for AES modeling) directly as SMOTE works on dataset with two classes, the minority, and the majority only. For multi-class problems, there are a few notable multi-class oversampling approaches.

2.2.2 One-versus-All with SMOTE

As multi-class classification implies additional complexity to data mining algorithms, due to the overlapping boundaries, it will lead to a drop in the resulting performance [5]. One of the approaches to tackle this problem is through implementation of class binarization techniques [1]. One-versus-All (OvA), also known as One-versus-Rest (OvR), is a binary classification algorithm for multi-class datasets. The combination of OvA and SMOTE is one of the most popular methods to implement SMOTE for multi-class datasets [10, 3]. OvA is implemented to split the multi-class dataset into multiple binary classification problems. Next, each binary classification problem are trained on a binary classifier based on the samples of selected class as positive and the rest of samples as negative [4]. After obtaining the binary class problems sets from OvA/OvR, SMOTE is implemented for each set to oversample the minority class instances. The

output of SMOTE will be merged back into the multi-class dataset for the training of the selected model.

2.2.3 One-versus-One + SMOTE

One-versus-one (OvO) [12] is another approach of binary classification algorithms for multi-class datasets. Similar to OvA/OvR, OvO binarizes multi-class datasets by splitting a multi-class dataset into binary classification problems [9]. However, OvO deals with the datasets differs in that it splits them into single datasets for each class against every other class.

3. PROPOSED GMC-SMOTE

We propose Gaussian Multi-Class Synthetic Minority Over-sampling Technique (GMC-SMOTE) to enhance the quality of the dataset in AES by introducing new synthetic samples for improved performance of the models. Instead of creating synthetic new samples uniformly, GMC-SMOTE individually processes each class to form a Gaussian-like distribution. The implementation of SMOTE in a multi-class dataset is not directly applicable. To implement SMOTE in a multi-class dataset, we selected OvA with SMOTE to perform the SMOTE for each class in the multi-class dataset as it has the superior performance over oversampling for multi-class dataset [10, 3]. It is one of the techniques suggested for multi-class oversampling by the author of SMOTE [9].

The default SMOTE algorithm requires six samples for each class, which can be reduced to two. In our proposed GMC-SMOTE algorithm, we propose to replicate classes with fewer than six samples to at least six samples. This ensures SMOTE has sufficient samples to generate synthetic samples and inherit the bias from the original dataset. Also, six samples per class are the minimum requirement to train a model [14].

3.1 GMC-SMOTE Algorithm

Algorithm 1 GMC-SMOTE algorithm’s pseudo-code

```

1: Inputs:
2:  $D$  = Dataset classes and its counts
3:  $Dataset$  = Dataset
4: Algorithms:
5:  $C \leftarrow getUniqueClass(D)$ 
6:  $M \leftarrow calculateMode(D)$ 
7: for class in  $C$  do
8:   if  $class = M$  then
9:      $FD_{class} \leftarrow D_M$ 
10:  else
11:     $posAway \leftarrow |M - class|$ 
12:    if  $\frac{D_{class}}{posAway} > 2.5$  then
13:       $FD_{class} \leftarrow D_{class} \times 2.5$ 
14:    else
15:       $FD_{class} \leftarrow \frac{D_{class}}{posAway}$ 
16:    end if
17:  end if
18: end for
19:  $newData \leftarrow SMOTE(Dataset, FD)$ 
20: return  $newData$ 

```

GMC-SMOTE is implemented based on the bell curve symmetric theory [24] for Gaussian distribution. The bell curves symmetric theory means the distribution is symmetric comparing the left distribution and right distribution from the

value at the peak of the curve. Algorithm 1 describes our implementation of the GMC-SMOTE. In line 4-7, C represents unique classes and M represents the mode class in D . Then, each unique class C in D is iterated through. The mode class of the dataset D_M is kept constant. The mode class will be the class with the most occurrences.

$$F_N = \frac{D_{class}}{posAway} \quad (1)$$

The Equation 1 is to calculate the new frequency, F_N for the rest of the classes where $posAway$ represents position away from the mode, and is stored in Frequency Dictionary FD_{class} . This equation is motivated by how the distribution is scaled away from the mode in the bell-curved symmetric. The author of SMOTE, Chawla et al. [6] have proven that between 200% and 300% oversampling rate is proven to be the most robust oversample ratio in SMOTE. Hence, we limit the amount to be oversample at 250% of the original frequency. With this, we can keep the naturally occurring distribution of the datasets and inherit the bias for training the models.

4. METHODOLOGY

4.1 Experimental Datasets

We use the same dataset from Figure 1. The selected datasets metadata can refer to [19]. To extract features for learning algorithms, we implement the Enhanced AI Scoring Engine (EASE) ². We selected EASE as it is a robust feature engineering method for AES that several researchers have implemented in recent years [19, 16]. The EASE system will generate 14 features refer to [19]. Five-fold cross-validation is implemented to generate the train and test set due to unreleased test data from the ASAP competition. We re-distributed the data into five-fold, where four-fold will be the train set and one-fold will be the test set in each round. Three different types of train set will be generated for the learning algorithms to train the models:

- (a) **Default.** The train set with original distribution.
- (b) **Uniform Distribution.** The train set is oversampled by SMOTE that makes the frequencies all classes to be uniformly same as the frequency of the mode class.
- (c) **GMC-SMOTE.** The train set is oversampled by GMC-SMOTE to generate Gaussian-like distribution of the classes.

4.2 Learning Algorithm

The Bayesian Linear Ridge Regression (BLRR) algorithm is chosen among the other prospective methods such as Naive Bayes (NB) and Support Vector Machines (SVM) based on the results from Phandi et al. [19]. It allows a natural language processing tasks to deal with insufficient data by create linear regression through probability distributors instead of point estimate. Also, it is robust and has often delivers good results in natural language processing projects.

Figure 2: Histogram of GMC-SMOTE generated distributions.

4.3 Evaluation Metric

We implement Quadratic Weighted Kappa (QWK) to calculate the rate of agreement among two graders; the human graders, and the scoring by the trained model. It varies from 0 to 1, where 0 represents no agreement, 0.01-0.20 as slight, 0.21-0.40 as fair, 0.41-0.60 as moderate, 0.61-0.80 as substantial, and 0.81-1.00 as almost perfect agreement [7]. QWK is proven to be robust since it takes into consideration the odds of accidental agreement [23]. Also, it is a common evaluation metric for AES models [19, 16].

5. RESULT AND DISCUSSION

New samples for each essay set using the proposed GMC-SMOTE are generated. A sample of the GMC-SMOTE distribution histograms are plotted in Figure 2. From the observation on the Figure 2a and 2b, the new distributions are closer to a Gaussian distribution symmetrical on the left and right of the mode value. For the Figure 2c, the histogram is much flatter than the default distribution. As for Figure 2d, the data quality remains of concern due to missing data for many classes and low data samples. From all these observations, the nature of default distribution is inherited into the new distribution, which brings the inherent bias of default distribution to the new distribution.

Train Set	QWK
(a)	0.808
(b)	<u>0.810</u>
(c)	0.823

(a) Essay Set 1

Train Set	QWK
(a)	0.688
(b)	0.707
(c)	<u>0.704</u>

(c) Essay Set 7

Train Set	QWK
(a)	0.650
(b)	<u>0.672</u>
(c)	0.688

(b) Essay Set 2

Train Set	QWK
(a)	0.644
(b)	<u>0.656</u>
(c)	0.676

(d) Essay Set 8

Table 1: Experiments result

We calculate the mean QWK scores for each trained model using the one-fold of test in five rounds. The results are

shown in Table 1. The best result is bold-faced and the second best is underlined. Overall, the BLRR scores for GMC-SMOTE datasets are better than all the default datasets and GMC-SMOTE performs the best in essay sets 1, 2, and 8.

- **Essay Set 1:** An increase in QWK by 0.015 even though it has an almost perfect agreement using the default dataset.
- **Essay Set 2:** A more modest increase in QWK by 0.038, which is expected as the dataset distribution is similar and the number of classes are few.
- **Essay Set 7:** The GMC-SMOTE’s QWK is better than the default dataset but slight poorer than Uniform distribution dataset produced by the default SMOTE algorithm.
- **Essay Set 8:** A significant increase in QWK by 0.032 even though it has many missing classes and several classes with one to five frequency counts.

With the exception of essay set 7, the uniformly distributed datasets have poor results. This shows that simply applying SMOTE to the datasets has probably removed the inherent bias in an essay scoring situation. The proposed GMC-SMOTE has shown that with proper oversampling, maintaining the inherent scoring biasness in an academic setting can improve the automatic essay scoring agreement with the human graders. For essay set 7, although the GMC-SMOTE improved the QWK scores over the default dataset, the uniform distributed dataset has the best result. This can be attributed to the fact that the default dataset is relatively platykurtic with negative skewness. This encompasses the majority of the samples (scores of 15 or greater from Figure 1). Hence, applying a uniform distribution will enhance the sample and does not significantly impact the human scoring biasness. It will also mean that if there are sufficient sampling sizes, the naturally occurring distribution is the optimal distribution. This can be observed in Figure 2, for essay set 7, where the histogram is plotted for the new data distribution generated by GMC-SMOTE. Comparing the GMC-SMOTE distribution (Figure 2) with the default distribution (Figure 1), the naturally occurring distribution is kept in the new distribution while new samples are generated.

6. CONCLUSION

The results show that the GMC-SMOTE is an effective oversampling method for situations with some imbalance in the dataset. The proposed GMC-SMOTE method can be applied for training datasets for other classifications domains where the naturally occurring distribution is Gaussian (normal). Kurtosis and skewness can be used to assess the type of naturally occurring distribution of the respective dataset distribution. As observed in our evaluation (essay set 7), it is also important to first assess whether the kurtosis is much lesser than the normal distribution (platykurtic), which may require a uniformly distributed dataset. The assessment can be conducted prior to deciding whether to use Multi-Class SMOTE or the proposed GMC-SMOTE for imbalanced datasets.

ABSTRACT

In the academic process, comprehension and analysis of literature is essential, however, time-consuming. Reviewers may encounter difficulties in identifying relevant literature, given the considerable volume of available texts. It is arduous not only for starting PhD students, but also for any researcher learning about a new field (called here "domain learners"). To address this issue, we present an *automated framework to assist in the literature review process*. Through the application of topic modelling of academic articles, our framework encourages senior researchers within a specific field to act as experts to contribute to the labelling of topics. Further to this, domain learners can benefit from visualisation tools intended to assist in the comprehension of vast amounts of academic texts. Our approach allows reviewers to identify the *topics, trends* as well as *relations between topics* in a given research field. We also accompany this method with a tool that we provide open source. For illustration, we apply here our method to a case-study of biological texts, specifically texts related to human protein kinases. To further enhance the educational capabilities of our approach, we perform triangulation of external biomedical databases, to illustrate how our multi-pronged approach can provide a comprehensive understanding of the research domain.

Keywords

Automated Literature Review, Topic Modelling, Crowdsourcing, Bioinformatics

1. INTRODUCTION

The process of understanding academic literature is a time-consuming process for both students and professionals. Thus, there is a necessity to enable the process of quickly comprehending such literature. Furthermore, limitations to the

amount of work which can be analysed by an individual or team may be encountered, due to the time it takes to understand each item of literature. This is of particular relevancy to the biomedical field, where estimates in 2016 proposed that the field observes 3 new publications per minute uploaded to the PubMed database alone [1]. Moreover, the identification and recognition of evidence and named entities within full-text biological literature - the Curator Assistance Problem [1], is limited by the requirement for manual analysis of text by experts within the field, using their own knowledge and intuition.

To address these issues, we propose an *automated approach to assist in the literature review process in biomedical literature*. By leveraging recent advancements in topic models, we seek to provide novel benefit to the academic and research process when learning about a certain new research area. Further to this, to address the Curator Assistance Problem [1], we perform rule-based identification of human-related protein kinases within the literature, for automatic triangulation of multiple external data sources, to assist in comprehension of research. We provide access to the case-study for reproducibility¹. Our research aims to address the following research questions: 1. *How may topic modelling algorithms be applied to assist in the comprehension of large volumes of academic data?* 2. *How may semantic similarity measures be leveraged to identify inter-topic relationships of identified literature?* 3. *Can rule-based extraction of named biomedical resources contribute to the comprehension of automatically generated literature topics?* 4. *Can scientific language-oriented embedding models provide improvements to the perceived accuracy of topic-modelling, when analysed by biological domain-experts?*

The main contributions of this paper are thus: (1) Provision of a novel framework for the analysis of literature topics by accounting for semantic relationships and temporal trends of identified topics. (2) A capability for the crowdsourcing [2] of domain experts for the labelling and filtering of topics within the literature. Experts such as educational tutors or senior researchers may contribute to the labeling of identified topics based upon their own knowledge. Subsequently, domain learners may then benefit from the visualisation tools

provided to assist in their learning on the subject. (3) Triangulation of multiple external data sources for the extraction and linking of named kinases present within literature, to assist in the expert labelling and comprehension of topics within the literature. Although this is a case-study based upon literature related to protein kinases, in a collaboration with bioscientists, this robust approach allows for further generalisation, and could be applied to the analysis of literature from any domain. (4) An unsupervised evaluation of the performance of scientific-domain transformer embeddings, compared to document embedding approaches when applied to document clustering for the identification of topics within scientific literature.

2. RELATED WORKS

As a data-intensive field, there has been an emergence of numerous biological data-sources of various quality and provenance. However, due to a lack of a standard ontology with fine granularity, it is difficult to conduct data mining on those heterogeneous biology data. Despite efforts to normalise data formats and collect observations in databases, a large amount of information relevant to biology research is still recorded as free text in journal articles and in comment fields of databases [3]. Therefore, retrieving information from papers and merging it with existing biological databases can provide a crucial foundation for data-mining in bioinformatics [1]. To address this, works have been proposed for the extraction of entities within biological texts, including RegulonDb [4], which applied rule-based identification of regulatory interactions in *Escherichia coli*, with the results demonstrating a rule-based approach sufficient in identifying 45% of all named entities when compared with a manual extraction approach. Extraction of genetic and protein interactions was performed by BioC-BioGRID, which released a corpus of 120 full-text articles with biological and molecular entity annotations [5]. Based upon these problems and subsequent approaches, [1] proposed the Curator Assistance Problem. This problem proposes four objectives, which were defined given a full-text biological research paper: 1. The recognition of evidence described in an article, compared to information in other articles. 2. The recognition of evidence which is supported by experimental data, compared to hypothetical or vague statements. 3. The distinction between statements on layout, compared to statements of results. 4. The recognition of negative statements.

No research was identified relative to the automated literature review process for biomedical data. However, in the wider domain, one framework has been demonstrated to identify relevant papers for a literature review based upon an input of seed papers [6]. This approach applied supervised learning classifiers, which were trained upon reference lists of existing papers. From an unsupervised perspective, [7] applied topic modelling to the task of conducting an exploratory literature review through the use of Latent Dirichlet Allocation (LDA). The approach required application of the elbow curve methodology within an exhaustive search, to determine the optimum number of topics within the literature. In contrast, a recent topic modelling approach, Top2Vec [8], has presented advantages over the application of LDA, through the elimination of the need to manually or exhaustively define the optimal topic number. Applications of Top2Vec to assist in literature analysis were presented in

Figure 1: An automated framework based on topic modelling and crowdsourcing

[9], through a case-study review of research in Intelligent Tutoring Systems. However, the approach required the manual analysis of resulting topics prior to the generation of visualisation and topic labels. Our study is based on this, but is expanding it in several ways. Importantly, we propose a framework for the e-learning domain, and illustrate it through an interface, to permit the crowdsourcing [2] of topic labelling on a large scale, as well as provide an expanded suite of tools to assist with learning. By creation of this framework, we are able to demonstrate the generalisable characteristics of the approach, such that it may be applied to any domain of literature, and may be subsequently enhanced through the implementation of domain-relevant features, such as the protein databases applied for our case-study. The resulting implementation of domain-relevant data triangulation may enhance the information available to researchers by providing supplementary information to aid in filtering and identification of relevant literature to a domain-user.

3. METHODOLOGY

The proposed framework (as summarised in Figure 1) entails three components. Firstly, topic modelling is performed on the academic literature that is identified as relevant to the case-study domain through the use of the API resource. Following this, senior researchers are presented with an interactive topic labelling and visualisation analysis tool, which allows them to determine whether a topic is relevant to their literature search, as well as assign a title for that topic. Finally, this visualisation analysis tool can facilitate the comprehension of relevant literature of the domain learners. To illustrate the framework, here, based on the full-text of documents assigned to a topic, extraction of human-protein-kinase terms (the topic of the literature review) is performed by rule-based extraction of kinase names. Also, in terms of the actual implementation, an internal relational database provides external links to the external resources – here, those coming from UniProt Knowledgebase (UniProtKB) [10] and InterPro [11], well-known protein databases. The resulting interface may be applied as a framework for learning through the crowdsourcing of domain experts within a field for the labelling and filtering of literature topics. Expertly annotated topics may then be provided to learners or experts, who may apply the visualisation tools provided to assist in their learning and comprehension of the literature.

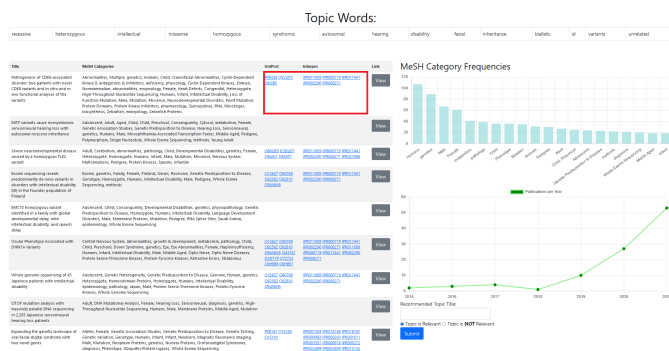

Figure 2: Labelling Interface for Topic "Genetic Disorders"

3.1 Data Sources

A full-text representation of publications is provided through the PubMed API, which ensures to capture the full semantic context of a text if it is analysed by a compatible language model for variable length document-embeddings. Two additional sources were selected for the triangulation of kinases identified within the literature, with these being the UniProtKB [10] and Interpro [11] databases. UniProtKB is a database of protein sequences and functional information, which includes information relevant to specific proteins, their function, organism, presence in biological processes, and relevant literature. InterPro serves as a similar platform, however includes hierarchical family classifications of protein entries as well as domains and functional sites found in proteins.

For the case-study, a list of 624 human protein kinases was firstly obtained from a kinase database [12, 13]. A comprehensive list of human proteins with links to their respective InterPro IDs was obtained from UniProtKB (Swiss-Prot, Jan 2014 version) [10]. Matching of protein kinase names to gene names including synonyms for proteins from UniProtKB was performed. The resulting 357 protein kinases that successfully matched to UniProtKB entries were used in this study. This entailed the names of relevant genes, kinase names and kinase families. Further to specific kinase names (e.g. *AATK1*), the data included full-named entities relevant to a kinase. Relevant to the given example, this would be *Apoptosis-associated tyrosine kinase 1*. This list of shortened and full terms was applied in an automated literature search via the PubMed API [14]. A total of 19,258 records were returned in this manner. Following this, filtering was performed, to ensure the elimination of any noise introduced into the dataset during the search stage. This was performed via filtering out publications that failed to contain Medical Subject Heading (MeSH) terms related to Humans. Following elimination of non-human-related subjects, 14,631 documents remained.

3.2 Topic Modelling

For the identification of topics within our literature, the Top2Vec [8] algorithm, which leverages the HDBSCAN [15] algorithm, is applied to identify dense clusters of document embeddings, and determine these to be topics. The algorithm automatically generates human-readable labels, based upon the top-scoring topic-words for each topic. In addition, a domain-expert may manually assign a title for each

topic on the topic labelling screen. The use of HDBSCAN presents a unique opportunity when clustering, given that HDBSCAN may label documents determined to be noise [15]. This provides the benefit of eliminating documents which do not directly fall within a topic.

3.3 Literature Analysis Toolkit

The main contribution of our approach centers around the development of a simple user interface for evaluating the results of literature topic analysis, and subsequent deeper analysis. Researchers may find difficulty in the application of algorithmic analysis approaches, as these require a degree of knowledge of programming and an understanding of the underlying algorithms applied. Therefore, through providing an interactive user interface, we ensure that researchers from the biomedical domain may analyse literature without the need to spend time learning the underlying system. Results from the topic modelling of the literature are presented to the domain-expert in a simple landing page, which provides a table format of top-scoring words for each topic, the manually assigned label, and relevancy classification which can be manually defined. By clicking on the *Edit Label* button, domain-experts may view a detail page (as shown in Figure 2), featuring top-scoring publications assigned to a topic, the top-scoring words for the topic, and a bar graph visualisation, detailing the total frequency of MeSH terms for publications assigned to that topic. Providing these features presents domain-expert with an opportunity to decide the title of the topic through a number of means. For example, MeSH subject headings can provide the frequency in which certain diseases are mentioned within documents in a topic. Further to this, by extracting mentions of human protein kinases within full-text articles, we facilitate the triangulation of the InterPro [11] and UniProtKB [10] databases, any may provide domain-expert with external links (as shown in the highlighted box in Figure 2) to related resources relative to a given publication. Domain-expert may also view the full publication at the place of publishing through a hyperlink, so that individual publications they find useful through the above analysis methods may then be read further.

Further academic features are provided to users (both domain experts and learners) through an analysis of the semantic relationships within topics, following the same methodology presented by [9]. Semantic relationships are generated through the calculation of the cosine similarity between all combinations of topic vectors, where a topic vector is defined as the average of all document embeddings belonging to that topic. We define each topic as a node, with the top three highest scoring topic similarity pairs (edges) for each topic being presented in the graph visualisation. Nodes are presented with at least three edge relationships. However, some nodes may have more than three edges. For instance, as shown in Figure 3, the node "DNA repair" displays the top 3 scoring edge relationships with "Genetic disorders," "Cancer genetics" and "Phosphorylation profiling". However, For the "Radiation effects" and "Alternative splicing" nodes, the "DNA repair" edge relationship is within the top-3 ranking for the nodes respectively, hence "DNA repair" demonstrating 5 edge relationships.

The topic-relationship graph is computed when initialising the system, and store this in a serialised format. Edge thick-

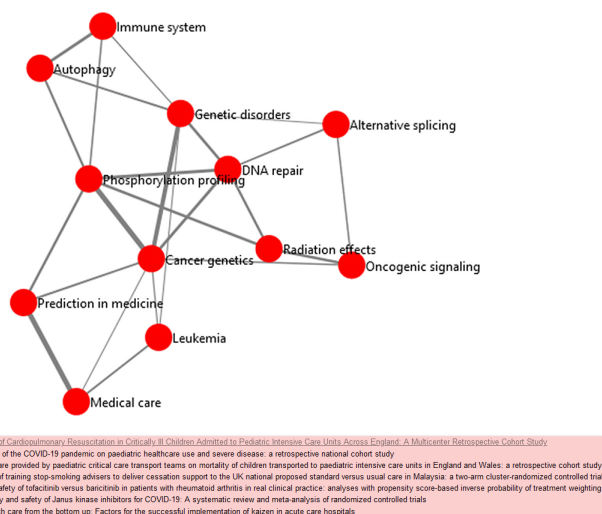

Figure 3: Relationships of Topics Identified by the Bioscientist Team and Expanded Link View

ness is a reflection of the cosine-similarity score between two nodes, for easy understanding of the strength of the relationship between those topics, with a tooltip presenting the similarity score when the user hovers their mouse over an edge. From this view, users may also further expand a topic, navigating to a view of the top-scoring academic texts that have been assigned to that topic based upon the distance of the publication to the topic centroid, by right-clicking on a node. For example, the pink panel on the bottom of Figure 3 is displayed when right-clicking the node "Medical care". This panel provides links of the paper directly to the external resources. Users may choose to view all identified topic-relationships from the topic modelling process, or only those that have been manually labelled as relevant.

4. CASE STUDY IN BIOLOGY - HUMAN PROTEIN KINASES

As a case study, the toolkit generated 279 topics from texts of publications related to the 357 human protein kinases. A representative list of associations, for each topic, is provided and contains the top twenty highest scoring topic-words, top ten individual publications, and MeSH category frequencies of publications assigned to the topic. For example, the 10th topic (shown in Figure 2) is provided with the following information: relevant topic words such as "recessive," "heterozygous," "inheritance," "missense," "homozygous," "syndromic," "autosomal," "disability," and "variants"; titles of individual publications with phrases such as "neurodevelopmental disease caused by a homozygous TLK2 variant," "variants in disorders with intellectual disability," and "phenotype associated with DYRK1A variants"; and MeSH categories such as "Humans" and "Genetics" with the highest frequency in the assigned publications. Based on this information, the topic can be labeled as "Genetic disorders" associated with human protein kinases. Moreover, links to UniProtKB and InterPro databases are listed for specific kinases included in each individual publication. For example, the publication titled "Pathogenesis of CDK8-associated disorder: two patients with novel CDK8 variants and in vitro

and in vivo functional analyses of the variants" is provided with the following links: the entry of the kinase CDK8 in UniProtKB; and the entries of domains, binding-sites, etc. found in CDK8 such as "Protein kinase domain," "Protein kinase, ATP binding site," and "Serine/Threonine protein kinases active-site" in InterPro. Such external databases provide detailed information such as biological functions, disease association, sequences, and domain architectures of protein kinases along with links to further explore other databases, should such a need arise for the user.

The toolkit also easily visualises relationships among topics based on their semantic similarity. To demonstrate its efficacy, the bio-experts in our team selected 12 topics that have at least six out of ten individual publications with links to protein kinases in UniProtKB, and then manually labeled the topics as shown in the previous paragraph. The resulting graph network (shown in Figure 3) generated from these topics has 12 nodes with the assigned labels and edges with different thickness that reflects the similarity between the linked topics. The node "Genetic disorders" is strongly connected to the nodes of "Cancer genetics" and "DNA repair." This is consistent with the idea that both genetic disorders and cancer genetics involve genetic changes and genomic technologies. Similarly, DNA repair defects are associated with certain genetic disorders. For example, ATM and ATR are DNA repair-associated serine/threonine kinases and their genetic mutations can cause hereditary disorders, ataxia telangiectasia and Seckel syndrome, respectively. Thus, it is reasonable to include both ATM and ATR in topic-words for the topic "DNA repair." Another strong connection visualised by the network is between "Medical care" and "Prediction in medicine," which aligns with the clinical aspect of treatment. The visualisation enables the users to easily explore major topics and their relationships. Collectively, the toolkit allows users to navigate a new field through vast amounts of literature in an efficient way.

5. CONCLUSIONS

In this work, an automated literature review framework is proposed for the analysis of large volumes of literature. The resulting topics from topic modelling of academic literature within specific domain, are provided via an interactive UI tool, which may allow the manual analysis and filtering of resulting topics, and exploration of entailing literature. Based on a case study on the biomedical domain of human protein kinases, we provide a further contribution to the comprehension of literature through the triangulation of biological relations present in identified publications. From an educational data mining perspective, our tool achieves the goal of grouping large amounts of academic text into understandable topics, and allows for crowdsourcing of expert-knowledge for the labelling of topics identified in the literature. The resulting framework achieves two objectives by serving as a base literature review assistance tool, or as an e-learning utility to allow expert analysis of topics, before providing the results to learners. By the inclusion of external databases UniProtKB and InterPro, we provide assistance in the extraction of named kinases within individual items of literature, allowing users to easily read further into the identified kinases present. Overall, this framework incorporates topic modelling with a crowd-sourcing approach, achieving the goal of expediting the task of analysing large volumes of literature.

ABSTRACT

This paper presents a course recommender system designed to support students who are struggling in their first semesters of university and who are at risk of dropping out. Considering the needs expressed by our students, we recommend a set of courses that have been passed by the majority of their nearest neighbors who have successfully graduated. We describe this recommender system, which is based on the explainable k -Nearest Neighbors algorithm, and evaluate the 2nd and 3rd semester recommendations using historical data. The evaluation reveals that the recommendations correspond to the actual courses passed by students who graduated, whereas the recommendations and actually passed courses differ for students who dropped out. The recommendations show to struggling students a different, ambitious, but hopefully feasible way through the study program. Furthermore, a dropout prediction confirms that students are less likely to drop out when they pass the courses recommended to them.

Keywords

Course recommender system, nearest neighbors, explainability, user-centered design, dropout prediction.

1. INTRODUCTION

In the last decades, universities worldwide have changed a lot. They offer a wider range of degree programs and courses and welcome more students from diverse cultural backgrounds. Further, teaching and learning in high schools differ from teaching and learning in universities. Some students cope well and keep the same level of academic performance at university as they had in high school. Others struggle, perform worse, and might become at risk of dropping out. The preliminary exploration of our data has shown, that most of the students drop out during the first three semesters of their studies. Therefore, the course recommendations proposed in this work focused on supporting struggling students after their 1st and 2nd semester. The final goal in developing such a system is to have it integrated in novel facilities that universities could put in place to support their diverse students better.

At the beginning of each semester in Germany, students need to decide which courses they enroll in. When entering university directly after high school for their 1st semester, most of them decide to enroll in exactly the courses planned in the study handbook. The decision becomes more difficult when they fail courses in their 1st semester and should choose the courses to enroll in their 2nd semester: should they repeat right away the courses they failed? Which courses planned in the 2nd semester in the study book should they take? Should they reduce the number of courses they enroll in to have a better chance of passing them all? Should they take more courses to compensate for the courses they failed? The study handbook does not help in finding answers to those questions.

In our previous work [18], most of the students mentioned that they rely on friends and acquaintances as one source of information when deciding which courses to enroll in. Further, any system assisting in enrollment should have explainable recommendations.

In this work, we propose a recommendation system to support students choosing which courses to take before the semester begins. We recommend students the set of courses that the majority of their nearest neighbors, who successfully graduated, have passed. Nearest neighbors are students who, at the same stage in their studies, have failed or passed almost the same courses with the same or very similar grades. The system proposed in the present work does not recommend top N courses as other systems do, e.g. [10, 14]. Rather, it recommends an optimal set of courses, and we assume that a student should be able to pass all the courses of that set. Because the recommendations are driven by past records of students who graduated, we also pose the hypothesis that students following the recommended set should have a lower risk of dropping out.

We describe a recommender system based on the explainable algorithm k -Nearest Neighbors (k -NN) and evaluate the recommendations given after the 1st and the 2nd semester using historical data. Although the recommendations are designed to support struggling students, every student should have access to them. By contrast, the recommendations should show a different, more academically successful way of studying to struggling students and therefore differ from the courses that they pass. More precisely, this paper tackles the following research questions:

RQ1. How large is the intersection between the set of recommended courses and the set of courses a student has passed? Are there differences between struggling and well-performing students?

RQ2. Do the recommendations lower the risk of dropping out, and if so, how much?

2. RELATED WORK

Course recommendations. Supporting students in choosing courses at the start of the semester has been studied in many works. The aims of the proposed recommender systems are diverse. For example, Parameswaran et al. [13] sought to provide students with courses that meet their constraints like availability and schedule, but also being favored and chosen by other students. Their goal was to recommend interesting courses that will also help students graduate and conduct evaluations using the academic performance data of students who have graduated. The goal of Pardos and Jiang [14] was to recommend courses “that are novel or unexpected to the student but still relevant to their interests”. The authors recommended courses based on a chosen favored course and evaluated the results using both historical data and student feedback as part of a user study. Backenköhler et al. [1] optimized recommendations by combining three aspects: a student’s preparedness for a course, the benefit of a course towards other courses, and the predicted performance in the course. The authors used historical data to evaluate how the recommendations match the student’s actual course choices. Nearer to our aim, Elbadrawy and Karypis [4] and Morsy and Karypis [10] recommended courses for which students can expect a good grade or an increase in their GPA. In both papers, the authors evaluated recommendations based on historical data, as we do.

User-centered design. Our work follows a user-centered approach as has been proposed for example by Martinez-Maldonado et al. [9]. The design of our recommendations has been developed with respect to insights obtained from a semi-structured group discussion conducted with 25 students [18]. The authors of several studies described their user-centered approach to involve stakeholders in the development of tools. De Quincey et al. [16] included students in the development of a dashboard that integrates study motivation to track engagement and predicted scores at Keele University (UK). To inform the development of a dashboard with relevant indicators to help students choose what courses to take in an upcoming academic period, Hilliger et al. [7] identified student information needs regarding course enrollment at Pontifical Catholic University (Chile) using a mixed-methods approach. Sarmiento et al. [17] described their approach as a series of co-design workshops for learning analytics tools with and for students at New York University.

Explainability. Not all machine learning algorithms used in educational data mining are explainable, such as neural networks, which are increasingly used as stated by Barredo Arritea et al. [2]. Pardos and Jiang as well as Morsy and Karypis used them in their respective works, [10, 14] for instance. According to Ning et al. [11], neighbor-based approaches are simple, justifiable, efficient, and stable. The number of neighbors, the features, and the distance function all influence the explainability of k -NN [2]. The nearest neighbors can be visualized as a table and students understand why the recommendations are given to them. As argued by Williamson and Kizilcec in [19], “educators and learners will not trust a model that cannot easily be explained to them”. Indeed, it was a concern of our students: recommendations should be explainable [18].

Our contribution. Using student-centered design, we have developed an approach to course recommendations that is explainable to students and aims to help students who are at risk of dropping out. Our evaluation, based on historical data, distinguishes two groups: students who have dropped out and students who have graduated. First, we compare the recommendations to the set of courses that students passed; this is similar to other evaluations like [4, 10].

Second, we investigate whether our recommendations decrease the dropout-risk. This is a novelty of our work.

3. DATA AND METHODOLOGY

Data and preprocessing. For the development of the course recommendation system, data from a six-semester bachelor program of a medium-sized German university was used. The initial dataset contains 1,484 students who started their study program between winter semester 2012 and summer semester 2019. We removed three types of students: A) outliers regarding the number of passed courses based on the interquartile range (IQR) since students can receive credit for courses completed in previous study programs and thus may pass more courses in a semester than foreseen in the study handbook [12], B) students who were still studying at the time of data collection since they can not be used to predict the risk of dropping out, and C) students without at least one record in each of the first three semesters. The final dataset contains 578 students who either graduated (status G) or dropped out (status D) and 9,500 records. The grading scale for passing a course is from best to worst [1.0, 1.3, 1.7, 2.0, 2.3, 2.7, 3.0, 3.3, 3.7, 4.0]. The grade for failing an exam is 5.0. Students must pass all mandatory courses and four elective courses to graduate. The study handbook includes a suggested courses schedule for the six semesters and students may follow this schedule or not. At any time in their studies, they are allowed to choose courses from all offered courses. It is worth noting that electives courses are scheduled in the 5th and 6th semester of the program. Table 1 shows the final number of students by student status and per semester the number of different courses, the number of academic performance records, the average number of courses passed per student, and the average grade. 134 students have the status dropout (D) and 444 the status graduate (G); in the 3rd semester (bottom line) there were 686 records concerning 20 different courses for students with the status D and 2,622 records concerning 26 courses for students with the status G. One notices that students with the status D pass fewer courses per semester and receive lower grades.

Table 1. Dataset overview by semester S (1, 2, 3) and student status (D, G). Number of courses C, Number or records R, mean number of passed courses MPC, and mean grade MG.

			C		R		MPC		MG	
D	G	S	D	G	D	G	D	G	D	G
		1	14	16	657	2,199	3.6	4.7	2.8	2.1
134	444	2	15	19	740	2,596	3.4	5.1	3.0	2.3
		3	20	26	686	2,622	3.0	5.4	3.2	2.2

Data representation. We use only data about academic performance: each student is represented by a vector of grades. It is possible for a student to, for example, enroll in a course in the 1st semester and not take the exam, then enroll and fail the exam in the next semester and enroll again and pass the exam in the following semester. In this case, a student has three different records for the same course in three different semesters. In our opinion, not only the final grade with which a course was passed is relevant, so we include the entire history of a student’s academic performance in the vector.

Missing values. To compute the nearest neighbors, we have to deal with missing values. If a student was enrolled in a course but did not take the exam, a 6.0 was imputed, if s/he was not enrolled at all, a 7.0 was imputed. This means that we rate enrolling but not taking the exam (6.0) more similar to failing (5.0) than not enrolling (7.0).

5. COURSE RECOMMENDATIONS

For our course recommendation system, we use the idea of a k -NN classifier: given a student S_x represented by the vector x_n of length n at the end of semester t , we use the majority votes of his/her already graduated neighbors to obtain a set of courses for the following semester $t+1$ that are classified as “passed” and accordingly recommended; any course not in that set is not recommended. We recommend courses for the 578 students in the dataset and then evaluate the recommendations.

Procedure. Let Y be the data of a program after semester t consisting only of graduated students S_{GR} , i.e. their vectors of grades with length n , let S_x be a student who needs a course recommendation, let C be the set of all courses of the program and let k be the number of nearest neighbors. Given C , the expected output is C_R the set of recommended courses and all courses that are in C but not in C_R are not recommended. First, we determine the k nearest neighbors of an observed student: the similarity of students is calculated using the Euclidean Distance between x and y where S_x and S_y are two students and x and y are the vectors of all their grades at the end of semester t where the length of the vectors n corresponds to the number of features that we use. The students are sorted by increasing distance and the top k vectors are selected as the neighborhood S_k of student S_x . Instead of considering each course in C , we preselect only courses that at least one of the students in S_k has passed in semester $t+1$, i.e. the grade is lower or equal to 4.0, and assign them to the set C_P of courses passed by the neighborhood. To classify each course in C_P to be recommended or not, we use the majority vote of the k neighbors: if a neighbor passed a course, it is labeled with 1 and otherwise 0. We calculate the probability P for student S_x to pass that course c as the mean of class labels, e.g. if $k=3$ and 2 out of 3 neighbors have passed the course, P is 0.66. If the mean is higher than 0.5, the course is recommended and assigned to C_R . To avoid a tie in majority voting, we use only uneven k and test our approach with $k = 1, 3, 5, 9, 19$. We check if S_x has already passed a recommended course and remove this course from the recommendation if necessary.

Baseline. We use the same approach not only with neighbors who graduated but also with all neighbors, i.e. students who dropped out and students who graduated. We expect that the recommendations differ between the two approaches and that the recommendations based on graduated students, but not necessarily the recommendations generated with all students, reduce the risk of dropping out. In the following, we distinguish the two recommendation types with AN (all neighbors) and GN (graduated neighbors).

6. COURSES’ INTERSECTION (RQ1)

To compare the recommended courses with those actually passed, we consider the recommendations as a binary classification problem and build a confusion matrix to evaluate the recommendation for each student and each semester as follows: a course recommended and actually passed in semester $t+1$ will be a true positive (TP), a course recommended and actually not passed will be a false positive (FP), a course not recommended but passed will be a false negative (FN), and a course not recommended and not passed will be a true negative (TN). The choice of metric is critical due to the relatively large number of courses and the resulting imbalance of recommendations or non-recommendations. Further, because we recommend a set of courses and not top N courses, it is crucial to measure not only that the recommendations contain all passed courses (recall) but also that they do not contain courses that students did not pass (precision). We chose the F_1 score to evaluate courses’ intersections since the F_1 score ignores true negatives,

which is in our context always a high value, and thus serves our needs. The score ranges from 0 to 1 with 1 indicating perfect classification (recall=1 and precision=1) and 0 indicating perfect misclassification (recall=0 or precision=0). The calculation is as follows: $F_1 = 2 \cdot TP / (2 \cdot TP + FP + FN)$.

Results. To evaluate the quality of the recommendation, we look at the intersection and evaluate the recommendations by F_1 score. We expect a high score for students with the status G in both semesters as the recommendations for them should match closely the courses that they passed. We do not expect a high score for students with the status D; the recommendations are meant to show them another way of studying that should bring more academic success and therefore should not match closely the courses that they passed. Table 2 provides the results as mean F_1 scores of all students. To better distinguish for which student groups the recommendations are more appropriate, the results are grouped by the following factors: semester (2, 3), student status (D/G), and type of neighbors (AN/GN). In addition, we provide the difference in each row between the mean score of the baseline AN and the mean score of GN. The differences in the number of neighbors k are not shown because no large differences emerged when k varied.

Findings. There is a difference between students who struggle and students who perform well. More precisely: A) AN-based and GN-based recommendations: The mean F_1 score for dropouts and graduates is higher for GN than for AN. B) Semester: The mean F_1 score is higher after the 1st for the 2nd semester than after the 2nd for 3rd semester. C) Graduates and dropouts: The mean F_1 score is higher for graduates than for dropouts. The mean F_1 score is high for graduates: this confirms our expectation that recommendations closely match the courses passed by graduates. For students with status D, the mean F_1 score tends to be low: the recommendations show another way of studying.

Table 2. Courses’ intersection based on mean F_1 score of all students for semester S and recommendation types AN and GN as well as their differences (Diff) by student status (D, G).

S	D			G		
	AN	GN	Diff	AN	GN	Diff
2	0.471	0.509	0.038	0.843	0.861	0.017
3	0.282	0.302	0.020	0.809	0.836	0.027

7. CHANGES IN DROPOUT RISK (RQ2)

A dropout prediction was performed using the following two steps: 1) based on the actual enrollment and exam information, a model has been trained to predict the two classes dropout or graduate; 2) the model of step 1 is used again to predict dropout or graduate after replacing the actual enrollment and exam information by the calculated recommendations. We call dropout risk the proportion of students who are predicted “dropout” by a model. To determine whether or not the recommendation approach helps to lower the dropout risk, we analyze the difference of these two dropout predictions.

Feature set. As investigated by Manrique et al. [8], there are several ways to select a feature set for dropout prediction and no way works better than the others in all contexts. Because we want to measure the impact of our recommendations on dropout prediction, and the individual courses are relevant accordingly, we use the courses taken by students as features and the grades obtained by students as their values.

Model training. To detect a change in the dropout risk in step 2, the models should be as accurate as possible which we aimed to

achieve through two approaches: A) train different types of algorithms including hyperparameter optimization (Logistic Regression, LASSO Regression, Decision Tree, k -Nearest Neighbors, Support Vector Classifier with different kernels (radial basis function, linear, polynomial), Random Forest), and B) use algorithm-independent parameters for optimization since we realized that hyperparameter optimization alone was insufficient. B1) Feature selection: we removed features with a low number of actual grades and tried different thresholds as a minimum number of actual grades for a course: (1, 5, 9, 19). B2) Training data balancing: we used two common techniques: Synthetic Minority Over-sampling Technique (SMOTE) [3] and RandomOverSampler (ROS). Both implementations are from the Python library `imbalanced-learn`. B3) Decision threshold moving: Usually, a classifier decides for the positive class at a probability greater or equal to 0.5, but in case of imbalanced data, it may be helpful to adjust this threshold, so we checked additionally to 0.5 the values: 0.1, 0.3, 0.7, 0.9.

Models selection. To emphasize that both correct dropouts and correct graduates are important for dropout risk prediction, we evaluated our models based on the test data with *Balanced Accuracy* (BACC) as the mean of the recall for class 1 (dropout) and recall for class 0 (graduate). The data sets sorted by the start of study were split into 80% training data and 20% test data, so that risk prediction is done for students who started their studies last. We trained models for both semesters $t=2$ and $t=3$ with actual grades and used the best models to evaluate a change in dropout risk in step 2. In both cases, RF achieved the highest BACC for step 1 (2nd semester: 0.859, 3rd semester: 0.935). The algorithm-independent parameters belonging to the models are: features selection (2nd: 0, i.e. no features were removed, 3rd: 1), decision threshold (2nd: 0.3, 3rd: 0.5), and balancing the training data (2nd: SMOTE, 3rd: ROS). Regarding hyperparameter optimization, we did not observe any improvements in BACC, which we relate to the small size of the training sets.

Step 2 dropout prediction. We used the selected models to predict dropout based on the recommendations. Since we assume the student will pass the recommended courses, we need a grade between 1.0 and 4.0 for step 2. If we had a grade in the records for that student and a recommended course, we used it. If the student had dropped the course or failed it, we imputed the average of two medians: the median of all the grades that the student has earned so far and the median of the historical grades for that course. We evaluated this imputation with the data we use in this work and obtained an *Root Mean Square Error* (RMSE) of 0.634, which is comparable with the RMSE from 0.63 to 0.73 in [4, 15].

Results. Table 3 shows three proportions of students who are predicted as dropout (P1, P2_AN, P2_GN) and the differences between these proportions. P1 is the prediction based on actual enrollment and exam data. P2_AN corresponds to step 2; the dropout prediction uses the courses recommendations calculated with all neighbors while P2_GN uses the recommendations calculated with graduate neighbors. The differences in the number of neighbors k are not considered because no large differences emerged when k varied: P2_AN and P2_GN are the average values from the risk predictions, based on the test data set. The three columns on the right provide the differences in the predictions: P2_AN vs P1, P2_GN vs P1, P2_GN vs P2_AN. For example, 81.4% of the actual dropout students for semester 2 are predicted as dropout in the first prediction, 75.8% using AN-based recommendations, and 70.2% using GN-based recommendations. The dropout risk based on the GN recommendation is 5.6% lower than the prediction based on the AN recommendation.

Findings. It turns out that, with our strong assumption that students will pass the recommended courses, the risk of dropping out can be reduced. More precisely: The proportion of students predicted as dropout are lower when the predictions are AN- and GN-based in step 2 than using the actual enrollment and exam data in step 1. The GN-based recommendations provide a lower dropout risk compared to the AN-based recommendations. The proportion of students predicted as dropout are lower for the 3rd than for the 2nd semester using AN- and GN-based recommendation. The dropout risk reduction in step 2 is higher for dropouts than for graduates.

Table 3. Mean predicted risk in step 2 dropout prediction (P2) for recommendation types AN and GN compared to step 1 (P1) by student status ST (D, G) and semester (S).

ST	S	P1	P2_AN	P2_GN	P2_AN vs P1	P2_GN vs P1	P2_GN vs P2_AN
D	2	0.814	0.758	0.702	-0.056	-0.112	-0.056
	3	0.884	0.665	0.293	-0.219	-0.591	-0.372
G	2	0.096	0.074	0.060	-0.022	-0.036	-0.014
	3	0.014	0.047	0.005	0.033	-0.008	-0.041

8. DISCUSSION AND CONCLUSION

In this paper, we have presented an explainable course recommender system designed primarily to support students who are struggling after their 1st or 2nd semester at university. The recommendations are based on the explainable k -NN algorithm and are built by selecting the courses that most of the nearest neighbors who graduated have passed. We have evaluated our approach on historical data in two ways. First, we have compared the recommendations with the set of the courses that students have passed using the F_1 score. Second, we have investigated whether students are less likely of dropping out when following the recommendations. Further, we also have evaluated the impact of choosing nearest neighbors from the set of students who dropped out and graduated, our baseline, instead of choosing them only from the set of students who graduated.

The F_1 score evaluating the recommended courses is higher when the neighbors are chosen from the set of students who graduated, as can be seen in Table 2. It is particularly high, mainly over 80%, for students with the status graduate, which confirms that, for them, the recommendations match closely the courses that they pass. Consistent with this finding, the number of students who are predicted with the status dropout is smaller when the recommendations are used in the prediction rather than the actual data. Preliminary work shows that these findings generalize to other degree programs.

The results suggest that the provided recommendations would help more students to graduate if the recommendations are both ambitious and realistic: students indeed do pass the courses recommended to them. A closer look at the recommendations reveals that a small number of students receive an empty set, which should be examined in detail. Further, it still needs evaluations with students in their 1st or 2nd semester on how ready and willing they are to use such recommendations, and which extra support they need to pass all courses recommended to them. As stated by Falk et al. [6] in the German context, most of the time a combination of well-orchestrated interventions brings academic success.

In terms of k -NN, it would be worth testing multilabel learning as shown by Zhang and Zhou [20] and if the same approach could be used for planning over several semesters, as proposed by Erzhuo et al. [5]. Finally, we would like to investigate which other approaches are equally visualizable and explainable to students.

A deep reinforcement learning approach to automatic formative feedback

ABSTRACT

Receiving formative feedback about open-ended responses can facilitate the progression of learning. However, educators cannot often provide immediate feedback and thus for students, learning may be slowed. In this paper, we will explore how an automatic grading model can be coupled with deep Reinforcement Learning (RL) to create a system of automatic formative feedback on students' open-ended responses. We use batch (offline) learning with a double Deep Q Network (DQN) to simulate a learning environment, such as an open-source, online tutoring system, where students are prompted to answer open-ended questions. An auto-grader is used to provide a rating of the student's response, and until the response is scored at the highest category, an RL agent iteratively provides suggestions to the student to revise the previous version of their answer. The automated suggestion can include either a key idea to consider adding to the response, or a recommendation to delete a specific part of the response. Our experiments are based on a simulated environment, within which we anticipate a how a real student might revise their answer based on the agent's chosen hint. Preliminary results show that in such environment, the agent is able to learn the best suggestions to provide a student in order to improve the student's response in the least number of revisions.

Formative Feedback, Deep Reinforcement Learning, Automatic Short Answer Grading

1. INTRODUCTION

It has been shown that the use of open-ended (OE) items is beneficial for student learning by self-explanation [2], or information recall [1]. Additionally, receiving formative feedback – information communicated to the learner intended to modify his or her thinking/behavior to improve learning – about OE responses may also contribute to the progression of learning for students [16]. However, assessing OE items

and subsequently providing formative feedback is time consuming for teachers [6] and consequently, feedback to students can be delayed.

We suggest the use of educational technology to help mitigate this issue. Technologies like online learning platforms or intelligent tutoring systems can enable students to take a proactive role in assessing their own abilities. In addition, they can help promote equitable learning for students who do not have the resources to receive quick and individualized feedback from a human tutor, parent, or private educator. Such platforms have the capability to provide instant feedback, allowing for students, of all types, to take control of their own learning through real-time formative self-assessment [11]. However, items that elicit instant feedback necessitate a structure for automatic grading, and the creation of useful feedback. While implementing automatic grading and producing related feedback for multiple choice items is seamless, as a student's response is limited to a small number of choices, it is not so simple for OE questions that elicit an infinite number of potential student responses.

In this paper, we explore how an Automatic Short Answer Grading (ASAG) model can be coupled with deep Reinforcement Learning (RL) to create a system that provides automatic formative feedback for students' OE responses. We will use batch (offline) learning to simulate an environment, such as an open source tutoring system, where students are prompted to answer OE questions. Once the ASAG model provides a rating of the response, the RL agent will give a hint to the user by suggesting either a key phrase that the user might consider adding to the response, or a portion of the response that the user might want to delete when revising their answer. The student's revision will be simulated by either the key phrase being added to the previous response at the agent's chosen index within the response, or the portion to consider removing deleted completely. The new response will be once again sent to the auto grader to be classified. This process will continue until the automated rating has reached some defined threshold (as a function of the reward), or a maximum number of hints has been provided.

The key idea of our work is to train an RL agent to choose the best sequence of revisions for an OE response, in order to arrive at an exemplary response in the least number of revisions. Although the space of student responses to a given question is infinite, we hypothesize that the agent can

learn which of a finite set of revisions will be most useful to improve a student’s answer.

The main contribution of this work is to explore a real-world application of deep RL. There has been little work so far studying the use of deep RL in educational contexts, and in addition, coupling deep RL with language models (the auto grader) has not been extensively investigated. In this paper, we will briefly describe the ASAG, but will mainly focus on the implementation of the deep RL algorithm.

2. RELATED WORK

Several works have focused on the use of RL for applications in education. Reddy et. al (2017) created a model-free review scheduling algorithm to learn a policy that operates on raw observations of a student’s study history, as opposed to explicitly modeling the student as employed by other scheduling algorithms [13]. Iglesias et. al (2009) used RL within a pedagogical module of an education system such that the system would automatically learn which pedagogical policy was best for a particular student [7]. Dorça et. al (2013) presented an automatic probabilistic approach for modeling student’s learning styles based on reinforcement learning [5]. They show that because of the dynamic aspects of detecting learning styles, the RL agent is able to constantly adjust to a student’s performance. Park et. al (2019) introduced an RL “social robot” for personalized and adaptive education [12]. They illustrate how the agent can utilize children’s verbal and nonverbal affective cues to exert influence over the student’s engagement, in order to maximize long-term learning gains. Rowe et. al (2015) employ modular RL, a multi-goal extension of classic RL, to dynamically tailor narrative-centered learning to particular students’ needs [14]. They show that including a data-driven, planning approach can enhance student learning. Finally, Shawky & Badawi (2018) use RL to build an intelligent environment that provides a method to account for the continuously-changing states of student learners [15].

3. BACKGROUND

In this section we will provide a brief overview of the methods used in our work necessary to understand the results, including the ASAG model, offline (batch) learning, Q-learning and Epsilon-greedy sampling.

3.1 Deep Reinforcement Learning

Reinforcement learning (RL) employs learning to control a dynamical system by providing feedback to an agent, via a reward system, in order to choose an action to take in a given state. The action consists of what the agent can do in the state, where the state represents the current condition of the agent. When the agent takes an action, it receives a reward (either positive or negative) as feedback from the environment. Thus, the agent learns a policy to maximize its total expected sum of rewards. The system can be defined as a fully or partially-observed Markov decision process (MDP) [17].

Deep RL utilizes high-capacity function approximators - deep neural networks - as the policy, in conjunction with RL. The incorporation of deep networks has improved performance for applications of RL in many domains [8]. With deep RL,

the agent can make decisions from unstructured data without any manual engineering of the state space and the algorithms can handle very large amounts of data for learning an optimal policy.

3.2 The ASAG model

The Automatic Short Answer Grading (ASAG) model that we use to provide an initial rating of student responses, as well as feedback to the agent through a reward function about the chosen action (response revision), is a BERT-base multi-class classification model. The BERT transformer language model, introduced in [4], is pre-trained on large amounts of natural language text from Wikipedia and BooksCorpus, and can be fine-tuned for downstream tasks such as classification. We use a compressed version of the model called BERT-base, and fine-tune the model as a supervised classifier using human ratings of the OE question(s) as ground-truth ratings.

3.3 Offline (batch) learning

Traditionally, RL algorithms employ online learning by iteratively collecting experiences, i.e. data, while actively interacting with the environment. The collected experiences are used by the model to improve the policy [17]. For some applications, however, using online data collection can be resource heavy or dangerous or impractical for settings that necessitate a large dataset [8]. In contrast, offline RL algorithms utilize previously collected data. Data is stored in a replay buffer and is not altered during training, allowing for the incorporation of very large, or pre-existing datasets. Issues posed by fully offline-learning algorithms include, most prominently, a vulnerability to distributional shift.

3.4 Deep Q Learning

Q-learning is categorized as a model-free reinforcement learning algorithm - i.e. it does not use the transition probability distribution or the reward function associated with the MDP. Essentially, the model-free algorithm is based on trial-and-error. For any finite MDP, the Q-learning algorithm will find an optimal policy that maximizes the expected total reward over all steps in the sequence, starting from the current state [9]. The Q-function determines the value of a state-action pair through the given reward. Deep Q-learning is a variant of Q-learning where a nonlinear function approximator - a neural network - represents Q.

4. TRAINING THE RL AGENT

In this section, we describe the dataset used for initial results as well as the RL formulation consisting of the state, reward, and action set.

4.1 The Dataset

To evaluate our proposed methods, we take the most simple approach and use only one OE science question from an open-source data set called the Automatic Student Assessment Prize, Short Answer Scoring data (ASAP-SAS). The data was used in a 2012 Kaggle competition¹ sponsored by the Hewlett Foundation, and consists of almost 13,000 short answer responses to 10 science and English questions. The questions were scored from 0 (most incorrect) to 3 (most

¹<https://www.kaggle.com/c/asap-sas>

correct), and each question includes a scoring rubric. We chose the question that achieved the highest validation accuracy, evaluated with a Cohen’s Kappa Metric, with the automatic grading model. We did so such that the reward signal, as it is a function of the autograder, would be strong and consistent, rather than using a question that the autograder has a difficult time scoring and may subsequently provide inconsistent reward feedback to the agent.

The question prompt asks students to *“List and describe three processes used by cells to control the movement of substances across the cell membrane.”* And the rubric states that an answer rated at the highest level will include three correct processes, down to the lowest level which will include zero correct processes. Examples of key statements that can/should be included in an answer, according to the rubric, include: *“Selective permeability is used by the cell membrane to allow certain substances to move across”,* or *“Osmosis is the diffusion of water across the cell membrane”*. The list of key statements include in the rubric drove the action space selection of phrases that the RL agent can add to a response (to simulate suggesting that a student consider the information in their revision).

4.2 The Algorithm

An overview of the proposed algorithm is as follows. For each episode, we will first initialize by randomly sampling one of the student’s short answers. The student answer text will be vectorized and fed to the agent. Based on this state input, the agent will choose an action to take, i.e., either adding a key phrase or deleting a portion of the response. This simulates the student taking the hint into account when revising their answer. Next, we send the new student response to our language model classifier, and receive a probability distribution of rating categories as output. Then we will calculate our reward as a function of the difference in class probabilities from the previous response, to the newly revised response, such that an increased probability of the highest rating category for the revised response would correspond to a higher reward. If the response has reached a high rating, the episode will terminate. Otherwise, the process is repeated with the revised student response (the original response plus the hint phrase, or minus the deleted portion) as the new state, and the agent will choose another action until the highest rating is achieved, or we reach a pre-defined maximum number of revisions. Details of the process are described below.

4.2.1 The State

The state is primarily represented by a student’s response. As our RL agent will not take in words as input, we vectorize the student responses using a Word2Vec [10] model, with embeddings of size 8, and a vocabulary specific to our dataset. Word2Vec produces an embedding for each word in the vocabulary, so in order to create one embedding for the entire response, we concatenate the individual word embeddings. W2V embeddings of size 8 are particularly small, but we chose to sacrifice some information within the word embeddings in order to keep our state space at a reasonable size. Additionally, we concatenate each word embedding instead of averaging them, which is a common method for producing sentence embeddings because we want the agent

to have a capacity to interpret the response at the word level, and not only as an aggregate response.

4.2.2 The Reward

The reward is a function of the difference in the ASAG model’s classification probability distribution of ratings between the old response and the revised response, with a penalty for each revision the agent makes. We include the penalty (subtracting 1) because we want the agent to learn how to revise the student’s response in the least number of revision steps. Additionally, we more heavily weighted the higher rating category probability changes because we care more about a change in the highest rating probabilities, as it is the ultimate goal to achieve the highest level rating. Finally, we multiply the weighted difference in probabilities by three, because the overall difference tended to be small, and we needed to send a stronger signal to the agent. The Reward formula is as such, where Δp_0 represents the difference in probability of the 0 rating category between the new and old response:

$$3 \cdot (0 \cdot \Delta p_0 + 1 \cdot \Delta p_1 + 2 \cdot \Delta p_2 + 3 \cdot \Delta p_3) - 1$$

4.2.3 The Action Space

The action space consists of both adding key phrases to the response or deleting a portion of the response. The agent can choose only one revision (one addition, or one deletion) in each step. The key phrases the agent can add must be pre-defined by either a subject-matter-expert or created based on a detailed scoring rubric, in order to determine what is necessary for a student to include in their explanation to achieve a high rating. For the question in our initial experiment, *“List and describe three processes used by cells to control the movement of substances across the cell membrane.”*, the list of 10 key phrases that the agent can choose from are shown below.

[‘energy to move’], [‘across cell membrane’], [‘diffusion substance across’], [‘active transport requires’], [‘osmosis water across’], [‘passive transport requires’], [‘no energy move’], [‘from high concentration’], [‘to low concentration’], [‘with concentration gradient’]

The phrases are vectorized with Word2Vec the same way the response is for the state space. The phrase can be added to the response at any index in increments of 3 (i.e., the phrase can be added to the very beginning of the response at index 0, or three words in at index 3, etc.). We hypothesized that it is necessary that the agent chooses where, within the response, the phrase will be added. Additionally, the action space includes removing any one trigram within the response. We limited the flexibility of the agent removing text to trigrams to keep the action space at a reasonable size. With a larger action space, it is reasonable to assume that the agent will take much longer to learn.

4.2.4 The Q Network

The Q-Network consists of a fully connected neural network with two hidden layers of size 300 and 200. The final layer corresponds to the dimension of the action space. In addition, both hidden layers use an Rectified Linear Unit (ReLU) activation function. As input, the network takes in the state space (vectorized student response) and outputs an estimate

Figure 1: Sum of rewards over 80K training episodes.

of the expected future sum of rewards of each action in the action space. Thus, the agent chooses the action that has the maximum Q Network output. Our algorithm is optimized using Adam stochastic optimization [3]. The size of the replay buffer for the Q-Network is 10,000. In addition, the Q-Network is trained with a batch size of 32, a discount factor of 0.99, and a learning rate of $5e-4$. We update the target network every 4 episodes.

5. RESULTS

Preliminary results shown in Figure 1 imply that the agent is indeed able to learn which revisions to make to a response in order to achieve a higher rating from the autograding model. Figure 1 shows the sum of rewards in an episode on the y-axis, and the episode number along the x-axis. The scale or number of the y-axis is not necessarily meaningful, as our reward function is only created as a means to give signal to the agent about the goodness of its sequence of decisions. Rather, the overall pattern of the reward becoming less negative, i.e. greater, as the training episodes increase shows us that the agent can learn, over many episodes of trial and error, an optimal policy to choose which actions to take, in order to maximize its future sum of rewards. It is worth noting that with limited computational resources, training the agent over 80,000 episodes is not quick, so future work will indeed include training over a greater number of episodes, to see if the agent can achieve a somewhat convergence to a higher total episodic reward than is shown in Figure 1.

6. DISCUSSION

We emphasize that this project is a work in progress and acknowledge that there is much more effort needed to explore the agent’s capacity to revise a student’s response. We believe that it is an important and successful first step to observe that the RL agent is indeed able to learn the task that we proposed, as there exist many sequential tasks that may not be appropriate for the RL formulation, or are too complicated for an RL agent to learn. Using a reward that is a function of a language model poses a unique challenge as we adopt the limitations of the autograding model itself

into our reward formulation. Additionally, using concatenated word vectors as a state space adds an additional layer of complexity because the variability in the state space is infinite, as any student may use an infinite combination of words in their response.

More importantly, we note that there are several practical application of an RL agent revising a student’s response. Our results are from a simulated environment that is meant to represent a real-life student interaction, but does not do so perfectly. When thinking forward to the real-life application of implementing the algorithm in the context of a real student revising their answer, many unanswered questions arise. Firstly, we assume that a student will take into account the RL agent’s revision suggestion directly in our simulation (the agent automatically adds the key phrase or deletes the segment), but a real student will have the choice to consider the suggestion or ignore it and make a different revision. This may pose confusing signals to the agent about whether or not the suggestion was the best one. Further, we must investigate how exactly to provide the hints, as formative feedback, such that the student actively learns from their revision.

ABSTRACT

Domain modeling is a central component in education technologies as it represents the target domain students are supposed to train on and eventually master. Automatically generating domain models can lead to substantial cost and scalability benefits. Automatically extracting key concepts or knowledge components from, for instance, textbooks can enable the development of automatic or semi-automatic processes for creating domain models. We explore in this work the use of transformer based pre-trained models for the task of keyphrase extraction. Specifically, we investigate and evaluate four different variants of BERT, a pre-trained transformer based architecture, that vary in terms of training data, training objective, or training strategy to extract knowledge components from textbooks for the domain of intro-to-programming. We report results obtained using the following BERT-based models: **BERT**, **CodeBERT**, **SciBERT** and **RoBERTa**.

Keywords

Domain modeling, knowledge component extraction, key phrase extraction, transformer based models, Intelligent Tutoring System

1. INTRODUCTION

Computer-based adaptive instructional technologies, our focus, must have a representation of the target domain, i.e., a domain model. Hence, there is a need for domain modeling, which specifies the key knowledge components or units of knowledge that students have to master in a target domain, such as physics, biology, or computer programming. Furthermore, a domain model should include a structure that specifies the relationship among the knowledge components, typically in the form of a prerequisite knowledge structure suggesting which basic concepts must be mastered before

more complex concepts that rely on the basic concepts, e.g., addition should be mastered before multiplication [14, 17, 8]. The prerequisite knowledge structure of a domain model implies a specific trajectory or trajectories towards mastery that students must follow. According to some, a domain model should also include links to related learning objects, i.e., instructional tasks, which help students practice to master the targeted concepts. More recently, A broader view of the domain model has been argued, which should include all the key concepts, skills, ideas, principles, and the values, identity, and epistemology of the community of experts or professionals active in the target domain [1].

Domain models can be developed from different information sources: experts, textbooks (written by domain and pedagogical experts), and learner performance data. Expert-driven approaches to domain modeling are expensive, time-consuming, and not very scalable within and across domains. To overcome these challenges, automated or semi-automated approaches are much needed. This work explores such novel automated methods for domain model discovery from textbooks, specifically for the target domain of intro to computer programming. In particular, we explore to what extent the process can be automated. While the proposed methods are fully automated, their output is not perfect, which means a human expert must be involved to curate the output before being used in an existing adaptive instructional system. Nevertheless, this semi-automated process is much more cost-effective and scalable than the manual approach to building domain models. It should be noted that another source of information for domain modeling for programming that has been explored in the past is code itself, e.g., using a Java parser [18, 38, 15].

There are two advantages of using textbooks to extract domain models for programming compared to using code only. First, textbooks contain both code examples and textual explanations of the concepts, which is advantageous for higher-level concepts such as sorting, which is challenging to infer from a block of code that implements it. Second, concepts extracted directly from code are difficult to interpret and are often programming language-specific constructs. A textual description can accompany the grammar of a programming language in the form of comments or descriptions, but this requires substantial additional expert involvement. Build-

ing more interpretable automated ways to extract domain models from source code is an interesting research topic beyond this paper’s scope. In this work, we experiment with a pretrained transformer-based model to extract key concepts or knowledge components from computer science (intro to programming) textbooks. We use the code examples in textbooks, but we do not parse them to extract candidate key concepts but to rank the concepts extracted from the textual explanations.

Transformer-based pretrained models, which are trained on massive unlabelled text collections, have been successful in various NLP tasks such as keyphrase extraction [3, 33] which is relevant to this work. However, with the rise of many pretrained models for various specific tasks, there is a need to explore which of these pretrained models are helpful for what tasks. In this work on domain model discovery for computer programming, we explore an overgeneration-and-ranking approach for keyphrase extraction using four pretrained transformer models: BERT[11], CodeBERT[13], RoBERTa [25], and SciBERT [2]. These pretrained models vary in different aspects, such as training data and training mechanisms. For instance, BERT is trained on general domain corpora such as news articles and Wikipedia, RoBERTa is trained on a larger dataset of English language corpora consisting of books, news, web text; SciBERT is trained on papers on computer science and biomedical domain whereas CodeBERT is pretrained in NL-PL (Natural language-Programming language) pairs for multiple programming languages. In this study, we experiment with embeddings obtained from each of these methods to evaluate and compare domain-specific models such as CodeBERT and SciBERT versus models such as Roberta and BERT trained on general corpora for the tasks of keyphrase extraction and subsequently domain modeling.

The paper is organized as follows. Section 2 discusses relevant works to domain modeling. In section 3, we detail the methodology followed to generate domain models from textbooks. Section 4 presents the evaluation dataset and the metrics used to evaluate the performance of the pretrained models. A conclusion section follows the results.

2. RELATED WORK

Our work focuses on extracting key knowledge components from textbooks using embeddings obtained from transformer based pretrained models in an unsupervised manner. This section presents most relevant prior works to concept extraction, unsupervised keyphrase extraction, and pretrained models in NLP.

Concept extraction or identifying important concepts that a learner should master has been studied for various applications in the educational domain, such as concept-based textbook indexing (adaptive hyperbook for constructive teaching, Elm-art [5]), concept prediction [19], and concept hierarchy creation [36]. Concept extraction is related to keyphrase extraction, which is extracting the most important concepts in a given document. Keyphrase extraction has been explored using different approaches: rule-based, supervised, and unsupervised including deep-learning [30]. Typically, keyphrase extraction consists of two steps: candidate generation and ranking. The first step extracts key concepts

based on heuristics, such as all noun phrases, while the second step ranks the extracted candidate phrases based on scoring rubric that indicates the importance of the candidate phrase for the document and/or goal. In our work, we use unsupervised embedding-based ranking methods for candidate concepts generated from sections or subtopics in chapters in intro-to-programming textbooks. We consider a subtopic as a reference document when assessing the importance of each candidate key concept.

Existing unsupervised keyphrase extraction methods can be broadly categorized as statistics based such as TF-IDF, e.g., KP-Miner [12], graph-based such as TextRank [27], SingleRank [35] and topic-based methods such as TopicRank [4] even though many of the works use a combination rather than a single approach. Recent advances in representational methods of words, phrases and documents like Word2Vec [28], Doc2vec [20], and Sent2vec [29] led to novel ranking methods for keyphrase extraction [3, 23, 33]. For instance, EmbedRank [3] uses sentence embeddings based on Doc2vec or Sent2vec to represent candidate phrases and the document in the same high dimensional vector space based on which a ranking of the candidate key concepts is obtained using the cosine similarity score between the embedding vectors of the candidate phrases and the documents. Our work is similar in the sense that we use pretrained embeddings for keyphrase extraction in the context of domain modeling.

Embeddings obtained using transformer [34] based pretrained models [31, 32, 37] have shown dramatic improvements in various tasks in different domains such as software engineering, computer vision, and education. The reason behind this improvement is the high-quality semantic representations. Models such as BERT have been trained on different domain-specific data, some examples being BioBERT [21] in biology, legalBERT [7] in legal documents, SciBERT in scientific articles, and CodeBERT on code and natural language text pairs. To the best of our knowledge, experiments on how these embeddings affect the downstream task of knowledge component extraction and consequently on domain modeling have not been done before. In this work, we experimented with embeddings obtained from four BERT models, BERT, CodeBERT, SciBERT, and RoBERTa, for knowledge component extraction and the larger task of domain modelling.

3. METHODOLOGY

Our method to extract knowledge components from intro-to-programming textbooks is based on pretrained embeddings inferred from various BERT-based models. To evaluate the automated methods, we annotated a dataset by selecting key concepts for each section in five randomly selected chapters in two textbooks. As noted, we rely on an overgeneration-and-ranking approach for key concept extraction. The embeddings are mainly used to rank the key candidate phrases. Since textbooks for intro-to-programming contain both code examples and related explanatory text, we can use bimodal pretrained models such as CodeBERT trained on both text and code. Even though we provide code to the CodeBERT model as input, the model is used only for ranking candidate keyphrases, i.e., our approach and evaluation is based on candidate concepts generated from the textual parts of the textbooks. We could consider statements, code blocks,

and code comments as sources of candidate concepts. However, we limit the scope of this work to candidate concepts from the textual part of intro to computer programming textbooks.

In this section, we explain the preprocessing steps, such as candidate concept extraction, phrase and document embedding generation, and candidate concept ranking. We also discuss the performance metrics of specificity and relevancy. Before applying methods related to candidate concept extraction, we resolve pronouns in the text to boost our knowledge component extraction methodology by resolving pronouns such as 'it', 'this', and 'their' using a pretrained deep learning model [22] based on span ranking architecture.

3.1 Candidate Concept extraction

The step of candidate concept extraction consists of noun phrase extraction and filtering. We used Stanford CoreNLP Tools ¹ for tokenizing, part-of-speech tagging, and noun phrase chunking. We only considered noun phrases which are unigrams (one token), bigrams (two consecutive tokens), trigrams (three consecutive tokens), and quadgrams (four consecutive tokens), for candidate generation.

3.2 Phrase and Document Embedding

From the prior step of generating 3.1 candidate phrases we obtain a tokenized form of a document D represented as $D = t_1, t_2, t_3, \dots, t_N$ where t_n represent tokens. We also obtain a list of candidate phrases C_0, C_1, \dots, C_N . Based on this, we then obtain contextualized embeddings for each of the tokens as shown by the Equation 1.

$$E_1, E_2, E_3, \dots, E_N = Model(t_1, t_2, t_3, \dots, t_N) \quad (1)$$

where E_n represents embeddings of each token, and the model refers to any of the four pretrained models we chose: BERT, CodeBERT, SciBERT or RoBERTa.

Each document embedding is obtained using average pooling across all the tokens of the document. Similarly, to obtain embedding for each candidate phrase from a document, we average across embeddings of tokens. Although the best pooling strategy is still an area of active research, we opted for the average pooling strategy as it has shown better performance than using the output of the first token [CLS] for different tasks[9].

3.3 Ranking

We have experimented with a number of ranking and performance metrics as presented in this section.

3.3.1 Cosine Similarity

Once the embeddings for each document and phrase are obtained, we compute the cosine similarity (normalized dot product) between the phrase and document embedding vectors. The cosine similarity scores for candidate phrases capture the semantic 'relatedness' or 'closeness' of a phrase to the underlying document. Those scores are used to rank candidate phrases.

¹<https://nlp.stanford.edu/software/tagger.shtml>

3.3.2 Adjusted Maximal Marginal Relevance To Balance General and Specific Concept Ranking

Our goal is to extract all important knowledge components of a target domain. A challenge to this coverage problem is that key concepts can have different granularity levels, making it more challenging to design a single metric that ranks more general and more specific concepts highly.

For instance, in the context of a chapter focusing on the concept of 'loop', some of the important key concepts are 'for loop' or 'while loop', which are broad, high-level types of loops. Nonetheless, a more specific concept such as a nested loop or loop continuation condition is important too.

In order to extract both the general and specific concepts, candidate key phrases must be similar to the current document and less relevant to other documents. Furthermore, in order to rank higher topic-specific concepts so that top k candidates consist of more topic-specific concepts, we modified the Maximal Marginal Relevance (MMR) [6] metric, which was used initially in information retrieval and text summarization to control relevancy and diversity of retrieved documents. The embedding-based keyphrase extraction method proposed by Bennani-Smires et al. [3] used a modified version of MMR to tackle redundant key phrases from a document. In our case, we modify MMR to balance through the control parameter λ general and specific key candidate phrases.

As indicated in the equation 2, we balance the similarity of a candidate phrase C_i to the current document doc , which is captured by the first term on the right-hand side of the equation, with its similarity with other documents which is indicated by the second term that represents the similarity between the candidate phrase C_i from all the other N documents in the corpus.

If a candidate phrase is highly relevant to a document other than the current document, the similarity measure with the current document is penalized, indicating the term is not specific enough to the current document.

$$MMR_{adjusted} := \arg \max_{C_i \in K} \left[\lambda \cdot \text{sim}_1(C_i, doc) - (1 - \lambda) \max_{doc_j \in N \setminus doc} \text{sim}_2(C_i, doc_j) \right] \quad (2)$$

4. EXPERIMENT AND RESULTS

As already noted, we experimented with four pretrained models and evaluated their performance on a dataset that we built.

4.1 Dataset

The evaluation dataset was built based on sections from two intro-to-programming textbooks, "Introduction to JAVA programming" [24] and "JAVA How to program" [10]. From each of the two textbooks, we randomly selected 20 sections that focus on some specific concepts such as 'while-loop,' 'sorting arrays,' and 'exception handling overview.'

For each of the 20 sections, two computer science graduate students manually extracted the key concepts using a

two-phase annotation scheme. In the first phase, each annotator selected key concepts. The inter-annotator agreement in this phase was 0.7 as measured by Cohen’s Kappa [26]. Then, annotators discussed iteratively and extensively until a final agreement was reached. The resulting key concepts form our gold standard for evaluating the proposed methods. We have also asked each annotator to rank the gold standard concepts. This ranking is used for another performance metric that compares the automated ranking to the human ranking.

4.2 Evaluation Metrics

We evaluated the four pretrained models using two approaches. First, we evaluated the key concept extraction using precision, recall, and the F-score at rank k for $k = 5, 10, 15$. This evaluation approach is widely used in key-phrase extraction systems[30]. The other evaluation approach is based on the Normalized Discounted Cumulative Gain at p ($NDCG_p$) [16]. $NDCG_p$ compares the target ranking to the positions that key concepts occupy in the gold standard ranking and penalizes any mismatches. We opt for this evaluation to evaluate the extracted concepts based on $MMR_{adjusted}$ ranking method described earlier.

4.3 Results

First, we report results based on precision, recall, and F-score for top k ranks where $k = 5, 10, 15$ using cosine similarity-based ranking. We also report results for $NDCG_p$ where $p = 10$ using adjusted MMR metric with $\lambda = 0.5$ and $\lambda = 1$. The $NDCG_p$ ranking results obtained using $\lambda = 1$ for adjusted MMR metric is same as ranking using cosine similarity only. Since the average number of key concepts per section in the gold standard is 11, we chose $p = 10$ for normalized discounted cumulative gain ($NDCG$) reporting.

Table 1: Precision, recall and Fscore at 5,10,15 for knowledge component extraction

K	Model	P	R	F
5	BERT	0.66	0.423	0.499
	CodeBERT	0.54	0.342	0.405
	RoBERTa	0.5	0.288	0.354
	SciBERT	0.58	0.41	0.480
10	BERT	0.578	0.659	0.597
	CodeBERT	0.456	0.521	0.473
	RoBERTa	0.522	0.589	0.538
	SciBERT	0.533	0.608	0.55
15	BERT	0.516	0.801	0.615
	CodeBERT	0.367	0.578	0.442
	RoBERTa	0.434	0.673	0.516
	SciBERT	0.483	0.745	0.576

Table 1 shows Precision, recall and F-scores for different pretrained embeddings for $k = 5, 10, 15$. We can see that BERT has the highest precision, recall, and F-score for all the values of k . Similarly, SciBERT yields better performance compared to RoBERTa and CodeBERT. We can observe that even though CodeBERT is trained in NL-PL pairs for different programming languages, it does not provide any advantage over BERT. This might be because the training data for CodeBERT, which is specific to the code in Github, relates to higher-level software engineering concepts than intro-to-programming concepts. Also, the natural language

Table 2: Normalized Discounted Cumulative Gain($NDCG_{10}$) using $MMR_{adjusted}$ for $\lambda = 1$ and $\lambda = 0.5$.

Model	NDCG@10	
	$\lambda = 1$	$\lambda = 0.5$
BERT	0.83	0.87
CodeBERT	0.75	0.73
SciBERT	0.81	0.80
RoBERTa	0.76	0.77

texts used for training CodeBERT is mainly code documentation which might not be directly relevant to basic programming concepts. RoBERTa, even though trained with a different strategy and more data, does not show any better performance than BERT and SciBERT.

Also, it is evident from the results that SciBERT, trained in scholarly documents from computer science and biomedical domain, performs on par with BERT. The results show that even though BERT is not trained on any domain-specific data, it performs better than other models trained with more domain-specific or more data.

Table 2 shows the $NDCG$ score using $MMR_{adjusted}$ in equation 2. The results are obtained using $\lambda = 1$ which is equivalent to using cosine similarity only and $\lambda = 0.5$ which gives equal importance to the general and specific components in the adjusted MMR metric. As shown in the results, BERT outperforms other embedding methods similar to the evaluation results shown in Table 1 based on precision, recall, and F-measure. The value of $NDCG$ of all the models except for CodeBERT was higher when ranking was done using $\lambda = 0.5$ for $MMR_{adjusted}$ compared to value of λ set to 1.

5. DISCUSSION AND CONCLUSION

Our results indicate that we can use pretrained models for domain model extraction. We also noticed that even though models like CodeBERT and SciBERT are trained on domain-specific data, they did not provide any advantage mainly due to the nature of their training data. Our experiments also evaluated ranking based on Maximal Marginal Relevance to balance general and specific concepts. The main idea behind the evaluation was to check if adjusted MMR as we propose, ranks topic-specific concepts higher. Even though control parameter λ can be trained across different documents to get a more precise value based on cumulative gain we used 0.5 for key concept extraction using a relevance score based on Mean Marginal Relevance to provide equal importance to general and specific concepts. Evaluation based on Table 2 shows that $MMR_{adjusted}$ ranking obtained when $\lambda = 0.5$ is closer to gold-standard ranking or preferred ranking by human annotators.

ABSTRACT

E-learning preparedness in higher education is an important aspect that determines students' interaction behaviors within online learning environments. This study is primarily motivated by the growing evidence pointing to the importance of constructing fair and unbiased learning analytics in higher education. The primary goal of this study was to examine the impact of potentially bias-driven variables in predictive learning analytics models. We used an empirical data set collected from 123 undergraduate students who participated in a remote asynchronous course in Fall 2021. Our study adopted various statistical and machine learning techniques to remedy the biased prediction behaviors in learning analytics. First, we conducted a path analysis to evaluate the connection between students' e-learning preparedness and their interaction within the e-learning system. We simulated a large synthetic dataset from the empirical dataset and adopted two fair artificial intelligence algorithms—Seldonian and Adversarial Networks algorithms. Our findings indicated that e-learning preparedness is significantly related to the commonly adopted temporal features in learning analytics, such as time-use entropy ($b=.449, p<.001$) and assignment submission time ($b=-.587, p<.001$), and indirectly associated with students' course performance ($b=.219, p<.001$). Both algorithms indicated that bias-reduced algorithms performed comparably worse than the naive algorithms in predicting students' performance (f1-score=0.72); however, they produced less biased predictions after taking students' e-learning preparedness into account. A significant shift in model weights were observed, where the models tended to emphasize the importance on the variety of activity sequence than the temporal information.

Keywords

Fairness in AI, Learning Analytics, E-learning preparedness, Seldonian Algorithm, Adversarial Networks

1. INTRODUCTION

The sudden instructional and pedagogical changes that the COVID-19 pandemic has brought in higher education have been tremendous. The recent U.S. statistics indicated that more than 52% of college students had to participate in remote learning during the year 2019-2020. Many universities and college-level courses that are designed for face-to-face in-person learning, transitioned online. Instructors prepared asynchronous or synchronous remote learning courses with lecture videos and learning materials to

accommodate the changes. Learning analytics systems were introduced to support managing distance learning for higher education institutions. Learning analytics frameworks adopt various statistical and machine learning techniques to enrich evidence-based instructions [1]. Many of the previously introduced learning analytics systems in higher education focused on detecting at-risk students [5, 16] and predicting student success [17]. Higher education institutions gained the capacity to gather, manage, and access student learning information more closely with the wide adoption of distance learning. The adoption of various learning analytics systems opened opportunities for an in-depth understanding of students' learning progress.

Despite the interesting benefits that learning analytics systems brought to higher education institutions, a growing concern evolved in the fairness and equitable uses of learning analytics [8, 10, 23]. One of the many underlying fairness and bias-related issues in learning analytics concerns the incomplete consideration and critical evaluation of the nature of the data and data collection [25]. For instance, with the sudden shift to remote learning, a considerable number of students faced significant challenges that arise from a lack of preparedness for distance learning [2, 6, 19, 21, 22]. Faculties and instructors indicated some of the challenges they faced during this period, such as students' lack of basic resources and equipment to participate in e-learning, and disruptions to learning time due to poor internet connections [29].

Likewise, students may require a more reliable setup for learning at home with the appropriate gears and equipment to participate in remote learning. The varying level of physical and psychological preparedness for e-learning showcases the important underlying nature of data and data collection in learning analytics, especially during the rapid transition to online learning in higher education institutions. For instance, reaction-time or temporal features are commonly adopted for student success prediction [14, 15]. They evaluate time-related students' interaction attributes, such as how rapidly students react to the uploaded learning resources. The reaction-time features are often positively associated with students' self-regulated learning behaviors and improved learning outcomes in many learning analytics algorithms [20, 27]. This study takes a different view on how "fairness" could be acquired in learning analytics for higher education. Fairness in learning analytics was often discussed in the previous studies with the light on students' unique personal and demographic backgrounds (e.g., gender). Instead, we focus on how the learning analytics could potentially make biased decisions or predictions for the students with the lack of preparedness in e-learning. The following research questions were addressed in this study: (1) *Does students' level of e-learning preparedness relate to their interaction behaviors in an online course platform?* (2) *Does students' level of e-learning preparedness relate to their course performance in an online course?* and (3) *Does the bias-reduced prediction model, which*

takes students' e-learning preparedness into account, achieve significantly lower accuracy?

2 RELATED WORK

2.2 E-learning Preparedness

An exhaustive review of the past 20 years of the literature revealed interesting underlying dimensions of students' e-learning preparedness in higher education, although there is no consensus on what exactly preparedness or readiness is. Earlier studies focused on students' "readiness" in online learning. For instance, Smith et al. [24] identified students' psychological factors and personal attributes, such as their comfort with e-learning and self-management of learning, as two primary underlying factors which define students' readiness in e-learning environments. Their findings were replicated and confirmed by other researchers (e.g., [3]). Watkins et al. [28] expanded the definition of e-learning readiness with six dimensions, including the two unique physical environmental attributes, such as the "Access to Technology" and "Online Audio/Video", as well as psychological aspects as "Online Skills and Relationships", "Motivation", "Internet Discussions", and "Importance to their Success". Similarly, Holsapple and Lee-Post [12] suggested that e-learning preparedness should be measured in the primary three dimensions of students' technical competencies, lifestyle aptitudes, and learning preferences. Parkes et al. [21] proposed a shift in focus between readiness and preparedness. They focused on the "necessary" skills and competencies students need to be prepared for e-learning. For instance, students' competencies in "managing learning in the online environment", "interacting with the e-learning content", and the "e-learning communities", were identified as important dimensions to define one's preparedness for e-learning.

2.3 Fair Prediction in AI

The following two frameworks are introduced and adopted in our study to demonstrate the potential bias that presents in algorithm.

2.3.2 Seldonian Algorithm

The Seldonian algorithm [26] introduces a three-stage framework to prevent machine learning algorithms from making biased outcomes. The algorithm takes the data (D) and partitions it into two sets of D_1 and D_2 . Using the first part of the dataset, the algorithm selects a solution candidate, θ_c , which is likely to pass the algorithm bias safety test. Then, the second part of the data, D_2 is used as a safety set. The Seldonian algorithm allows safety constraints to be represented as $(g_i, \delta_i) \forall_i \in m$. $g: \theta \rightarrow R$ is a function that quantifies the safety of the solution and is the permissive probability of returning an unsafe solution. The safety constraint ensures that the algorithm could achieve $g_i(\theta, D) \leq 0$ to ensure a safe choice of solution candidate. When only one constraint is given, this constraint can be understood as an equalized odds constraint [11]. The equalized odds constraint is defined based on the true positive rate (or TPR) across groups that are designed to evaluate and compare the degree of bias in model performance. Assume that A is the sensitivity feature to create two groups (0 = unprepared, 1 = prepared in e-learning) and Y is a predicted outcome variable (1 = success in the course). The equalized odds are satisfied when both the true-positive and the false-positive rates are equal across the two groups (equation 2).

$$\begin{aligned} Pr(\hat{Y} = 1|A = 0, Y = 1) &= Pr(\hat{Y} = 1|A = 1, Y = 1) \\ Pr(\hat{Y} = 0|A = 0, Y = 0) &= Pr(\hat{Y} = 0|A = 1, Y = 0) \end{aligned} \quad (2)$$

Using the equalized odds constraint, the constraint, $g(\theta)$, can be expressed when we decide to create an equalized odds score that is smaller than 0.05. In other words, this constraint has the upper bound of 0.05 to account for the absolute differences between the accuracy in predictions between the two groups.

2.3.3 Adversarial Neural Networks

Adversarial networks are supervised learning techniques that systematically associates the uncertainties in the data generation process to represent the real-world setting more accurately. Given a set of probabilities, $Pr(X, Y, Z)$, which consists of the data X target, Y, and the contextual sensitive parameter, Z, in fair AI prediction, we aimed to develop a solution that maps $f(X) = Y$, with the classifier f that is robust to the value of Z. This process can be learned efficiently using the adversarial networks [9]. For fair AI models, we could constrain the predictive classifier f to satisfy a certain constraint which has to do with the sensitive parameter Z. The goal of our classifier is to learn the parameters θ_f which map $f: \chi \rightarrow S$. Hence, we minimize the cross-entropy loss function, $L_y(\theta_f)$ to obtain the parameters, θ_f . In the case of student performance prediction, $s \in S$ represents students' performance outcome. The initial inference of the classifier will be defined based on $f(X; \theta_f)$ and the value of $z \in Z$ will be unknown to the model now. This indicates that the model outputs the equal conditional probability for any $z, z' \in Z$ and $s \in S$ (equation 3).

$$Pr(f(X; \theta_f) = s|z) = Pr(f(X; \theta_f) = s|z') \quad (3)$$

3 METHODS

3.2 Data

Our dataset was collected from a total of 123 undergraduate students who are enrolled in an educational assessment course in a western Canadian university in Fall 2020. This course was traditionally delivered as an in-person course but transitioned to an asynchronous online course in Fall 2020. At the beginning of the semester, the students were provided with a "welcome survey" questionnaire. The questionnaire included four items evaluating students' physical and psychological readiness and preparedness for an online course (see Appendix). We recoded the responses to define a variable representing "e-learning preparedness" in an online learning environment. We hypothesized that the students who are physically well-prepared for the online course would currently be located at the same time-zone, have devices that are equipped with the required functionality to participate and interact with the course materials, and have reliable devices that are portable. This was based on the course outline and the requirements related to the course materials and assignments. Once the physical/environmental preparedness score is computed, it is combined with the psychological preparedness score. Final preparedness is represented as a binary score of those who are above (1) or below (0) average in environmental and psychological preparedness for online learning (see Tables 1 and 2).

3.3 Interaction Log Data

To understand students' learning behaviors within the online course module, we extracted a comprehensive list of students' behaviors and selected the deterministic features to construct a prediction model. To replicate commonly extracted features in prediction-focused learning analytics systems, we used a commonly adopted open-source automated feature engineering tool called *Featuretools*. It performs Deep Feature Synthesis to extract aggregative and transformative features from the interaction log data. The extracted features represent descriptive instances (e.g.,

absolute, count, mean, mode), as well as the advanced interactions (e.g., entropy, time since previous). This feature analysis framework was selected as they are frequently adopted in learning analytics [4]. In addition, we extracted a list of n-gram-based log activity features. The features represent a sequence of instructional activities that students frequently perform. A total of 132 unique activities are captured and classified into 14 overall categories. The n-gram-based features represented a frequent sequence of actions that students partake among these 14 activity categories. The feature and the values were extracted using a TF-IDF vectorization.

3.4 Path Analysis Model

We aimed to understand the association of students' e-learning preparedness with their interaction activities which are represented by the log features. We constructed a path analysis model using the empirical data collected from the undergraduate participants (n=123). The hypothesized model path model first controlled for the effect of students' familiarity with the course content (Familiarity) on the students' course outcome (Summative). This allowed us to evaluate the relationship between e-learning preparedness with other variables while controlling for the effect of familiarity. The path model evaluated the associations between the preparedness and interaction log activities. Two interaction log variables were selected from the final feature sets extracted in the previous stage. Last, the two interaction log features were related to the students' formative and summative course performance. Our hypothesized model evaluated the importance of preparedness in understanding students' interaction in an online course as well as the relationship with the course outcomes.

3.5 Simulation Setting

We used the distributional characteristics of the variables and the correlations among the variables in our empirical dataset to simulate a larger-size dataset (N = 10,000). The data simulation process consisted of several steps. First, we obtained the distribution parameters for the variables included in the path analysis model. Second, we calculated the target correlation matrix based on the observed correlations in the empirical dataset. Third, we checked the lower and upper bounds of the pairwise correlations for the given distribution parameters to ensure that the target correlation matrix is within the bounds. Next, we simulated the dataset using the *SimMultiCorrData* package [7] in R. Last, we reviewed the generated variables and the maximum error between the final and target correlation matrices.

4 RESULTS

4.2 Features

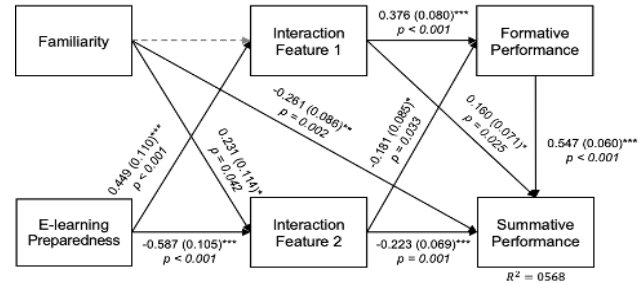

The survey results with the empirical dataset indicated that close to 32.5% of the students scored below the average in the total preparedness score. The rest of the students (67.5%) scored above the average. The e-learning preparedness score had a mean of 4.46 and a standard deviation of 1.61. The familiarity with the content with the total of 9 key concepts indicated the mean of 16.54 and the standard deviation of 6.55. The interaction log feature engineering using the Featuretools extracted a total of 137 variables. The n-gram tf-idf features extracted a total of 102 features to represent the frequency and the sequence of students' log actions. The feature dimension reduction process resulted in a total of 13 features.

4.3 Path Analysis Results

Figure 1 provides a diagram of the final path analysis model which is hypothesized and evaluated in our study. The path analysis results showed a good model-fit (CFI > 0.90, TLI > 0.90, RMSEA

<0.06, SRMR <0.09; [13]). The two variables representing students' interaction with the online course platform (Interaction Features 1 and 2) were also significantly associated with students' preparedness ($b=0.433$, $s.e.=0.073$, $p<0.001$; $b=-0.421$, $s.e.=0.074$, $p<0.001$). This was evaluated while controlling for the effect of students' familiarity with the course content. Interestingly, the familiarity of course content was significantly related to only one of the interaction log activities (interaction feature 1: $b=-0.022$, $s.e.=0.115$, $p=0.851$; interaction feature2: $b=0.231$, $s.e.=0.114$, $p=0.042$). This shows that the students' level of preparedness for e-learning is significantly related to their activities in online learning platforms when controlling for their familiarity with the material.

The level of interaction with the learning platforms were also significantly related to students' formative ($b=0.376$, $s.e.=0.080$, $p<0.001$; $b=-0.181$, $s.e.=0.085$, $p=.033$) and summative course performance ($b=0.160$, $s.e.=0.071$, $p=.025$; $b=-0.223$, $s.e.=0.069$, $p=.001$), respectively. The findings also showed that the interaction log activities which were highly associated with students' "E-learning preparedness" were also highly related to students' formative and summative performance. In summary, we observed a significant total indirect effect of e-learning preparedness on summative performance score ($b=0.219$, $s.e.=0.048$, $p<0.001$) with the direct effect that is statistically not significant ($b=0.107$, $s.e.=0.060$, $p=0.073$). This shows that students' preparedness in e-learning may not be directly associated with their online learning performance when controlling for the students' familiarity with the course content. However, e-learning preparedness was highly associated with students' interaction activities in online learning, which were highly associated with the performance outcomes. In summary, the path analysis model demonstrated the importance of acknowledging the presence of varying levels of "e-learning preparedness"

Model-fit: CFI (0.987), TLI (0.938), RMSEA (0.081), SRMR (0.042).

Figure 1. Path Analysis Model Results with Significant Paths.

4.4 Fair AI Prediction Results

4.4.2 Logistic Regression Performance

Table 3 (see Appendix) provides a comparison of Seldonian model performance results. The classification performance results were provided based on the binary target of students' summative performance that is created using the quantile cut-offs (0.10 - 0.90). The findings showed that the bias-reduced logistic regression (LR) models based on students' "E-learning preparedness" may not perform as well as the unconstrained LR model. It showed that our logistic regression algorithm could achieve the highest accuracy and f1-scores in classifying the target variable across all quantile cut-offs. The best classification performance of the unconstrained LR model achieved the f1-score of 0.95. Seldonian models with the bigger equalized odds values performed better (acc=0.72, f1-score=0.76 vs. LR acc=0.76, f1-score=0.80).

4.4.3 Adversarial Networks Performance Results

Figure 2 provides diagrams that represent the distribution of the prediction of unprepared (yellow) and prepared (red) students when using the adversarial networks. The evaluation results were based on classifying students' summative performance with the 0.40 quantile as a cut-off. The initial performance of the biased classifier achieved an accuracy of 0.74, f1-score of 0.78, and the AUC-ROC score of 0.81. The classification distribution indicated that students from the unprepared category showed a noticeably higher probability to be less successful in the summative assessment (see Figure 2 - Unconstrained). By contrast, the well-prepared students showed a higher probability to be successful. Likewise, the classifier showed relatively biased classification results with the AUC-ROC score of 0.66 to classify students based on their preparedness. After a total of 100 epochs, we noticed that the adversarial algorithm with a constraint (or bias-reduced model) achieved an accuracy of 0.63, f1-score of 0.72, and AUC-ROC of 0.63 in classifying students based on their summative performance outcome. The final algorithm could no longer differentiate the students based on their e-learning preparedness (AUC-ROC 0.51). This indicates the final model was well-trained to remove the potential influence from the bias classification. The last figure in Figure 2 provides a visual representation of the final model classification distribution comparisons. It showcases how the two distributions converged. We noticed that the final bias-removed model could acquire a relatively good classification performance.

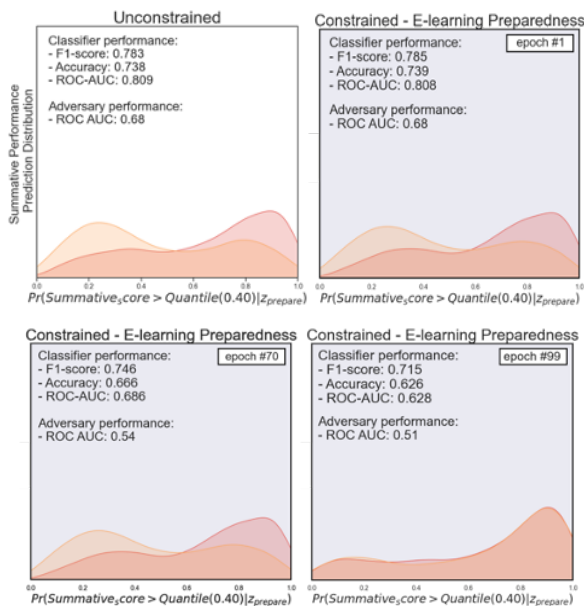

Figure 2. Unconstrained & Adversarial networks model results

We compared the final model weights of the biased model and the bias-reduced model. The relative impact of a total of 13 interaction log features (see Figure 3; Appendix) on classification was investigated using Shap [18]. The feature values (high or low, red, or blue) indicated the impact of the feature in producing higher or lower values in classification. Each dot (red or blue) represents the location of feature values in each sample. The x-axis represents the correlation between the final classification outcome and the feature values. The interaction log features were ranked in descending order based on their importance in classification. For instance, a high value in Feature 6 (red dots) was associated with the final classification (1=success) with a negative correlation (Shap values <0) in the biased classification model. Instead, the lower values

(blue dots) in Feature 6 were positively associated with the outcome classification in the biased model. By contrast, the lower values in Feature 10 were negatively correlated with the student success in the unconstrained model. Features 6 followed by the Features 10, 12, 4, 3, and 9 were identified as important and contributing features in the biased model to classify students based on their performance. Interestingly, the importance of features and direction of relationships with the outcome shifted quite drastically in the bias-reduced model. In the biased-constrained model, feature 2 was considered the most important, with its higher values (red) associated negatively with student success. Features 2 followed by the Features 10, 5, 4, and 6 were identified as important and contributing features in the bias-reduced model to classify students based on their performance. The direction of the relationship and the relative importance of Feature 10 remained the same for both models. Feature 10 represents the frequency of engaging in an activity related to learning resources (e.g., downloading).

5 DISCUSSION AND CONCLUSION

The primary goal of this study was to investigate the presence of the potentially biased behaviors of learning analytics models in higher education. We introduced empirical (N=123) and simulated (N=10,000) datasets of students' course logs to understand the biased-prediction behaviors of learning analytics models based on students' e-learning preparedness. Our study was conducted in two stages. First, we evaluated the association between students' e-learning preparedness and their online course performance outcomes. We specifically investigated the indirect (via the interaction log features) and direct relationship between the preparedness and summative performance outcomes (i.e., course exams). Students' interaction behaviors in the course were represented by the commonly adopted learning analytics features, such as their activity sequence and temporal information. Second, we investigated how the fair artificial intelligence (AI) models—Seldonian Algorithm and Adversarial Networks—could perform when attempting to reduce the bias in predicting students' performance outcomes. The two models were designed and implemented so that they could acknowledge students' varying levels of preparedness in participating in remote learning.

Our analytic framework using the path analysis model and two fair AI algorithms -- the Seldonian algorithm and the adversarial networks -- demonstrated efficient and effective means to evaluate the "e-learning preparedness" as a potential source of bias in learning analytics in higher education. We also visually demonstrated how the bias-reduced model shifted its model weights to emphasize the features that are potentially more robust to the (physically and psychologically) unprepared groups of students in remote learning. For future work, we aimed to generalize the findings with more empirical datasets in higher education settings, such as the e-learning interaction log datasets from different audiences and domains. We would like to examine how such dynamics differ as remote learning matures and students' preparedness (especially physical preparedness) changes with the consistent support from higher education institutions. Namely, our ultimate objective is to provide and promote less biased and more informative learning analytics in higher education, which could provide timely interventions to at-risk students. The findings from our study delineate the importance of careful consideration of the potentially biased source of information when constructing learning analytics models in a higher education environment. Our findings suggest that students' e-learning preparedness should be carefully considered to provide effective and diagnostic evaluation using learning analytics systems.

ABSTRACT

As computer-based learning platforms have become ubiquitous, there is a growing need to better support teachers. Particularly in mathematics, teachers often rely on open-ended questions to assess students' understanding. While prior works focusing on the development of automated open-ended work assessments have demonstrated their potential, many of those methods require large amounts of student data to make reliable estimates. We explore whether a problem specific automated scoring model could benefit from auxiliary data collected from similar problems to address this "cold start" problem. We examine factors such as sample size and the magnitude of similarity of utilized problem data. We find the use of data from similar problems not only provides benefits to improve predictive performance by increasing sample size, but also leads to greater overall model performance than using data solely from the original problem when sample size is held constant.

Keywords

Auto-scoring, Open-ended questions, Mathematics, Natural Language Processing, Machine Learning

1. INTRODUCTION

The development of online learning platforms [12, 10] have transformed the instructional practices and learning experiences in traditional and expanded learning environments. These online-based learning platforms offer automated supports for assessing students' work as well as providing feedback. While in the past these supports were generally restricted to closed-ended problems with a finite number of accepted correct responses, advancements in machine learning and natural language processing methods have led to the development of tools that support open-ended work [15, 4, 2]. As open-ended questions in mathematics are widely used by teachers to understand the students' knowledge state and

their understanding of a topic, these types of tools have great utility for both teachers and students using these systems.

Automatically scoring mathematical expressions and explanations has several distinctive challenges due to the interleaving of linguistic and non-linguistic terms (e.g. such as numbers and mathematical expressions). For example, [13] provides automatic grading and feedback for math open response questions using clustering techniques, but it ignores all text explanations to focus solely on numerical expressions. In the past few years, there have been several works focused on the development and improvement of automated methods for assessing student open-ended responses in mathematics [6, 18, 17, 8]. These methods are mostly based on evaluating given student answers based on historical student answers and the scores given by teachers to such data. [6] compared the performance of different models for scoring math open-ended responses and attempted to establish a benchmark evaluation procedure to evaluate future models. Building on that work, [2] improved performance by using Sentence-BERT (SBERT) [14] embeddings on the same dataset to score student responses. SBERT modifies the pre-trained BERT (Bidirectional Encoder Representations from Transformers) [5] model to generate sentence-level embeddings. Similar approaches are utilized in recommending feedback messages for teachers to give to students.

As is prevalent in several machine learning applications, many of these approaches are susceptible to the cold start problem, where implementations of such methods may lack sufficient data to make informed estimates. While the impact will vary depending on the model and the context, most assessment models require non-trivial amounts of data to make accurate predictions (c.f. [1]) which may take time and effort to acquire. In cases when there is a newer student response that has not been encountered in the past, these types of methods often fall behind in suggesting an accurate score/feedback message posing this as the cold start problem. In light of this, mitigating the impact of this cold start problem would provide support for teachers across a wider range of problems. Transfer learning [16] is commonly used as a means of addressing the cold start problem. Within the field of mathematics education, we may be able to leverage data from similar content to improve performance in cases where there would otherwise be insufficient data to train an automated assessment model.

We seek to explore the effectiveness of leveraging auxiliary data (student responses) to similar open-ended problems in the auto-scoring of a new problem with limited labeled data. With the goal of addressing the cold start problem, we intend to answer the following research questions: 1. Does the addition of new labeled data from a similar open-response problem, improve the predictive performance of single problem based auto-scoring models? 2. Does leveraging data from a similar problem lead to better model performance in comparison to using data from a randomly selected problem? 3. What is the effect of incorporating auxiliary data into the training of an auto-scoring model and are there any benefits beyond that of increasing sample size?

2. METHODOLOGY

2.1 Dataset

For this study, data¹ consists of all student answers that have ever been submitted to open-ended problems within ASSISTments. For this study, we arbitrarily selected an open response problem within this dataset that contained at least 40 student responses ($n=45$) to act as a representative problem. For consistency of terminology, this representative problem will be referred to as the “original problem” throughout this paper, and will represent the problem for which we would like to train an auto-scoring model (e.g. we will treat it as the problem with insufficient data).

The selected problem pertains to logarithms, and presents the students with the following equation: “ $5\log(x+4) = 10$ ”; students are asked to either solve for x and explain their steps to solve or to type “no solution” if no viable solution exists. We then collaborated with a content expert to select a similar open-ended problem with a comparable number of existing labeled student answers ($n=43$) to train a model. This second problem, referred to as the “similar problem” throughout the remainder of this paper, had the same prompt as the original problem but with the following equation: “ $\log_2(1-x) = 4$ ”. While we acknowledge that the selected problems border on the threshold of what might be considered open-ended, much of the content of open curricula pair close-ended and open-ended components within many of their questions (e.g. solve and explain). In this way, the selected problems result in sufficient variation in student answers to examine auto-scoring models, and allow us to easily identify a problem with undeniable similarity both in terms of content and structure. As part of our analyses, we removed any problem from the remaining dataset containing fewer than 10 labeled student responses to mimic a practical application where such problems would not be considered sufficient in providing auxiliary data since we will be sampling from random problems.

Minor preprocessing was performed on the data to match the format of [2] which introduced the SBERT-Canberra model. These steps included the removal of HTML tags, other special characters, and references to images. Like in [6, 2], teacher-provided scores follow a 5-point integer scale

¹The data and code used in this work cannot be publicly posted due to the potential existence of personally identifiable information contained within student open response answers. In support of open science, this may be shareable through an IRB approval process. Inquiries should be directed to the trailing author of this work.

ranging from 0, indicating poor performance, through 4, indicating high performance. While we acknowledge that ordinal relationships are lost by representing the labels in this way, the scale is converted to a 5-valued categorical one-hot encoded vector and modeled as a multi-class prediction task (i.e. the model treats each score as a mutually-exclusive label) to keep consistent with [2].

2.2 Model

The “SBERT-Canberra” model [2] follows a similarity-ranking procedure to generate its predictions. When producing a prediction for a given student response, it applies SBERT to generate an embedding that captures semantic and syntactic meaning, such that similar responses are mapped to closer points within the embedding space. The SBERT embedding for this student response is compared to SBERT embeddings of historic labeled student responses. Using the Canberra distance measure [11], the score for the historic response corresponding to the smallest distance (i.e. the most similar response) is used as the score prediction. We chose to use this model as 1) it outperformed existing benchmarks in assessing student responses in mathematics [2], 2) no “training” involved in the traditional machine learning sense so we do not need to optimize hyperparameters, and 3) the model performance is directly linked to the scale and diversity of the historic responses.

2.3 Model Evaluation

To examine the use of auxiliary data, we conduct 2 analyses that each compare the SBERT-Canberra model with 3 different training sets. The analyses follow a bootstrapping procedure which samples with-replacement from the available data at increasing intervals. At each interval, student responses are randomly sampled to train and evaluate the model using 10-fold cross validation, where sampling is conducted within the training folds. This entire process is repeated 25 times, with the model performance being averaged across these iterations (to reduce noise caused by unlucky sampling). To evaluate the scoring results, the area under the curve, AUC, (calculated using the simplified multi-class calculation of ROC AUC from [9]) is used as the primary metric to compare the model’s predicted score of a student response to the actual score that was provided by a teacher.

The models are distinguished by their training data. The *Baseline Model* uses only student responses from the original problem. The *Similar Problem Model* uses a combination of student responses from the original problem as well as auxiliary responses sampled from the similar problem. Finally, the *Random Problem Model* uses a combination of student responses from the original problem as well as student responses sampled from 5 randomly-selected problems from the remaining dataset; per design and due to the scale of the data used, it is very unlikely for these problems to be similar to the original problem, allowing for comparisons to be made in regard to differing magnitudes of similarity.

We randomly sample 40 scored responses from the similar problem and from the 5 random problems to create a comparable set. Due to the large variations in sample sizes across problems within the dataset, we sample student responses for the Random Problem Model using a stratified selection method. From the 5 randomly-selected problems per inter-

Figure 1: Average AUC varying original problem sample size.

val, 8 scored student responses are randomly selected per iteration in the interval and they compose the 40 samples to supplement the training data from the original problem.

The first analysis replicates a real-world scenario where we may have a small number of labeled samples for the original problem, but a larger number of samples that may be leveraged from other problems. For each bootstrapping interval, we randomly sample data from the original problem ranging from 0 to 40. The average performance of each model is then plotted with 95% confidence intervals calculated over the 25 repeated runs per interval. While the Baseline model is limited to only the 0 to 40 original problem samples, both the Similar Problem Model and Random Problem Model are able to use 40-80 samples over the set of intervals.

As it is hypothesized that the largest benefit of using auxiliary data is the added sample size, we conduct a second bootstrapping analysis that observes a constant sample size while varying the proportion of data used from the original problem. All models (except for the baseline) utilize 40 samples allowing us to see how the source of content affects model performance independent of data scale. The percentage intervals range from 0% to 100% of the training samples are from the original problem in 10% increments. So, at the first interval, all samples are responses from other problems, while at the end, all 40 samples are from the original problem. As the Baseline Model only utilizes data from the original problem, we are unable to maintain a consistent sample size across intervals. For comparative purposes, we increase the training sample size with the increasing percentage (i.e. using 0 samples, then 4 corresponding with 10%, etc.).

3. RESULTS AND DISCUSSION

For intervals 0 and 0%, no training data was provided for the baseline model so the average AUC of the baseline model is assigned to be 0.5 which is equivalent to chance.

Observing the Similar Problem Model in Figure 1, the model outperforms the average AUC of the baseline model across every increment of training samples from the original problem by approximately 0.073 in terms of average AUC per interval. This difference is also statistically reliable across a majority of intervals by comparing the confidence intervals.

Regarding the Random Problem Model, the model outper-

Figure 2: Average AUC varying sample proportion.

forms the average AUC of the baseline model across 43% of the increments tested. At an average difference of just 0.007 in terms of average AUC per interval, very little difference is observed between the Random Problem Model and the Baseline Model. It is worth noting that the performance of the Random Problem Model does outperform the Baseline over the initial intervals when sample size is the smallest, suggesting that even randomly-selected problems may provide benefit. However, this model also exhibited large variations in performance, leading us to omit the error bars to improve the readability of the figure; this variation is presumably attributable to the random selection of problems with varying magnitudes of similarity to the original problem.

An interesting trend emerged in regard to the Similar Problem Model as seen in Figure 2. When using 40 total training samples (and keeping this constant) with some percentage of samples from the original problem and the remaining samples from the similar problem, the modified model outperforms or equals the average AUC of the baseline model across every increment of training samples from the original problem by around 0.053 in terms of average AUC per interval. After the peak performance in terms of average AUC, the model's performance lessens as the percentage of training samples coming from the original problem increases.

The Random Problem Model follows closely with the performance of the baseline. When using 40 total training samples with some percentage of samples from the original problem and the remaining samples from 5 random problems, the modified model outperforms or equals the average AUC of the baseline model across 54% of the increments tested and by around 0.005 in terms of average AUC per interval.

The Baseline Model across both analyses provide insights into the current implementation of auto-scoring models. While the performance of the SBERT-Canberra model will likely vary across problems, we observe here that the model converges within a relatively small set of samples. After training from 12 samples from the original problem, the baseline model converges in terms of average AUC performance. It does seem to matter, however, which samples are used to train the model. We can see in both analyses that the Baseline Model's confidence intervals decrease with more sam-

ples. The relatively wide bounds over low sample sizes suggests that there are subsets of training samples that are better than others. This is not surprising as the diversity of data is often considered just as important as the scale in many machine learning applications [7].

There is a similar trend in regard to the scale of confidence bounds for the Similar Problem Model. Although the average AUC performance stabilized after 10 samples, the confidence intervals continued to shrink in the first analysis, but remained relatively constant in the second analysis. In both analyses, however, we see consistent, if not statistically reliable differences in comparison to the Baseline Model. In addressing our first research question, this finding suggests that the use of auxiliary data can lead to notable benefits to model performance. We see in the first analysis that the added sample size leads to notable performance through all intervals. While our initial hypothesis was that this benefit would likely be attributable to increased sample sizes, the trend of this Similar Problem Model in the second analysis contradicts that hypothesis. While this model still outperforms the baseline, as sample size is held constant, this cannot be the contributing factor to the differences we observe. We expected the final interval of Figure 2 to be an upper bound for model performance as this is when the data is most closely related to the test set, but we found that the inclusion of data from a similar problem added benefits that extend beyond the impact of sample size. This finding addresses our third research question, but still remains inconclusive as to what benefit is provided. It is possible, for example, that the auxiliary data acts as a regularization method (c.f. [3]), but the analyses conducted here are only able to rule out sample size being the contributing factor. These findings further confirm that scoring models can be improved upon when provided with more varied training samples from both the problem it is trying to score and similar problems rather than only being trained from samples of the original problem. Even when trained with the same number of samples, the Similar Problem model’s average AUC decreases after a peak training percentage composition which supports the theory that the quality of the training samples from the original problem are less than the quality of the combined samples.

What is perhaps most surprising about this comparison in the second analysis is that the model trained from 100% of data from the similar problem seems to outperform the model trained from 100% of the original problem. We believe that this is an artifact of the selected problems and the level of similarity that they exhibit. As such, we would not expect this finding to extend to every open-ended problem, but rather could extend to a subset where there is strong similarity between problems both in terms of content and the structure of student responses; this is the scenario where we believe this method would provide the most benefit.

This is particularly the case considering that the same level of benefit was not observed in regard to the Random Problem Model across the two analyses. Our hypothesis, as previously introduced, is that the added benefit is likely correlated with the magnitude of problem similarity. Even if this hypothesis is flawed, we are seeing that certain subsets of problems lead to better performance than others, emphasizing

the importance in selecting suitable problems from which to draw auxiliary data. In light of this, we can address our second research question in that problem similarity, loosely defined, does seem to impact performance.

4. CONCLUSIONS AND FUTURE WORK

In this paper, we explore a possible solution to the cold-start problem in automating the assessment of student open-ended work. We have shown that our SBERT-Canberra method using similar auxiliary problem data consistently and significantly outperformed the model using data solely from the original problem. When there are few training samples, even the modified SBERT-Canberra method using random problems’ data to supplement helped improve the performance. Throughout the exploration of both analyses, there is a noticeable benefit to supplementing the training samples with data from other problems. By supplementing the original training samples with multiple similar problems, we hypothesize that it will lead to even larger performance improvements to automatic scoring regardless of the number of original training samples. This would be particularly the case if our hypothesis is correct where some of this benefit is derived from regularizing factors.

The largest limitation is that this paper focuses on predicting the scores of only one specific problem. While we argue that the analyses conducted here were sufficient to address our research questions, there is a larger uncertainty that remains in regard to how representative these results are. This work should be tested across a variety of problems to ensure that the results generalize well to other problems. When deciding what constitutes a similar problem, future work could explore other methods that consider a wide range of comparison characteristics. Descriptives including the problem text, knowledge component, grade level, average difficulty, etc may be utilized in comparing problems to determine similarity. Defining such attributes would also provide opportunities to build models to better understand how matching characteristics correlate with model performance gains.

Future work should use transfer learning to use the SBERT-Canberra model of a similar problem as a starting point to score a new problem’s open-ended response. As more data from problems are collected, we found that there may still be benefits to using auxiliary data even beyond addressing the cold start problem. Furthermore, teachers often need supports in providing more meaningful feedback beyond that of a numeric score. ASSISTments is already able to recommend feedback for trained problem models, but it requires a lot of data in order to do so (more than for the automated scoring task). The use of auxiliary data as explored in this work may prove useful in other such contexts.

ABSTRACT

Previous studies suggest that Deep Knowledge Tracing (or DKT) has fundamental limitations that prevent it from supporting mastery learning on multi-step problems [15, 17]. Although DKT is quite accurate at predicting observed correctness in offline knowledge tracing settings, it often generates inconsistent predictions for knowledge components when used online. We believe this issue arises because DKT’s loss function does not evaluate predictions for skills and steps that do not have an observed ground truth value. To address this problem and enable DKT to better support online knowledge tracing, we propose the use of a novel loss function for training DKT. In addition to evaluating predictions that have ground truth observations, our new loss function also evaluates predictions for skills that do not have observations by using the ground truth label from the next observation of correctness for that skill. This approach ensures the model makes more consistent predictions for steps without observations, which are exactly the predictions that are needed to support mastery learning. We evaluated a DKT model that was trained using this updated loss by visualizing its predictions for a sample student learning sequence. Our analysis shows that the modified loss function produced improvements in the consistency of DKT model’s predictions.

Deep knowledge tracing, loss function, online learning

1. INTRODUCTION

Intelligent tutoring systems are widely used in K-12 education and online learning platforms to enhance learning. Knowledge tracing algorithms are embedded in such intelligent tutoring systems to support automatic selection of the

problems a learner should work on next based on their mastery of different skills. There are multiple popular knowledge tracing algorithms that are frequently used to predict students’ performance in offline settings. While these approaches have all achieved satisfactory performance in these settings, there is only limited work investigating the use of knowledge tracing algorithms in online settings [11, 17].

Deep Knowledge Tracing (DKT) is a knowledge tracing approach that has gained in popularity in recent years. It employs a recurrent neural network (RNN) [16] to predict student’s correctness on problem-solving steps that use particular skills. Though some studies demonstrated that DKT outperforms other knowledge tracing models such as Bayesian Knowledge Tracing [1] and Performance Factors Analysis (PFA) [10], it has some fundamental limitations and drawbacks. For example, DKT’s neural network representation is not easily interpretable, making it difficult for people to understand DKT’s predictions. Additionally, Yeung and Yeung [15] identified two problems with DKT—the model fails to reconstruct the observed input, and the DKT predictions are inconsistent and fluctuate over time.

In this paper, we investigate the issue of inconsistent predictions. Our work explores the hypothesis that DKT’s inconsistent behavior is primarily due to its loss function. We propose a novel modification to the DKT loss functions designed to produce more consistent behavior. Multiple authors have proposed ways of modifying the loss function by adding regularization terms [7, 8, 15]. However, our research explores a novel modification that evaluates predictions for each skill that does not have an observed ground truth value by using the next observed correctness for that skill.

We use the “Fraction Addition and Multiplication, Blocked vs. Interleaved” dataset accessed via DataShop [5] to evaluate a DKT model generated through training with this new loss function by visualizing its predicted correctness for each skill at each time step in a heatmap. We then compare these results with the predictions generated by a DKT model trained using the original loss function. Our results indicate that training with the revised loss function produces a DKT model that generates more consistent predictions than one produced by training with the original loss function.

2. BACKGROUND

2.1 Knowledge Tracing

Knowledge tracing approaches model a student’s knowledge over time and predict their performance on future problem-solving steps. Knowledge tracing algorithms are embedded in Intelligent Tutoring Systems to support automatic selection of the next problem a student will practice [13]. Much of the research on knowledge tracing has explored its use in offline settings; however, little work has explored the use of knowledge tracing in online settings. In offline settings, knowledge tracing models are fit to existing data sets, typically to evaluate different knowledge component models to identify those that better fit the data. In contrast, the objective of online knowledge tracing is to keep track of the student’s level of mastery for each skill (or knowledge component) and/or predict the student’s future performance based on their past activity. In a nutshell, knowledge tracing seeks to observe, depict, and quantify a student’s knowledge state, such as the level of mastery of skills underlying the educational materials [6]. The outputs of knowledge tracing support mastery learning and intelligent selection of which problems a student should work on next.

2.2 Deep Knowledge Tracing

Pieche et al. [12] proposed the Deep Knowledge Tracing (DKT) approach, makes use of a Long Short-Term Memory (LSTM) [4] architecture (complex variant of Recurrent Neural Network, or RNN) to represent latent knowledge. The use of an LSTM has become increasingly popular because it reduces the effect of vanishing gradients. It employs cell states and three gates to determine how much information to remember from previous time-steps and also how to combine that memory with information from the current time-step.

The DKT model accept an input matrix X , which is constructed by one-hot encoding two pieces of information for each step: q_t , which represents the knowledge components, and a_t , which represents whether the question was answered correctly. The information at each time step is packed into a tuple denoted as $h_t = \{q_t, a_t\}$. h_0 represent the initial state at time 0 (where $t = 0$). The network outputs the prediction Y based on the input and previous state. Y is a matrix that represents the probability of each KC being correctly answered at each step by a given student. y_t is the predicted probability at time t .

The objective of DKT is to predict performance at the next iteration (given the data from time 0 to t , predict $t + 1$). To optimize next iteration results, a dot product of the output vector y_t and the one-hot encoded vector of the next practiced KC $\delta(q_{t+1})$ is calculated. We take the cross entropy (denoted as l) of the dot product, average over number of steps and number of students. All together, the original loss function of DKT $L_{Original}$ can be expressed as:

$$L_{Original} = \frac{1}{\sum_{i=1}^n (T_i - 1)} \sum_{i=1}^n \sum_{t=1}^{T_i-1} l(y_t \cdot \delta(q_{t+1}^i), a_{t+1}^i) \quad (1)$$

where n is the number of students, and T_i is the length of the interaction sequence for student i .

When the size of a dataset increases, deep knowledge tracing generally has an edge over the classical statistical models, such as Bayesian Knowledge Tracing, Streak Model or Performance Factor Analysis, when it comes to predicting learner performance. The original DKT work [12] demonstrated that it can produce tremendous gains in AUC (e.g., 25%) when compared to prior results obtained from other knowledge tracing models. However, subsequent work suggests that the gains are not as large as originally anticipated [14]. One of the key advantages of DKT over classical knowledge tracing methods, such as BKT, is that it has access to more precise information about the temporal order of interactions as well as information about KCs not involved in the current step [2]. We intend to leverage these advantages of DKT to support online knowledge tracing [17] and explore whether it is possible to get better mastery learning behavior when using DKT rather than classical knowledge tracing approaches, such as BKT.

2.3 Challenges with DKT

Even though DKT has many advantages over other knowledge tracing models like Bayesian Knowledge Tracing (BKT) [1], Streak Model [3] and Performance Factor Analysis (PFA) [10], the model still has several limitations. Specifically, DKT models are difficult to interpret [14], make inconsistent predictions [15], and only consider the correctness of skills that are observed on each time step [7].

Correctness		✗	✗	✗	✓	✓	✓	✗	✓
DKT Mastery	36%	0%	0%	100%	0%	0%	0%	2%	0%

Figure 1: This example, drawn from Zhang and MacLellan (2021) [17], shows DKT model predictions on a single knowledge component given one student correctness sequence.

Yeung and Yeung [15] identified that the DKT predictions are not consistent and fluctuate over time. They also showed that the DKT model fails to reconstruct the input information in its predictions. For example, DKT may predict lower correctness on steps tagged with a particular skill even when the student correctly performs steps that contain the skill. Figure 1 is an example of this effect. From the first to the third steps, the student did not answer the problem correctly, but DKT predicted the third step would have a 100% chance of being correct. From the fourth to the sixth steps, the student correctly answered the question while DKT’s predictions dropped. Upon closer investigation of the DKT model, we believe that this unexpected behavior is due to the way that the loss is computed.

Our previous work [17] highlighted DKT’s shortcoming with respect of giving reliable predictions of correctness on steps tagged with each skill during online knowledge tracing. We want to further investigate the issues that prevent DKT from giving consistent predictions in the scenario of multi-step problem solving and online knowledge tracing. In this paper, we propose a novel revision of DKT’s loss function. We will discuss our approach in Section 3.1.

3. METHODOLOGY

We propose a novel approach to make the DKT model predictions more consistent by modifying the loss function used during training. We trained and tested on the ‘‘Fraction Addition and Multiplication, Blocked vs. Interleaved’’ dataset accessed via DataShop [5] with 80% training data and 20% testing data. This data was collected from a study presented in [9], the students solved problems by interacting with a fraction arithmetic tutor and solved three different types of problems. The three problem types are: Add Different (AD), add fractions with different denominators; Add Same (AS), add fractions with same denominators; Multiplication (M), multiply two fractions.

We created two DKT models: one trained using the original DKT loss function and another trained using the modified loss function. We then used the two models to make predictions on the same student sequence. Lastly, we visualized the predictions for each knowledge component (KC) as heat maps and evaluated the prediction consistency by comparing the heat maps generated using the different DKT models.

All DKT models in this paper consists of a input layer, a hidden layer, and a output layer with size 28, 200, and 14, respectively. The number of knowledge components determines the size of the input and output layers. The LSTM (long short-term memory) contained 200 hidden units. We trained the model over 1000 epochs, with a learning rate of 0.0025, a dropout rate of 0.4, and a batch size of 5. The only difference between the original DKT approach and our approach is the loss function used during training.

3.1 Revision of DKT Loss Function

As outlined in Section 2.3, DKT’s original loss function only evaluates the DKT predictions that have observed ground truth values. To overcome this challenge, we propose a revision to the loss function. Rather than using the original ground truth values typically provided to DKT’s loss function, our revised approach uses modified ground truth data that fills in steps without any observations by taking the next observation of that skill (see Figure 2).

Skill 1	0	1	1	1	1	1	1	1	1	1	1	1	1	1	1	1	1
Skill 2	0	0	0	1	1	1	1	1	1	1	1	1	1	1	1	1	1
Skill 3	0	0	0	0	1	1	1	1	1	1	1	1	1	1	1	1	1

Figure 2: Graphical depiction of \hat{a} . Colored cells denote observed student performance (0/red equals incorrect and 1/green equals correct). Cells with white backgrounds are extrapolated from the next observation of each skill.

Mathematically, we use \hat{a} to represent the updated ground truth values that populate missing cells using the value from the next observation of each skill, see Figure 2. For example, for a specific knowledge component, if there is no ground truth at t_i and the next ground truth is at t_{i+n} , then the \hat{a} contains an entry at t_i that has the same value as the entry at t_{i+n} . As a result, the entries from t_i to t_{i+n-1} would share the same ground truth with t_{i+n} .

Next, we updated the loss function so that it evaluates the

model’s predictions for all entries that have a value in the updated ground truth values (\hat{a}). Here is the mathematical representation of this new loss function:

$$L_{Next} = \frac{1}{\sum_{i=1}^n \sum_{k=1}^K (T_{i,k} - 1)} \sum_{i=1}^n \sum_{k=1}^K \sum_{t=1}^{T_{i,k}-1} l(y_{t,k}, \hat{a}_{t+1,k}^i) \quad (2)$$

This updated loss function will evaluate most of the DKT predictions that did not originally have observed ground truth values. Note, some predictions are still not evaluated (those that occur near the end and do not have a next observation to use for evaluation). Because this new loss function evaluates more of DKT’s predictions in between observations, we believe it will result in more stable predictions.

4. MODEL EVALUATION

To evaluate the performance of DKT model after revising the loss function, we took a complete student sequence and generated correctness predictions for each skill using the DKT model. We have 14 skills (knowledge components) and three types of problems as introduced in Section 3. There are 8 steps for an Add Different (AD) problem, 3 steps for an Add Same (AS) problem, and 3 steps for a Multiplication (M) problem. Figure 3 is a comparison of the student’s predicted mastery of each KC at each step when solving a problem (problem type shown on the x-axis). We use the color to represent DKT’s prediction, with green indicating the student mastering a skill and red indicating not mastering a skill. We use the numbers to represent the ground truth where 1 equals correct and 0 equals incorrect. Figure 3b shows a substantial improvement in prediction consistency over Figure 3a.

In Figure 3a, the DKT predictions fluctuate over time. There is also a pattern of inconsistent predictions on the ‘‘AD Right Convert Numerator’’, ‘‘AD Answer Numerator’’ and ‘‘AD Done’’ skill even though the ground truth values for these skills are 1 during the series of problems practiced. Initially, the DKT model trained using the original loss predicts that the student masters this skill after a few practices. However, we see that for certain repeating periods over the remainder of the sequence, the model predicts the student will get steps with these skills wrong. The student mastered these three skills initially. As the student starts solving additional steps, however, the DKT model alternates between correct and incorrect predictions over the remainder of the sequence. These behaviors are unexpected and contrary to the typical assumption that students will not forget skills once they obtain mastery.

In Figure 3b, the problem of wavy DKT predictions (alternating correct and incorrect predictions for different skills) is largely addressed. The DKT model with the revised loss predicts that the student obtains mastery on all the AD skills and retains this mastery through the end of training. The DKT predictions are consistent with the ground truth in this case.

These results suggest that our revised loss function produces more consistent DKT model predictions. Besides the

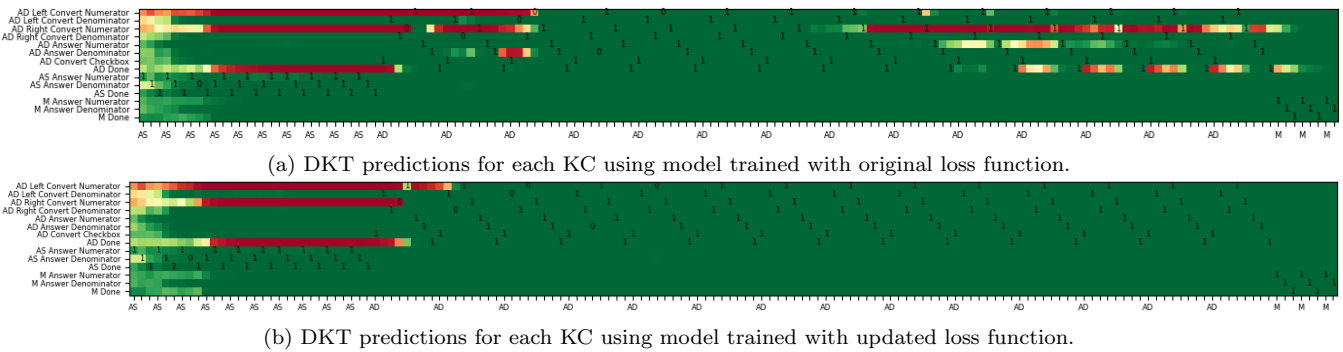

Figure 3: A comparison model performance between DKT models trained using the original and revised loss functions.

improvement, we noticed a common issue that occurred in both the original and the revised DKT model. The student started with 10 AS problems but both DKT models predict improvement of mastery in M and AD skills even before M and AD problems were given to the student. We believe that more work is needed to better understand how DKT relates the corresponding skills in a multi-step problem.

5. RELATED WORKS

Multiple authors have discussed the limitations of DKT in handling multi-skill sequences and possible modifications to the loss function to improve model behavior. Yeung and Yeung [15] proposed regularization terms to address the reconstruction problem (where model predictions move opposite to student performance) and the wavy prediction transition problem (where skill predictions cycle between high and low). Inspired by their study, we believe that revising the loss function is the key to enhancing the consistency of DKT model predictions. Rather than addressing these two problems separately using regularization terms, our approach modifies the loss function so that it evaluates predictions that lack ground truth observations.

Beyond modifying the loss function, Pan and Tezuka [8] proposed pre-training regularization, which incorporates prior knowledge by including synthetic sequences to the neural network before training DKT with real student data. Their motivation is similar to ours—their goal is also to solve the inverted prediction problem (referred to as the reconstruction problem by Yeung and Yeung). They added synthetic data to a baseline model trained with student data and then introduced two regularization measures to measure the severity of the inverted prediction problem. This approach is different from ours as we are using the ground truth value of each skill to populate skills and steps that do not have observations.

6. CONCLUSIONS AND FUTURE WORK

We revised DKT’s loss function to improve prediction consistency across all KCs over time. Our main contribution is that we propose a novel way of modifying the DKT loss function by evaluating skill predictions at the time steps that lack ground truth observations. Instead of only addressing DKT’s consistency issues, our ultimate goal is to use DKT as an approach to keep track of student performance in online learning environments and recommend problems to support personalized learning.

Through our heat map analysis, we demonstrated that a DKT model trained with our improved loss function generates more consistent predictions than a DKT model trained with the original loss. Our analysis showed that predictions for certain skills would cycle between high and low for a DKT model trained with the original loss function; i.e., generated inconsistent predictions over time. In contrast, the DKT model trained with the revised loss function showed much smoother, more consistent predictions that started lower and improved steadily over the course of training.

Moving forward, we have a number of additional future directions that we would like to explore to improve DKT’s stability and accuracy. In our current work, we propose an updated loss function that evaluates the DKT predictions for each skill in terms of the next observation of that skill. In future work, we instead want to evaluate each prediction in terms of all future predictions. Further, we plan to weight each evaluation by a decay factor γ as Yeung & Yeung [15] proposed in their future direction. Finally, we should move online and evaluate how well the revised DKT operates in an online mastery learning context.

Clustering Students Using Pre-Midterm Behaviour Data and Predict Their Exam Performance

Huanyi Chen

pasward@uwaterloo.ca

ABSTRACT

Student behaviour should correlate to the course performance. This paper explored different types of clustering algorithms using the pre-midterm student behaviour data. We found meaningful and interpretable results when clustering algorithms generate three clusters. The clusters can be briefly summarized as potential top performance (PTP) students, potential poor performance (PPP) students, and mixed performance (MP) students. We found that PTP students usually submit early and gain a high score, PPP students usually submit late and gain a low score, and MP students usually make most submissions. MP students are hard to cluster. However, we found a good connection between other students' behaviour and performance if we leave out MP students.

1. INTRODUCTION

Students expose different learning behaviours in programming courses. Several studies focused on analysing the students' data in order to understand student behaviours [5, 1, 14, 11]. The clustering technique was one of the common methodologies used in such studies. There are several benefits to identifying students' behaviours. First, groups of students with similar academic and behaviour characteristics would benefit from the same intervention, which can reduce the time for instructors to identify and implement the right intervention for individual students [12]. Second, a better understanding of students' misconceptions can lead to a better support system for novice programmers and provide adaptive feedback for students [4]. Last but not least, it is also a common technique used to predict student performance [6, 20, 17].

Although clustering techniques can be a valuable tool for re-

searchers to categorize different student behaviours, several studies only applied a single type of clustering algorithm in their experiments [4, 15, 3, 8]. However, clustering results can be affected by the wrong choice of the clustering algorithm, which can cause the result under the threat of validity. To address this issue, people should experiment with multiple clustering algorithms to confirm that different clustering algorithms produce similar results where the essential characteristics of the resulting clusters are identical. Our experiment confirms that clusters' essential characteristics are the same across multiple clustering algorithms, forming further discussion foundations.

Many studies applied clustering techniques to predict student performances [10, 7, 16]. However, the data used in these studies generally include both the pre-midterm data and the post-midterm data. Because of a strong correlation between the midterm exam grades and the final exam grades [2, 6, 9], which is also true for our data (Pearson correlation of 0.81), it suggests that students who failed the midterm are likely to fail the final exam. Therefore, it is critical to identify at-risk students before the midterm. Our study merged multiple clustering algorithms into a predictive model to predict students' performance using pre-midterm data.

This study applied the clustering techniques to students' behaviours exposed in their pre-midterm submissions in an auto-grading system, Marmoset [18], to categorize them into different clusters. We applied multiple clustering techniques and compared their results to remove any effects caused by the wrong choice of the clustering algorithm. Then we tried to predict students' performance using these clustering techniques. The research questions we want to ask are:

- **RQ1:** Are different clustering algorithms producing different results?
- **RQ2:** What are the characteristics of students in different clusters?
- **RQ3:** What were the exam grades of students in different clusters?

We want to clarify that we want to separate RQ1 and RQ2 because RQ1 is closely related to the predictive power of the clustering techniques, while RQ2 mainly focuses on providing better insights into the clusters.

2. COURSE BACKGROUND

The data we used in the study is collected from an introduction-level programming course in an R1 university in Canada. Students were supposed to learn how to carry out operational tasks using the C and C++ languages, perform procedural and object-oriented programming, and other relevant programming knowledge. The preliminary experiments were based on the data of 130 students who attended both the midterm and final exams in the course. Programming knowledge was not required.

In the course, an auto-grading system, Marmoset [18], was used. We refer to a coding/programming question in Marmoset as a *task*. A task may contain multiple tests. For any task, a student can make multiple submissions against it. Marmoset will automatically test it for each submission and reveal some test results to the student. Students can thus learn some feedback from those test results and then improve or fix their code accordingly.

In the course, there were different types of coding questions.

i) Coding Labs: coding labs took place in the lab room. There was exactly one assigned task for each coding lab, which was to be completed and submitted during the lab period (2 hours in the morning). Before the midterm exam, the coding lab was scheduled weekly. After the midterm exam, the coding lab was scheduled biweekly. There was a corresponding extended deadline (the same date but in the evening). Some students may rely on that deadline rather than finish during the lab. **ii) Homework Assignments:** homework assignments were assigned for students to do at home. They were assigned during lab time. Before the midterm, homework problems were due the following week. After the midterm, homework problems were due approximately two weeks later. In every homework assignment, there were multiple tasks, all of which had the same deadline. **iii) Coding Examination:** there was an in-lab coding examination during the course. It was similar to a coding lab. However, its grade comprised a portion of the midterm grade. An extended deadline was also allowed for the coding examination.

3. EXPERIMENT AND RESULTS

3.1 Features

The auto-grading system Marmoset stored every student’s submission during the course. In our study, we extracted three features.

- **passrate:** for every Marmoset task, we calculated the best score (the best number of tests passed among the submissions) a student made before the task deadline. Then we divide the total number of tests of that task to form the *passrate* feature. Because every assignment had multiple tasks, so for assignments, we need to sum the tasks’ best scores to form the best score for an assignment, and we sum tasks’ total number of tests to form the total number of tests for an assignment. For example, assignment 1 had 4 tasks and a total number of 54 tests. If a student’s best submissions of that 4 tasks passed 6, 6, 7, and 8 tests separately, then the passrate of that student for assignment 1 will be $(6 + 6 + 7 + 8)/54 = 0.5$. This process was not

Table 1: Total number of tests for different assignments and coding labs pre-midterm, “a” stands for homework assignment, “l” stands for coding lab

assignment	# total tests	coding lab	# total tests
a1	54	l1	8
a2	85	l2	19
a3	73	l3	19
a4	87	l4	19

needed for coding labs since there was only one task in a coding lab. Table 1 shows the total number of tests for different assignments and coding labs.

- **lastsub:** we extracted the *lastsub* feature as how many minutes between the last submission a student made and the task deadline. If a student made any submission before the deadline, this feature would contain a non-zero value. Only if a student did not submit before the deadline can the value be zero. Note that this feature will be zero for students whose submissions met the extended deadline but did not meet the original deadline for coding labs.
- **nsub:** the *nsub* feature represents how many submissions a student made before the task deadline for a given task. For assignments, we summed the numbers of submissions of tasks to form the nsub of an assignment.

The features used in clustering algorithms is summarized in Table 2.

3.2 RQ1: What are the clustering results from different clustering algorithms given the pre-midterm data?

For research question 1, we explored all types of the clustering algorithms provided in the scikit-learn python package [13]. It includes: *K-Means* (KM), *Affinity Propagation* (AP), *Spectral Clustering* (SC), *Hierarchical Clustering* (HC), and *Density-based Spatial Clustering* (DBSC). We standardize every feature by removing the mean and scaling to unit variance before clustering. For a sample x , the standard score is calculated as:

$$z = \frac{x - u}{s}$$

where u is the mean of the samples and s is the standard deviation of the samples.

We tested different options for setting the number of clusters in different algorithms. We found that setting the number to 3 will give us good interpretive results. In this section, we will only compare the labelling. For the characteristics of different clusters, we will discuss them in RQ2.

Table 3 presents the size of different clusters using different clustering algorithms. To compare the cluster results across different clustering algorithms, we used *adjusted rand index* [19] for evaluation. Random labelling samples will make the adjusted rand index close to 0.0, and the value will be exactly 1.0 when the clustering results are identical. Table 4 presents the results. Note that a cluster may be given different labels in different clustering algorithms. We re-numbered them according to the findings in the discussion of RQ2.

Table 3: The size of different clusters in different clustering algorithms

first algorithm	second algorithm	adjusted rand index
KM	AP	0.780665
AP	SC	0.730717
KM	SC	0.682500
KM	HC	0.557372
HC	DBSC	0.521486
HC	SC	0.515544
AP	HC	0.475727
AP	DBSC	0.414938
SC	DBSC	0.382402
KM	DBSC	0.322811

From Table 3 and Table 4, we can tell the clustering results from KM, AP, and SC are similar to each other (similar cluster sizes and high adjusted rand index value). In contrast, HC and DBSC produced different clustering results. Combining KM, HC and DBSC should help reduce the effect of an improper pick of the clustering algorithms.

3.3 RQ2: What are the characteristics of students in different clusters?

We carefully examined students in different clusters. Interestingly, although the cluster results differed in the cluster size and the adjusted rand index metric, we found that students in different clusters share similar characteristics across different clustering algorithms. We name the students in the three clusters as: **Potential-Top-Performance (PTP) students**, **Potential-Poor-Performance (PPP) students**, and **Mixed-Performance (MP) students**.

Table 5 summarizes the characteristics of different students.

We also examined the students that were put into different clusters from different algorithms. In general, those stu-

dents put into different clusters from different algorithms were those whose behaviour was in the middle of PTP students and MP students or the middle of PPP and MP students. However, we found there were no students put into the PTP cluster in one algorithm while being put into the PPP cluster in another algorithm. We can tell that students from these two clusters share no typical behaviour from any aspect.

3.4 RQ3: What were the exam grades of students in different clusters?

Because some students were put into different clusters from different clustering algorithms, we consider students in the PTP cluster only if they were put into the PTP cluster by all clustering algorithms. Similarly, students in the PPP cluster were only put into the PPP cluster by all clustering algorithms. The remaining students will be MP students.

In addition to the midterm grades and final exam grades, there was a coding examination grade, which will comprise a portion of the midterm grade. Figure 1 shows us the relation between the coding examination grades and different clusters. Figure 2 shows us the relation between midterm grades and final grades of different clusters.

Figure 1: The box-plot of coding examination grades. PPP students all got zero while PTP students mostly got 100%.

From Figure 1, we can see PTP students achieved a very high score on the coding examination, while PPP students achieved 0% on the coding examination. The result is expected since PTP students mostly performed well on assignments and labs, which were programming questions. It is reasonable that they achieved a high score on the coding examination. In contrast, for PPP students, since they performed poorly on those questions, it is not surprising that they got a significantly low score.

From Figure 2, we can see the performances of MP students messed up with other clusters of students. However, if we exclude them, as shown in Figure 3, we can see the performances of PTP students and PPP students were completely different. The reason we set a cut off point as 50% for the exam grades is that it is the required grades for passing a course in the university.

It is essential to consider how many students genuinely need

Table 5: Characteristics of different clusters. Because there are multiple clustering algorithms, we calculated the medians of students of different clustering algorithms and then combined them into ranges. The lastsub feature of the coding lab 1 was treated separately from other labs because it was due on the second day rather than the 2-hour lab time, while lab 4 was due to the significant time differences observed.

	PTP students	MP students	PPP students
assignment passrate	96% – 98%	85% – 95%	34% – 66%
assignment lastsub	2 – 3 days early	16 – 27 hours early	2 – 6 hours
assignment nsub	25 – 29	26 – 42	8 – 21
lab 1-4 passrate	95% – 100%	lab 1,4: 100%, lab 2: 52% – 74%, lab 3: 0% – 53%	0%
lab 1 lastsub	14 – 16 hours early	3 – 4 hours early	7 – 14 minutes early
lab 2,3 lastsub	30 – 58 minutes early	0 – 15 minutes early	0 – 2 minutes early
lab 4 lastsub	70 – 77 minutes early	42 – 54 minutes early	0 – 2 minutes early
lab 1-4 nsub	3 – 6	lab 1,2,4: 4 – 6, lab 3: 1 – 2	0 – 4

Figure 2: Midterm Grades and Final Exam Grades (as percentage). The total grade for midterm was 120% because there were bonus questions.

Figure 3: Midterm Grades and Final Exam Grades (as a percentage). The total grade for the midterm was 120% because there were bonus questions.

help from the identified PPP students. In other words, precision is important [2]. It is the higher, the better. Then we can calculate the precision of the PPP students, which is $4/7 = 0.57$ (4 students out of the total 7 PPP students were below 50% in the midterm). Similarly, the precision of the final grades is 1.0, since no PPP students had a final grade above 50%. These results are promising, implying that the clustering technique can predict student performance.

4. LIMITATIONS

The limitation of this study was that the data used in the study was of a limited amount. We appreciate any replicate studies to help validate the results in our study.

5. DISCUSSION

This study applied clustering techniques to pre-midterm students' behaviour data by using an auto-grading system, namely how early students make their last submissions, how many submissions they make, and the best score. We found that different clustering algorithms label students differently and put them into different clusters, thus providing different predictive power. However, combining k-means, hierarchical clustering, and density-based spatial clustering algorithms

should help reduce the negative effect of an improper pick.

We found that the clusters share the same characteristics regardless of the labelling. We can summarize those clusters as Potential Top Performance (PTP) cluster, Potential Poor Performance (PPP) cluster, and Mixed Performance (MP) cluster (in which students might be put into different clusters from different clustering algorithms). We found that students in PTP/PPP are generally exposing behaviours at the extreme, and they perform well/poorly on the exams.

Better understanding the MP students is one of the future works. For example, whether there are sub-groups within this cluster, how to understand their learning behaviours, and what factors might prevent them from being successful in the course?

Although we are still at the preliminary stage, we believe our finding allows a fair evaluation of the participation of students in a course. Also, because our finding shows that predicting at-risk students in advance is possible, thus corrective actions to improve the final results might be implemented to help people achieve a learning environment with fairness and equity.

ABSTRACT

Vocabulary proficiency testing plays a vital role in identifying the learner's level of vocabulary knowledge, which can be used to provide personalized materials and feedback in language-learning applications. Item Response Theory (IRT) is a classical method that can provide interpretable parameters, such as the learner's ability, question discrimination, and question difficulty in many language-proficiency testing environments. Many vocabulary proficiency tests include more than one type of question format. However, traditional IRT lacks the capability to tap into the information present within question texts and question formats, which can be ideally used to gauge a learner's underlying skills in more detail. In addressing this, we propose a model to reinforce traditional IRT with deep learning to exploit the information hidden within question content and format. Experimental results on a sample real-world dataset demonstrate the effectiveness of the proposed model, highlighting that question-related information can be utilized to predict a learner's performance more accurately.

Keywords

Item response theory, Deep learning, Item difficulty, English vocabulary.

1. INTRODUCTION

Vocabulary proficiency assessment plays an important part in language education and has lately gained increased popularity in online language learning. It is crucial to identify the learners' English vocabulary proficiency to higher accuracy in providing personalized materials and adaptive feedback in language-learning applications [1]. With the estimated learners' vocabulary knowledge state, systems can better gauge the attainment levels of learners and tailor the learning materials accordingly. Moreover, learners may also develop better learning plans to deal with their specific weaknesses and maximize their learning efficacy depending on the results. Most importantly, it can help place a second-language learner quickly in the ideal content space when returning to the application after a long break during which he or she may have forgotten a lot or, conversely, have progressed in the target language outside the realm of the application [2].

Computerized adaptive testing (CAT) is a mode of testing that has gained popularity because of its unparalleled ability to measure latent abilities in large-scale testing environments [3]. In CAT,

estimating the difficulty level, also called item calibration, is essential for maintaining, updating, and developing new items for an item bank. Item Response Theory (IRT) [4] is a classical method widely used to determine item difficulties. IRT can predict student performance using the logistic-like item response function and provide interpretable parameters. For this reason, different IRT models have been widely applied in CAT applications [5].

Although IRT has made a great deal of success and is widely applied, some problems still limit its usefulness. The critical drawback of traditional IRT is that it can only exploit the response results and ignore the actual contents and formats of the items [6]. Thus, IRT cannot capture the rich information hidden within question texts and underlying formats. This problem leaves no possibility of generalizing item parameters to unseen items and understanding the format's impact on the difficulty of items [2]. In addition, IRT only provides an overall latent trait for learners, while each question usually assesses different knowledge concepts or skills [7]. Thus, enhancing IRT to provide detailed results on each knowledge concept or skill in a reliable way is still an open issue.

Many researchers are beginning to focus on new approaches for estimating the difficulty of questions or items to improve traditional IRT. Studies have already shown that the representational information of questions is significantly related to the difficulty level. For English vocabulary questions, word length and corpus frequency prove to be essential factors for predicting vocabulary difficulty [8], while the average word and sentence lengths have been used as key features to predict English text difficulty [9]. Along these lines, many works have begun to estimate difficulty parameters based on items' textual content using deep neural networks [2].

In vocabulary proficiency assessment, some studies have indicated that even for the same vocabulary item, different question formats impact the difficulty level and explanatory power in predicting receptive skills [10]. The ability of learners to fully comprehend a specific word can be divided into different components. The best-known and most widely used framework is Nation's division of vocabulary knowledge into nine components of 'word knowledge' (e.g., spelling, word parts, meaning, grammatical functions, and collocation) [11]. The framework has been instrumental in describing the totality of what learners need to know. However, no single question format can adequately describe vocabulary comprehension. Usually, different question formats are used to assess different skills, such as learners' reading, writing, listening, and speaking skills collectively. However, IRT only provides an overall latent trait on the question level and cannot provide more detailed results on the underlying skills.

2. RELATED WORK

IRT is one of the most time-tested theories for estimating latent abilities and has been used in educational testing environments since the 1950s [12]. There are several IRT models widely in use, such as the 1-parameter, 2-parameter, and 3-parameter models [13,14,15]. Extended from IRT, Multidimensional Item Response Theory (MIRT) [17] tries to meet multidimensional data demands by including an individual's multidimensional latent abilities for each skill. Although MIRT goes a step further to include the knowledge-concept proficiencies of individuals, it is sensitive to the knowledge concepts on which they have high latent abilities [17]. In addition, since the process of estimating the parameters for MIRT is the same as IRT, these two models share the same shortcomings.

With the recent surge in interest in deep learning, many works have begun to incorporate deep learning models into IRT to address the shortcomings of traditional IRT models. For example, the synthesis of Bayesian knowledge tracing (BKT) and IRT [18, 19] empowers the individualization of questions and learners. Recently, Deep-IRT [20] was proposed by combining a dynamic key-value memory network (DKVMN) [21] with an IRT module to improve the explanatory capabilities of the parameters. Furthermore, Emiko et al. [22] improved Deep-IRT with two independent neural networks for students and items.

Other IRT-based works have focused on improving the estimation accuracy of parameters by exploiting the semantic representations from question texts. Cheng and Liu [23] proposed a general Deep Item Response Theory (DIRT) framework that uses deep learning to estimate item discrimination and difficulty parameters by extracting information from item texts. Benedetto et al. [24] adopted transfer learning on Transformer language models [25] and performed the estimation of the difficulty parameter. Hsu et al. [26] proposed a method for automated estimation of multiple-choice items' difficulty for social studies tests. Their findings suggest that the semantic similarity between a stem and the options strongly impacts item difficulty. Susanti et al. [27] proposed a system for automatically generating questions for vocabulary tests. Factors such as the reading passage difficulty, semantic similarity between the correct answer and distractors, and distractor word difficulty level are all considered for controlling generated items' difficulty in this system.

Studies looking into language tests also tried to predict the item difficulty and automatically generate items of various difficulty levels. Many of these studies have investigated the relationship between test item difficulty and linguistic features such as passage length, word length, and word frequency. Hoshino and Nakagawa [28] used a support vector machine to estimate the difficulty of cloze items for a CAT. Beinborn et al. [29] used Natural Language Processing (NLP) to predict c-test difficulty at the word-gap level, using a combination of factors such as phonetic difficulty and text complexity. Loukina et al. [30] conducted a study to investigate which textual properties of a question affect the difficulty of listening items in an English language test. Settles et al. [31] used Machine Learning and NLP to induce proficiency scales and then used linguistic models to estimate item difficulty directly for CAT. However, these studies did not consider a variety of item formats that would typically appear in a test, and failed to consider linguistic skills in vocabulary learning. Recently, Brian and Andrew [48] have incorporated rich linguistic features (lexical, morphological, and syntactic features) as skills in skill-based models for learners' vocabulary learning performance prediction. It highlighted that the use of linguistic skills is quite

helpful in this regard. However, their work also failed to consider question formats' influence on the difficulty level and different receptive skills. In addressing this, here we incorporate item-format information and associated skill requirements to improve the estimations of IRT parameters, and in effect, the prediction accuracy of a learners' performance.

3. PROPOSED METHOD

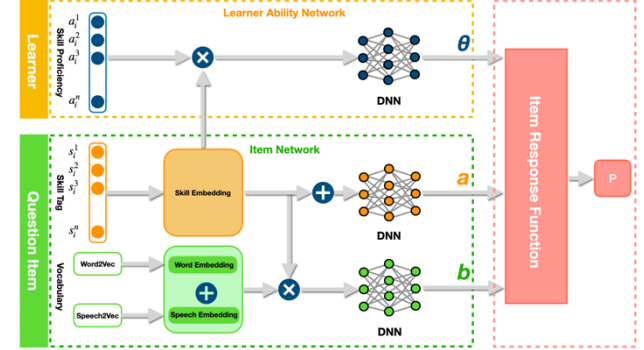

Figure 1. Overview of the proposed framework.

3.1 Framework

Inspired by previous studies [6, 23], we propose a framework to enhance traditional IRT with deep learning, which aims to obtain the learner parameter (ability) and item parameters (discrimination and difficulty) to predict learner performance in vocabulary questions. In achieving this, as shown in Figure 1, our framework comes with three parts: the learner ability network, item network, and prediction module.

3.1.1 Item Network

The items' characteristics, i.e., the difficulty and discrimination parameters, are calculated in the item network.

For a vocabulary question presented in a specific format, two elements influence the item's characteristics: the target vocabulary and the required skills to respond correctly. For the target vocabulary, the semantic features are embedded into a d -dimensional vector v using pre-trained Word2Vec [32] vector v_w and Speech2Vec [33] vector v_s , where $v = v_w \oplus v_s$ and $d = 50$. And the required skills for this question are represented by one-hot vectors $S = (S_1, S_2, \dots, S_n)$, $S_i \in \{0,1\}^n$, where n is the number of required skills. Then, we utilize a d -dimensional dense layer to acquire the dense embedding for each skill S_i for training, the dense embedding of S_i as s_i , and $s_i \in \mathbb{R}^d$:

$$s_i = S_i W_s, \quad (1)$$

where $W_s \in \mathbb{R}^{p \times d}$ are the parameters of the dense layer. Then we use the target vocabulary embedding and the skill embedding to obtain the item parameters (discrimination and difficulty).

Discrimination. Question discrimination a can be used to analyze learner performance distribution on the question. Inspired by previous works [17, 23], we learn a from required skills that correspond to the question. A deep neural network (DNN) is trained to estimate a . Specifically, we sum the dense embedding of required skills to get a d -dimensional vector $A \in \mathbb{R}^d$. Then, we input A into the DNN to estimate a . Finally, we normalize a so that it is in the range $[-4, 4]$ [16]. The definition of a is as follows:

$$a = 8 \times (\text{sigmoid}(\text{DNN}_a(A)) - 0.5), A = s \oplus s. \quad (2)$$

Difficulty. Question difficulty b determines how hard the question is. Adopting from previous works [8, 9], we predict b based on the semantic features of the target word. In addition, the depth and width of the required skills examined by the question also significantly impact the difficulty. The deeper and broader the required skills being examined, the more difficult the question is [23]. Therefore, we adopt a DNN to model b based on the target vocabulary embedding v and the required skills s depending on the corresponding question format. Like the discrimination, we normalize b so that it is in the range $[-4, 4]$ [16]. The definition of b is as follows:

$$b = 8 \times (\text{sigmoid}(DNN_b(B)) - 0.5), \quad B = s \odot v. \quad (3)$$

3.1.2 Learner Ability Network

In the learner network, the proposed method calculates a learner’s ability. For a learner, we initialize a proficiency vector $\alpha = (\alpha_1, \alpha_2, \dots, \alpha_n)$ randomly, where $\alpha_i \in [0, 1]$ represents the degree of proficiency of a learner on a specific skill i .

Ability. Learners’ ability θ has strong interpretability for their performance on questions. It is closely related to the proficiency of various skills tested in the questions [23]. Therefore, we multiply the corresponding proficiency α with the skill dense embedding of the questions s and get a d -dimensional vector $\theta \in \mathbb{R}^d$. Then we input θ into a DNN to learn the ability parameter, which is defined as follows:

$$\theta = DNN\theta(\theta), \quad \theta = \alpha \odot s. \quad (4)$$

3.1.3 Prediction of Learner Response

Like previous works [20, 22, 23], the proposed method predicts a learner’s response performance to a question as a probability. We input the trained parameters, namely, θ , a , and b into the item response function (Eq.5) to predict $P(\theta)$, the learner’s probability of answering the specific question correctly.

$$P(\theta) = \frac{1}{1 + e^{-a(\theta - b)}}. \quad (5)$$

3.1.4 Model Learning

The parameters to be updated in the proposed framework mainly exist in two parts: learner ability network and item network. The updating parameters include the proficiency vector α and skill dense embedding weights W_s . In addition, the weights of the three DNNs $\{W_{DNN_a}, W_{DNN_b}, W_{DNN_\theta}\}$ are updated as well.

The loss function of the proposed method is the negative log-likelihood function. The learner’s response is recorded as 1 when he/she answers the item correctly and 0 otherwise. For learner i and question j , let r_{ij} be the actual score for learner i on question j , and \tilde{r}_{ij} be the predicted score. Thus, the loss for learner i on question j is defined as:

$$\mathcal{L} = r_{ij} \log \tilde{r}_{ij} + (1 - r_{ij}) \log(1 - \tilde{r}_{ij}). \quad (6)$$

Using Adam optimization [34], all parameters are learned simultaneously by directly minimizing the objective function.

4. EVALUATION

4.1 Dataset

Our real-world dataset came from one of Japan’s most popular English-language learning applications. We tentatively used a sample dataset from 129 application users who newly registered in 2021, and most of them are Japanese students learning English. This dataset included 1,900 English words labeled by the

Common European Framework of Reference for Languages (CEFR), mainly in the B1/B2 range. Each word in the dataset had six different question types collectively assessing reading, writing, listening, and speaking skills. The dataset included the initial responses (when encountering for the first time) of the users to such questions.

4.1.1 Item Formats

The knowledge pertaining to English words is not all-or-none as with the case with any other language. Rather, there are different aspects, such as knowledge of the reading, writing, listening, speaking, grammatical behavior, collocation behavior, word frequency, stylistic register constraints, conceptual meaning, the associations a word has with other related words, and so on [11, 35]. Hence, as summarized in Table 1, there are six different question formats to collectively assess reading, writing, listening, and speaking skills of vocabulary learning in our dataset. For each format, we indicate the linguistic skill(s) required to tackle the question (L = listening, R = reading, S = speaking, W = writing) and some of the evidence from the literature supporting this assignment. Below are the descriptions of the six question formats. Multiple-choice definition: choose the Japanese description of the English word. Multiple-choice recall: choose the corresponding English word given the Japanese description. Spelling: type the spelling of the English word given the Japanese description. Cloze test with spelling: type in the blank with the appropriate English word. Multiple-choice listening: choose the corresponding English word given the pronunciation. Multiple-choice cloze test: choose the appropriate English word to fill the blank.

Table 1. Summary of question formats and required skill(s).

Label	Question Format	Skills	References
Format 1	Multiple-choice definition	R	[40,41,44]
Format 2	Multiple-choice recall	R	[40,41]
Format 3	Spelling	R S W	[39]
Format 4	Cloze test with spelling	R S W	[39,42]
Format 5	Multiple-choice listening	L R	[38,43]
Format 6	Multiple-choice cloze test	R W	[31,39,42]

4.2 Experimental Settings

We conducted extensive experiments to evaluate the accuracy of our model in predicting the performance of learners and compared it with several existing models. To set up the experiments, we partitioned the dataset, where the question-user interactions were divided into the training and testing sets at different ratios: 60%, 70%, 80%, and 90%.

We name our method Format-Aware IRT(FIRT). FIRT-S is a variant of FIRT, which only uses speech embedding based on the Speech2Vec, and FIRT-W is a variant that only uses word embedding based on the Word2Vec. We compared our method’s performance with IRT, MIRT, and Probabilistic matrix factorization (PMF) [36].

Following previous works [23, 37], we chose four widely used metrics for the evaluation: Prediction Accuracy (ACC), Area Under Curve (AUC), Mean Absolute Error (MAE), and Root Mean Square Error (RMSE). The smaller the values of RMSE and MAE, and the larger the values of AUC and ACC, the better the results.

Figure 2. Comparison of learner performance prediction among different methods.

Figure 3. Comparison among different question formats.

4.3 Results

4.3.1 Performance Prediction

The overall results on all four metrics are shown in Figure 2 for six different models predicting learners' performance. We observe that our proposed models (FIRT, FIRT-S, and FIRT-W) perform better than other traditional baseline models, such as IRT, MIRT, and PMF. It is clear that our deep learning-based models can effectively make use of the vocabulary content and format information to improve the performance.

4.3.2 Impact of Different Formats

Many studies predicting vocabulary knowledge use only a single question format. However, results based on a single format can be misleading because it might be gauging a limited skill space pertaining to vocabulary knowledge. Understanding the differences among various formats may provide insight for developing tests and tools that can measure proficiency on a much-balanced scale [47]. Along this line, we conducted experiments to evaluate our model's ability to predict performance on different question formats, and to illustrate the variability of performance depending on the format.

The results in Figure 3 show that our models perform better in all question formats. This indicates that the vocabulary content and format information, together with the underlying skill proficiency, help predict learners' performance better, which are typically ignored in the traditional methods. Also, we observe that the prediction performance is strongly affected by the question format. As we mentioned earlier, different question formats assess different linguistic skills like reading, writing, listening, and speaking. The results show that all models have considerably satisfactory performance for multiple-choice items, which assess only one or two underlying skills and are easy to understand and

answer [45, 46]. However, the prediction performance for Format 3 (Spelling) and Format 4 (Cloze test with spelling) are deficient compared with others, which intuitively suggests that responses to question formats that necessitate multiple underlying skills are more difficult to predict accurately. In addition, we noticed that FIRT-S (using speech embedding) performs slightly better than other models for Format 5 (Multiple-choice listening). This implies that using other features besides semantic features may improve the performance. Moreover, the findings implies that testers should consider the effect of different formats when assessing vocabulary knowledge and strive to use a combination of formats in vocabulary assessment to gauge a broader skill space.

5. CONCLUSION

In this work, we proposed a framework that reinforces IRT with deep learning routines that take full advantage of the questions' representational information, such as the question contents, formats, and the required linguistic skill(s) to tackle the question. Experiments were conducted to confirm the effectiveness of the proposed approach, and the results showed that our method performs better than other methods. We highlight that vocabulary content and format information together with the required skill set is useful in accurately predicting learners' vocabulary proficiency.

However, there are some limitations in this work. The dataset is relatively small, and the learner base is limited to learners of the same language background. For future work, we plan to collect more data on learners of various backgrounds, which may be useful when generalizing the method to a broader audience. Also, it is likely that the six item formats explored in this work over-index on language reception skills rather than production skills (i.e., writing and speaking). In going forward, we need to test more writing and speaking questions, and include additional linguistic skills to expand the capabilities of our model.

ABSTRACT

Students learn more from doing activities and practicing their skills on assessments, yet it can be challenging and time consuming to generate such practice opportunities. In this work, we present a pipeline for generating and evaluating questions from text-based learning materials in an introductory data science course. The pipeline includes applying a T5 question generation model and a concept hierarchy extraction model on the text content, then scoring the generated questions based on their relevance to the extracted key concepts. We further classified the generated questions as either useful to learning or not with two different approaches: automated labeling by a trained GPT-3 model and manual review by expert human judges. Our results showed that the generated questions were rated favorably by all three evaluation methods. We conclude with a discussion of the strengths and weaknesses of the generated questions and outline the next steps towards refining the pipeline and promoting NLP research in educational domains.

1. INTRODUCTION

As education across grade levels continues to transition towards online platforms in response to the COVID-19 pandemic, the need for effective and scalable assessment tools emerges as a pressing issue for instructors and educators. Amid many other logistical issues that arise from emergency online education [5], instructors often find themselves having to generate a large question bank to accommodate this new learning format. In turn, this challenge motivates the need for supporting instructor efforts via methods that automatically generate usable assessment questions based on the learning materials, in a way that requires minimal inputs from instructors and domain experts.

Recent advances in natural language processing (NLP), question answering and question generation (QG) offer a promising path to accomplishing this goal. Most theories of learning emphasize repeated practice as an important mechanism for mastering low-level knowledge components, which altogether contribute to the high-level learning objectives [7]. We therefore envision that having the ability to generate questions on-demand would accommodate students' varying levels of learning needs, while allowing instructors to allocate resources to other components of the course. Our work presents an initial step towards realizing this capability. We applied Text-To-Text Transfer Transformer (T5) models [15] on conceptual reading materials from a graduate-level data science course to generate potential questions that may be used for assessment. We then evaluated these questions in three different ways. First, we conducted a separate concept hierarchy extraction process on the reading materials to extract the important concept keywords and scored each generated question based on how many such keywords it contains. Second, we applied a fine-tuned GPT-3 model to classify the questions as either useful to learning or not. Finally, we had two data science instructors perform this same classification task manually. Our results contribute insights into the feasibility of applying state-of-the-art NLP models in generating meaningful questions, with a pipeline that generalizes well across learning domains.

2. METHODS

2.1 Dataset

We used the learning materials from a graduate-level introductory data science course at an R1 university in the northeastern United States. The course has been offered every semester since Summer 2020, with class sizes ranging from 30-90 in general. The course content is divided into the conceptual components and the hands-on projects. Students learn from six conceptual units, further broken down into sixteen modules, each corresponding to a data science topic such as *Feature Engineering* and *Bias-Variance Trade-off*. Each module consists of reading assignments, ungraded formative assessments and weekly quizzes serving as graded summative assessments. Students also get to practice with the learned concepts through seven hands-on coding projects, which are evaluated by an automatic grading system. In the scope of this work, we will focus on generating

questions from the textual content of the sixteen modules in the course, using the following pipeline.

2.2 Question Generation Pipeline

First, we extracted the learning materials from an online learning platform which hosts the course. This extracted data is in XML format, which preserves not only the text content but also its hierarchy within the course structure (i.e., which module and unit each paragraph belongs to). We scraped the text content from the XML files using the BeautifulSoup¹ library and cleaned the content to remove leading questions, such as “*What does this accomplish*” and “*Why would this make sense?*”. These questions were included to help students navigate the reading more effectively but do not contain meaningful information on their own. From this point, the resulting text data was input to two separate processes as follows.

Concept Hierarchy Extraction. This process was carried out by the MOOCCubeX pipeline [16], which performs weakly supervised fine-grained concept extraction on a given corpus without relying on expert input. As an example, given a paragraph that explains Regression, some of the extracted concepts include *least-squared error*, *regularization*, and *conditional expectation*; these could be viewed as the key concepts which students are expected to understand after reading the materials. A researcher in the team reviewed the generated concepts and manually removed those which were deemed invalid, including prepositions (e.g., ‘around’), generic verbs (e.g., ‘classifying’) and numbers (e.g., ‘45’ – this is part of a numeric example in the text, rather than an important constant to memorize).

Question Generation. For this process, we applied Google’s T5 [15], a transformer-based encoder-decoder model. Since its pre-training involves a multi-task structure of supervised and unsupervised learning, T5 works well on a variety of natural language tasks by merely changing the structure of the input passed to it. For our use case, the input data is the cleaned text content prepended by a header of the text. Our rationale for including the header is to inform the model of the high level concept which the generated questions should center around. We had previously tried extracting answers from the text content using a custom rule-based approach with a dependency parse tree, but found that this resulted in the creation of more nonsensical than sensible questions; in comparison, incorporating the headers led to higher quality questions. There were three hierarchical levels of header that were used in our input: Unit, Module and Title, where the former encompasses the latter. For example, the unit *Exploratory Data Analysis* includes the module *Feature Engineering*, which has a section titled *Principal Component Analysis*, among others. Before applying the model to our dataset, we also fine-tuned it on SQuAD 1.1, a well known reading comprehension dataset and a common benchmark for question-answering models [11].

2.3 Evaluation

We evaluated the generated questions with three different methods as follows.

¹<https://www.crummy.com/software/BeautifulSoup/bs4/doc/>

Information Score. This is a custom metric that denotes how relevant each question is to the key concepts identified in the Concept Hierarchy Extraction step. We denote this set of key concepts as C . For every generated question q , we further denote $T(q)$ as the set of tokens in it and compute the *information score* as the number of tokens in q that coincide with an extracted concept,

$$IS(q) = \frac{1}{|T(q)|} \sum_{t \in T(q)} 1(t \in C), \quad (1)$$

where the division by $|T(q)|$ is for normalization. With this formulation, higher scores indicate better questions that touch on more of the key learning concepts.

GPT-3 Classification. We used a GPT-3 model as it has been a popular choice for text classification tasks such as detecting hate speech [3] and text sentiment [17]. Our classification task involves rating each generated question as either *useful for learning* or *not useful*. A useful-for-learning question is one that pertains to the course content and is intended to assess the domain knowledge of the student. On the other hand, a question is classified as not useful if it is vague, unclear, or not about assessing domain knowledge. For example, the question “*What programming language do I need to learn before I start learning algorithms?*” is a valid question, but it is classified as not useful for learning because it pertains to a course prerequisite rather than domain knowledge assessment. To perform this classification, we first fine-tuned the GPT-3 model with default hyperparameters on the LearningQ dataset [2], which contains 5600 student-generated questions from Khan Academy. Each question contains a label to indicate if it is useful for learning or not, as annotated by two expert instructors. Next, we passed in the T5-generated questions as the GPT-3 model’s input, obtaining the output as a set of binary labels indicating if it rated each question as useful for learning or not.

Expert Evaluation. To further validate the question quality, we had two expert raters with 5+ years of teaching experience in the domain of data science rate each question. Following the same classification process as in [2], the two raters indicated if each question was useful for learning or not. We measured the Inter-Rater Reliability (IRR) between the two raters and found they achieved a Cohen’s kappa of $\kappa = 0.425$, with similarity in 75.59% of the question ratings, indicating a moderate level of agreement [9]. The remaining discordant questions were discussed between the two raters until they reached a consensus on their classification, resulting in all of the generated questions being classified by both human judges and the GPT-3 model.

3. RESULTS

Following the above pipeline, we generated a total of 203 questions across the three header levels - Module, Unit, and Title. The Appendix shows a number of example generated questions, along with their information scores and GPT-3 model evaluation. Among the 203 questions, 151 (74.38%) were classified as useful for learning by the GPT-3 model. To compare this classification with the human raters’ consensus, we constructed a confusion matrix as shown in Table 1. We observed that the model agreed with human raters in 135 (66.50%) instances; in cases where they disagreed, most of

the mismatches (52 out of 68) were due to the GPT-3 model overestimating the questions’ usefulness.

	Expert: 0	Expert: 1
GPT-3: 0	36	16
GPT-3: 1	52	99

Table 1: Confusion matrix for comparing GPT-3 and expert ratings on the generated questions. 0 denotes Not Useful and 1 denotes Useful rating.

We followed up with a qualitative review of the questions rated as not useful by human experts to better understand (1) what separated them from the questions rated as useful, and (2) why the GPT-3 model might still rate them as useful. For (1), we identified two important requirements that a question generally needs to meet to be rated as useful by human experts. First, it has to thoroughly set up the context (e.g., what is the scenario, how many responses are expected) from which an answer could be reasonably derived. An example question that satisfies this category is “*What are **two** types of visions that a data science team will **work with a client** to develop?*,” where the bolded terms are important contextual factors which make the question useful. We further note that useful questions with thorough contexts tend to be longer, because they necessarily include more information to describe such contexts. At the same time, short questions may still be considered useful by expert raters if they target a sufficiently specific concept. For example, “*what is a way to improve a **decision tree’s performance**?*” is considered useful because the bolded term is very specific. On the other hand, a similar-looking question such as “*what is a way to analyze business data*” is not useful, due to “*analyze business data*” being too broad. The GPT-3 model typically fails to recognize this specificity criterion – many of the questions rated as useful by GPT-3, but not by human raters, are similar to ones such as “*What are two types of data science tasks?*,” which could be useful if “*data science tasks*” was replaced with a more targeted concept.

Next, we examined whether our score metric, which calculates the normalized number of important concepts that a question encapsulates, aligns with the expert classification of question usefulness for learning. We observed from Figure 1 that, across the three header levels, questions rated as useful tended to have similar or higher information scores than their counterparts.

4. DISCUSSION AND CONCLUSION

In this work, we propose and evaluate a domain-independent pipeline for generating assessment questions based on reading materials in a data science course. Our results showed that the GPT-3 model, fine tuned on the LearningQ dataset [2], was able to reach an acceptable level of agreement (on 66.50% of the questions) with the consensus of two expert raters. The model appeared to learn that long questions are likely useful, which is a reasonable assumption as these questions might contain more relevant contextual information. However, it also classified some short questions as useful, despite the lack of specificity which human evaluators could easily recognize. As the LearningQ dataset did not contain data science questions, it is no surprise that our model was not particularly good at differentiating between specific

Figure 1: Distribution of information score, partitioned by expert raters’ evaluation, at each header level.

data science concepts (e.g., “*decision tree’s performance*”) and ambiguous ones (e.g., “*business data*”). Additional fine-tuning of the GPT-3 model on a labeled dataset closer to our learning domain would therefore be a promising next step.

When treating the expert rating of question usefulness as the ground truth, we found that the useful questions generally had higher information scores than those not rated as useful, suggesting that our rationale for the formulation of these metrics (i.e., that higher scores reflect more concepts captured and therefore higher quality) was justified. At the same time, several questions had relatively low information scores but were still rated as useful by experts (e.g., “*What are two types of decision trees?*”) because they target a sufficiently *specific* concept. To detect these questions, it would be beneficial to incorporate measures of the generated questions’ level of specificity [6] into the existing information score metric.

The above results have been obtained without the need for any human-labeled domain encoding, which makes our question generation pipeline highly domain-agnostic and generalizable. At the same time, there are ample opportunities to further promote its adoption across different learning domains. First, more research is needed to investigate question generation when the learning contents are not entirely textual, but may include multimedia components. Recent advances in the area of document intelligence [1, 4], combining NLP techniques with computer vision, could be helpful in this direction. Second, there remains the need to diversify the generated questions to meet a wider range of assessment goals. In particular, most of our current questions start with “what” (e.g., those in Table ??), which are primarily geared towards recalling information. Incorporating other question types in the generation pipeline could elicit more cognitive processes in Bloom’s taxonomy [8] – for example, “how” questions can promote understanding and “why” questions are designed for analyzing – which in turn contribute to better learning overall. This diversifying direction is also an area of active research in the NLP and

QG community [13, 14].

We further note that the proposed pipeline is also customizable to individual domains, so as to enable higher quality questions. First, hyperparameter tuning on a dataset relevant to the learning domain would likely improve the performance of the T5 and GPT-3 models. Second, the concept extraction process could be enhanced with a combination of machine-generated and human-evaluated skill mappings, which have been shown to result in more accurate knowledge models [10, 12]. Finally, the question evaluation criteria may also benefit from subject matter experts' inputs to closely reflect the distinct nature of the learning domain; for example, chemistry assessments could potentially include both conceptual questions (e.g., "what is the chemical formula of phenol?") and scenario-based questions (e.g., "describe the phenomenon that results from mixing sodium metal and chlorine gas?").

ABSTRACT

In this work, we address the information overload issue that learners in Massive Open Online Courses (MOOCs) face when attempting to close their knowledge gaps via the use of MOOC discussion forums. To this end, we investigate the recommendation of one-minute-resolution video clips given the textual similarity between the clips' transcripts and MOOC discussion forum entries. We first create a large-scale dataset from Khan Academy video transcripts and their forum discussions. We then investigate the effectiveness of applying pre-trained transformers-based neural retrieval models to rank video clips in response to a forum discussion. The retrieval models are trained with supervised learning and distant supervision to effectively leverage the unlabeled data—which accounts for more than 80% of all available data. Our experimental results demonstrate that the proposed method is effective for this task, by outperforming a standard baseline by **0.208** on the absolute change in terms of precision.

Keywords

MOOC, Discussion Forum, Video Clip Transcripts, Clip Recommendation

1. INTRODUCTION

Massive Open Online Courses (MOOCs) provide open access to world class courses for the public, which greatly improves the opportunities in online learning. The discussion forum is a major component of a MOOC as it is the primary communication tool among learners and instructors [1] to moderate the lack of physical access in MOOCs. It can help learners build a sense of belonging and learn from peers, or help instructors monitor learner affect and academic progress [2]. However, since questions targeting the same video content are scattered among discussion threads, without supporting

navigation facilities, learners cannot effectively retrieve valuable discussions for a particular piece of content. In addition, learners' posts seeking help may be drowned out by the many other competing posts, making it hard for learners to get attention from instructors and peers. The unstructured, unorganized forums with a large amount of discussions (that can lead to information overload [19]) are hindering instructors and learners to benefit from them, decrease community interaction, reduce responsiveness in forums and in the end lead to low MOOC retention rates [20, 13].

Figure 1: Overview of MOOC-Rec.

Existing works directed at addressing the information overload issue in MOOC forums have proposed more effective navigation tools to identify instructional video contents and make recommendations of a ranked list of video clips. For example, [2] classify posts that need help and employ bag-of-words based retrieval techniques to map those posts to minute-resolution course video clips. The clip recommendation algorithm is evaluated on posts from one course. [17] built a recommender system to generate a ranked list of video clips giving a student's question with a deep neural network; they evaluate the system with 50 questions. Despite these attempts, we argue that prior works on video clip recommendation suffer from a lack of training data, and as a consequence report evaluations only on small-scale data. It remains a challenge to develop and evaluate a system that can scale to thousands of MOOCs, across different domains.

In our work, we first address the lack of training data issue by creating MOOC-CLIP, a novel large-scale dataset from Khan Academy¹, that includes video transcripts and forum posts (both questions and answers) using raw data available from LearningQ [3], an open source tool and dataset for educational question generation. Second, we propose MOOC-Rec,

¹<https://www.khanacademy.org/>

a dense retrieval based instructional video clip recommendation system for MOOC forum questions. For each content-related thread, **MOOC-Rec** recommends a ranked list of video clips that are likely relevant and helpful for answering the question. Although dense retrievers have been applied in various retrieval tasks such as DPR [6] and ColBERT [7], it is unknown whether they are an effective approach for MOOC video clip recommendation. Lastly we point out that only 11.57% of all discussions in our dataset are labeled with a target video clip, which poses challenges for training **MOOC-Rec** with limited labeled data and abundant unlabeled resources.

We here first investigate the effectiveness of **MOOC-Rec** and then we address the scarcity of labeled data by using distant supervision and in-batch negatives to train the ranker. The comprehensive experiments on our large-scale dataset which consists of about 274K discussions show that our systems significantly improve the clip recommendation performance by outperforming a standard baseline by 0.208 in terms of precision.

2. THE MOOC-CLIP DATASET

To address the lack of research data, we create a large-scale dataset using raw data crawled with **LearningQ**² from Khan Academy, a MOOC platform which allows learners to ask and answer questions about the learning materials during learning. We keep video transcripts, forum questions and answers of MOOCs which have both transcripts and discussions available.

Learners use discussion forums in different ways. Besides asking questions related to the course materials, they may also discuss irrelevant topics [14] for the purposes of socializing, spamming, or expressing their appreciation for the course materials. Some questions posted by learners also suffer from a lack of proper context, or are too generic. Therefore, it is necessary to remove these relatively—for our purposes—low-quality questions. In line with **LearningQ**, we consider a user-generated question to be useful for learning when all of the following conditions hold: (i) the question is concept-relevant, i.e., it seeks for information on knowledge concepts taught in lecture videos; (ii) the question is context-complete, containing sufficient context information to enable other learners to answer the question; and (iii) the question is not generic. Besides labeled questions in **LearningQ**, we manually labeled 2K (2,344 in total) as unknown set for our cross-topics evaluation, 8,766 questions on the remaining 5 topics for training, and 2,186 questions as known topic test set. We train a BERT-based text sequence classifier for useful question classification. Table 1 summarizes its performance.

During preprocessing, we first remove noisy discussions which

²<https://github.com/AngusGLChen/LearningQ>

Method	Same Topic			Cross-Topics		
	Acc	Rc	F1	Acc	Rc	F1
Q	89.40	96.68	92.90	77.20	74.49	75.82
Q+C	89.75	96.54	93.02	73.30	82.68	77.71

Table 1: Useful question classifier results.

contain only meaningless tokens, as well as videos which have no discussions. Then we apply the useful question classifier on all items(522K) and retain only items are classified as useful. In the end, we retain 273,887 discussions from 7,349 videos of 6 topics. We use regular expressions to retrieve discussions where learners label posts with exact timestamps in questions or answers. We split the video transcripts into snippets with a one minute length. The discussions and the snippets which cover the timestamp are labeled as *positive* items. The other discussions are treated as unlabeled. Table 2 and Figure 2 summarize the data statistics. In summary, there are 31,680 positive labeled items and 240,551 unlabeled items, i.e. 11.57% of all discussions are labeled.

Split	#V	#S/V	#W/S	#W/Q	#W/A
Train	4590	7.91	198.51	39.96	80.89
Dev	895	8.37	199.04	40.02	79.26
Test	1126	8.14	198.64	39.67	81.92
Unlabeled	7283	7.70	197.96	38.46	78.58

Table 2: Dataset overview, in terms of videos (#V), snippets (#S) per video, discussions (#D) per video, clip (#W), the number of words per question (Q) and the number of words per answer (A)

Figure 2: Dataset overview regarding the number of labeled and unlabeled questions in each topic. We can see the unbalanced distribution questions in each topic.

This dataset also covers a series of educational topics including math, science, careers, humanities, etc. We conduct an exploratory analysis along each topic dimension which is shown in Fig 2. We observe a topic imbalance, e.g. discussions under math and science topics account for 78.88% of labeled items and 76.82% of all items. The labeled data is then split into 80% and 20% for training and test sets respectively based on the number of discussions in each set.

3. METHODOLOGY

The problem of MOOC video clip recommendation studied in this paper can be described as follows. Given a forum

discussion question, the system retrieves a ranked list of the most relevant video clips as represented by their transcripts. We assume the questions filtered by the useful question classifier are relevant to the course materials, and the most relevant video clips should be instructional for learners. Assume a MOOC video \mathcal{V} lasts for T seconds, then we split it into s $t = 60$ seconds clips, where $s = \lceil \frac{T}{t} \rceil$. Then the video \mathcal{C} contains clips c_1, c_2, \dots, c_s . Each clip c_i is represented with its transcripts, which can be viewed as a sequence of tokens $w_1^i, w_2^i, \dots, w_{|c_i|}^i$. We also formally define a discussion as $d_i = [q_i, \{a_i\}]$, where $\{a_i\}$ are the answers to the question q_i . Note that in some cases the question has not been answered yet, which is common in MOOC forums. The task is retrieve a ranked list of clips $c_{i,1}, c_{i,2}, \dots, c_{i,s}$ given each discussion d_i . Notice that the video clip recommender needs to work effectively for MOOCs in different domains that the corpus covers. Formally speaking, the recommender $\mathcal{R} : (d, \mathbf{C}) \rightarrow \mathbf{C}_{\mathcal{R}}$ is a function that takes a discussion d and video clip list \mathbf{C} as the input and returns a ranked list of clips $\mathbf{C}_{\mathcal{R}}$. We can also choose to only return the top- K most relevant clips.

3.1 Dual-Encoder

We employ a standard neural IR architecture [6] for the ranker. It uses a dense encoder $E_C(\cdot)$ which encodes the video clip transcripts into m -dimensional real-valued vectors. At run-time, MOOC-Rec maps the input discussion $d = [q, a]$ to another m -dimensional vector using the query encoder $E_Q(\cdot)$, and retrieves the top- k most closest video clip vectors from the same video. We use cosine similarity to model the similarity between the discussion and the clip vectors by the following function:

$$\text{sim}(d, c) = \cos(E_Q(d), E_C(c)). \quad (1)$$

The goal of training is to learn a better embedding function for both the clips and discussions which can map relevant pairs of discussions and clips to vectors with smaller distance, i.e. higher similarity, so that the similarity function $\text{sim}(d, c)$ becomes a good ranking function for the task of MOOC video clip recommendation. This is essentially a *metric learning* problem [9, 11, 6].

Let $\mathcal{M} = \{(d_i, c_i^+, c_{i,1}^-, \dots, c_{i,n}^-)\}_{i=1}^m$ be the training MOOC discussion corpus that contains m instances. Each example has one discussion $d_i = [q_i, a_i]$, one relevant (positive) video clip transcript c_i^+ , and n irrelevant (negative) clips $c_{i,j}^-$. We train the retrieval model by optimizing the negative log likelihood of the positive clip:

$$L(d_i, c_i^+, c_{i,1}^-, \dots, c_{i,n}^-) = -\log \frac{e^{\text{sim}(d_i, c_i^+)}}{e^{\text{sim}(d_i, c_i^+)} + \sum_{j=1}^n e^{\text{sim}(d_i, c_{i,j}^-)}}$$

Positive and Negative Video Clips. For labeled discussions, positive and negative video examples are explicit. We use the video clip whose time duration contains the timestamp of the discussion as the positive example. All other video clips from the same video can be treated as negatives. As MOOC videos vary in the number of clips and to boost the model training and balance the number of positive and negative examples, we selected n of them as the training

negative examples. We apply in-batch negatives [5, 6] for training. In this case, the positive clips for other questions are also treated as the negatives for the current question.

Distant Supervision with Unlabeled Data. As we show in Table 2, over 80% of all discussions are unlabeled (i.e. there is no video timestamp available). It would be labor-intensive and expensive to create human annotations. Thus, we adopt *distant supervision* [10] to effectively utilize the rich unlabeled data and train a better model with them. This process involves training the model with noisy weakly labeled data. MOOC-Rec is able to achieve over 50% precision in top-1 prediction and over 70% in top-3 with a Recall@3 of over 80%. Therefore, we use the ranker trained on the labeled training set as the scorer and clips with the highest $\text{sim}(d, c)$ are selected as positives while the clips with the lowest $\text{sim}(d, c)$ (besides top-3) as negatives. The weakly labeled data are then used to train the ranker.

Inference. During inference time, we pre-compute all clip embedding v_c by applying the clip encoder E_C to all MOOC video clips offline. Given a discussion $d = [q, a]$ at run-time, we concatenate the question and answers if a is available and compute the discussion embedding $v_d = E_Q(d)$. The clips are then ranked by $\text{sim}(d, c)$ and the top- k are retrieved.

Although encoders can be implemented in many different ways [10], in this work, we use two independent BERT [4] variant models as encoders and the mean value of all token embeddings is used as the final representation. We tokenize clip transcripts and truncate the token list to maximum length of 512 (starting with [CLS] and ending with the [SEP] token). The discussion encoder works as a *query* encoder in typical neural IR systems. Instead of using separate encoders for questions and answers of the discussion, in our design both of them share the same encoder. In this way, we train a better query encoder for questions by taking advantage of important answer information.

3.2 Cross-Encoder

Both the cross-encoder and dual-encoder are two common approaches for matching sentence pairs. While the dual-encoder produces sentence embedding vectors for clips and discussions independently, the cross-encoder treats the clip recommendation for discussions as a sequence classification task and performs full self-attention over the entire sequence. We concatenate the video clip transcripts and the discussions (question and answers) with the [SEP] token as the input to the transformer network. The [CLS] token embedding is then passed to a binary classifier to predict the binary relevance between them.

4. EXPERIMENTS AND RESULTS

4.1 Experimental Settings

Implementation. Two BERT variants: MPNet [16] (*abbrv.* MP, embedding size: 768) and MiniLM [18] (*abbrv.* MP, embedding size: 384) are used as text encoders. We implement dual-encoders using pre-trained weights provided by

Sentence-Transformers library³ [15]. Both models are pre-trained on a large and diverse dataset of over 1 billion training query-paragraphs pairs for the semantic search task. The Adam optimizer [8] with warming-up and cosine schedule is used for training; we set the maximum learning rate to $lr = 2e^{-5}$, $\epsilon = 1e^{-8}$ and the warmup steps to 1000. For the **cross-encoder** baseline, we follow previous research [10, 12]. The **BM25** baseline is based on the Okapi BM25 implementation of the `rank_bm25` library⁴. We train our models using 8 GTX-1080 GPUs for 10 iterations with a batch size of 32. As Figure 3 shows, after one iteration, both clip recommendation systems outperform the BM25 baseline.

Table 3: Performance of the proposed MOOC-Rec ranker and baselines on the test set in terms of rank-aware metrics. MLM/MP_{dual} represents the MiniLM or MPNet based dual-encoder and MLM/MP_{cross} represents the MiniLM or MPNet based cross-encoder. “PT” represents ranker performance using pre-trained encoders without fine-tuning. “FT” means fine-tuned model performance. “WL” means the model performance after training with weakly labeled data.

Method	P@1	MRR	MRR@3	nDCG	nDCG@5	
BM25	0.417	0.600	0.550	0.696	0.593	
PT	MLM _{cross}	0.132	0.346	0.254	0.497	0.297
	MLM _{dual}	0.422	0.614	0.568	0.707	0.617
	MP _{cross}	0.135	0.344	0.248	0.495	0.288
	MP _{dual}	0.386	0.583	0.529	0.683	0.576
FT	MLM _{cross}	0.511	0.677	0.641	0.755	0.683
	MLM _{dual}	0.529	0.692	0.658	0.767	0.700
	MP _{cross}	0.613	0.745	0.716	0.807	0.750
	MP _{dual}	0.570	0.720	0.690	0.788	0.730
WL	MLM _{cross}	0.540	0.696	0.661	0.770	0.700
	MLM _{dual}	0.520	0.683	0.646	0.760	0.687
	MP _{cross}	0.625	0.751	0.722	0.812	0.754
	MP _{dual}	0.557	0.711	0.680	0.782	0.720

4.2 Effectiveness of Dense Retrieval

Performance Comparison with Baseline. After several iterations, the models’ performance first improves gradually and then becomes steady as illustrated in Figure 3, which shows the effectiveness of the training system and the effectiveness of the proposed models. Table 3 summarizes the models’ effectiveness on the test set. We use BM25 as our baseline. Sparse vector-space models and the probabilistic BM25 model have been widely used in instructional clip recommendation systems. BM25’s effectiveness in terms of Precision@1 (P@1) and MRR is 0.417 and 0.60 respectively, which shows queries possess more lexical similarity to related MOOC clips than other clips in the course video and BM25 is an effective and strong baseline for this task. First, we find that without fine-tuning, the pre-trained dual-encoder can achieve similar (MPNet), or even better (MiniLM-L6) performance than the BM25 baseline, while the cross-encoders cannot make clip recommendation for discussions without

³<https://github.com/UKPLab/sentence-transformers>

⁴https://github.com/dorianbrown/rank_bm25

training. Second, we observe significant gains ($p = 1.95e^{-7}$) when using the MOOC-Rec neural ranker after it has been trained on the data, with gains of over 0.15 in P@1 and over 0.19 in nDCG scores compared to the BM25 baseline. Thus, dense retrieval is an effective instructional MOOC clip recommendation approach for forum discussions which can model the relevance between discussions and clip transcripts.

Impact of Model Size. To compare the impacts of model size, we use one distilled transformer model MiniLM which contains **22M** parameters and one BERT size model MPNet which contains **109M** parameters. As Table 3 shows, in both cross-encoder and dual-encoder settings, the larger model (i.e. MPNet) achieves better effectiveness after training, which shows that the transformer model with more parameters may have a better potential to model the relevance between clips and discussions.

Comparison of Cross-Encoder and Dual-Encoder. Both cross-encoder and dual-encoder are commonly used for sentence pair matching problems. In Table 3, we observe that with the distilled transformer model the dual-encoder outperforms the cross-encoder by 0.018 in terms P@1. However, with large model, the cross-encoder outperforms dual-encoder by 0.043 on P@1, and around 0.02 on other metrics. Despite the performance advantage of the cross-encoder with a large model, as outlined in Section 3.2, we observe a massive computational overhead with the cross-encoder as illustrated in Figure 5.

Effect of Distant Supervision. In the weakly-labeled data (WL) section of Table 3, we summarize the different models’ performance after distant training with weakly labeled data. Compared with model trained with labeled data only, cross-encoders benefit from WL (+0.029 for MiniLM and +0.012 for MPNet in terms P@1), while dual-encoders perform gets worse (-0.009 for MiniLM and -0.013 for MPNet in terms P@1). Our hypothesis is that although MOOC-Rec achieves a good effectiveness after the initial training, the weakly labeled data created with it still contains considerable noisy content.

5. CONCLUSIONS

We studied the task of video clip recommendation in the context of MOOC forums which has the eventual goal to reduce learners’ information overload. We created a novel dataset MOOC-Clip which includes video transcripts and discussions. We systematically investigated how well the state-of-art pre-trained neural IR models work for the task of MOOC clip recommendation, and proposed a framework including data preparation, useful question classification, clip ranker and weak supervision training for this task. We conducted the experiments with both cross-encoders and dual-encoders. The results on our dataset show that neural IR approaches are indeed effective—at the same time, a P@1 value of less than 0.63 (at best) shows that we are still far away from solving this task. In future work, we plan to further investigate the factors that affect MOOC-Rec’s effectiveness such as the clip duration and methods of creating weak labels.

ABSTRACT

Knowledge tracing (KT) is an essential task in online education, which dynamically assesses students' mastery of concepts by predicting the probability that they correctly answer questions. One of the most effective solutions for knowledge tracing is graph-based methods. They maintain multiple vectors to represent students' mastery of concepts, and use these vectors to predict the probability of students correctly answering questions. To give more accurate predictions, the graph-based methods require concept relations to update these vectors once students answer questions. However, the concept relations usually require manual annotation in a real-world scenario, limiting the application of the graph-based method. In this paper, we proposed a method called Automatical Graph-based Knowledge Tracing (AGKT), which is a graph-based method that updates these vectors without requiring manually annotated concept relations. We evaluate our method on four public datasets and compare it with ten advanced methods. The experiment results demonstrate that AGKT yields superior performance.

Keywords

online learning, knowledge tracing, graph-based method

1. INTRODUCTION

Knowledge tracing is a task that estimates students' mastery of knowledge by predicting the probability that they correctly answer questions. It plays a significantly important role in the online educational application, like exercise recommendation and knowledge diagnosis. The input of knowledge tracing is the question-answering history of a student and a new question, and the output is the probability of the student correctly answering the question. For instance, in step 4, the knowledge tracing aims to use the student's performance on q_1, q_2, q_3 to predict the probability of the student correctly answering q_4 in Figure 1.

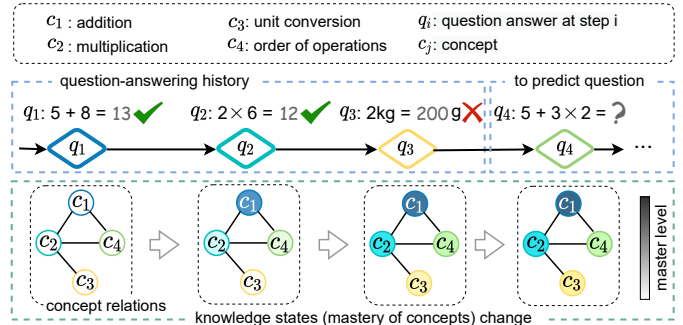

Figure 1: An example of a student's question-answering sequence and the change of her (his) knowledge states. The darkness of a circle's color represents the level of the student masters the corresponding concept, and more darkness denotes a better mastery.

To address the knowledge tracing problem, many outstanding methods [11, 17, 8, 19, 7, 1, 5, 3, 10, 18, 12, 9, 14] have been proposed, which could be grouped into graph-free methods [11, 17, 8, 19, 7, 1, 5, 3, 10, 18, 12] and graph-based methods [9, 14]. Graph-free methods are directly built based on the sequential models, like auto-regressive methods [13, 6, 2], Transformer [15]. They maintain one or multiple vectors to represent students' mastery of knowledge concepts, which denotes as knowledge states, and they predict students' performance based on vectors. As students' knowledge states change with time, to maintain the latest knowledge states for prediction, they update the vectors which represent knowledge states according to the questions and question-concept relation immediately after students answer questions. However, according to the previous research, concepts in one specific domain are correlative with each other [7, 19]. Thus, when a student has a deeper understanding of one concept, her (his) mastery of the correlative concepts also changes. For instance, answering q_1 enhances the student's mastery of *addition* in Figure 1. Since *addition* is correlative with *multiplication* in the concept relation graph, the deeper understanding of *addition* enhances her (his) mastery of *multiplication*. Hence, the knowledge states are not only influenced by questions and question-concept relations, but also influenced by the relations among concepts.

Due to this reason, the graph-based methods introduce the concept-relation graph when they update students' knowl-

edge states. Though the graph-based methods gain many achievements in performance and interpretability, the concept-relation graph usually relies on manual annotation, which is almost impossible for cases with thousands of concepts. To address this issue and keep the superiority of graph-based methods, we proposed a method called Automatic Graph-based Knowledge Tracing (AGKT), which is independent on the manual-annotated concept relation, but could update students' knowledge states like graph-based methods by considering question, question-concept relation and concept-concept relation. We perform experiments on four real-world datasets, and compare our method with ten excellent models. The experiment results reveal that our method has superior performance to the other methods.

2. PROBLEM FORMULATION

Suppose the learning history of a student is $\mathcal{X}_{t-1} = \{(q_1, r_1), (q_2, r_2), \dots, (q_{t-1}, r_{t-1})\}$. Here, q_i denotes the question the student answers at step i . r_i denotes the correctness of the student's response on q_i , and

$$r_i = \begin{cases} 1, & \text{if the student's answer is right;} \\ 0, & \text{otherwise.} \end{cases} \quad (1)$$

Each question is related to one or multiple concepts. We denote the set of concepts as $C = \{c_j\}_{j=1}^{|C|}$, and the set of the concepts which are related to q_i as C_i , and the set of the concepts which are unrelated to q_i is denoted as D_i . Obviously, $C_i \cup D_i = C$.

The task of knowledge tracing is formulated as estimating the probability that the student correctly answer a new question q_t given the question-answering history \mathcal{X}_{t-1} , *i.e.*, $P(r_t = 1 | q_t, \mathcal{X}_{t-1})$. We approach that by learning a function to estimate the probability:

$$\bar{r}_t = f_{\Theta}(\cdot), \quad (2)$$

where $\bar{r}_t = P(r_t = 1 | q_t, \mathcal{X}_{t-1})$ and the input of $f_{\Theta}(\cdot)$ represent the features used to predict the correctness of the student.

3. METHOD

As we discussed previously, students' latest knowledge states are necessary to predict the probability of students correctly answering questions. Moreover, considering the question, the question-concept relation and concept-concept relation in knowledge state update benefits for the performance. Nevertheless, annotating the concept-concept relation is almost impossible. To reserve the superiority of the graph-based methods in the condition of manual annotated concept-concept relation absent, we proposed a method called Automatic Graph-based Knowledge Tracing (AGKT). It is composed of three components, as Figure 2 (a) illustrates: Automatic Graph (AG), state update module and prediction module. AG is obtained according to question-concept relation, which replaces the concept relation graph to assist the state update module in updating students' knowledge states. The prediction module predicts the probability of students correctly answering questions by students' knowledge states and the question information. In the following, we will discuss the AG first. Then, we will present how to update students' knowledge states based on AG in the

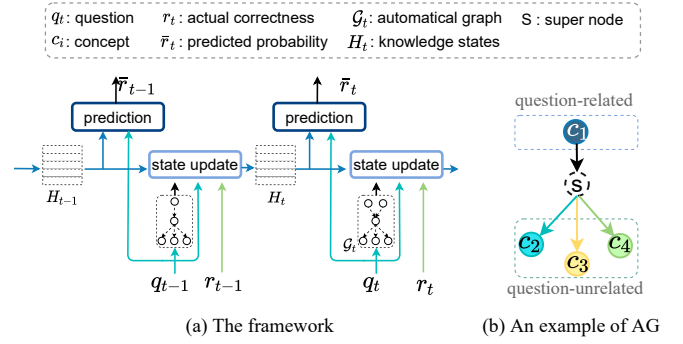

Figure 2: (a) The framework of Automatic Graph-based Knowledge Tracing (AGKT). (b) An example of the Automatic Graph (AG) for the q_1 in Figure 1.

state update module. Finally, we will discuss the prediction module.

3.1 Automatic Graph (AG)

Each question corresponds to an Automatic Graph (AG). Figure 2(b) illustrates the corresponding AG for q_1 in Figure 1. We denote the graph corresponds to q_t as \mathcal{G}_t , and $\mathcal{G}_t = \{\mathcal{V}_t, \mathcal{E}_t\}$. \mathcal{V}_t is the node set, and $\mathcal{V}_t = \{V_t^c, V_t^d, s\}$. Here, each node in V_t^c represents a concept in C_t . That is, each node in V_t^c represents one question-related concept. Each node in V_t^d represents a question-unrelated concept (D_t). For the ease of presentation, we call these nodes by concepts when there is no ambiguity. s is the supernode, which connects the question-related concepts and question-unrelated concepts. \mathcal{E}_t represents the edges on \mathcal{G}_t , and $\mathcal{E}_t = \{E_c, E_d\}$, E_c represents the edges between V_t^c and s , and E_d represents the edges between V_t^d and s .

3.2 The state update module

Since the questions require students to utilize their knowledge of question-related concepts to answer, which increases their comprehension of the question-related concepts, and causes their knowledge states on these concepts to change once they answer questions. As concepts are correlative, these changes will also influence the knowledge states of some question-unrelated concepts. Based on this, we maintain a vector for each concept to represent a student's knowledge state on it. When a student answer a question, we update the knowledge states of question-related concepts first, and then we update the knowledge states of question-unrelated concepts according to the AG.

3.2.1 The state update of question-related concepts

Suppose a student interacts with question q_t at step t . After the student answer q_t , we update the knowledge states of question-related concepts by concepts' attributes and the student's response on q_t . Specifically, for a concept $c_i \in C_t$, we integrate its embedding and the student's correctness by:

$$\mathbf{z}_i^c = \begin{cases} \mathbf{e}_i^c \oplus \mathbf{0}, & r_t = 1, \\ \mathbf{0} \oplus \mathbf{e}_i^c, & r_t = 0, \end{cases} \quad (3)$$

where $\mathbf{0} = (0, 0, \dots, 0)$, is a d dimension zero vector. $\mathbf{e}_i^c \in \mathbf{R}^d$ denotes the embedding of c_i . \oplus denotes the concatenation.

Then, we feed the concatenation into the cell of recurrent neural network (RNN) to update the knowledge state of c_i :

$$\mathbf{h}_{t+1}^i = GRU(\mathbf{z}_t^i, \mathbf{h}_t^i), \quad (4)$$

where \mathbf{h}_t^i denotes the knowledge states on concept c_i at step t , it is the i -th row of the knowledge states matrix \mathbf{H}_t . GRU denotes the gated recurrent unit [2].

3.2.2 The state update of question-unrelated concepts.

The knowledge states of one concept will influence the concepts that correlate to it, *e.g.*, the knowledge state of *multiplication* is influenced by the knowledge state of *addition* after the student answer q_1 in Figure 1. Thus, the update of question-unrelated concepts should be based on the relation of concepts. Since the concept relation is unknown in many cases, we update the knowledge states of question-unrelated concepts based on AG (Figure 2 (b)). Since the question-related concepts connect to the supernode, and the supernode connects the question-unrelated concepts in AG, the supernode integrates the message about the knowledge states of all the question-related concepts first. Then it transmits the integrated message to question-unrelated concepts. Finally, the question-unrelated concepts update their knowledge states according to the message transmitted from supernode. Specifically, we take the following steps to update the knowledge states of the question-unrelated concepts:

First, we represent the original message that a question-related concept c_i sent to the supernode by:

$$\mathbf{m}_t^i = \mathbf{h}_{t+1}^i \oplus \mathbf{o}_i, \quad (5)$$

where \mathbf{o}_i is the one-hot encoding of concept c_i to denote the identity of the message source. The supernode aggregates the messages from the question-related concepts by:

$$\mathbf{h}^s = \frac{1}{|C_t|} \sum_{c_i \in C_t} f_s(\mathbf{m}_t^i), \quad (6)$$

where f_s denotes multi-layer perceptrons (MLP). \mathbf{h}^s denotes the states of the supernode.

Then, the supernode transmits the message it receives to the question-unrelated concepts. We represent the message obtained by the question-unrelated concept c_j ($c_j \in D_t$) as

$$\mathbf{m}_t^j = f_{d,j}(\mathbf{h}^s), \quad (7)$$

$f_{d,j}$ denotes the mapping function, which is implemented by MLP, to extract the message which is interested by c_j , *e.g.*, the knowledge states of its correlative concepts. Note, for different question-unrelated concepts, the mapping functions in Eq. 7 are different. However, for the same question-unrelated concept in different time steps, the mapping function is shared to guarantee the pattern are compatible in all steps.

Finally, we update the knowledge state on question-unrelated concept c_j by:

$$\mathbf{h}_{t+1}^j = GRU(\mathbf{m}_t^j, \mathbf{h}_t^j). \quad (8)$$

3.3 The prediction module

To predict the probability of students correctly answering questions, we consider the attributes of question q_t , the level

Table 1: Dataset statistics.

Dataset	ASSIST09	ASSIST12	EdNet	Junyi Math
Students	2,968	22,422	50,000	1,146
Records	185,110	1,839,429	3,266,010	101,854
Questions	15,003	45,543	12,077	1,145

Attempts Per Question	12.34	40.39	270.43	71.98
Attempts Per Concept	1,914.21	18,580.10	39,959.14	2,611.64
Positive Label Rates	63.80%	69.60%	59.54%	66.78%

of the student master question-related concepts, and her(his) knowledge background. We represent the attributes of question q_t by the question embedding \mathbf{e}_t^q , and $\mathbf{e}_t^q \in \mathbf{R}^d$. We represent the level of the student master the question-related concepts by the mean knowledge state:

$$\mathbf{h}_m = \frac{1}{|C_t|} \sum_{c_i \in C_t} \mathbf{h}_t^i. \quad (9)$$

We represent students' knowledge background as

$$\mathbf{h}_c = \frac{1}{|C|} \sum_{c_i \in C} \mathbf{h}_t^i, \quad (10)$$

and then we predict the probability of the student correctly answering q_t by

$$\bar{r}_t = \delta(f_r(\mathbf{h}_c \oplus \mathbf{e}_t^q \oplus \mathbf{h}_m)), \quad (11)$$

where f_r denotes MLP, and δ denotes the Sigmoid function.

3.4 Model Learning

The objective function of our model is to minimize the negative log-likelihood of the observed sequence. The sequence is the question-answering history of the student from step 1 to T . The learning parameters of our method are the embedding of concepts and questions, the weights in GRU, the parameters of all the MLPs. The parameters are jointly learned by minimizing the cross-entropy between the predicted probability \bar{r}_t and the students' actual correctness r_t as

$$\mathcal{L} = - \sum_{i=1}^T (r_i \log \bar{r}_i + (1 - r_i) \log(1 - \bar{r}_i)). \quad (12)$$

4. EXPERIMENT

4.1 Dataset

We evaluate our method on four public datasets: ASSIST09, ASSIST12, EdNet, and Junyi Math. These datasets record the question-answering history of students. We take the questions, the concepts related to the questions, and the students correctness of responses from the records. The maximum length of students' question-answering history is set to 200. We split 80% data for training and validation, and 20% for testing. The statistics of the four datasets are shown in Table 1. Note, the statistics are the actual samples we use in our experiments after preprocessing, which are different from the statistics of raw data.

4.2 Baselines

To evaluate the effectiveness of our model, we compare our method with graph-free methods, and graph-based methods. The graph-free methods trace students' knowledge

Table 2: The AUC on four public datasets.

Model	ASSIST09	ASSIST12	EdNet	Junyi Math
BKT	0.6815	0.6142	0.5729	0.6293
KTM	0.6734	0.6881	0.7071	0.7207
SAKT	0.6884	0.6914	0.7313	0.7422
SAINT	0.6901	0.6917	0.7336	0.8079
AKT-NR	0.6940	<u>0.7098</u>	0.7450	0.7705
DKT	0.6769	0.6884	0.7496	0.8397
DHKT	<u>0.7499</u>	0.6966	<u>0.7547</u>	<u>0.8594</u>
EERNNA	0.7244	0.7000	0.7437	0.8196
DKVMN	0.7235	0.6664	0.7009	0.8426
GKT	0.7488	0.6857	0.7039	0.8257
AGKT	0.7765	0.7232	0.7589	0.8656

states without considering concept-relation, and they could be grouped into four groups. The first group are traditional methods, *i.e.*, BKT [4], KTM [16], which trace the students’ knowledge states according to the factors that affect students’ learning. The second group are single-state methods, *i.e.*, DKT [11], DHKT [17], EERNNA [7], which use one vector to represent students’ knowledge states on all concepts. The third group is multi-state methods, *i.e.*, DKVMN [19], which maintain a vector for each concept to represent students’ knowledge states on them. The fourth group are state-free methods, *i.e.*, SAKT [10], SAINT [3], AKT-NR [5], which maintain no explicit vector to represent students’ knowledge states. The graph-based methods apply a concept-relation graph in the knowledge state update. Here we choose the GKT [9].

4.3 Student Response Prediction

We measure the AUC to evaluate the performance of models. A higher AUC indicates a better performance. Table 2 shows the converged ACC, AUC. According to Table 2, on the ASSIST09, our method is better than the best baseline DHKT by 2.66% in AUC. On ASSIST12, our model outperforms the best baseline AKT-NR 1.34% in AUC. On EdNet, our model is better than the best baseline DHKT by 0.42% in AUC. On Junyi, our method is better than the best baseline DHKT 0.64% in AUC. Thus, the performance presented in Table 2 demonstrates that our method is effective.

4.4 Ablation Study

To further verify the contribution of AG, we conduct experiments on ASSIST09 with three comparative settings:

- **MovGraph** removes the AG from AGKT. Thus, this setting removes the concept-concept relation.
- **DenGraph** replaces the AG in AGKT with the dense graph in GKT [9]
- **TransGraph** replaces AG with the transition graph in GKT.

The experimental results are shown in Figure 3. We can find that: (1) *AGKT*, *DenGraph* and *TransGraph* have better performance than *MovGraph*. That means the consideration of concept-concept relation is beneficial; (2) Replacing AG in AGKT with other graphs (*DenGraph*, *TransGraph*) decreases the performance. That means the AG is more effective in the framework of AGKT.

4.5 Case Study

**Figure 3: The contribution of AG.****Figure 4: The state of supernode and the message received by the question-unrelated concepts.****Figure 4: The state of supernode and the message received by the question-unrelated concepts.**

To investigate whether the states update of question-unrelated concepts is interpretable, we randomly pick two question-answering records, and visualize the state of supernode and the message obtained by question-unrelated concepts. We expect the knowledge states of question-unrelated concepts could be automatically updated according to the actual relationship with the question-related concepts when AGKT converges. Thus, for the correlative concepts of the question-related concepts, the message they receive from supernode should be correlated with the state of the supernode.

The results is presented in Figure 4. We can observe the message obtained by *triangle properties* (No.21) is highly close to supernode when the student answer the question related to *congruent triangles* (No.9), and message obtained by *rates and ratios* is highly close to the state of supernode when the student answer the question related to *ratio-percentage* (No.29). Thus, the state update of question-unrelated concepts is interpretable in our method. which demonstrates our method has good interpretability.

5. CONCLUSION

In this paper, we proposed a method called Automatic Graph-based Knowledge Tracing (AGKT). Different from the previous graph-based methods, it adopts the Automatic Graph (AG) to automatically update students’ knowledge state without requiring the manually annotated concept relation. We evaluate the performance of our method on four public real-world datasets, and compare it with ten methods. The experiment result reveals that our method is effective in tracing student’s knowledge states.

Process-BERT: A Framework for Representation Learning on Educational Process Data

Alexander Scarlatos¹, Christopher Brinton², and Andrew Lan¹

University of Massachusetts Amherst¹, Purdue University²

ajscarlatos@cs.umass.edu, cgb@purdue.edu, andrewlan@cs.umass.edu

ABSTRACT

Educational process data, i.e., logs of detailed student activities in computerized or online learning platforms, has the potential to offer deep insights into how students learn. One can use process data for many downstream tasks such as learning outcome prediction and automatically delivering personalized intervention. In this paper, we propose a framework for learning representations of educational process data that is applicable across different learning scenarios. Our framework consists of a pre-training step that uses BERT-type objectives to learn representations from sequential process data and a fine-tuning step that further adjusts these representations on downstream prediction tasks. We apply our framework to the 2019 nation’s report card data mining competition dataset that consists of student problem-solving process data and detail the specific models we use in this scenario. We conduct both quantitative and qualitative experiments to show that our framework results in process data representations that are both predictive and informative.¹

1. INTRODUCTION

Student modeling [14] is a key research area in educational data mining since it produces estimates of individual factors that affect learning outcomes, including knowledge factors and psychosocial factors such as affect and interest, and informs personalization. There exist a wide range of student models, from those that analyze student *responses* to questions, such as item response theory [12] and models for knowledge tracing [3], to those that analyze student *activity* within digital learning platforms [1, 15, 16].

Educational process data, i.e., data that logs detailed student activity in digitized learning/testing environments, offers us an opportunity to look deeper into the process of learning for each individual student. One can use this process data in many ways: First, standalone process data, especially data from intelligent tutoring systems, learning management systems, or massive open online courses A. Scarlatos, C. Brinton, and A. Lan. Process-BERT: A framework for representation learning on educational process data. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 715–719, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

<https://doi.org/10.5281/zenodo.6853006>

(MOOCs), can help us capture student behavioral patterns and predict future learning outcomes [9] or help prevent early dropout [6]. Second, process data during assessments, such as the dataset used in the 2019 nation’s report card (NAEP) data mining competition [11], can help us reconstruct the exact process behind how students construct their response to a question. This reconstructed process can potentially help us improve our estimate of student knowledge levels more than using only observed response [2].

One key challenge in educational process data analysis is how to represent process data. Creating good representations is key to improving performance in downstream tasks, as evident in recent advances in other fields, such as pre-trained language models like BERT [4] in natural language processing. The idea is simple: since we often lack a large amount of labels on the variable of interest in the prediction task, e.g., student learning outcomes, using these labels to learn representations of student process data in a supervised learning setup is insufficient and can lead to overfitting. Instead, we start with using the rich process data itself in a *pre-training* step to learn representations through self-supervised learning before *fine-tuning* these representations in the actual downstream prediction task.

1.1 Contributions

In this paper, we propose a generic framework for representation learning from educational process data and apply it to the NAEP Competition dataset [11]. First, we detail how to learn process data representations in a pre-training setup using objectives similar to those used in BERT. We then detail how to fine-tune these representations and use them in a downstream supervised learning task, e.g., predicting learning outcomes. Second, we apply our framework to problem-solving clickstreams as students take an online NAEP assessment and detail our modeling designs. Third, we conduct quantitative experiments to show that our framework is competitive with existing methods in multiple learning outcome prediction tasks. We also conduct qualitative experiments to show that our framework is able to learn meaningful process data representations.

2. METHODOLOGY

In this section we describe our framework, as well as apply it to several learning outcome prediction tasks using the NAEP 2019 competition dataset [11]. The basic ideas behind our framework follow from those in natural language processing (NLP) research but are adapted for student learning process

Figure 1: The process model is pre-trained by predicting the properties of each event given surrounding context.

data. There are three main technical components in our framework: 1) the **process model**, which takes a student’s process data as input and produces its *latent representation vectors* as output, 2) the **pre-training objectives**, which are a series of prediction tasks that we use in a self-supervised pre-training phase on the process data to learn its representations via the process model, and 3) the **transfer function**, which adapts the output of the process model, i.e., the latent representations of process data, for use in a downstream learning outcome prediction task.

2.1 Dataset

The dataset contains clickstream logs from students working on two blocks of online NAEP assessments, referred to as blocks A and B. Students are given a time limit of 30 minutes per block, in which they can complete questions in any order. The questions vary in type, including multiple choice, matching, fill in the blank, and “mixed” types. Each event in the log represents a single student action, such as selecting an option in a multiple choice question, typing a character into an answer field, opening the calculator tool, etc. Each raw event in the log contains the student ID, question ID, question type, event type, timestamp, and possibly additional event-specific information such as the target of a click event or the field and character of a key press event. To apply our framework to the NAEP assessment scenario, we process each event so that it has the form $e_t = (a_t, m_t, q_t, c_t)$, where a_t is the event type, m_t is the number of seconds since the student started the test, q_t is an identifier for the current question, and c_t is a response status, which is either *correct*, *incorrect*, or *incomplete*. We additionally define a *visit* as a contiguous sequence of events that are part of the same question, as students may return to previously visited questions within a block. The sequences we provide to the process model each comprise all events of a single student working on a single question across all visits to that question.

2.2 Process Model and Pre-training

We now detail our process model, as well as the objectives used to pre-train it before it can be used on downstream tasks. Our process model is a Bi-LSTM [7], which contains two LSTM’s that run in parallel; one processes the sequence

in order, and the other processes it in reverse. The hidden state of the forward LSTM at time step t , \vec{h}_t , contextualizes e_0, \dots, e_t . Similarly, the hidden state of the backward LSTM at time step t , \overleftarrow{h}_t , contextualizes e_t, \dots, e_T , for sequences of length T . As input to the model, we use a vectorized form of each event, e_t , which contains the concatenation of m_t , learnable embeddings of a_t and q_t , and a one-hot encoding of c_t .

To pre-train the model, we design separate objectives to predict the *event type*, *timestamp*, and *response status* of each event in a student’s process data for a question. By learning to predict these features of the input using context, as we will show, the model becomes able to make inferences about the data, which will be useful for making predictions in downstream tasks. Note that we don’t include a pre-training objective for q_t because it is the same for every event in a question. The flow of data from input sequence to prediction is shown in Figure 1.

We predict the properties of event e_t at each time step by leveraging its full context, which includes all preceding and following events, i.e., $\{e_1, \dots, e_{t-1}, e_{t+1}, \dots, e_T\}$. Since \vec{h}_{t-1} uses on information from $\{e_1, \dots, e_{t-1}\}$ and \overleftarrow{h}_{t+1} uses on information from $\{e_{t+1}, \dots, e_T\}$, we use $\mathbf{z}_t = (\vec{h}_{t-1}, \overleftarrow{h}_{t+1})$ as the encoded context that will be used for prediction. We predict a_t by passing \mathbf{z}_t through a linear prediction head, P_a , using the softmax function [5] to get a probability distribution over possible event types, and use cross-entropy to calculate the loss. We predict c_t in the same way. We design a similar objective for m_t , except that we predict an alternate target, $r_t = \frac{m_t - m_{t-1}}{m_{t+1} - m_{t-1}}$, which represents the portion of time between the prior and following events when m_t occurs. This value is bounded by 0 and 1, which allows us to use binary cross-entropy as the loss function. The advantage to this method over mean-squared error is that because time lapses between student events can vary greatly, the loss for each event is treated more equally. The final pre-training loss for the sequence, \mathcal{L}_{PT} , is the sum of the prediction loss for a_t , m_t , and c_t for each event in the sequence. My minimizing \mathcal{L}_{PT} , the process model learns to reconstruct events based on surrounding context in a self-supervised setup, thus encoding relevant information in its latent states as a result.

2.3 Transfer Learning

We now detail a transfer function, Q_ϕ , that produces a fixed-size output for a downstream prediction task, given the latent states of the process model as input. For the purpose of transfer learning, we define the outputs of the process model to be $\mathbf{z}_1, \dots, \mathbf{z}_T = ((\vec{h}_1, \overleftarrow{h}_1), \dots, (\vec{h}_T, \overleftarrow{h}_T))$. This setup results in each \mathbf{z}_t containing contextualized information that is relevant to the input at time step t , as was ensured by the pre-training process. We combine these outputs using a learnable attention module [5], which assigns a weight to each output latent state of the process model, and then uses the weights to combine all outputs into a single vector. We define the weight vector as $\mathbf{w} = \text{softmax}(\phi_w(\mathbf{z}_1), \dots, \phi_w(\mathbf{z}_T))$, where ϕ_w is a learnable linear projection. We then generate a single vector to represent the entire sequence: $\mathbf{b} = \sum_{t \in \{1, \dots, T\}} w_t \cdot \mathbf{z}_t$.

We can now use this representative vector in a several ways to solve downstream tasks. In the simple case, where we predict the learning outcome at the level of a single question, e.g., the correctness of the student’s response to the question, we can generate the prediction $\hat{y} = \phi_q(\mathbf{b})$, where ϕ_q is a learnable linear projection. Additionally, we may want to predict the learning outcome at the level of a student, e.g., the student’s score on a future test, which requires us to combine the representative vectors for each question in the student’s process data. To achieve this, we define a feed-forward neural network ϕ_s , and generate predictions using the concatenation of the representative vectors for each question: $\hat{y} = \phi_s([\mathbf{b}_1, \dots, \mathbf{b}_Q])$, where \mathbf{b}_j corresponds to the representation of the student’s activity on question j and Q is the total number of questions. In either case, each ϕ in the transfer function can be trained by using an appropriate loss function on the predicted label. In the next section, we show an example of how the transfer function can be used to enhance a separate prediction task.

2.4 Item Response Theory

A popular framework for making predictions at the question level is item response theory (IRT) [8]; we now detail how to enhance it with behavioral data. The 1PL version of IRT learns an *ability* value for each student and a *difficulty* value for each question, which are used to predict the probability that a student will answer a question correctly. We introduce a new *behavior* term, which will adjust the model’s prediction based on the student’s process data for the question. We derive the term using the transfer function: $B_{ij} = \phi_q(\mathbf{b}_j^i)$, where \mathbf{b}_j^i is the representative vector for student i ’s process data on question j , as generated by the process model and the attention module. The predicted probability of a student getting a question correct is defined as $P(Y_{ij} = 1) = \sigma(k_i - d_j + B_{ij})$, where Y_{ij} is an indicator of the correctness of the student’s response, k_i is the learned student ability, d_j is the learned question difficulty, and σ is the sigmoid function. By minimizing the binary cross-entropy loss of the prediction with the actual correctness label, the model can jointly learn \mathbf{k} , \mathbf{d} , and Q_ϕ . Note that for this task, we must remove all indications of response status from the data and not perform the response status pre-training objective, since including them would leak information that could infer the label directly.

3. EXPERIMENTS

In this section, we present the experimental results of our framework applied to the NAEP competition data on two learning outcome prediction tasks. We compare our framework to existing baselines for both the NAEP process data and other process datasets. We finally investigate the interpretability of the process model’s latent representations using visualizations and qualitative analysis.

3.1 Baselines

We use two baselines to compare our framework against. The first is **Feature Engineering (FE)**, for which we used the method of the 2nd place submission from the NAEP 2019 competition [10]. Their technique calculates a large number of features for each student activity sequence, uses a genetic algorithm (GA) to select the best set of features for a target prediction label, and then trains a model ensemble to

Table 1: We report the AUC of predictions on the score label, as well as the AUC when response status is removed.

Model	Test AUC	Test AUC without c_t
FE	0.828	–
CKT	0.854 ± 0.005	0.797 ± 0.010
Ours	0.868 ± 0.008	0.792 ± 0.004

produce a final prediction for the task. We re-ran their GA and ensemble algorithms to obtain predictions for our per-student prediction label. The second baseline is **Clickstream Knowledge Tracing (CKT)**, for which we adapted the technique developed in [2], which uses student problem solving process data for the downstream task of knowledge tracing (KT). Their technique uses an autoencoder pre-training setup where question-level process data is encoded, passed through a bottleneck vector, and reconstructed. We use the bottleneck vector as input to downstream prediction tasks.

3.2 Per-Student Label

We first evaluate our method on a per-student label, referred to as the *score label*, which is a binary indicator of if a student scored above or below average in the second block (B) of the exam. We predict this label by observing process data exclusively from the first block (A).

Experimental Setup. For our model and the CKT baseline, we perform a multi-phase cross-validation experiment. For each fold, using the questions in the training split, we pre-train the process model, and then train the transfer function on the score label. For both of these, we use the validation split for early stopping. Finally, we evaluate the model on the test set, which is fixed across folds. We measure area under the receiver operating characteristic curve (AUC), and report the average and standard deviation of the AUC on the test set over all folds. Note that the FE baseline only returns a single set of predictions for the ensemble.

Results and Discussion. As shown in the second column of Table 1, both CKT and our model outperformed the FE baseline. This observation fits our expectation: since sequential neural models have direct access to the raw process data, they are able to pick up on subtleties that may not be captured by human-engineered features. Our method slightly outperforms CKT on this label, indicating that our process model and transfer function are able to capture more information that is indicative of student performance than CKT. We also examine the ability of the models to predict performance strictly using behavioral information, without any indication of correctness. To do this, we repeat the experiments but remove the response status c_t from the input and do not perform the associated pre-training objective. We see from the third column of Table 1 that the AUC drops, as expected, but is still considerably high, indicating that these models can infer student performance from their behavior.

3.3 Item Response Theory

We now evaluate our model in the IRT setting in order to examine if our methodology can improve performance predic-

Table 2: We report the AUC of predictions on the IRT task, as well as the AUC when incomplete questions are not considered.

Model	All Questions	Completed Questions
Base	0.824 ± 0.001	0.823 ± 0.001
CKT	0.836 ± 0.000	0.830 ± 0.001
Ours	0.836 ± 0.002	0.828 ± 0.001

tion on questions using additional data on student behavior within a question.

Experimental Setup. For the IRT experiments, we use all student activity sequences across blocks A and B. We split the questions into train/test sets using multi-label stratification to ensure all ability and difficulty parameters are sufficiently trained. We then perform a similar cross-validation experiment to the score label, where for each fold, the process model is pre-trained, and then the transfer function and IRT-specific parameters are trained on the question correctness label. The AUC on the test set is recorded after each fold, and the average and standard deviation are reported.

Results and Discussion. We see from Table 2 that the behavioral data leveraged by both our model and CKT result in a small improvement in test AUC over the base IRT model. We also observe that questions that were left incomplete by students were very easy to predict as incorrect with process data since certain event types missing in a student activity sequence clearly indicate incomplete status. To account for this observation, we also report the AUC after removing incomplete questions from the test set. We see that the performance drops for all models, although more significantly for the behavior-enhanced models, leaving our method’s performance slightly below CKT. However, the fact that the behavior-enhanced models still improve over the base IRT model suggests that student behavior provides important additional information on student performance beyond the original student ability and question difficulty parameters in IRT.

3.4 Qualitative Analysis

We now examine the interpretability of the latent behavioral vectors that our methodology produces. We will examine student-level latent vectors extracted from a version of the student-level model, which was modified to capture task-switching behavior. We also performed an analysis of question-level latent vectors extracted from the behavior-enhanced IRT model, where we saw strong behavior-based clustering patterns. However, because question-level behavior representation is similar to the capabilities of CKT, we omit this analysis from this paper, and its details can be found in the long version. For the following figure, we use t-SNE [13] to visualize the latent vectors in 2D and investigate characteristic behavioral patterns in the visible clusters.

To investigate if our model can capture high-level task-switching and test-taking behaviors, we investigate student-level representations, which combine all question visits of a student into a single latent vector. We train a model on

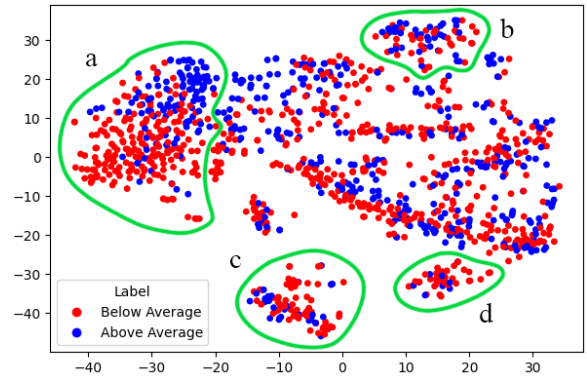

Figure 2: The vectors extracted from the final hidden state of an RNN that processes all visit-level vectors from a student’s process data in block A, colored by the score label.

the score label task with the following modifications to our original setup: 1) we provide the process model with sequences of events in a single visit to a question, rather than across all visits to a question, 2) we add a new pre-training objective to predict the question ID of each event to encode task-switching information in the latent representations, and 3) we replace the fully-connected neural network with an RNN, since the visits are sequential in nature. We use the final hidden state of the RNN for both label prediction and representation visualization.

In Figure 2, we visualize the student-level vectors generated from block A data, colored according to the score label. We identify 4 distinct clusters, while the rest of the vectors have no obvious pattern: a) Rapid testing: most students in this group finished all questions in block A with a significant amount of time remaining. b) Checked their work: students in this group made multiple visits to most questions, often not making changes in the second visit. c and d) Ran out of time: both of these clusters represent students that took the whole time but did not answer all the questions.

4. CONCLUSIONS

In this paper, we developed a BERT-style framework for pre-training and transfer learning on educational process data. We applied our framework to several downstream learning outcome prediction tasks on NAEP assessment process data used in the NAEP 2019 data mining competition. Through quantitative and qualitative experiments, we demonstrated that models developed with our framework can 1) leverage process data to make accurate learning outcome predictions, and 2) generate meaningful representations of student behavior from process data. There are several potential areas for future research. First, our process model currently only represents single questions, which results in student-level representations that are less meaningful than the question-level representations. Future work should aim to develop a process model that can simultaneously represent events across all questions in a student’s process data. Second, future work should aim to implement this framework on complementary datasets, such as video clickstreams, to validate its ability to capture behavioral data across settings.

ABSTRACT

In this study, we proposed an Online Item Response Theory Model (OIRT) by combining the Item Response Theory and Performance Factor Analysis (PFA) models. We fitted the proposed model with modified Variational Inference (VI) to perform real-time student and item parameter estimation using both simulated data and real time series data collected from an online adaptive learning environment. Results showed that modified VI parameter estimation method outperformed other Bayesian parameter estimation methods in efficiency and accuracy. We also demonstrated that OIRT tracked students' ability growth dynamically and efficiently, it also predicted students' future performance with reasonable AUC given limited input features.

Keywords

Item Response Theory, Performance Factor Analysis, Online Learning, Bayesian Parameter Estimation, Variational Inference

1. INTRODUCTION

As time series data become increasingly prevalent in online learning system, tracking students' ability changes during their learning processes is important for the analysis of teaching and learning activity. There have been three commonly used models for estimating students' cognitive mastery: Item Response Theory (IRT) model is a general tool to provide a quantitative description of students' ability in academic testing. Knowledge Tracing (KT) model tries to predict a students' future performance through their historical interaction logs [5]. Performance Factor Analysis (PFA) [15] analyzes learning rates of students by considering multiple Knowledge Components (KCs) of each exercise item.

None of the above approaches are perfectly applicable to monitor students' ability changes in online learning. IRT roots on the assumption that students' true abilities are fixed [18], which may not be true in online learning environment, because student abilities are dynamic. Bayesian KT only estimates binary hidden states (either mastery or non-mastery) and models each KC separately. Standard IRT and PFA models are not able to perform real-time parameter estimation due to model format or estimation methods.

L. Peng and C. Wei. Online item response theory (OIRT) - tracking student abilities in online learning system. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 720–724, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

In this study, we propose an Online Item Response Theory Model (OIRT) to track students' ability changes in real-time fashion using both simulation and real data.

In summary, the contribution of the work is three-fold: (1) propose OIRT model by estimating students' initial abilities, item difficulties as well as ability changes for different KCs; (2) modify Variational Inference (VI) [24] under OIRT model to track students' ability changes; (3) compare the computational time and accuracy of the modified VI with other parameter estimation approaches, and demonstrate answer accuracy prediction by OIRT.

2. BACKGROUND

In this part, IRT and PFA models as well as common real-time parameter estimation approaches are briefly reviewed.

2.1 Item Response Theory Model

IRT is widely used in assessing student abilities and item difficulties due to its high interpretability. The one-parameter logistic (1PL) model [16] is given in Eq.1,

$$p(y_{ij}|\theta_i, b_j) = \frac{1}{1 + e^{-(\theta_i - b_j)}} \quad (1)$$

where y_{ij} is the i -th student's response to the j -th item. $y_{ij} = 1$ indicates a correct answer and 0 otherwise. θ_i denotes the ability of the i -th student and b_j denotes the difficulty of the j -th item. We developed our OIRT model based on 1PL model in Eq.1, but OIRT can be extended to 2 or 3PL IRT models [7,8] easily.

2.2 Performance Factor Analysis

IRT model only estimates a constant ability for each student and cannot model the changes of student abilities as learning proceeds [18]. To address this problem, especially in the adaptive online learning environment, Learning Factor Analysis (LFA) model [4] and PFA model [15] are proposed to further include the prior practice counts for each KC. Specifically, PFA model, an extension of LFA model, is given in Eq.2,

$$p(y_i = 1|\beta_k, \gamma_{i,k}, \rho_{i,k}) = \frac{1}{1 + e^{-\sum_{k=1}^K (-\beta_k + \gamma_{i,k} * s_{i,k} + \rho_{i,k} * f_{i,k})}} \quad (2)$$

Here, β_k is the difficulty of the k -th KC, $s_{i,k}$ and $f_{i,k}$ are the prior successes and failures of the i -th student on the k -th KC, $\gamma_{i,k}$ and $\rho_{i,k}$ are the learning rates of these observation counts, implying the effects of accumulated successes and failures ($s_{i,k}$ and $f_{i,k}$) on answer accuracy in the processes of learning.

Some other models also try to track the changes of student abilities in a short period [10, 13, 23]. The main principle here is

to estimate the ability change, $\Delta\theta_t$, based on students' responses to items. We also follow this principle by modeling $\Delta\theta_t$ using learning rate parameters and their corresponding practice counts, which will be introduced in Section 3.

3. ONLINE ITEM RESPONSE MODEL

Online Item Response Theory (OIRT) model is an extension of the existing PFA model. Suppose there are N students, M items covering a total of K KCs, the OIRT model is given in Eq.3,

$$p(y_{ij}|\theta_i, \bar{\gamma}_i^s, \bar{\gamma}_i^f, b_j) = \frac{1}{1 + e^{-(\theta_i - b_j + (\bar{\gamma}_i^s \odot \bar{s}_i + \bar{\gamma}_i^f \odot \bar{f}_i)^T \bar{T}_j)}} \quad (3)$$

where θ_i and b_j denote the i -th student's general ability and the j -th item's difficulty, respectively. Let K be the total number of KCs covered by all the items, \bar{s}_i and \bar{f}_i are $K * 1$ vectors containing successful and unsuccessful practice counts for the i -th student. $\bar{\gamma}_i^s$ and $\bar{\gamma}_i^f$ are the $K * 1$ learning rate vectors for \bar{s}_i and \bar{f}_i , respectively. \bar{T}_j is a pre-specified $K * 1$ distributional vector of KCs for item j . The \odot and \cdot are element-wise product and dot product, respectively.

OIRT contains four extensions compared to PFA model in Eq.2. (1) An initial ability θ_i for each student is added in OIRT due to the prior knowledge of students. (2) Note that modeling item difficulty as $\sum_k \beta_k$ in PFA is unreasonable in that the item with the same KCs will have same difficulty. To solve the problem, we added a unique difficulty b for each item in OIRT. (3) Instead of using a binary vector indicating which item covers which KC, we used a distributional vector \bar{T}_j to avoid a bias (working on items with more KCs will lead to higher ability gain when adding up the learning effects of all KCs covered by an item) towards the items with many KCs. To construct \bar{T}_j , suppose we have a total of $K = 3$ KCs, if item j covers KC 1 and 3, instead of representing the item-KC vector as $[1, 0, 1]$, we represent it as $\bar{T}_j = [1/2, 0, 1/2]$, whose sum is always equal to 1. (4) The parameters in OIRT will be updated in a real-time mode: once a student receive the feedback after answering an item, we update \bar{s}_i and \bar{f}_i and hence the corresponding learning rate vectors, this is a major difference between OIRT model and other IRT and PFA models, because of the dynamic updates of \bar{s}_i and \bar{f}_i , we can update the learning rate parameters, and hence track ability changes.

In online learning system, \bar{s}_i and \bar{f}_i are initialized to 0, which will then be accumulated once an item is completed by the student. Therefore, the general ability θ_i and item difficulty b_j will be estimated in the beginning, learning rates $\bar{\gamma}_i^s$ and $\bar{\gamma}_i^f$ will then be estimated as more practice data being collected.

4. PARAMETER INFERENCES OF OIRT

We applied and compared four parameter estimation methods in OIRT model: Maximum Likelihood Estimation (MLE) in Logistic Regression (LR), MCMC, EP and VI. We consider LR as a baseline and mainly introduce the other three methods under OIRT.

4.1 Markove Chain Monte Carlo

Markov Chain Monte Carlo (MCMC) [2, 3] can be directly used to perform real-time parameter estimation, because the prior of the interested parameter η at time t can be updated using the posterior based on the data at time $t - 1$, specifically, $p(\eta|Data_t) \propto p(Data_t|\eta) * p(\eta|Data_{t-1})$ given the conditional independence of data. It draws samples from the approximated posterior distributions from which the expectations and variances of the parameters are constructed. Researchers successfully applied MCMC to IRT parameter estimation [1, 14, 19, 20].

4.2 Expectation Propagation

Recall the parameters we need to estimate are $\eta = \{\bar{\theta}, \gamma^s, \gamma^f, \bar{b}\}$. Here γ^s and γ^f are $N * K$ matrices, $\bar{\theta}$ is an $N * 1$ ability vector and \bar{b} is an $M * 1$ item difficulty vector. We can reformulate the parameters as a long vector $\tau = [\bar{\gamma}_1^s, \bar{\gamma}_2^s, \dots, \bar{\gamma}_1^f, \bar{\gamma}_2^f, \dots, \bar{\theta}^T, \bar{b}^T]$. If the complete data is given, we can easily solve τ by a LR. However, data comes batch by batch, therefore, we can use Expectation Propagation (EP) [11, 12, 21].

Given N responses y_1, y_2, \dots, y_N , the posterior of η can be written as $p(\eta|y) \propto p(\eta) * p(y_1|\eta) * p(y_2|\eta) * \dots * p(y_N|\eta)$ if responses are conditionally independent. In EP, $p(y_i|\eta)$ is usually complicated function and approximated by \tilde{p}_i , $i \in 0, 1, 2, \dots, N$ (often chosen to be normal distribution). Here, $\tilde{p}_0 \approx p(\eta)$ and $\tilde{p}_i \approx p(y_i|\eta)$. Generally, we compute the following steps:

- (1) Initialize all \tilde{p}_i ,
- (2) Calculate the approximating posterior $q(\eta) = \frac{\prod_i \tilde{p}_i}{\int_{\theta} \prod_i \tilde{p}_i d\eta}$
- (3) Until all \tilde{p}_i 's converge for $i = 1, 2, 3 \dots N$:
 - i. Calculate cavity distribution $q^{(i)}(\eta) \approx \frac{q(\eta)}{\tilde{p}_i}$
 - ii. Update q by $argmin_{KL} KL(q(\eta) || q^{(i)}(\eta) * p(y_i|\eta))$
 - iii. Update $\tilde{p}_i \approx \frac{q(\eta)}{q^{(i)}(\eta)}$

In the KL divergence step for the IRT models, $q^{(i)}(\eta)$ is a normal density function but $p(y_i|\eta)$ is a logistic function, it is difficult to get a normal distribution approximation of this product. Therefore, some other approximation forms are proposed [6, 22] and we applied the approximation in [9] as well as its update rule in the KL step for logistic function, see [9] for details.

4.3 Variational Inference

Inspired from [24], we derived an ELBO function for our OIRT in Eq.4 by assuming the joint posterior distribution factors as $q(\eta|y) = q(\bar{\theta}|\bar{b}, y)q(\gamma^s|\bar{b}, y)q(\bar{b}|y)q(\gamma^f|\bar{b}, y)$,

$$ELBO = E_{q(\eta)}[\log p(y | \bar{\theta}, \bar{b}, \gamma^s, \gamma^f)] \quad (4)$$

$$-E_b[KL(q(\bar{\theta} | \bar{b}) || p(\bar{\theta} | \bar{b})) + KL(q(\gamma^s | \bar{b}) || p(\gamma^s | \bar{b})) + KL(q(\gamma^f | \bar{b}) || p(\gamma^f | \bar{b}))] - KL(q(\bar{b}) || p(\bar{b}))$$

For simplicity, we simplified Eq.4 as $ELBO = likelihood - KL_{\theta} - KL_b - KL_{\gamma^s} - KL_{\gamma^f}$. Then, the following algorithm is used to estimate parameters:

- (1) At time $t = 0$, initialize the priors of the parameters $p_0(\bar{\theta}), p_0(\bar{b}), p_0(\gamma^s), p_0(\gamma^f)$

- (2) Set shrink, enhance, decay hyperparameters.¹ Loop over iterations on loss optimization at each time t :
 - i. Update priors $p_t(\eta)$ at time t based on the combination of the approximated posterior $q_{t-1}(\eta)$ and the original prior $p_0(\eta)$ for each parameter in η : $p_t(\eta) = (1 - decay) * q_{t-1}(\eta) + decay * p_0(\eta)$
 - ii. Optimize $loss = likelihood - shrink^{iteration} * [(1 + enhance * \frac{g}{max}) * (KL_\theta + KL_b) + KL_y^S + KL_y^f]$ to obtain current posterior $q_t(\eta)$ to be used in each KL , g/max is the number of student-item pairs up to time t over the total number of pairs.

There are three differences compared to the standard VI: (1) We set the shrink factor to 0.95 after the first time point because the prior distributions now keep the information from the previous data and should not be shrunk. (2) We used a weighted average instead of directly replacing the prior at time t with the posterior at $t - 1$ so that the prior gets updated gradually and the previous information play in role smoothly. (3) We enhanced the KL_θ and KL_b gradually. At the first several sessions of student data, \vec{s}, \vec{f} are close to zero, therefore, student abilities and item difficulties are the only parameters being estimated in OIRT. As \vec{s}, \vec{f} increase, and since student abilities and learning rates are not identifiable (both are parameters of individual student), we gradually fixed student abilities and item difficulties so that the algorithm can focus on the estimation of those learning rates only. Our experience showed that shrink = 0.95, decay = [0.3, 0.5] and enhance = 7 is reasonable.

5. EXPERIMENTS AND RESULTS

We compared the performances of modified VI with MCMC, EP and LR in parameter estimation on two simulated datasets. We also demonstrated the online ability tracking of OIRT using a real data, and compared OIRT with XGBoost on answer prediction task on the real data. The software environment in these experiments is under Python 3.7, Pytorch-1.7.1, the hardware is Intel(R) Xeon(R) Gold 6130 CPU @ 2.10GHz, Tesla P4 GPU.

5.1 Simulation Studies

5.1.1 Standard Normal Distribution for Learning Rates

In the first experiment, we examined two conditions: 100 students and 500 students, both with 4 KCs and 100 items. The data simulations are as following:

- (1) We simulate student abilities, learning rates for s_i and f_i for each KCs, item difficulties from standard normal distributions independently. Generate and normalize the KC distribution vector for each item. Initialized \vec{s} and \vec{f} to be 0
- (2) Since the person-item pairs in each condition is 100*100 and 500*100, respectively, at each time point, we sample a random number of pairs from the remaining unused person-item pairs (in this case, person-item pairs could be generated sequentially)

- as the current data, and extract the corresponding parameters sampled in step (1) for each chosen person and item
- (3) Construct responses based on OIRT model in Eq.3
- (4) Update the \vec{s} and \vec{f} for each student at each session based on the responses in (3) and apply them in step (3) of next session
- (5) Repeat step (2) (3) (4) until all pairs are chosen

Table 1 shows the results for the 500 students condition. Under the standard normal distributions for the learning rates, LR (default setting in sklearn) has the highest accuracy in parameter estimation. MCMC is the second best, but it is more time-consuming. Even though the estimation accuracy of the modified VI is worse than MCMC and LR, its computational time is comparable to that of LR. EP has the worst parameter estimation performance due to its approximation issue discussed in Section 4.2. Similar results were obtained for the simulation with 100 students.

Table 1. Correlations with real values under standard normal parameter distribution: with 100 items and 4 KCs

Student s	Method s	ABI	DIFF	LS	LF	Time
500	LR	0.806	0.968	0.778	0.771	35.4s
	MCMC	0.656	0.977	0.702	0.725	5d
	EP	0.7	0.905	0.658	0.669	650m
	VI	0.706	0.789	0.532	0.491	84.5s

5.1.2 Non-standard Normal Distribution for Learning Rates

In the second experiment, student abilities and item difficulties were sampled independently from standard normal distribution, while learning rates for success and failure were sampled independently from non-standard normal distributions, $N(0.01, 0.03)$. Other simulation procedures remained the same.

In this case, the true distributions of the learning rates are no longer standard normal distributions, which may be more realistic because learning rates are usually small and positive. Since MCMC is time-consuming, we only compared VI, EP and LR. Results about the estimation accuracy with respect to abilities, difficulties and two learning rates are shown in Table 2.

It is clear from Table 2 that VI is still robust in estimating the learning rates when their true distributions are non-standard normal, it is also comparative to LR in ability and item difficulty estimations. VI is also more computationally efficient in dealing with more students and more KCs (500 items and 5KCs in Table 2). Similar results were obtained for 100 students.

Results about computational speed are shown in Figure 1 with varying students, KCs and item numbers. The computational time is the time each method spent on estimating all parameters throughout all generated sessions. The lines for EP and LR are incomplete because LR fails when it needs more than 256G memory and EP fails when it takes more than 5 days.

¹ Shrink controls the contribution of the KL terms in optimizing the loss function. Enhance gives more importance to KL terms as more data flows in, because the prior in KL at time t contains the information from the previous data that we want to keep. Decay controls the weight given to the posterior at time $t - 1$ in contributing to the prior at time t .

Table 2. Correlations with real values under non-standard Normal parameter distribution: with 500 items and 5 KCs

Students	Methods	ABI	DIFF	LS	LF	Time
500	LR	0.939	0.992	0.778	0.303	573s
	VI	0.936	0.969	0.658	0.661	145s
	EP	0.827	0.731	0.532	0.153	100h
	LR	0.939	0.992	0.778	0.303	573s

Figure 1. Computational time comparison

It is obvious to note that the results of the modified VI are better compared with that of the other methods in three aspects: (1) the computational speed of VI is faster as number of persons and items increase; (2) the modified VI gives better parameter estimation when the prior distributions disagree with the true distributions of the learning rates; (3) the modified VI supports real-time parameter estimations and requires less memories.

5.2 Real Data Study

In the third experiment, we used a real dataset, Riid public dataset² from Kaggle competition, to demonstrate the ability change tracking and answer prediction by OIRT.

We selected the event for a question being answered by the user (content_type_id=0) with prior question having explanation. We also removed the items and users with response frequencies fewer than 50. The data contained 6800 students, 1983 items and 146 KCs after preprocessing. We sorted the data by time the question was completed by the user, for ability tracking task, we used the whole data to estimate parameters; for answer prediction task, the first 90% was used train models, and the remaining 10% was used as testing set. We partition the data into 50 sessions with person-item pairs and feed one session into the model at a time.

We compared OIRT with XGBoost technique in answer prediction task. The reason for comparing with XGBoost is that both methods are single-layered and explainable models, which by nature are different and incomparable with the models based on deep neural networks. We only used ‘Timestamp’, ‘Tags’, ‘User ID’, and ‘Item ID’ as the input features for both OIRT and XGBoost. The ‘answered correctly’ was the label for the models. OIRT outperformed XGBoost in accuracy prediction of future question

responses with limited input features: AUC=0.702 vs 0.689, ACC=0.733 vs 0.717 (since the XGBoost in the competition uses complex feature engineering, its AUCs reported in the competition are much higher). OIRT also provides reasonable estimates for user ability and item difficulty due to its high correlation with the observed accuracy proportion for students and items (0.751, 0.696, respectively).

We randomly selected 2 users and plotted Figure 2 to show the ability change tracking of OIRT by comparing with the observed differences of the accuracy proportion between two adjacent time points, averaging all KCs at each session. The estimations are equal to $(\bar{\gamma}_i^s \odot \bar{s}_i + \bar{\gamma}_i^f \odot \bar{f}_i)^T \bar{T}_j$ in Eq.3 at each time t (below). The observed changes in accuracy proportion is equal to $(\# \text{correct KCs}_{1:t} - \# \text{correct KCs}_{1:t-1}) / \# \text{KC}_s$ for each user (above), indicating how many more accurate KCs completed by a user at time t relative to that at time $t - 1$.

Figure 2. Students' ability tracking by OIRT

It can be seen when the observed increase in accuracy proportion are high between two adjacent time points, the estimated ability growth is more abrupt, such as sessions in the blue and orange windows for student 8 and student 55, respectively.

6. CONCLUSIONS

In this study, we developed OIRT model and modified VI parameter estimation method to track student abilities in real-time and predict answer correctness for online learning system. Results show that the modified VI can estimate the parameters fast and effectively despite of the difference between the priors and the true distribution of the learning rate parameters.

Although OIRT performs relatively well in different tasks introduced above, it takes the form of generalized linear model, which has parameter identification issue and limits its performance in the accuracy prediction for future questions. We only predict answer accuracy based on historical data for individuals, and didn't examine the prediction accuracy for new students, which will be explored more in future study.

ABSTRACT

This paper proposes to discover which data fusion approach and classification algorithm produced the best results from smart classrooms data, and how useful would be the prediction models for detecting University students at risk of failing or dropout. The results showed that the best predictions were produced using ensembles and selecting the best attributes approach with discretized data; the REPTree algorithm demonstrated the highest prediction values. The best predictions also show the teacher what set of attributes and values are the most important for predicting student performance, such as the level of attention in theory classes, scores in Moodle quizzes and the level of activity in Moodle forums.

Keywords

Data fusion, student prediction models, smart classroom.

1. INTRODUCTION

Nowadays, new learning models are used in Higher Education such as Blended learning, Smart Learning and Multimodal learning.

Blended learning (b-learning) is an approach to learning and instruction that combines online educational materials and opportunities for interaction online with traditional place-based classroom methods, although the terms "blended learning", "hybrid learning", "technology-mediated instruction", "web-enhanced instruction", and "mixed-mode instruction" are often used interchangeably in research literature [5][6]. Its rise is due to the fact that there are some disadvantages to current e-learning environments such as inhibiting socialization resulting in a lack of face-to-face communication [7]. Otherwise, EDM has been widely used to improve and enhance learning quality, as well as in the pursuit of pure research objectives, which tend to improve our understanding of the learning process [8]. In this context, it is still a challenge to predict student learning achievement in blended learning environments combining online and offline learning [1, 6], making data fusion techniques necessary.

Smart learning environments (SLEs) have been recently defined [9] as learning ecologies wherein students perform learning tasks

C. Romero, W. Chango, and R. Cerezo. Looking for the best data fusion model in smart learning environments for detecting at risk university students. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 725–728, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

<https://doi.org/10.5281/zenodo.6853089>

and/or teachers define them with the support provided by tools and technology. SLEs can encompass physical or virtual spaces in which a system senses the learning context and process by collecting data, analyzes the data, and consequently reacts with customized interventions that aim at improving learning [9].

In Multimodal Learning Analytics (MLA), learning traces are extracted not only from log-files but also from digital documents, recorded video and audio, pen strokes, position tracking devices, biosensors, and any other data source that could be useful for understanding or measuring the learning process. One important question in MLA is how to combine, or fuse, the data extracted from different modalities in order to provide a more comprehensive view of learners' outer and inner processes [1].

In this study we propose applying different data fusion approaches and classification algorithms to data gathered from several sources (theory classes, practical sessions, online sessions, and final exams) in a blended, smart, multimodal course in order to predict the students' final academic performance [11]. Data fusion, or information fusion, is the study of efficient methods for automatically or semi-automatically transforming information from different sources and different timepoints into a representation that provides effective support for human or automated decision making. Specifically, data fusion can reduce the size and dimensions of data, optimize the amount of data and extract useful information [10]. There are different types of multimodal fusion approaches such as: feature-level or early fusion, decision-level or later fusion and Hybrid fusion.

2. EXPERIMENTS

We used information from 57 first-year electrical engineering students at the University of Cordoba (Spain) in the Introduction to Computer Science course during the first semester of academic year 2017-2018. We have gathered all the information from four data sources: theory classes, practical classes, on-line sessions and final exam. The first three data sources gave us the input attributes and the final exam, the output attribute or class to predict. The students all gave their written consent to being recorded, after being informed about the study, and to have their data from practical and online sessions in Moodle collected for the study.

We have used four different data fusion approaches (merging all attributes; selecting the best attributes; using ensembles; and using ensembles and selecting the best attributes) and several white-box classification algorithms with the datasets. Then, we compare the predictions produced by the models (%Accuracy and ROC Area) to discover the best approach and classification model so that it is used for predicting students' final performance.

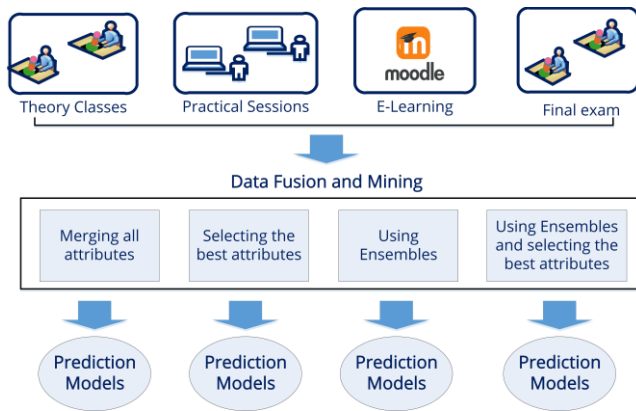

Figure 1. Proposed data fusion and mining methodology for predicting students' performance from multiple data sources.

2.1 Experiment 1: Merging all attributes

In experiment 1 we applied the classification algorithms to a single file with all the attributes merged. Firstly, we fused the different values of the 6 attributes collected in the theory and practical sessions in order to have just one single value for each attribute. In our case, we had 15 values (15 lectures) for each one of the 4 attributes collected in the face-to-face theory classes and 10 (10 sessions) and 5 (5 practicals) values respectively for each of the 2 attributes for face-to-face practice sessions. Fusing the 4 values about the on-line sessions was not necessary because the specific tool that we used for preprocessing the Moodle logs gave a single value for each attribute directly.

Table 1. Results produced by merging all attributes

	NUMERICAL DATA		DISCRETIZED DATA	
	% Accuracy	AUC	%Accuracy	AUC
Jrip	77.1930	0.8440	78.9474	0.8880
Nnge	80.4561	0.8760	75.4386	0.8630
PART	78.9474	0.8640	80.4561	0.9170
J48	75.4386	0.8640	78.9474	0.8780
REPTree	75.4386	0.8630	76.6667	0.8480
Randomtree	70.1754	0.7820	73.6842	0.8180
Avg.	76.2749	0.8488	77.3567	0.8687

Table 1 shows that the best results (highest values) were produced by Nnge (80.45 %Acc) and Part (80.45%Acc and 0.91 AUC) algorithms. On average, most of the algorithms exhibited slightly improved performance in both measures when using discretized data.

Table 2. PART decision list when merging all attributes

IF Moodle.Quiz = Medium AND Theory.Attention = Medium THEN Pass
IF Moodle.Quiz = High THEN Pass
IF Theory.Attention = Low AND Moodle.Forum = Low THEN Dropout
IF Moodle.Quiz = Low THEN Fail
ELSE Pass
Number of Rules : 5

This prediction model (see **Table 2**) consists of 5 rules that show that the students who pass the course are students who have medium scores in Moodle quizzes and also pay attention in theory classes, or students who simply have high scores in Moodle

quizzes. The students who drop out from the course are students who pay little attention in theory classes and also show low activity in the Moodle forum. The students who fail the course are the students who get low scores in the Moodle quizzes. The remaining students are classified as passing.

2.2 Experiment 2: Selecting the best attributes

The selection of characteristics is important in the classification process by reducing not only the dimensions of the characteristic set but also the additional calculation time required for the classification algorithms. We used the well-known CfsSubsetEval (Correlation-based Featured Selection) method [11] provided by the WEKA tool [36]. It evaluates the worth of a subset of attributes by considering the individual predictive ability of each feature along with the degree of redundancy between them. Starting from our initial 10 input attributes, we produced two sets of 3 different optimal attributes for the numerical and discretized datasets (see Table 3).

Table 3. Results obtained when selecting the best attributes

	NUMERICAL DATA		DISCRETIZED DATA	
	% Accuracy	AUC	%Accuracy	AUC
Jrip	80.7018	0.8490	82.4561	0.9140
Nnge	82.4561	0.9140	78.9474	0.8430
PART	77.1930	0.8750	80.7018	0.9140
J48	80.7018	0.8680	82.4561	0.9230
REPTree	77.1930	0.8940	78.9474	0.8880
Randomtree	75.4386	0.8320	82.4561	0.9170
Avg.	78.9474	0.8720	80.9942	0.8998

Table 3 shows that the best results (highest values) were produced by Jrip (82.45%Acc), Nnge (80.45 %Acc), and J48 (82.45 %Acc and 0.92 AUC) algorithms. Again, on average most of the algorithms exhibited slightly improved performance in both measures when using discretized data.

Table 4. J48 pruned tree when selecting the best attributes

IF Moodle.Quiz = Low
Moodle.Forum = Low
Theory.Attention = Low THEN Dropout
Theory.Attention = Medium THEN Fail
Theory.Attention = High THEN Fail
Moodle.Forum = Medium THEN Fail
Moodle.Forum = High THEN Fail
ELSE IF Moodle.Quiz = Medium
Theory.Attention = Low THEN Fail
Theory.Attention = Medium THEN Pass
Theory.Attention = High THEN Pass
ELSE IF Moodle.Quiz = High THEN Pass
Number of Leaves: 9
Size of the tree: 13

This prediction model (see Table 4) is a decision tree with 9 leaves that can be transformed into 9 prediction rules. These rules show that the students who pass the course are students who have medium scores in Moodle quizzes and also pay medium to high attention in theory classes, or students who simply have high scores in Moodle quizzes. The students who drop out from the course are students who have low scores in Moodle quizzes, show low activity in the Moodle forum, and also pay little attention in theory classes. In addition, students who fail are the students that

have low scores in Moodle quizzes, show low activity in the Moodle forum and pay medium to high attention in theory classes. There are also other failing student profiles: students who have medium scores in Moodle quizzes and also pay little attention in theory classes; students who have low scores in Moodle quizzes, show low activity in the Moodle forum, and pay medium to high attention in theory classes.

2.3 Experiment 3: Using ensembles

In experiment 3 we applied an ensemble of classification algorithms to each different source of data. However, instead of merging all of the attributes from the 4 data sources into a single file, we added the students' final academic performance to each dataset. This produced three sets of datasets (6 files in total): two files (numerical and discrete version) for the theory classes with 4 input attributes and 1 output attribute or class; two files (numerical and discrete version) for the practical session with 2 input attributes and 1 output attribute or class; and two files (numerical and discrete version) for the online Moodle sessions with 4 input attributes and 1 output attribute or class.

A classifier is accurate if it works better than a random prediction of the data; sets perform better when base models are unstable with output undergoing significant changes in response to small changes in training data. We used the well-known Vote [4] automatic combining machine learning algorithm provided by WEKA. It produces better results than individual classification models, if the classifiers of the sets are accurate and diverse. Vote adaptively resamples and combines so that resampling weights are increased for those cases more often misclassified and the combination is done by weighted vote.

Table 5. Results obtained when using ensembles.

	NUMERICAL DATA		DISCRETIZED DATA	
	% Accuracy	AUC	%Accuracy	AUC
Jrip	82.4561	0.9230	85.9649	0.9380
Nnge	77.1930	0.8770	77.1930	0.8770
PART	80.7018	0.9040	82.4561	0.9130
J48	82.4561	0.9110	82.4561	0.9220
REPTree	82.4561	0.9230	82.4561	0.9220
Randomtree	77.1930	0.8360	79.9474	0.9170
Avg.	80.4094	0.8957	81.7456	0.9185

Table 5 shows that the best results (highest values) were produced by Jrip (85.96 %Acc and 0.93 AUC). Once again, on average most of the algorithms exhibited slightly improved performance in both measures when using discretized data

Table 6. JRIP when using ensembles.

JRIP rules (Theory):

```

=====
IF (Theory.Attendance = High) THEN Pass
IF (Theory.Attention = Low) THEN Dropout
ELSE Dropout
Number of Rules : 3

```

JRIP rules (Practice):

```

=====
IF (Practice.Attendance = High) and (Practice.Score = High)
THEN Pass
IF (Practice.Attendance = Low) and (Practice.Score = Low)
THEN Fail
ELSE Dropout
Number of Rules : 3

```

JRIP rules (Moodle):

```

=====
IF (Moodle.Task = Low) and (Moodle.Quiz = Low) THEN Fail
IF (Moodle.Quiz = Medium) and (Moodle.Forum = Low) THEN
Fail
IF (Moodle.Task = Medium) THEN Pass
IF (Moodle.Quiz = High) THEN Pass
ELSE Dropout
Number of Rules : 5

```

This prediction model (see Table 6) the students who regularly attend theory classes pass the course; the students who exhibit low attendance finally drop out. The students who regularly attend practical classes and exhibit high performance in those practical classes then pass the entire course. In contrast, the students who rarely attend practical classes and have low performance in practicals then fail the entire course. The students who upload a moderate number of activities to the Moodle platform or get high scores in Moodle quizzes are students who pass the course; and logically, the students who upload a low number of activities to the Moodle platform and get low scores in Moodle quizzes are students who fail the course, but the students with medium performance in quizzes and low contributions to the forum also fail.

2.4 Experiment 4: Using ensembles and selecting the best attributes

In experiment 4 we applied an ensemble of classification algorithms to the best attributes from each different source of data. Firstly, we selected the best attributes for each of the three different sets of datasets (6 files in total) generated in experiment 3. For that, we again used the well-known CfsSubsetEval attribute selection algorithm. The best result with our data was obtained when combining a weight of 1 for Theory and Practical with a weight of 2 for Moodle by using the average as combination rule for weights. We executed the six classification algorithms as base or individual classification models of our Voting method for the 6 previously generated summary datasets (see Table 7).

Table 7. Results obtained when using ensembles and selection of the best attributes.

	NUMERICAL DATA		DISCRETIZED DATA	
	% Accuracy	AUC	%Accuracy	AUC
Jrip	82.4561	0.9170	84.2105	0.9310
Nnge	80.7018	0.9020	78.9474	0.8900
PART	80.7018	0.9010	82.4561	0.9350
J48	82.4561	0.8990	84.2105	0.9350
REPTree	84.2105	0.9130	87.4737	0.9420
Randomtree	77.1930	0.9160	82.4561	0.9330
Avg.	81.2866	0.9080	83.2924	0.9277

Table 7 shows that the best results (highest values) were produced by REPTree (87.47 %Acc and 0.94 AUC). Again, on average, most of the algorithms exhibited slightly improved performance in both measures when using discretized data.

Table 8. RepTree when using ensembles with selecting the best attributes.

REPTree (Theory)

```

=====
IF Theory.Attention = Low THEN Dropout
IF Theory.Attention = Medium THEN Fail
IF Theory.Attention = High THEN Fail

```

Size of the tree : 4
REPTree (Practice)

IF Practice.Attendance = Low THEN Dropout
IF Practice.Attendance = Medium THEN Fail
IF Practice.Attendance = High
| AND Practice.Score = Low THEN Fail
| OR Practice.Score = Medium THEN Fail
| OR Practice.Score = High THEN Pass

Size of the tree : 7
REPTree (Moodle)

IF Moodle.Quiz = Low
| AND Moodle.Forum = Low THEN Dropout
| OR Moodle.Forum = Medium THEN Fail
| OR Moodle.Forum = High THEN Fail
ELSE IF Moodle.Quiz = Medium THEN Pass
ELSE IF Moodle.Quiz = High THEN Pass
Size of the tree : 7

This prediction model (see Table 8) is also a combination of three models that show differential student behavior related to theory, at the same time, students exhibiting medium or high attention, or medium to high Moodle forum participation fail; those demonstrating medium practical attendance or high practical attendance plus low or medium practice score also fail. The students that demonstrate high practical attendance and performance pass, as do the students with medium to high scores in Moodle quizzes.

In general, we can see that these white-box models are very useful for explaining to the teacher how the predictions of pass, fail or dropout are arrived at. The teacher can discover what the main predictive attributes and values are directly from the background of the IF-THEN rules.

3. CONCLUSIONS

This paper proposes to use four different data fusion approaches and six white-box classification algorithms to predict university students' academic performance, from multiple-source and multimodal data in smart learning environments. We carried out 4 experiments to answer two research questions as conclusion:

- Which data fusion approach and classification algorithm produce the best results from our data? The REPTree classification algorithm produced the best results in this approach from discretized summary data.
- How useful are the prediction models we produce to help teachers detect students at risk of failing courses or dropping out? The white-box models we produced give teachers very understandable explanations (IF-THEN rules) of how they classified the students' final performance or classification.

In the future, we intend to carry out more experiments in order to improve our process and to overcome some limitations:

- Analyzing the video automatically rather than manually or semi-automatically. Processing the video recordings automatically would gather information more efficiently compared to manual coding with the multiple modalities that characterize the classroom[1].
- Using raw data and other specific data fusion techniques. We used a basic Naïve and knowledge-based fusion method that uses summary data. However, there are many mathematical theories for fusing data [2] such as

Probability-based methods (PBM) and Evidence reasoning methods (EBM) that we can use with raw data.

- Using more sources of information, including videos of practicals and on-line session interaction with Moodle; audio from theory classes and practicals, text analytics or text mining of what students write during theory classes, practicals or in Moodle.

ABSTRACT

We propose a distance measure between instructor-recommended and learners' learning pathways and discuss how it may be used. The context of this study is a 15-week undergraduate course. The digital learning activities consisted in reading materials, interactive videos, quizzes and worksheets. They allowed the collection of many time-stamped digital traces. The course instructor recommended to engage in the activities regularly and prior to attending weekly synchronous tutorials. However, learning was largely self-regulated. This led to different learning strategies, which were captured and visualised in the form of learning pathways. Several patterns emerged: "regular learners" followed the recommendations; "irregular/selective learners" tended to engage in some activities only and irrespectively of the timing of the tutorials; and "late learners" waited until the end of the course to start engaging. We have formulated a distance measure (D) between the students' and the instructor-recommended learning pathways and found D to be a good indicator of a learner's time management and self-regulation skills. D was also found to have a moderate negative correlation ($r = -0.6087$) with exam marks, implying that the visualisation of learning pathways combined with a distance measure could be useful to raise students' awareness of their lack of self-regulation skills.

Keywords

Self-regulated learning, digital traces, learning pathways, distance measure.

1. INTRODUCTION

In Self-Directed Learning (SDL), the responsibility to learn shifts from an external source (typically a teacher) to the individual learner. In its broadest meaning, SDL describes a process by which individuals take the initiative in identifying their learning needs, formulating goals, identifying resources for learning, choosing and implementing appropriate strategies, and evaluating learning outcomes [15]. Many consider self-direction to be a fundamental difference between children and adults in a learning situation; and many argue that higher education is where and when learners should be given the tools to become independent self-directed learners, and educators should move away from an authoritative position to take a role of facilitator of learning.

The goal of SDL is not necessarily to become a fully autonomous learner. In a formal learning situation such as a university course, it

should be seen as a collaborative process between the instructor and the learner [11]. SDL is multidimensional and can be perceived through the notions of control [7] and personal responsibility [6] along a continuous scale. When the learning tasks are generated by the instructor, it may be more appropriate to talk about self-regulation [24], a notion that is close to self-direction and encompassed by it [16][18]. Self-Regulated Learning (SRL) strategies include rehearsal, elaboration, organisation, critical thinking, time management, effort regulation, peer learning and seeking help [4].

The design of learning materials and activities in a Learning Management System (LMS) can affect learners' self-regulation strategies [12]. There is convincing evidence that people who are given some initiative in their learning learn more and learn better than people who are passively being taught [10][14]. In online learning settings characterised with autonomy, such as Massively Open Online Courses (MOOCs), self-regulation becomes a critical factor for success [1][2][8]. When comparing online and blended learner's SRL strategies, Broadbent [5] has found that they differed in their use, but that overall predictors of grade were equivalent: time management, elaboration and rehearsal strategies were found to be key predictors. There seems to be general agreement among researchers that effective time management especially is an essential element of SRL [22].

Time management can be short-range and focus on the day-to-day planning and organisation of time or be long-range and used to regulate effort [3][17]. Studies exploring the academic procrastination (i.e., the intentional delay of an intended course of action) of undergraduate students have highlighted the relationships between procrastination tendencies and poor self-efficacy for self-regulation and low academic achievements, e.g., [19] [13]. In [9], procrastination is described as "self-regulation failure of performance". Negative relationships between procrastination, self-control and self-esteem [21], as well as health, wealth and happiness [23] have also been demonstrated.

Poor SRL and time management (such as procrastination) typically result in a learning pathway that is significantly different from the optimal or instructor-recommended pathway [20], where a *learning pathway* is defined as the route taken by a learner through a range of learning activities, which allows them to build knowledge progressively. In this paper, we present a study to understand if students' chosen learning pathways can be indicators of poor SRL skills and be predictors of course performance when they differ significantly from the instructor-recommended pathway. With this objective in mind, we have formulated a distance measure (D) between the students-generated and the instructor-recommended learning pathways.

2. METHOD

2.1 Participants and Context

The context of the study is a 15-week course on Multimedia Fundamentals, delivered online during the Autumn 2021 to a rather large class of 234 3rd year undergraduate students on a Telecommunication Engineering programme. The learning objectives for this course are: (1) to be able to discuss and compare multimedia data representations; (2) to relate data properties, representation, and size; (3) to apply digital signal processing techniques for the compression of multimedia data; and (4) to describe modern multimedia standards and formats. It covers the following nine topics: digitisation, colour models, image, sound and video representations, lossless compression techniques, JPEG, MPEG, perceptual encoding (MP3), and digital broadcasting.

The students were all Chinese nationals, between 20- and 21-year-old, enrolled on a 4-year UK-China transnational programme delivered in China. About 40% of the students are female. For the duration of the course, the students were physically on campus in Beijing, while the instructor was in another country.

The digital learning activities made available on the LMS consisted in reading materials, short interactive videos (H5P technology), quizzes and exercise worksheets. In each interactive video, various exercises were embedded, which encouraged active learning and served as formative assessment: multiple choice questions, drag and drop exercises, fill in the blank exercises, select the right words exercises, etc. For each topic, further formative assessment was provided in the form of a 5-question quiz. The questions were randomly taken from a question bank, and each attempt could retrieve a different set of questions from the bank. Students were encouraged to attempt the quizzes several times to be exposed to a greater variety of questions. In addition, exercise worksheets could be downloaded, completed, and submitted again to the LMS. These worksheets could not be automatically marked, so no marks were allocated to them, but marks gained from the video embedded exercises and the quizzes were visible to the students and used for formative assessment only. At the end of the course, students would get 2 marks for completing at least 66% of the online learning activities (which included accessing the reading materials, interacting with the videos, answering the quizzes and uploading the completed worksheets), 1 mark for completing between 33% and 65% of these activities, and 0 mark if 32% or less had been completed. A total of 65 digital learning activities were proposed for which time-stamped digital traces could be collected, as summarised in Table 1.

In addition, weekly online synchronous tutorials were scheduled to answer students' questions, give live demonstrations, explain some of the topics in more detail, and discuss the quiz questions and worksheet exercises. Each week, an open-ended question was posted in a discussion forum for students to debate between themselves. Two mandatory labs were also scheduled, in week 4 and 10 respectively, for which reports had to be submitted as part of the summative assessment. In the first lab, students used Matlab to create audio spectrograms and observe various sound signals; in the second lab, they programmed a simple JPEG encoder and decoder. By the end of the course, the summative assessment was made of 80% final closed-book examination; 13% lab reports; 5% in-class test (a 20-question quiz generated from the same question bank as the weekly quizzes); and 2% for completion of the online activities.

The learning activities (reading material, interactive videos, quiz and worksheet) were released on a weekly basis, the week before the corresponding tutorial. For example, the introduction material

was released in week 0 and covered in the week 1 tutorial; the digitisation topic activities were released in week 1 and covered in the week 2 tutorial, etc. An activity released on the LMS would then remain available until the end of the course and could be attempted as many times as desired, including during the revision period (weeks 12 to 14) and until the final examination, scheduled in week 15.

The lecturer recommended to engage in learning activities weekly, prior to attending the tutorials. However, the learning was mostly self-regulated as students could choose when to engage in the learning activities, or even not to engage at all. Two hours a week was the recommended time to engage in the learning activities, and time and space were scheduled in the students' timetable for self-studying, but attendance at these sessions was not mandatory nor recorded. Most students chose to engage at different times and in their private space. The responsibility given to the students for their learning led to various strategies, which, thanks to the digital traces could be captured in the form of various learning pathways.

Table 1. Number of digital learning activities with digital traces per type (reading material, video, quiz, worksheet) and per course topic: 65 activities in total.

Topic (week)	Reading	Videos	Quiz	Worksheet	TOTAL
Introduction (w1)	2	0	0	0	2
Digitisation (w2)	1	3	1	1	6
Colour (w3)	1	4	1	1	7
Images (w4)	1	3	1	1	6
Video/Sound (w5)	1	5	1	1	8
Compression (w7)	0	4	1	1	6
JPEG (w8)	1	5	1	1	8
MPEG (w9)	1	6	1	1	9
MP3 (w10)	1	7	1	1	10
Broadcasting (w11)	1	0	1	1	3
TOTAL	10	37	9	9	65

2.2 Data Collection and Analysis

Each week and for each student the following data were collected: (1) date of latest engagement or attempt in each available learning activity on the LMS; and (2) updated video and quiz marks (students could improve their marks by re-engaging in the activities). The data were then anonymised: students names and email addresses were removed from the records, only student enrollment numbers were preserved to be able to track a student's activity across the duration of the course.

Data collection was constrained by the fact that, at any point in time, only one time-stamped digital trace would remain on the LMS for each activity: a new attempt at the same activity would overwrite the previous trace. It was thus important to carefully plan the timing of the data collection and to collect data repeatedly and regularly. We collected data the day before each weekly tutorial, when the material related to that tutorial had already been available on the LMS for a week. That way, we could capture whether a student had engaged in the learning activities before (as recommended) or after the corresponding tutorial. Data were collected weekly until the date of the final examination in week 15.

3. RESULTS

3.1 Learning Pathways

Figure 1 shows several examples of learning pathways. On the horizontal axis, the 65 learning activities are plotted in chronological order. The vertical axis shows all the teaching weeks of the semester. The gaps between weeks 3 and 4 and between weeks 5 and 6 correspond to weeks with no scheduled tutorial. The graphs indicate when a learning activity has been completed for the first time. The recommended pathway represents the lecturer’s intent, where each learning activity has been completed by the time of the corresponding tutorial.

Several patterns emerged as illustrated in the examples of Figure 1. Regular learners are students who followed the lecturer’s recommendations. Their pathway is typically just below the recommended pathway, showing that they have engaged in the learning activities within the week preceding the tutorial. Irregular or selective learners tended to choose the type of activities they engaged in (e.g., some students used only the videos, others only the quizzes) and often did this irregularly and irrespectively of the timing of the tutorials. Finally, the late learners are students who seldom engaged during the semester and typically used the learning activities at the end of the course to prepare for the final examination (i.e., combining massing and procrastination).

Figure 1. Recommended pathway and examples of regular, irregular/selective, and late learners’ pathways.

3.2 Distance Measure

We have formulated a distance measure (D) between a student’s and the lecturer-recommended learning pathways. It is calculated by adding together all the differences (in number of days) between when an activity was due and when it has been completed for the first time (see equation below). When an activity has not been completed, the maximum distance between the expected day and the end of the course (date of the examination in week 15), plus one day, is added to the sum. The sum is then normalised, dividing it by the maximum distance value (corresponding to a student who has not completed any of the activities) and multiplying by 100. D ranges from 2.38 (minimum distance found) to 96.9 (maximum distance found). The mean value of D is 31.61 (std = 25.95). Using K-means clustering (k = 3), the pathways were then grouped into three clusters.

$$Distance = \sum_{k=1}^{65} |expected_{day} - completed_{day}|$$

$$D = \frac{Distance}{Max\ Distance} \times 100$$

The first (low distance) cluster contains 47 pathways (20% of the students). These students can be classified as regular learners (see Figure 2). The maximum value of D in this cluster is 25.5, which can be used as a threshold value to “qualify” as a regular learner. All the pathway examples of Figure 2 follow the recommended pathway fairly closely, but each present a few “glitches”. The pathway with distance D = 8.30 shows that one of the latest activities has been missed, while another activity has been a bit delayed: until week 11 (final topic of the course) this student had been a very regular learner. The pathway with distance D = 12.81 shows that one of the early activities has been completed with a significant delay, while a few other activities were slightly delayed. It is possible that this student joined the course a bit late, did not understand what was demanded of them at first, or that it took them a bit of time to adopt the correct strategy (some “catch up” seems to have been done around week 9). The pathway with distance D = 17.37 is characterised by three undone activities, and one significantly delayed activity. The distance measure in this cluster seems to be a good indicator of the number and gravity of the “glitches”.

Figure 2. Examples of low distance (D=8.30; D=12.81; D=17.37) learning pathways (including the recommended pathway).

The second (middle distance) and largest cluster contains 128 pathways (55% of the students). The value of D in this cluster ranges between 25.5 and 56.8 (see examples in Figure 3). The examples of Figure 3 show that the students started as regular learners, but they shifted to selective or late learner profiles after some time (around week 5). Although the three values of D are close (28.61, 31.64 and 31.96 respectively), the pathways look quite different. The distance measure does not allow us to precisely discriminate between the selective and the late learners, so more work is needed in this respect. However, a student in this cluster may be described as an “irregular learner”.

Figure 3. Examples of middle distance ($D=28.61$; $D=31.64$; $D=31.96$) learning pathways (for reference, the recommended pathway is also shown).

Finally, the third (high distance) cluster contains 59 pathways (25% of the students) (see Figure 4). In this cluster, the students adopted either a selective or a late learning strategy from the start of the course. Some of these students concentrated on one type of activity only, others did all the activities, but very late in the semester, i.e., when they started revising for the final examination. The pathway with distance $D = 60.30$ is characteristic of a late learner: all the activities have been completed but were all seriously delayed. The pathway with the highest distance ($D = 96.87$) is characteristic of a learner who almost never engaged in any of the activities. The pathway with a slightly lower distance ($D = 91.22$) shows a learner who is both selective and late. A high distance measure seems to be a good indicator of poor time management and lack of engagement.

Figure 4. Examples of high distance ($D=60.30$; $D=91.22$; $D=96.87$) learning pathways (for reference, the recommended pathway is also shown).

Finally, we found D to have a moderate but significant negative correlation ($r = -0.6087$) with the students' final examination marks.

4. DISCUSSION

The negative correlation ($r = -0.6087$) between exam performance and the distance to the recommended learning pathway confirms that regular learning is conducive to deeper learning. There could be several reasons for this: (1) having studied the learning material before attending a tutorial allows students to make the best of the

time they have with the lecturer as they can prepare questions and better understand the additional content provided in the tutorial; (2) students have more time to assimilate and reflect on their learning before sitting the final examination; (3) it shows better time management skills, which are likely to have been effective also when preparing for the final examination.

As future work, we plan to test if, at the level of each student, the visualisation of their learning pathway combined with the distance measure D , may effectively raise their awareness of their lack of time management and self-regulation skills. Another possible application may be to use this information to nudge students who do not follow the recommended pathway and provide them with regular, timely, and personalised feedback.

At course level, a dashboard providing weekly information about the mean distance between the students' pathways and the recommended pathway, could be useful to alert the instructor about a worrying students' disengagement trend. A constantly high distance value could be indicative of a flaw in the course design, for example with respect to the amount of effort required from the students. A sudden increase of the distance measure could be indicative of a particularly challenging topic which causes disengagement from the students. It could also indicate that the students have a busy schedule forcing them to make undesirable choices concerning their time and effort allocations.

Our study suffers from several limitations. First, the data was collected on a weekly basis, where daily collection would have provided more accurate time stamps. This is easy to correct, and more data will be collected for the future cohorts of students. Second, in its current formulation, the distance measure does not allow us to precisely discriminate between the different learner profiles (selective, late, irregular, etc.). One possibility, which is under investigation, would be to use different weightings for different types of activity and to vary the weightings as the semester advances. Another possibility would be to formulate different distance measures, each measure being designed to capture a particular learner profile. Better discrimination between the different types of learners will enable the formulation of more accurate and pertinent nudging.

We have a lot of data that we have not yet exploited. Future work includes calculating correlations between different types of activity (completion and scores) and course performance. We have also started to work on the design of different dashboards for students and for instructors.

ABSTRACT

Studies have shown that **on-demand assistance**, additional instruction given on a problem per student request, improves student learning in online learning environments. Students may have opinions on whether an assistance was effective at improving student learning. As students are the driving force behind the effectiveness of assistance, there could exist a correlation between students' perceptions of effectiveness and the computed effectiveness of the assistance. This work conducts a survey asking secondary education students on whether a given assistance is effective in solving a problem in an online learning platform. It then provides a cursory glance at the data to view whether a correlation exists between student perception and the measured effectiveness of an assistance. Over a three year period, approximately twenty-two thousand responses were collected across nearly four thousand, four hundred students. Initial analyses of the survey suggest no significance in the relationship between student perception and computed effectiveness of an assistance, regardless of if the student participated in the survey. All data and analysis conducted can be found on the Open Science Foundation website¹.

Keywords

Online Education, On-Demand Assistance, Student Perception

1. INTRODUCTION

Collecting student perceptions on educators' performances, practices, and generated content has been well established in higher education, along with its ability to potentially improve student instruction [3, 10]. However, very few have been conducted on student perception in secondary education settings [11]. Additionally, surveys conducted on student perception rarely consider individual pieces of content and their effectiveness in context.

On-demand assistance generally improves student leaning [8, 12, 17, 20] in online learning platforms. Educators and their assistance are evaluated through computations to maintain or improve the level of quality and effectiveness [13, 16]. As such, student perceptions on assistance effectiveness are rarely polled, leaving a gap in their evaluation.

In 2017, ASSISTments, an online learning platform [9], deployed the Special Content System, formerly known as TeacherASSIST. The Special Content System allows educators to create and provide on-demand assistance for problems assigned to their students. On-demand assistance was known as *student-supports* within the application, with most as either hints or explanations. Additionally, educators marked as *star-educators* had their *student-supports* provided to any student, regardless of their class, for any problem a class's educator did not generate a *student-support* for. The effectiveness of a *student-support* was evaluated using whether the student answered the next problem in the problem set correctly on their first try [13, 16].

In the Fall semester of 2018, the Special Content System, on providing *student-supports* to the students, would prompt the student to provide feedback on the helpfulness of the *student-supports* as shown in Figure 1. The student may have chosen to evaluate the *student-support* by clicking the "Yes" or "No" button or not responded by completing and moving to the next problem. The feature was disabled in 2020 within the new, redesigned ASSISTments platform; however, educators who have not migrated from the original platform will still be provided this feature: prompting students on the helpfulness of a given *student-support*.

The first part of this work will analyze the students' perceptions of helpfulness and compare them to the overall effectiveness of the *student-support*. If correlated, students could be effective in filtering *student-supports*. In online learning environments which crowdsource their on-demand assistance [13, 12, 17], it may improve automation and independence from moderating bodies. The second part of this work will analyze the students' perceptions of helpfulness and compare them to the responding students' effectiveness of the *student-support*. This may give stronger claims towards a student's ability to predict the effectiveness of assistance provided to themselves.

In summary, this work aims to answer the following research

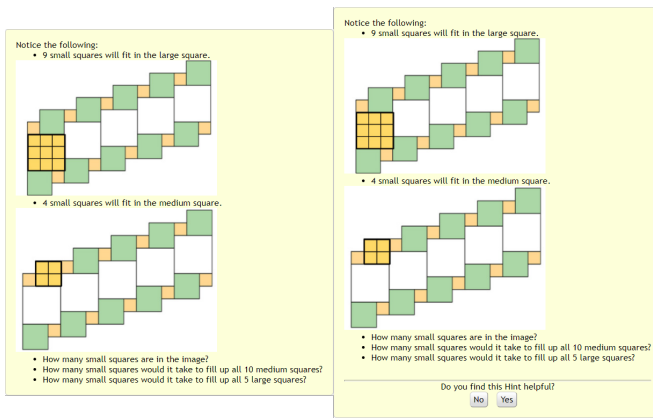

Figure 1: A *student-support* provided to the student (left) prompting the student for their perception on its helpfulness (right).

questions:

1. Can student perceptions accurately predict the overall effectiveness of *student-supports*?
2. Can student perceptions accurately predict the effectiveness of *student-supports* for students who participated in the survey?

2. BACKGROUND

In this work, ASSISTments will be used to conduct the studies. ASSISTments² is a free, online learning platform providing feedback to inform educators on classroom instruction [9]. ASSISTments provides open source curricula, the majority of which is K-12 mathematics, containing problems and assignments that teachers can assign to their students. Students complete assigned problems in the ASSISTments Tutor. For nearly all problem types, students receive immediate feedback on response submission, which tells the student the correctness of the answer [6]. When a *student-support* has been written for a problem, a student can request to receive a *student-support* during the span of problem completion. *Student-supports* may come in the form of hints which explain how to solve parts of the problems [8, 17], similar problem examples [12], erroneous examples [17, 1], and full solutions to the problems [18, 19].

ASSISTments runs an application known as the Special Content System in which *student-supports*, usually as hints or explanations, are crowdsourced from educators. *Student-supports* are created by educators and then provided to students when solving. In this work, data from the ASSISTments Dataset generated by the Special Content System [14, 15] alongside the student perception on *student-support* effectiveness is used to analyze whether student perceptions accurately predict the effectiveness of *student-supports*.

3. METHODOLOGY

Data was collected within the original ASSISTments platform over the course of three years. During this time period,

²<https://assistments.org/>

when a *student-support* was provided to a student, a prompt may appear asking about the effectiveness of the *student-support*, as shown in Figure 1. The student additionally had an equally likely chance that a prompt may not be shown. 46,620 responses across 13,509 students were recorded on the effectiveness of a *student-support*. Preprocessing on the responses removed any where the effectiveness of a *student-support* could not be determined. Additionally, any students who only answered one of the available choices across many problems were discarded as the provided answers may not be in full consideration of the question or without major bias. After processing, 21,736 responses across 4,374 students remained. The responses consisted of 5,861 *student-supports* across 4,120 problems.

After the response were processed, they were grouped by problem and sub-grouped further by *student-support*. Each sub-group of *student-supports* contained the data for the student perception of effectiveness and the effectiveness data as specified by the research questions: overall effectiveness and the effectiveness across the students who responded respectively. For every pair of *student-supports* with a problem group, a Sign Test [5] was performed between the student perception of effectiveness and measured effectiveness of the *student-supports*. As A Sign Tests measures whether the differences between pair of data is consistent, the results are expected to follow a binomial distribution. As such, a two-sided Binomial Test [4] was performed to measure whether the student perception of effectiveness and the measured effectiveness is consistent. If there was less than two *student-supports* available for a problem or the difference between the perception or measured effectiveness was zero, then no useful comparison could be made and was thus discarded [5]. The results of the pairwise comparisons between all *student-supports* are reported using the *Pair* prefix within Table 1. To make claims on the effectiveness of *student-supports* on a given problem, another two-sided Binomial Test was performed only on the two supports with the largest combined sample size. The results of the pairwise comparison between the two *student-supports* with the largest sample size per problem are reported using the *Problem* prefix within Table 1. As multiple analyses were being performed on the dataset, the Benjamini-Hochberg Procedure [2] was applied to the corresponding p-values to reduce the false discovery rate.

To measure the effectiveness across only those who participated in the survey, a Chi-squared Test [7] was performed comparing the relationship between the student perception of effectiveness and the measured effectiveness across students who responded for a *student-support* in addition to the Sign Test. In comparison to the Sign Test which measures consistent differences, a Chi-Squared Test measures the difference in frequencies between two relationships. A Chi-squared Test was not conducted on the overall effectiveness as the sample size considers all students who were provided the associated *student-support* which violates the equality of sample sizes across observation. As the results of all the Chi-Squared Tests performed is infeasible to report, only those which found significant results are shown in Table 2.

4. RESULTS

Table 1: Binomial Test of the Sign Tests on student perception of effectiveness and the measured effectiveness of *student-supports*.

Test Performed	Sample Size	Number of Successful Sign Tests	P-Value	Corrected P-Value
Pair: Overall	1,699	876	0.2071	0.379
Problem: Overall	1,182	607	0.3672	0.379
Pair: Responding Students	1,320	695	0.0575	0.23
Problem: Responding Students	942	485	0.379	0.379

4.1 Overall Effectiveness

As shown in Table 1, across the 5,861 available *student-supports* with responses, 1,699 pairs of *student-supports* were created with 876 pairs (proportion estimate of 0.5156) returning a correlated difference on the Sign Test for overall effectiveness. Across the 1,699 pairs of *student-supports*, there were 1,182 problems, of which 607 (proportion estimate of 0.5135) had a correlated difference on the Sign Test. Both results were not significant ($\alpha < 0.05$) before Benjamini-Hochberg correction.

4.2 Effectiveness Across Responding Students

Also in Table 1, 1,320 pairs of *student-supports* were created with 695 pairs (proportion estimate of 0.5265) returning a correlated difference on the Sign Test for effectiveness across responding students. Across the 1,320 pairs of *student-supports* there were 942 problems, of which 485 (proportion estimate of 0.5149) had a correlated difference on the Sign Test. Both results were not significant ($\alpha < 0.05$) before Benjamini-Hochberg correction.

The Chi-squared Test ($z_{0.05} \geq 3.8415$) revealed only six out of the 5,861 responded *student-supports* with a relationship between the student perception of effectiveness and the measured effectiveness across the responding students. The results of the significant Chi-squared Tests are shown in Table 2. The significance of the results can be attributed to randomness due to sample size ($6/5861 = 0.001 < 0.05$). The corrected p-values using the Benjamini-Hochberg Procedure[2] also conveys the non-significance of the results at $p = 1$.

5. CONCLUSION

In this work, initial findings show no significant relationship between student perception of effectiveness and the measured effectiveness of a *student-support*. Only 5% of students who used the original system were considered in the performed analysis. Additionally, less than 1% of the responses collected showed any significance in the relationship. As such, the significance of any current results can be attributed to randomness. The response set is unlikely to be generalizable to other online learning platforms or across students and problems.

Potential improvements to further analysis could view the features of the participating students or problems, such as prior knowledge or problem accuracy. The prompts could also be subdivided further to determine if phrasing has a desired effect on student perception. Accurate markers of student response times could also be recorded to differentiate responses before and after completing the given problem. Additionally, the location of when the prompt was delivered

could be moved to better reflect the measure of effectiveness used for an on-demand assistance.

Although no evidence of the relationship between student perception of effectiveness and the measured effectiveness of a *student-support* was found in this work, other qualities could attempt to better provide understanding of student perceptions on effectiveness in more granular surveys. Future work can explore better opportunities in student perceptions on effectiveness of *student-supports* for themselves. Afterwards, further steps can be taken to gradually generalize effectiveness overall and eventually to other online learning platforms.

ABSTRACT

This study applied a problem-based learning framework to visualize students' problem-solving patterns using sequential log data. Comparing the theory-informed visualization with a graph without theoretical guidance proved that problem-solving visualizations with a theoretical foundation were more interpretable for researchers and educators. The presentation of the graph was more explicit, and the outcomes can be generalizable to other related PBL studies. Besides, the theory-informed visualization can also be used by teachers to provide differentiated scaffoldings to support different groups of students when facilitating problem-based learning activities.

Keywords

Learning analytics, problem-based learning, theory-informed, data visualization.

1. BACKGROUND & INTRODUCTION

Problem-based learning (PBL) is an instructional method in which students learn through facilitated problem solving that centers on an ill-structured problem [8]. It is a constructivist educational strategy and should be performed via a student-centered pedagogical approach [6]. In other words, when engaging in a PBL activity, learners should take a more active role in obtaining knowledge and skills [9]. Instructors need to serve as facilitators who provide individualized instructions to accommodate students' diverse progress [17].

In a constructivist activity like PBL, students would be at different paces and engage in various tasks. Thus, to better facilitate students' problem-solving, it is vital to monitor their progress [6]. Only after educators or researchers tracked students' different progress successfully and precisely, then they could provide individualized instructions to facilitate students [13].

The recent advancement of virtual PBL environments provided researchers opportunities to track students' problem-solving progress [3]. When students were engaging with virtual PBL environments, a large number of usage clickstream log data would be generated. The clickstream log data is time-stamped and captures students' fine-grained behaviors [18]. Researchers and educators can employ these data to monitor students' real-time progress or to provide just-in-time interventions.

Z. Pan and M. Liu. Theory-informed problem-solving sequential pattern visualization. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 738–742, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

© 2022 Copyright is held by the author(s). This work is distributed under the Creative Commons Attribution NonCommercial NoDerivatives 4.0 International (CC BY-NC-ND 4.0) license.
<https://doi.org/10.5281/zenodo.6853059>

The collected log data is often large amounts and consists of multiple features including student ID, timestamp including start time, end time, the name of accessed tool, tool use actions such as tool open or close, and so on. Collecting the clickstream log is just the first step, a more crucial step is how researchers and educators process the log data to make it interpretable for further educational practices. In this case, educational theories are needed in guiding researchers to process the collected log data and make it interpretable and relevant to educators.

2. PURPOSE OF STUDY

The research involving collecting, analyzing, and reporting learners' usage log data is considered learning analytics studies (LA). Researchers have been exploring and refining the approaches of incorporating educational theories when conducting LA studies [2]. For instance, a study [7] incorporated the framework of engagement in processing student-generated log data on MOOCs. Researchers applied exploratory and confirmative factor analysis upon collected log data, and related the outcome factors to three engagement constructs: affective, cognitive, and behavioral engagement. This theory-informed data processing allowed researchers better to interpret the association between usage logs and learner performance. For example, learners' video watching duration is associated with final scores because they were positively correlated with the behavioral and cognitive engagements. In another study [15], researchers mapped usage logs on learning management systems to self-regulated learning (SRL) phases. For instance, students' actions of accessing objectives or lesson overviews were associated with the Forethought phase of SRL. These actions reveal the traces of learners' goal-setting behaviors, an important component of the forethought phase. Following the SRL framework, researchers could draw a clear path between nuanced learning analytics features and the nuances of learning theories. In return, the framework provided a solid theoretical foundation for further instructional practices and the future designs of the learning platforms. Although researchers have taken initiatives of involving theories to process log data generated from various educational platforms. However, seldom studies have focused on incorporating theories to process problem-solving behavioral logs. Although previous studies applied LA techniques to analyze problem-solving logs [3, 12], however, to produce inferable and generalizable research findings for future PBL research, more theory-based log processing approaches are needed.

In addition, data visualization was widely applied in representing log data outcomes, especially when the amount of data is large [11]. LA studies can be benefited from data visualization techniques is because the visualizations can represent the large amount of data in a compact format without losing essential information [1]. For example, a study [4] extracted student log data from a virtual geometry game to visualize their problem-solving patterns. These graphs helped researchers to examine students' problem-solving patterns explicitly, they were able to see whether students were on

the expected path during the activity. In another study [14], researchers used area graphs to represent students' different tool usage frequencies in a virtual PBL environment. These graphs allowed researchers to efficiently identify the different usage patterns between different groups of students. Using log data to create data visualizations brings researchers larger flexibility to examine user behavior patterns from different aspects. The outcomes of the visualizations could also be used in the classroom to inform teachers about providing just-in-time supports [16].

Considering the advantage of data visualization and the need to incorporate educational theories in processing log data, especially in the PBL context. The purpose of this study is to merge the gap by providing a theory-informed LA method to process sequential behaviors generated in a PBL activity. Then, by visualizing the sequential outcomes, the ultimate goal of proposing this approach is to (1) generate theory-based interpretable sequential patterns for researchers and (2) assist teachers in being better informed about students' progress to support their PBL facilitation.

3. METHOD

3.1 Research Context

The PBL environment applied in this study is called Alien Rescue (AR). In this environment, students play the role of scientists to help six alien species to relocate to our solar system. By solving the problem of which species can survive on which planet or moons in our solar system, students would gain related scientific knowledge aligned with 6th-grade science standards.

Figure 1 presents the screenshots of the AR environment. It is a 3D immersive problem-solving platform, and there are ten different cognitive tools embedded for students to use. These tools, like the Solar system database or Notebook, can provide students with needed information and scaffoldings to find the solutions.

Figure 1. Alien Rescue PBL environment

3.2 Participants and Data Source

A total of 114 six grade students engaged with the AR PBL environment through 15 class sessions. More specifically, 61 students conducted this activity virtually at home, and 53 students conducted this activity in-person at school.

In all, 45554 lines of behavioral log data generated by participants were collected for data processing and analysis. The features of the collected log data include:

- Student ID.
- Activity start time (by second).
- Activity end time (by second).
- The name of the accessed tool.
- Tool usage actions such as tool open or close.

3.3 Theory-Informed Data Processing

To track and analyze students' problem-solving behaviors and present generalizable outcomes, the framework of PBL process was applied [8]. Based on the framework, problem-solving usually consists of multiple phases, including identifying facts (IF) and Knowledge deficiency (IKD), generating hypotheses (GH), and

Solutions (GS). Learners perform the phases iteratively or in different order until solutions are produced. To better interpret students' problem-solving patterns using log data and related to the framework, 28 different kinds of behavioral log actions in AR were connected with several problem-solving phases based on the concept of each phase [8]. Table 1 presents an example of the alignment. The first phase in the framework is the activities for students to understand the problem scenario. AR environment provides several tools such as Alien or Concept Databases for students to collect the information they need for solving the problem. Thus, the access to these tools aligns with the idea of Identify Facts (IF) phase. Plus, students needed to generate possible hypotheses as they gathered more information. The probe sending feature in AR is a critical component that students can actively obtain information to generate hypotheses. Thus, the actions related to sending probes were aligned with Generate Hypothesis (GH) phase. Moreover, AR provided students with a Notebook tool to organize collected information and identify missing pieces, which resonates with the phase Identify Knowledge Deficiency (IKD). Plus, Notebook also allows students to generate possible solutions via a Comparing Notes feature. This feature lets students conveniently compare the information they obtained in the environment to decide which place is suitable for which alien. In this case, actions relevant to comparing notes were aligned with Generate Solution (GS) phase.

Table 1. Examples for alignment process

Log Activities in AR	Phases in PBL Cycle	Definition
Alien Database: Click Concept Database: Click	Identify Facts (IF, index = 1)	Students identify the relevant facts from the environment, which helps them represent the problem.
Probe Design: Change Probe Name; Click Back Button	Generate Hypothesis (GH, index = 2)	Students take the initiative to generate possible hypotheses as they understand the problem better.
Notebook: Click; Create; Delete; Edit	Identify Knowledge Deficiency (IKD, index = 3)	Students identify the knowledge that is gathered against knowledge that is still needed.
Notebook: Compare; Edit	Generate Solutions (GS, index = 4)	Students use the obtained knowledge to produce solutions.

Ultimately, all log data were transformed into 1789 sequences that reflect students' problem-solving sequential patterns. Table 2 presents an example of processed outcomes. For instance, the first row indicates the sequence performed by student 1 in May. 25th is IF, IKD, GH, IF, IKD, and GS, which is different from the sequence the student conducted in May. 26th. These sequences were then used for sequential analysis and creating visualizations to examine student problem-solving patterns.

Table 2. Example of processed sequences

Student	Date	Activity Sequence
Student 1	May.25th	[1, 3, 2, 1, 3, 4]
Student 1	May.26th	[1, 3, 1, 3, 1, 4, 1, 4, 1]
Student 2	May.25th	[1, 2, 1, 3, 2, 1, 3, 1, 2, 3]

Note. 1 = Identify Facts (IF), 2 = Generate Hypothesis (GH), 3 = Identify Knowledge Deficiency (IKD), 4 = Generate Solutions (GS)

3.4 Data Visualization Techniques

Problem-solving is a sequential activity that consists of multiple phases such as Identify Facts or Generate Hypothesis. The paths students go through during these phases are not always linear. In fact, during a PBL activity, students usually go iteratively or circle among different problem-solving phases [8]. The Sankey graph is a type of graph that symbolizes sequential activities. It can mimic users' iterative sequential behaviors. More importantly, the graph can also present the strength of each sequential path: the wider the path between two phases, the larger proportion of the sequential activity between two phases among all sequences in the graph. Thus, Sankey graphs were used to visualize the iterative manner of students' problem-solving efforts.

4. RESULTS & DISCUSSION

4.1 Theory-informed visualization

Figure 2 was created to represent students' problem-solving behavioral patterns. For instance, the label 20% on the top of the figure means, among all the paths performed by students, 20% of the sequential actions were from Identify Knowledge Deficiency (IKD) to Identify Facts (IF) phase.

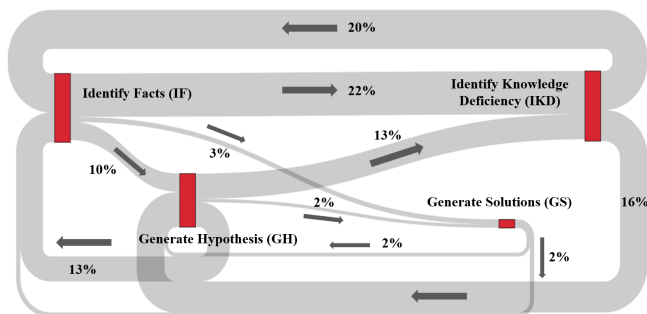

Figure 2. Theory-informed problem-solving patterns

Based on Figure 2, following highlights can be extracted:

- Relatively large proportions of the sequential behaviors were conducted between IKD and IF phases (20%, 22%). It means students were inclined to keep seeking information until they figured out what information was obtained and what was missing, and they would find out the ones they needed.
- The paths involving Generate Solutions (GS) were relatively smaller among all the paths (e.g., IF to GS is 3%; GH to GS is 2%). These outcomes indicate GS is more of an end of problem-solving activity instead of a mean. It is aligned with the PBL environment setting. In the GS phase, students just needed to submit their solutions to a console in the environment, the action itself does not enhance or intervene in their problem-solving progress. In total, students are required to compose six solutions; that's why the GS phase paths are smaller. To be noted, there were some paths coming out from GS phase; it means students were reconfirming their solutions either by going back to IF (2%) to examine some information, or to GH phase (2%) to refine their hypothesis.
- The paths among IF, GH, and IKD occupy medium proportions compared to the above two findings. For instance, 16% of the actions were from IKD to GH. GH phases involve the actions that students were sending probes to narrow down their hypothesized solutions. Students may or may not have a

solution ready after the GH phase, which explains why the proportion of paths from GH to GS is relatively small (2%).

In all, figure 2 presents the problem-solving sequential patterns performed by students during a PBL activity. This graph provided an overview of how students conducted problem-solving in an iterative manner across multiple PBL phases. More importantly, this graph provided a theory-informed representation of the sequential problem-solving patterns generated by a group of middle school 6th-graders in a science PBL activity. Because the paths presented the actions transiting across different PBL phases, this outcome would be informative for other PBL research that is either in a similar or a different educational context.

In fact, to examine the benefits of theory-informed visualizations, Figure 3 was created by the authors for providing a contrast to figure 2. Figure 3 is also a Sankey graph but without aligning the problem-solving actions and the PBL phases. All nodes presented were different tools provided in the PBL environment, and all paths were students' sequential paths across each tool. For instance, from this figure, we can find out relatively large proportions of sequential actions were performed among Notebook, Solar System Database, and Alien Database. These three tools are all essential features provided in the environment for students to solve the problem. Indeed, it provided a fine-grained visualization of how students transited across different tools in the environment. However, figure 3 could be less interpretable than figure 2 in the following two aspects.

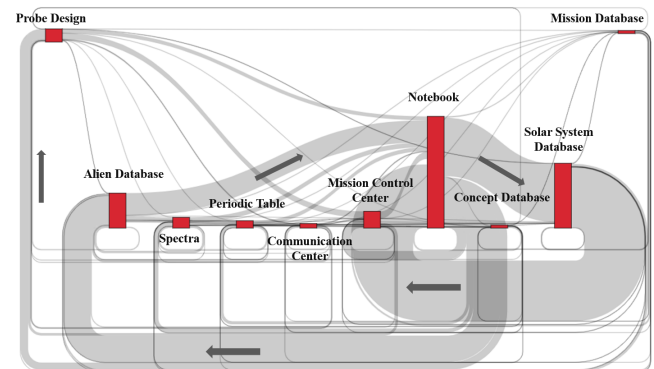

Figure 3. Patterns without PBL framework alignment

The first aspect is information presentation. In the AR PBL environment, there are a total of 10 different tools. A graph that presents students' problem-solving patterns in such an environment should incorporate all the actions among these ten tools. Compared to figure 2, which only contains four nodes, figure 3 brings a larger amount of information or cognitive load for readers to process [1]. Plus, the presentation of this graph is already congested even without the authors inputting direction and percentage for each path. In fact, many current PBL environments, such as River City [10] or Crystal Island [5], involve more than ten tools or features that students need to access. Even though a fine-grained graph that includes all tools can reveal detailed sequential behaviors and is informative to readers familiar with the environment, it might be challenging for both researchers and readers to interpret those less acquainted.

The second aspect is generalizability. A fine-grained graph like figure 3 can indeed reveal exact sequential action performance by students. For example, after accessing Probe Design, the figure shows students would engage with a series of tools such as Alien Database or Spectra. However, what do these actions mean in terms

of problem-solving patterns in general? It may be more informative for developers of this environment than researchers conducting PBL studies in different contexts. Whereas for figure 2, since the Probe Design is aligned with the GH phase (see Table 1), the figure shows 13% of actions afterward were to IDF, and 13% were to IF. These outcomes provide a more explicit picture of how students performed their PBL paths and strategies, since it is aligned with the PBL framework [8]. Other studies that also applied this framework could compare and contrast the outcomes with this study and draw inferences. In addition, researchers or educators who are contemplating conducting PBL studies or activities could pick up the information that depicts students' problem-solving patterns easily from the theory-informed graphs to apply to their future PBL design or activities.

4.2 Uses of the theory-informed visualization

Expect for interpretation, the theory-informed visualizations also present in-depth outcomes for researchers and educators about students' problem-solving patterns based on conditions. Since participants engaged in the AR PBL environment under virtual or in-person modes, the theory-informed visualizations can also provide a comparison between these two groups.

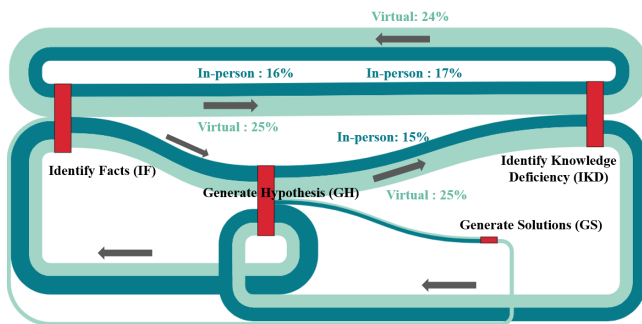

Figure 4. Problem-solving patterns grouped by learning modes

A Sankey graph was made with light blue representing the paths conducted by students in the virtual mode and dark blue representing the paths by students in the in-person mode (see Figure 4). The statistical results showed that students in the virtual mode ($M = 106$, $M = 97$) performed significantly more paths from Identify Facts (IF) to Identify Knowledge Deficiency (IKD) phase ($U = 901.00$, $z = 3.86$, $p < .01$), and from Identify Knowledge Deficiency (IKD) back to Identify Facts (IF) phase ($U = 829.00$, $z = 4.28$, $p < .01$) than their in-person mode peers ($M = 82$, $M = 72$), these statistical outcomes are resonated with the Sankey graph that light blue path is wider than dark blue paths. Moreover, as indicated in Figure 4, students in the virtual mode ($M = 8$) were more inclined to use the generated hypothesis to assist their knowledge deficiency identification process ($U = 879.50$, $z = 2.16$, $p < .05$) than students in the in-person mode ($M = 12$). Based on these results, the students in the virtual mode appeared to be more careful when identifying knowledge deficiency by organizing their collected information on Notebook. They were more likely to collect information from different databases (ID) or draw results from the probes they sent (GH) first, then input the information on Notebook for further uses. In fact, carefully identifying sufficient information from different databases and collecting returned data from probes are expected problem-solving sequential paths that would provide students with better solution outcomes [8].

In addition, the graph also showed that students in the in-person mode did not perform the paths from Generate Solutions (GS) to Identify Facts (IF), the dark blue path is missed between these two

phases. To conceptualize and finalize robust solutions, it would be helpful for students to check with different databases to ensure the correct information supported the solution. Therefore, the above outcomes indicate that students in the virtual mode would perform the problem-solving actions close to the expected path, leading to better problem-solving outcomes. These results presented that students under different learning modes performed distinctive problem-solving strategies. It indicates that when teachers facilitate PBL activities, different scaffoldings instructions should be provided based on students' learning mode. For example, teachers can encourage in-person students to identify what information they still need before generating hypothesis, or remind them to examine the facts before submitting their final solutions.

In addition, the gender variable can also be incorporated by the theory-informed visualization. Figure 5 was made to visualize the different problem-solving sequential patterns between genders. The light blue color represents the paths conducted by male students, and the dark blue color represents female students. It is noticeable that from Identify Facts (IF) to Generate Hypothesis (GH) phase, the light blue path is wider than the dark blue path. A similar pattern could be observed from Generate Hypothesis (GH) back to Identify Facts (IF) phase as well. Statistical results showed that under condition A, male students ($M = 13$, $M = 17$) performed significantly more paths from Identify Facts to Generate Hypothesis (GH) phase ($U = 1027.00$, $z = 3.14$, $p < .01$), and from Generate Hypothesis back to Identify Facts (IF) phase ($U = 1137.00$, $z = 2.50$, $p < .05$) than their female peers ($M = 8$, $M = 12$). These results indicate that male students dedicated more efforts to generating hypotheses directly after collecting information from different databases (see Table 1), and these actions were presented in a repeated manner. On the other hand, female students might be more cautious when generating hypotheses, as indicated on the graph, female students (dark blue) were more likely to generate hypotheses after identifying knowledge deficiency than male students (light blue). Although this path is not significantly different by gender, it still reveals nuanced sequential differences between genders. Therefore, teachers can provide scaffoldings to different students based on gender accordingly. For instance, teachers can remind male students not to make prompt hypotheses right after identifying facts from databases. But instead, they can check what information is missing and what they already have to draw better hypotheses.

Figure 5. Problem-solving patterns grouped by genders

5. CONCLUSION

In conclusion, this study's findings revealed that theory-informed visualizations could provide more interpretable outcomes when examining students' sequential activities during problem-solving activities. The overall presentation of the visualization would be more explicit and generalizable to other relevant studies.

Moreover, the theory-informed visualizations can also demonstrate students' patterns based on different conditions such as learning modes or genders. These nuanced outcomes can inform teachers' differentiated scaffoldings when facilitating PBL activities.

ABSTRACT

The modern educational ecosystem is not one-size fits all. Students are accustomed to personalization in their everyday life and expect the same from education systems. Additionally, the COVID-19 pandemic placed us all in an acute teaching and learning laboratory experimentation which now creates expectations of self-paced learning and interactions with focused educational materials. Consequently, we examine how learning objectives can be achieved through a learning platform that offers content choices and multiple modalities of engagement to support self-paced learning and propose an approach to personalized education based on network science and data mining. This framework brings attention to learning experiences, rather than teaching experiences, by providing the learner engagement and content choices supported by a network of knowledge based on and driven by individual skills and goals. We further discuss the proposed prototype of such a learning platform, called CHUNK Learning. In this work, we present this tool, its benefits for students, challenges in personalized education, and future plans.

Keywords

CHUNK Learning Prototype, Personalized Education, Network of Knowledge, Network Data Mining.

1. INTRODUCTION

Education must meet the changing needs of a complex environment where learners are expected to contribute as creative problem-solvers. Education solutions must satisfy the specific educational needs of each learner while meeting the rapidly changing learning objectives for each degree or job in a resource-efficient way. Consequently, the educational ecosystem must also provide a flexible and rich cognitive

environment, supported by adaptable high-quality content for academic performance and complemented by effective learning analytics, as well as social networking for strong emotional support of students.

We identify the current shortcomings of learning platforms and propose solutions to improve personalized learning using data mining and network science techniques. At the content level, we focus on exploring the relevance of content by anchoring it to each learner's existing knowledge and how content connects to the skills of each learner. Additionally, we discuss how interconnecting people, content, goals, and skills support student learning outcomes and collaborative learning and what is the impact of these interactions on educational experiences.

Our goal is to facilitate a learning culture that cultivates curiosity and inquiry. While learners interact with different content to show the same proficiency, learning differentiation is based on branching off the main knowledge thread driven by each student's unique attributes, such as experience, existing skills, and learning goals. In this work, we propose a personalized education model driven by data science and network science, and present a solution, a prototype called CHUNK Learning [12]. We create this agile system by interconnecting the content, skills, and learners that creatively address learning theory while supporting an ecosystem that motivates students and improves learning outcomes. Our focus is on creating a network of knowledge, individualized education pathways, and a social network of users to improve personalized education.

2. OUR VISION AND STATE-OF-THE-ART

We present our vision for personalized education and the synthesis of state-of-the-art research in support of personalized education using network science and data mining.

2.1 The Design of a Network of Knowledge

Traditional education is linear, one chapter after another through a whole course or course after the course through a degree. An interconnected model of education brings an interconnected (non-linear) view of the knowledge, where a user can navigate through a network of knowledge built

R. Gera, D. Bartolf, S. Tick, and A. Saxena. CHUNK Learning: A tool that supports personalized education. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 743–747, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

based on an ontology, pre-requisites, or dependency. Recent research identifies the benefit of interconnecting the knowledge for the learners, seeking models for a network of knowledge. For example, one way to model it is by “quantifying and analyzing the structure of students’ knowledge of a given discipline as a knowledge network of interconnected concepts”. Once this network is created, we can capture the learning pattern and retrieve the information of learners’ interactions over time [7, 17].

We propose a model that supports the interconnected world of 21st-century education, where subject matter experts co-create a network of knowledge as a curated collection of networked learning modules [1, 10]. A successful prototype was built and used since 2018, namely the Curated Heuristic Using a Network of Knowledge for Continuum of Learning (CHUNK Learning), i.e., a real-time, adaptive teaching-learning modular method for enhanced and personalized education.

2.2 The Education Pathways for Personalized Learning

Education is improving, but not as fast as our aspirations. Learners bring distinct backgrounds, learning style preferences, and different motivations for engaging with the content. This surfaces the need for personalized learning that assesses each learner’s gaps, skills, and prior experience before bringing in new information, thus preventing more gaps creation or repeat of lessons already learned.

It also requires that a variety of learning styles be available for learners when engaging with an instructor or the asynchronous content. Content and applications of the newly learned content must differ based on each learner’s experience and background; for example, learning and using a mathematical concept for an economist versus a mathematician is different. Content must have applications that are relevant to the learner’s background to anchor it to the learner’s experience since they will be applying it in the future. Besides this, some learners are directed to learn specific content for certification as needed by a job or degree, while some learners explore the network of knowledge for personal indulgence to up-skill their existing expertise. With the goal of providing a personalized experience to each student, choices of learning paths for each student need to be dynamically created. A method to create these learning paths can utilize network science and data mining techniques on the annotated network of content and users [7].

Cognitive flexibility theory discusses learning within complex and ill-structured knowledge domains through the inability of linear educational structures to support meaningful learning experiences [6]. In these environments, the network of knowledge demonstrates complex concepts’ interconnections and supports semantic memory. Additionally, the use of nodes and edges creates visual learning pathways that provide an avenue for supporting and tracking learners’ knowledge acquisition [17].

The use of network science to create a structural representation of learning paths supporting knowledge acquisition allows educators to determine if there is an optimal path. Networked education pathways provide the necessary envi-

ronment to examine the average length of paths between two nodes in the network and the relationship to students’ understanding of material [16]. This also presents an opportunity to examine the use of bridging concepts within a complex knowledge structure [17]. This will also provide a feedback mechanism to inform educators about how to improve educational experiences for learners, filling in gaps within the knowledge structure as needed in order to support desired learning outcomes. Once users have navigated even a portion of the network of knowledge, their experiences create a database of learning paths, which can be analyzed to understand the learning patterns based on gender, age, background, learner type (directed versus exploratory learner), or other attributes of the learners [13]. These findings can be used to further improve the personalized learning platform by suggesting what content should be added and designing a better recommendation system for learners.

2.3 Incorporating Online Social Networking in Learning Platforms

Online learning platforms complement or replace classroom learning for students; however, they usually lack students’ engagement. One way to support students’ engagement in such educational platforms is by incorporating social networking into the learning platform. Researchers have studied the benefits of networking the learners in learning and professional development [15]. Various existing platforms, such as Coursera [3], Moocs [4] provide the ability for students and instructors to communicate with each other. While this supports modern students’ learning, they lack social networking among students for content recommendation or live collaboration.

A learning platform can provide a service to maintain social connections for increasing users’ engagement in the following ways. First, users can follow or be friends with people they know or want to connect with for personal interest. Secondly, the platform should suggest new users to connect with based on similar backgrounds and same learning interests. Additionally, to incorporate group learning, the platform should suggest the teams either for instant collaboration or group projects based on users’ current learning paths. The recommendation system must be adaptive in recommending such teaming patterns based on the past performance of the students and their interests.

CHUNK Learning includes the vision for such a platform that is empowered by social networking to support meaningful learning timely and respectful of each learner’s time in a cost-effective manner [1]. Research on the CHUNK Learning platform considered the social network to recommend similar content to similar learners, as well as connecting similar learners based on their learning paths, background, and mentor-mentee type relationships [11].

3. A WORKING EXAMPLE: CHUNK LEARNING PLATFORM

We have designed a prototype of personalized education using the network of knowledge, learning pathways, and network of students, called CHUNK (Curated Heuristic Using a Network of Knowledge) Learning platform [1, 10, 12]. We now point out how CHUNK Learning fulfills some of the

CHUNK Explorer (right):

A curated collection of networked learning modules, organized to meet strategic objectives (academic or professional). Prerequisites directed by yellow arrows on the right.

Chunk (below): A self contained knowledge module.

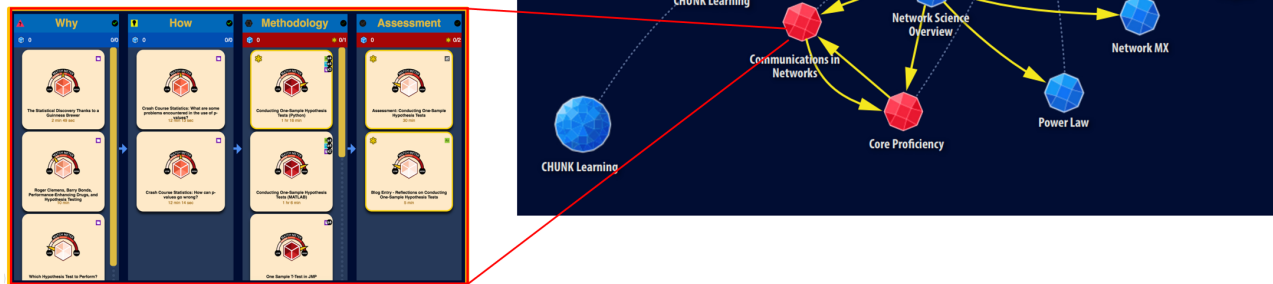

Figure 1: The network explorer and a chunk's content in CHUNK Learning [1]

identified needs for personalized education. Since the existing CHUNK Learning system is in its infancy stage, we will conclude this section with ideas that can extend the current version based on the discussion in Section 2.

The CHUNK Learning prototype offers several features identified in this work: (i) a personalized learning journey by using the information provided in the learner's profile to automatically recommend the most relevant-to-you content, (ii) content mapping that illustrates how a learner can progress through the network of knowledge by including the choices of learning paths through the network, and (iii) a framework to support social network of learners based on their profile and content they are engaging with at each time they log into CHUNK Learning. CHUNK Learning platform focuses on empowering students by ensuring that the learning journey is cohesive, flexible, and respectful of learners' time and interests. This personalized education is accomplished through the use of the following components.

- Content is chunked into intense, short, and focused educational modules (chunks) that are interconnected in the network of knowledge to provide (a) learner's choices and platform's recommendation to build personalized learning paths, (b) view of the learning path choices through the content, and (c) a big picture of cohesive learning.
- Choices of interchangeable and reusable content stimulate each learner's interest and provide relevance of each topic to each learner [10].
- Learners' are placed into a social network to support each other, such as pairing senior learners as mentors

for junior ones, based on their automatically updated profiles [14].

- Personalized content driven by implicit recommendations from a user's social network based on tie strength between learners [8].

Based on the learner's profile, CHUNK Learning optimizes both the content and the methodology delivery to meet the needs of each learner. It is intended to fit typical academic needs, much like curriculum mapping, while personalizing the content within the chunk of knowledge. Therefore, the content is organized hierarchically using Topics, Units, Chunks, and Chunklets to index content in a way that meets and improves the overall coherence of a course of study (more information on CHUNK Learning Wiki [2]).

Figure 1 shows the personalized adaptive learning framework by displaying a portion of the network of knowledge on the right and the personalized content of a chunk of knowledge on the bottom left of the figure. Within a chunk, the top row of content reveals the system's recommendations based on the learner's profile, and the other tiles are the choices of the ranked alternatives. The system displays content in a manner that can be viewed in a network format through the CHUNK Learning explorer at the topic, unit, and chunk levels. The explorer view at the topic-unit-chunk level is a concept mapping that follows a logical order to provide each learner a well-rounded and comprehensive educational experience, with choices for deeper dives and connections to other topics-unit-chunk. At the chunklet level, a learner can see the choices for all the building blocks needed to attain any specific academic competency

Figure 2: A view of personalized learning pathway in CHUNK Learning [1]

while being recommended the most relevant one based on that learner’s profile. Each column of a chunk provides the recommended chunklet at the top, followed by rank-ordered choices to complete that part of the chunk before heading to the assessment.

Figure 2 shows an example of personalization in CHUNK Learning achieved through (i) interchangeable chunklets that personalize the application of the content (on the left side of the figure) and (ii) personalized interchangeable activities for different styles of learning, such as video, PDF, code, demo, interactive activity (on the right side of the figure).

CHUNK Learning is a prototype used for hybrid teaching at our university. For these classes, students learn part of the content asynchronously using CHUNK Learning, complemented by synchronous practice and discussions. The assessment of students’ experience in these classes shows promising benefits in using CHUNK Learning for hybrid teaching. Besides the self-paced environment, students valued the mix of modalities of engagement with the content available on CHUNK Learning, supporting meaningful and engaging interactions with the class while enhancing their learning experience.

3.1 Extending the CHUNK Learning Platform

How can this prototype be further extended using network data mining? We see four primary areas of extension, and some progress has already been made in each of the areas: (i) the network of knowledge’s explorer view, (ii) the content within a chunk, (iii) the social network of users, and (iv) create a network-driven recommendation system and learning analytics. Below we expand on the existing work on each of these extensions.

CHUNK Learning’s explorer view of the Network of Knowledge in CHUNK Learning is static and identical for all users (except the color coding based on the enrolled and completed chunks). To focus and place the learner on a meaningful learning path, we propose a personalized display of the network of knowledge based on assessment and relevancy to the user’s learning objectives. Complementing the personalizing of the explorer view, we can personalize each chunk’s content. Currently, it is performed using the content’s tags compared to a learner profile’s tags, in addition to the ranking of the content based on the user’s rating of each chunklet. The two existing rankings are based on the quality of the content and relevance to the learner.

Currently, the recommender system updates the learning plan based on each learner’s activities (learned, viewed, tested), keyword searches, and content ratings [5, 9, 11]. We aim to update further the recommendation system using the social network of learners and their learning history.

4. CONCLUSION

In this paper, we introduced a prototype named CHUNK Learning to improve personalized education at scale using network data mining. The proposed prototype is based on the network of knowledge, education pathways, the network of learners, and the content recommendation system. We presented this tool, its existing features, and further plans. We also discussed some challenges to consider in creating and using such a personalized learning ecosystem. We aim to extend the tool further by including a social network of users to support personalized and collaborative learning. We share this work to promote conversations and research towards a new field of personalized education driven by network data mining.

Do College Students Learn Math the Same Way as Middle School Students? On the Transferability of Findings on Within-Problem Supports in Intelligent Tutoring Systems

Michael Smalenberger
The University of North Carolina at Charlotte
msmalenb@uncc.edu

Kelly Smalenberger
Belmont Abbey College
kellysmalenberger@bac.edu

ABSTRACT

A widely used minimum criterion for intelligent tutoring system (ITS) status is that the system provides within-problem support. The ITS literature abounds with comparisons of supports, but investigations on the transferability of findings, particularly between education levels, are scant. There are, however, significant impediments to investigating the transferability of these findings. First, ITSs are used throughout K-16, and findings from past studies naturally serve as guideposts for subsequent ITS developments and research. If findings do not transfer, these guideposts may be illusory. Furthermore, learners change over time, and the efficacy of ITS supports that do not adapt to these changes may vary. This study conceptually replicates investigations conducted at the middle school level by assigning 330 college students in introductory mathematics courses homework that have the same within-problem support formats. The support formats are either text hints, text explanations, or video explanations. We compare the efficacy of these support formats within the college student sample and between college student and middle school student samples. Our findings at the college level indicate that on-demand within-problem explanations displayed as text rather than videos lead to higher next problem correctness and that both outperform text hints. Our results differ from those in the literature using middle school student samples and therefore buttress the assertion that studies investigating the transferability of findings between education levels are necessary.

Educational Data Mining, ASSISTments, Within-Problem Supports, Replication, Intelligent Tutoring Systems

1. INTRODUCTION

A widely used criterion for intelligent tutoring system (ITS) status is that the system has an inner loop [1], i.e., provides within-problem support and not just end-of-problem feedback. The ITS literature abounds with comparisons of supports, including scaffolding versus hints [2], worked examples versus erroneous examples [3], and the supports that will be compared in this study, namely video hints versus text hints [4] and explanations versus hints [5]. Many ITS studies that evaluate the efficacy of these supports commonly involve a single segment of the student population,

e.g., middle school students. Investigations on the transferability of findings, particularly to college students, are scant.

There are, however, significant impediments to investigating the transferability of findings to other segments of the student population. First, ITSs are used throughout K-16, and findings from past studies naturally serve as guideposts for subsequent ITS developments and research. If findings do not transfer, these guideposts may be illusory. There is evidence to believe this is the case since [6] considered if the findings in [2] transferred to adult learners in a MOOC and found that the findings between hints and scaffolds did not transfer. Therefore, learners change over time, and the efficacy of ITS supports that do not adapt to these changes may vary.

For example, when describing what can be considered a good hint in an ITS, [7] in part states “Hints should abstractly (but succinctly) characterize the problem-solving knowledge (Anderson et al., 1995), by stating in general terms both the action to be taken, the conditions under which this particular action is appropriate, and the domain principle (e.g., geometry theorem) that justifies the action.” However, [8] asserted that young adolescents between the ages of 10-15 are in a transition period from concrete thinking to abstract thinking. Findings in [9] support this assertion and showed that middle school students benefited more from concepts with which they could directly relate, whereas college students benefited more from abstract concepts. This is relevant to within-problem supports while solving a mathematics problem. Hints which abstractly characterize the problem-solving knowledge, state in general terms the action to be taken and the conditions under which it is appropriate as [7] suggests may better serve college students who have the cognitive ability to assimilate and apply theorems and abstract definitions, whereas middle school students may be better served by an exposition through relatable or worked examples.

Similarly, a significant consideration in any instructional setting is Cognitive Load Theory (CLT) which stipulates that some difficulties in learning are due to unnecessary and extraneous working memory load. Here again, research has grappled with worked examples [10], including in comparison to tutored problem solving [11] and in ITSs [12, 13]. For example, the *redundancy principle* builds on the idea that learners utilize distinct information processing channels to internalize information, and hence stipulates that information should not be conveyed through multiple channels simultaneously to avoid depressing the intake from both channels and hampering learning. Research rooted in CLT at the middle school level compared the delivery medium of feedback messages within an ITS and stated that information is better internalized and learning gains are greater when feedback is presented as a video instead of text [4]. However, recent research suggests that executive function skills, which include monitoring and manipulating information in mind (working memory), suppressing distracting information and unwanted responses (inhibition), and flexible thinking (shifting), play a critical role in the development of

mathematics proficiency [14]. Although the literature is limited in terms of disentangling the neurodevelopmental aspects of specific cognitive processes in relation to their impact on arithmetic skill development, the research by [15] shows that with development there is a shift from prefrontal cortex-mediated information processing to more specialized mechanisms in the posterior parietal cortex. Freeing the prefrontal cortex from computational load and thus making available valuable processing resources for more complex problem solving and reasoning is a key factor in mathematical learning and skill acquisition [16]. According to [17], some of these processes, especially decision making and working memory, have protracted developmental timelines, but large changes can be detected in relatively small timeframes including from the beginning of middle school to the end of middle school [18, 19]. Therefore, when devising pedagogical supports, it is important to consider the differential effects on cognitive load depending on the student's attainment of neurodevelopmental milestones and subject matter fluency.

In this study, we break ground on investigating the transferability of findings from the middle school level to the college level regarding the efficacy of within-problem supports for mathematics ITSs. Specifically, this study conceptually replicates investigations conducted at the middle school level by assigning college students homework problems that have the same within-problem support formats. The support formats are either text hints, text explanations, or video explanations. We compare the efficacy of these support formats within the college student sample, and between college student and middle school student samples. For the within college sample investigation, we hypothesize that the findings from the replicated studies will transfer. For the between educational level investigation, we hypothesize that on average college student performance on the subsequent similar question will be similar given the support format (i.e., the relative frequency that the initial action is the correct solution will be equal).

Thus, we pose the following research questions:

1. Does the format of within-problem support impact learning outcomes for college students?
2. Are learning outcomes the same for college students and middle school students, given the within-problem support format?

2. BACKGROUND

For this study, we used ASSISTments which is a free web-based platform that allows teachers to choose from thousands of problems, each of which can provide immediate feedback and support. This support can be customized, e.g., it can be hint messages conveyed as either text or videos, explanations of step-by-step solutions, correctness feedback, etc. One facet of the ASSISTments ecosystem is E-TRIALS, which allows teachers and external researchers to create randomized control trials (RCTs) that run in ASSISTments to test the efficacy of supports.

The literature contains numerous RCTs using E-TRIALS which compare the efficacy of supports. To investigate the transferability of findings from the middle school level to the college level regarding the efficacy of supports, we will next briefly discuss the studies which we conceptually replicate.

2.1 Explanations Versus Hints

Cognitive scientists have investigated the role of worked examples and explanations in reducing cognitive load, and there have been several studies on their effectiveness [10, 12]. On the other hand, several studies in the literature have found evidence of the benefit of greater interaction in tutored problem-solving in ITSs [12, 13], including for less proficient students [11].

[5] investigated whether students in a classroom setting benefit more from interactive tutored problem solving than from worked

examples given as a feedback mechanism. For the experiment, researchers created nine problem sets, each consisting of four to five ASSISTments. The ASSISTments questions were taken from 6th Grade MCAS tests for Mathematics (2001 – 2007) focusing on the Patterns, Relations and Algebra section, which concentrates on populating a table from a relation, finding a missing value in a table, using fact families, determining equations for relations, substituting values into variables, interpreting relations from number patterns, and finding values from a graph.

In their study, 186 8th grade students from three middle schools participated. Over 80% of students who participated were from a school that had state test scores in the bottom 5% of that state. Results from this study show that there was a significant effect for the

condition with tutored problem solving receiving higher gain scores than worked examples (35% versus 13% average gain), $t(67) = 2.38, p = 0.02$.

2.2 Video Versus Text

Prior research has found that dynamic graphics are more effective than static graphics in mathematics realms [20], and videos and web-based homework support have grown increasingly popular in educational settings [21]. Some research suggests that video is not universally successful in promoting learning gains [22]. [4] assess the effects of feedback medium within a problem set derived from preexisting ASSISTments certified

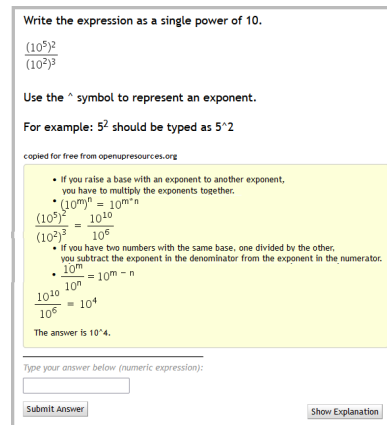

Figure 1. Example of Text Explanation

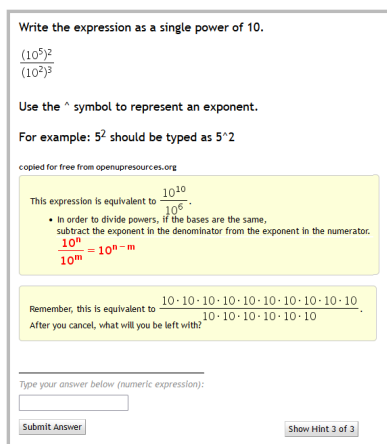

Figure 2. Example of Text Hints

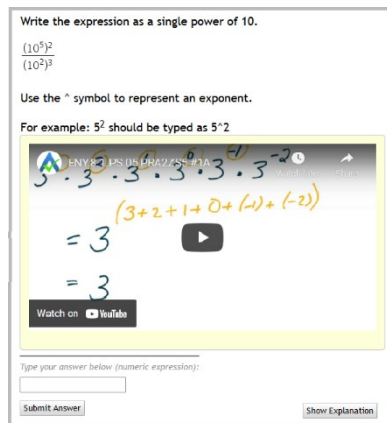

Figure 3. Example of Video Explanation

material. The structure of the problem set relied on three questions with text feedback and three isomorphic questions with video feedback and was presented to students in fixed question patterns to allow all students an equivalent opportunity to experience both feedback styles. Video content mirrored textual feedback to provide identical assistance through both mediums.

139 8th grade students from four classes comprised of four classes that spanned four suburban middle schools participated in this study. After exclusion criteria, 89 remained for analysis. The study's primary analysis assessed student performance on the second question as a function of the feedback medium they experienced after incorrectly answering the first question. As will be again addressed in the discussion section, learning outcomes were not enhanced for students who received video feedback rather than text feedback. There was also no significant difference in the overall number of feedback levels experienced by students.

3. METHODOLOGY

3.1 Procedure

330 college students in 6 sections of introductory mathematics courses at two institutions participated in this study. Demographic information of this group is as follows: 9% transfer students, 56% female, 44% male, 52% White, 19% Black, 16% Hispanic, 7 % Asian, 4% two or more races, 1% International, and 1% Unknown.

Students were assigned up to 5 problems sets (PS) as homework during the last three weeks of the Fall 2021 semester in a manner that was consistent with regular educational practices. Each problem set covered one topic, namely rational exponents (PS 1), multiplying and dividing monomials (PS 2), scientific notation (PS 3), writing linear equations given ordered pairs (PS 4), and systems of linear equations (PS 5). A problem set was only assigned to a class if it fell within the course's curriculum.

Students were free to work at their own pace and were not required to complete the assignments in one sitting. Log data was recorded for each student's actions, including first action, correctness, response time, attempts, hint requests, and feedback type, and this data was received from The ASSISTments Foundation.

3.2 Design

The five problem sets were made using preexisting ASSISTments certified material. Problem sets 1-3 consisted of 30 problems each, and problem sets 4 and 5 consisted of 20 problems each. Problems had between 1 and 9 parts, for a combined total of 196 parts in all problem sets. Each part had exactly one input field which required a free-response answer usually consisting of a number or mathematical expression. Questions within a problem set were assigned in random order to eliminate potential ordering effects.

Students could attempt any part an unlimited number of times until they entered the correct answer. Each part had on-demand within-problem supports consisting entirely of either text hints, text explanations, or video explanations. Students were aware that there were different kinds of support types but did not know which types of support any particular question had. If a student requested within-problem support, we relied on ASSISTments to randomly assign the student one of the available supports.

Our analysis assesses student performance on the question part immediately after the question part for which support was requested, which we will refer to as the next question and previous question, respectively. As such, one of our exclusion criteria is that any problem for which a student did not complete the next question is omitted. We assess student performance based on the next problem's correctness which we refer to as learning outcomes. To

that end, we consider the next question to be incorrect if a student's first action is to either submit a wrong solution or request support.

4. RESULTS

4.1 Next Question Performance Analysis Within College Student Sample

To address our first research question, we assessed the next question performance of students who received feedback on the previous question. In total, 40126 solution steps were completed by students included in our analysis, and on 4820 solution steps (4820/40126 = 0.120) supports were provided, as Table 1 shows.

Learning outcomes were more enhanced for students who received text explanations ($\hat{p} = 0.493$, $SD = 0.009$) rather than video explanations ($\hat{p} = 0.390$, $SD = 0.018$), and the difference in proportions of 0.103 was statistically significant ($p \ll 0.01$). This indicates that students answered the next question correctly over 26 percent more often ($0.493/0.390 = 1.264$) after receiving on-demand within-problem text explanations than video explanations.

Table 1. Summary of Next Question Performance Analysis

Support Format 1	Support Format 2	Difference in Proportions	95% Confidence Interval for Difference in Proportions
Text Explanation (N = 3161)	Video Explanation (N = 757)		
0.493 (0.009)	0.390 (0.018)	0.103*	[0.064, 0.142]
Text Explanation (N = 3161)	Text Hints (N = 902)		
0.493 (0.009)	0.135 (0.011)	0.358*	[0.329, 0.386]
Video Explanation (N = 757)	Text Hints (N = 902)		
0.390 (0.018)	0.135 (0.011)	0.254*	[0.213, 0.296]

Note: Performance metrics are depicted as mean (standard deviation). * $p \ll 0.01$.

Learning outcomes were enhanced for students who received text explanations rather than text hints ($\hat{p} = 0.135$, $SD = 0.011$). The difference in proportions of 0.358 was statistically significant ($p \ll 0.01$) indicating that students were over 3.5 times more likely ($0.493/0.135 = 3.652$) to answer the next question correctly after receiving ext explanations than text hints.

Learning outcomes were enhanced for students who received video explanations rather than text hints, and the difference in proportions of 0.254 was statistically significant ($p \ll 0.01$). This indicates that students were nearly 3 times more likely ($0.390/0.135 = 2.889$) to answer the next question correctly after receiving on-demand within-problem video explanations than text hints.

5. DISCUSSION

5.1 Comparison of Next Question Performance Between Education Levels

To address our second research question, we compare the enhancements of learning outcomes for middle school students to those

from our college student sample using the combinations of support formats in [4] and [5].

Before drawing comparisons to our results, it should first be noted that the statistical analysis in [4] has apparent flaws based on the data provided in that paper, and these flaws affect the conclusion of that study. After correcting those analysis errors using the data the authors provided in [4], the correct conclusion of [4] should be that the modality of the support in that study did not have a statistically significant effect on learning outcomes. Nevertheless, the corrected results of [4] are only partially reflected in our results. That is, college students were nearly 3 times more likely to answer the next question correctly after receiving video explanations rather than text hints, but over 26 percent more likely to answer the next question correctly after receiving text explanations rather than video explanations. As previously indicated, both results are also statistically significant.

Another important difference to note is the magnitudes of the efficacies of the different forms of support. At the middle school level, [4] found that students who received video support answered the next question correctly 76% of the time on average, whereas in our study students who received video support answered the next question correctly only 39% of the time on average, with a 95% confidence interval of [0.354, 0.426]. Furthermore, [4] found that middle school students who received text hints answered the next question correctly 52% of the time on average, whereas in our study students who received text hints answered the next question correctly only 13.5% of the time on average, with a 95% confidence interval of [0.113, 0.157]. Therefore, the results in [4] fall well outside of our expected range.

[5] found that learning outcomes were greater for middle school students who received tutored problem solving rather than worked examples and that this difference was statistically significant. This is not reflected in our results since college students were over 3.5 times more likely to answer the next question correctly after receiving on-demand within-problem text explanations than text hints. As previously indicated, the results from our sample are also statistically significant.

Since the results in [5] are presented as average learning gains from a pre- to a post-test, and our results are given as next problem correctness, we cannot draw similar point estimate comparisons to that study.

5.2 Contributions, Limitations, and Future Research

We make a significant contribution by breaking ground on investigating the transferability of findings from the middle school level to the college level regarding the efficacy of on-demand within-problem supports for mathematics ITSs. The ITS literature abounds with investigations using on-demand within-problem supports, particularly for middle school and high school students. Some studies have compared the efficacy of these supports and have led to what has been coined “Best So Far” supports – those supports which have led to the highest measures of learning outcomes for comparable studies [23, 24]. Our conceptual replication of these studies with college students did not support the same hierarchy of supports nor magnitude of efficacy at the college level.

This beckons the question, “Best So Far” for *whom*? To that end, our study identifies a rich area of research since there are abundant ITS studies that often include only one segment of the student population. While it is understandably hard to include students from several education levels in a study, particularly for mathematics ITSs, our results buttress the assertion that studies investigating the transferability of findings between education levels are

necessary. Our study also lends credence to the importance of considering who is or is not included in a study, and disaggregating results when possible to ensure inclusion, diversity, equity, and accessibility in research and practice.

Another rich area of research is to data-mine the results from such transferability studies to supplement the limited literature on neurodevelopmental aspects of specific cognitive processes in relation to their impact on learning and best practices for instruction.

Future iterations in this line of research should consider a closer replication of the literature. While our study investigated the modality effects of on-demand within-problem supports, we compared video *explanations* to text *explanations*, while [4] compared video *hints* to text *hints*. Similarly, while our study compared the impact of interactive forms of tutored problem solving to static forms of support, our study used *text explanations* and text hints, whereas [5] used *worked examples* and text hints.

Future research should also consider that while in this study problem sets were only assigned to a class if they fell within the course’s curriculum, a potential concern is that likely exposure to these topics in prior courses may lead to a college student being more familiar with the topics in the problem sets than middle school students, resulting in a confound that could influence results. Possible indicators of this would be fewer support requests from college students, or higher measures of next problem correctness. Our results indicate the opposite. As was previously shown, college students requested support on 12 percent of solution steps ($4820/40126 = 0.120$), but in [4] middle school students requested support on approximately 8 percent of solution steps ($60/720 = 0.083$). Furthermore, as was also previously shown, next problem correctness was consistently lower for college students than for middle school students when comparing similar supports.

On the other hand, since the assignment topics in the original studies differ from each other and from those used in this study, it can be argued that the difficulty of these topics may also differ, again leading to a confound. This too may be indicated by different levels of support requests or different levels of next problem correctness. Based on the just presented discussion, one conclusion which could be drawn from our results may indicate that the topics covered in the problem set by the college students were more difficult than those completed by middle school students. Another conclusion could be that the problems in assignments completed by college students were equally difficult to those completed by middle school students and that the overall relative mathematics skill levels of the two groups differed.

Disentangling these results further is not possible using the results of our study or the available information from the replicated studies. While challenging to implement, something that could mitigate this ambiguity is for future research to include a measure comparing mathematics abilities across education levels, e.g., a pretest, and assign identical problem sets to all study participants across education levels. Furthermore, by including a posttest, future research should also further analyze other learning outcomes, such as that of [5].

Finally, an exclusion criterium in this study is that any problem for which the student did not complete the next question is omitted, and therefore attrition may not have been entirely random. While we do not believe this had any substantial impact on our results, future research should definitively ensure this is true by establishing a more controlled experimental environment.

6. ACKNOWLEDGEMENTS

We thank The ASSISTments Foundation. As always, K.H.S., J.M.S., E.M.S., and W.J.S. thank you and I.I. y.

Comparison of Learning Behaviors on an e-Book System in 2019 Onsite and 2020 Online Courses

Hiroaki Kawashima
Graduate School of Information Science
University of Hyogo, Kobe, Japan
kawashima@gsis.u-hyogo.ac.jp

ABSTRACT

In this study, we compare e-Book log data from onsite face-to-face courses in 2019 and synchronized online courses in 2020 to elucidate the difference in students' learning behaviors. We focus on short periods before and after class time by considering locational and temporal constraints in onsite courses, i.e., students should be physically presented in a classroom and leave the room after each class. As online courses are free from such constraints, we show that learners' behavior in 2020 has characteristic patterns before and after class time and that the activity of students in those periods relates to their final grades.

Keywords

Learning analytics, onsite vs. online, e-book system

1. INTRODUCTION

The learning environment has changed drastically due to the COVID-19 pandemic. In particular, online classes have been widely used when the number of infections is large. There are several styles of online classes, such as synchronized and asynchronized [3]. While asynchronized courses make students watch prerecorded videos in an on-demand fashion, synchronized online courses often require students to connect to a video-conferencing system and attend the class online from their homes at a specified class time. In addition, the media transmitted by the video-conferencing system is not limited to video of a lecturer captured by a camera, but a variety of other styles are used; for example, if class materials (e.g., slides) are shared in another way, it is enough to transmit only audio of lecturers' speech.

How have learning styles changed with the introduction of such synchronized online classes? This study aims to clarify changes in learning behaviors and their relationship to final grades (e.g., A, B, and C) by analyzing browsing log data from 2019 onsite face-to-face classes and 2020 synchronized online classes in university lectures where the e-Book

system has been introduced. We focus on the fact that the face-to-face format has locational and temporal constraints that require students to go to the classroom at a specific time and leave the room just after class, whereas the online format frees students from such constraints. From these considerations, in this study, we particularly analyze students' activity in short periods just before and after class time to understand the difference in learning styles between 2019 and 2020. The contributions of this study are twofold:

1. We show that onsite face-to-face and online teaching formats cause different patterns of students' activity during short periods of time (e.g., 15 minutes) before and after class time.
2. We also show that the activity patterns before and after class time relate to students' final grades.

2. RELATED WORK

Clickstreams from e-Book systems are often used in the field of learning analytics to provide detailed analysis of how students are viewing course materials [16, 14]. Such log data is used for a wide range of applications, including feedback to instructors during classes [13], grade prediction [10, 2, 8], and summarization of teaching materials [15]. For final grade or score prediction, methods for identifying important features [5] and predicting final grades using various machine learning methods have been proposed [10, 2, 8]. This can also be used for early dropout prediction [2].

Comparisons between onsite (face-to-face) and online classes have been studied in the education of various fields. Aggarwal et al. [1] conducted a randomized study to test the difference in learning effects between onsite and online courses on Biostatistics and Research Ethics and found no significant differences. Jones and Long [6] compared onsite and online students in the same mathematics course from 2005 to 2011 and showed that onsite students performed better for overall ten semesters but were comparable when limited to the last seven semesters. Paul and Jefferson [12] conducted a comparative analysis in an environmental science course from 2009 to 2016 and reported no difference in academic performance between onsite and online formats.

There are some later studies conducted after the onset of the COVID-19 pandemic. For example, Yang et al. [17] examined the viewing time and completion rates of online dental education courses and found that the completion rate

H. Kawashima. Comparison of learning behaviors on an e-book system in 2019 onsite and 2020 online courses. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 753–757, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

Table 1: Basic information of the courses in the dataset.

Course ID	Weeks	# of students	Class time			
A-2019	8	50	8:40-12:00 (Mon.)			
A-2020	7	62	8:40-12:00 (Mon.)			
B-2019	8	164	B-2020	7	93	14:50-16:20 (Tue.)
B-2020	7	93	14:50-16:20 (Tue.)			

was related to the time the content was first visited (within 60 minutes before, further before, or after the start of the class). Amin et al. [3] analyzed the end-of-course surveys in electronic circuit courses from 2007 to 2021 and reported that online classes provided as good as or better learning experiences than onsite classes.

Many of the existing studies mentioned above mainly compared onsite and online courses based on grades/questionnaires or analyzed students’ learning behaviors such as viewing duration of contents and first accessed time. On the other hand, this study aims at finding a new perspective to compare onsite and online students’ behaviors by defining the amount of activity using detailed operation logs of an e-Book system in short periods of time before and after classes.

3. LECTURE COURSES AND DATASET

3.1 Courses and Teaching Formats

The dataset used in this study was open for the Data Challenge at the International Conference on Learning Analytics & Knowledge 2022 [9, 4, 7] and provided on a request basis. It consists of four courses whose course IDs are A-2019, A-2020, B-2019, and B-2020, where "A" and "B" denote the subjects of the courses, and the numbers 2019 and 2020 denote the offered year. For simplicity, we denote the pair of courses X-2019 and X-2020 as "course X" in the following. Each of course A and course B covers the same topics for both years (e.g., B-2019 and B-2020 dealt with the same topics).

In 2019, the teaching format was onsite face-to-face, and each student operated the e-Book system in a classroom using his or her own laptop computer while listening to a slide presentation by a lecturer on the podium. In 2020, on the other hand, the teaching format was synchronized online. Lecturers gave audio-only lectures during each class time, and students used their own PCs to operate the e-Book system at home or from other locations.

3.2 Class Weeks and Materials

While the topics are essentially the same within each of courses A and B, the number of weeks and materials differs over the two years. First, both courses A and B were offered for eight weeks in 2019 and seven weeks in 2020. In course A, the content of Weeks 5 and 6 in 2019 was taught in Week 5 in 2020, and in course B, the content of Weeks 2 and 3 in 2019 was taught in Week 2 in 2020. In addition, the course materials were updated in 2020 to some extent. In course A-2019, a summarized version of the materials was also distributed on the e-Book system. Basic information about each course is shown in Table 1.

Figure 1: Visualization of activity in each day of the week (0: Monday, 6: Sunday). Active periods correspond to the class time of each course. See also Table 1.

3.3 e-Book Log Data

The data used in this study are students’ operation logs obtained through an e-Book system [9, 4]. Students browse provided class materials (e.g., slides) by performing, for example, page forwarding and marking operations. Each line of the log data records what operation is performed by which student on which page of which course material, along with a timestamp consisting of date, hour, minute, and second. Types of operations include page transitions, adding notes and markers, and bookmarking. However, as described later, this paper focuses on the number of operations, which we also refer to as operation count or frequency, as the amount of activity. All data are anonymized, and timestamps are slightly blurred on a scale of seconds while maintaining order from the original.

Each student’s final grade is recorded as A, B, C, D, or F in every course, where A is the highest grade, and F is the lowest grade. The records are also included in the dataset.

4. ANALYSIS

4.1 Visualization of Activity by Time of Day

To examine the overall trend of students’ activity for each course, we first visualize the total activity at each hour of each day of the week. We here define "activity" as the frequency of operations without distinguishing operation types, where page transition operations (moving to the previous or next page) comprise the majority of activities.

Figure 1 shows the visualization of total activity in each hour. The color in each time slot shows the total frequency of operations through the course period. Note that the frequency is normalized by dividing by the number of students in the course. As for the colormap range, we set 300 as the highest value to be covered (colored by yellow). The figure shows that the time slots with the highest activity correspond to the class time of each course.

When the value on a particular grid is significantly high, the other grids are buried in this kind of heatmap visualization. Therefore, we visualize the same data with different colormap that ranges from 0 to 40 in Fig 2, i.e., each time slot with yellow color has an average of 40 operations or more per student. We can see in this figure that the amount

Figure 2: Visualization of activity in each day of the week (0: Monday, 6: Sunday) with colormap ranges from 0 to 40.

Figure 3: Activity patterns around the class time in courses A and B. Vertical lines show the start and end of class.

of activity on Sundays is relatively high in both 2019 and 2020 for course A. This may be due to the deadline setting of assignments. In addition, both course A and course B have more activity outside of class time on the day of the class in 2020 compared to 2019.

To detail the activity patterns around the class time, we aggregated activity with 10-minute intervals during the class time with a margin of two hours before and after the class, which is shown in Fig. 3. Compared to 2019, the patterns in 2020 are characterized by before and after the class time. In A-2020 and B-2020, activity continues after the class for a certain period, which we refer to as “post-class activity.” In addition, in course B-2020, activity increases before the class starts, namely “pre-class activity” exists. On the other hand, A-2020 has no significant pre-class activity, which may be because course A was scheduled in the early morning while course B was taught in the afternoon.

4.2 Relationship to Final Grades

To further investigate the pre-/post-class activity, we divided students into groups based on their final grades and examined the differences in the amount of pre-/post-class activity. Figure 4 shows the average pre-/post-class activity in each grade level. Specifically, we first calculated the pre-/post-class activity of each student based on the total operation frequency during a specific period (i.e., 15min before or after class) on all class days. We then calculated the average students’ pre-/post-class activity in each grade level. Error bars indicate 90% confidence intervals using t -distributions. We can find that, in 2020, the amount of post-class activity tends to be higher the better the final grade.

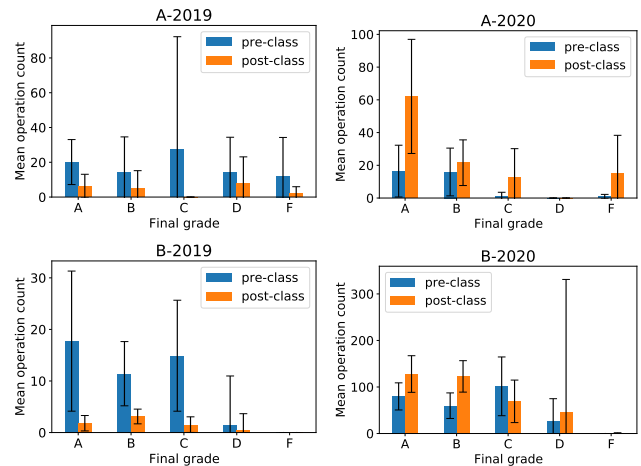

Figure 4: Average pre-/post-class activity (the number of operations) in each grade level. Blue bars: pre-class activity; orange bars: post-class activity. Error bars show 90% confidence intervals.

Table 2: Results of the Kruskal-Wallis tests for post-class activity. The rightmost column shows the sample size of each grade.

Course ID	p -value	n (A, B, C, D, F)
A-2019	0.7023	(24, 6, 4, 6, 10)
A-2020	0.0067	(22, 24, 6, 3, 7)
B-2019	0.4088	(26, 104, 30, 2, 2)
B-2020	0.0078	(37, 38, 12, 2, 4)

For each course, we conducted a statistical test for the difference in the amount of post-class activity among grade levels. The results (p -values) of the Kruskal-Wallis tests are shown in Table 2, indicating significant differences among grade levels in 2020 for both courses A and B. While the computation of the confidence intervals in Fig. 4 assumes that each population is normally distributed, the actual activity distribution tends to be biased toward lower values and often contains outliers. We, therefore, used nonparametric tests here and in the following.

In order to examine in detail which grade groups have the gap of activity, we conducted the Mann-Whitney U-test separately for divided two-group pairs: grade group {A} vs. {B, C, D, F}, {A, B} vs. {C, D, F}, and {A, B, C} vs. {D, F}. The reason for grouping the grade levels in this way is that the criteria for grading may differ from course to course; for example, two grade levels in one course may correspond to a single grade level in another course. We did not include only grade F as a group because of the small sample size.

The results are shown in Table 3. We can find from the table that some grade groups have significant gaps in the post-class activity. For example, in course A-2020, there are significant differences between grade group {A} and {B, C, D, F}, which corresponds to the gap in orange-bar heights in Fig. 4. In course B-2020, between {A, B} and {C, D, F}.

Table 3: Results (p -values) of the Mann-Whitney U-tests for the post-class activity. Vertical lines in the column names show how the grade levels were divided into two groups.

Course ID	A BCDF	AB CDF	ABC DF
A-2019	0.6221	0.2676	0.5449
A-2020	0.0005	0.0139	0.0317
B-2019	0.8662	0.0786	0.3716
B-2020	0.4232	0.0020	0.0023

5. DISCUSSION

The results of the analyses in the previous section suggest that the change of teaching format from onsite face-to-face classes in 2019 to synchronized online classes in 2020 frees students from constraints of class time and locations. As a result, some students continue to examine class materials even after class time, observed as the post-class activity. Such students' behavior on a relatively short time scale (e.g., 15 minutes after class) may provide important clues for understanding students' learning in online environments.

The pre-/post-class activity might be an indicator of students' self-regulation [11] in some sense. However, it should be examined with further study combining other clues, such as learning behaviors (e.g., the frequency of reviewing class materials), learning strategies, and motivations.

Some limitations exist in our analyses in the previous section. One is the effect of class attendance. As we computed the amount of activity from the total frequency of operations in a specific time period, it also contains information on attendance or absences. For example, if a student is absent from a class, post-class activity may also become close to zero on that day. While we decided to include such effects in the present study, in order to investigate pre-/post-class activity conditioned on "attended" students, we need further analysis by estimating whether each student attended or not on each class day.

Another limitation is that the objective of this study is not on the utilization of features, e.g., improvement of prediction accuracy of grade levels. Therefore, it is unclear whether features extracted from the pre-/post-class activity are useful, and other activities (e.g., in-class activity) can be more critical, for example, for final-grade prediction. To directly compare the importance of pre-class, post-class, and in-class activity, we trained gradient boosting classifiers, widely used for various data challenges including educational data.

Figure 5 shows the feature importance obtained through the model training. Here, we used the LightGBM implementation. Note that our objective here is not the evaluation of prediction accuracy itself but a brief comparison of feature importances. We, therefore, trained a model from all data in each course. We also constrained model complexity to a certain degree with the hyperparameters (the maximum tree depth: 3, the minimum number of data in a leaf: 10, and the number of iterations: 20) to avoid too much overfitting. As for the in-class activity feature, we computed operation frequency during class time in the same manner as pre-/post-class activation.

Figure 5: Feature importances computed by the gain of gradient boosting models.

From the figure, in-class activity seems to be the most crucial feature for the grade prediction task throughout 2019 and 2020. Meanwhile, it is worth noting that the importance of pre-/post-class activity substantially increased in 2020 compared to 2019.

While appropriate evaluation of the grade-prediction task requires appropriate cross-validation with a larger amount of data, the results of this study show some potential to design and combine various detailed features in out-class time periods in the context of online courses.

6. CONCLUSION

This study analyzed student behavior in 2019 and 2020 before and during the COVID-19 pandemic, based on operation logs obtained through an e-Book system, for two courses whose teaching format changed from face-to-face to online in the two years. Because online classes do not have the restriction of leaving the lecture room after class, activity after class, which was not seen in 2019, was often observed in 2020. In addition, our study suggested that the activity has some relation to students' final grades.

ABSTRACT

Recognizing the potential of the preference-inconsistent recommendation systems (RS) for learning, this paper aims to examine two recommendation algorithms for mobile language learning applications: RS with similarity and RS with diversity. Diversity was measured through learning styles (how learners learn) and achievement goals (why learners learn). A total of 160 learners participated in the study for building learner profiles and the recommendation algorithm. Overall, our results with RSME indicate that both RS with similarity and RS with diversity performed better than the random recommendation.

Keywords

Recommendation system, Mobile language learning applications, Diversity

1. INTRODUCTION

Recommendation systems (RS) that suggest preferable items intend to help people make proper decisions in a flood of information and choices. In the field of education, researchers have developed RS to recommend learning resources based on ontology [22], learning styles [4], ranked lists of learning objectives [6], and learner preference [5]. Thus far, most educational RS have been based on the algorithm of learners' preferences, recommending items that learners are likely to prefer based on their previous data or learners with similar profiles. Cognitive dissonance theory [10] explains the popularity of this preference-consistent recommendation. When humans process information that does not conform to their existing thoughts and beliefs, they are in a state of cognitive dissonance and experience an uncomfortable psychological state. Hence, for psychological comfort, people tend to only pursue information and items that they prefer to avoid cognitive dissonance.

However, some scholars have started questioning the efficacy of preference-consistent recommendations, arguing that such recommendation methods may reinforce learners' confirmation bias and narrow the opportunity to discover new information and

experiences [3]. Researchers have proposed 'preference-inconsistent' recommendations that induce discovery learning and higher-order thinking by intentionally providing information that does not match learners' preferences or recommending information that contradicts learners' beliefs [19]. While the preference-inconsistent mechanism has been widely researched in political science and media study to minimize confirmation or information bias, its application in the educational RS is still in its infancy and lacks empirical data to support its efficacy.

Recognizing the potential of the preference-inconsistent recommendation for learning, this paper presents our work-in-progress research that aims to examine two recommendation algorithms for mobile language learning applications (apps): RS with similarity and RS with diversity. Here, 'RS with similarity' refers to the preference-consistent method that recommends the list of apps compatible with learners' learning styles and achievement goals. In contrast, 'RS with diversity' refers to the method that recommends the list of apps that do not match learners' current preferences but have the potential to help learners exposed to new learning styles and achievement goals. It should be noted that RS with diversity does not mean that the system recommends items that learners do not like. Instead, the method is intended to lead learners to discover new items that are likely to have learning efficacy in the future by extending learning experiences beyond a preferred comfort zone.

2. LITERATURE REVIEW

2.1 Recommendation Systems in Education

Recommendation systems have been widely used in the e-commerce area to suggest information and items for potential customers [18]. Recently, RS has been studied in the education sector for various purposes such as suggesting learning activities and courses based on learners' knowledge levels and preferences [16].

From a technical view, there are two main methods of RS: content-based filtering and collaborative filtering. Content-based filtering recommends items that are similar to what users already selected and liked in the past [15]. However, when there is a lack of data on previous behaviors by users, it is hard to recommend appropriate items that match users' preferences. Also, the attributes of items should be well-structured for the accuracy of content-based filtering. In contrast, collaborative filtering recommends items based on similar users' preferences [15]. It is possible to predict items that new users are likely to prefer even if there is a lack of available data

for the target user. Collaborative filtering, however, has a scalability issue. As the number of users or items increases, the complexity of computation becomes higher [11]. Moreover, user-based collaborative filtering systems tend to provide a low number of available items, making final recommendations biased toward popular items.

In the field of technology-enhanced learning (TEL), it has been suggested that there are two perspectives of enhancing filtering techniques: top-down and bottom-up [7]. The top-down perspective focuses on well-defined educational metadata whereas the bottom-up perspective collects user-generated data such as likes, tags, and ratings from learners. In this study, we focus on language learning with mobile applications, which are often used in informal learning contexts. As informal learning is self-directed and less structured with learning goals and time [7], it is difficult to divide applications into specific categories for educational metadata. Hence, this study focuses on the RS from the bottom-up perspective such as learner ratings of respective mobile apps.

2.2 Diversity in Learning Styles and Achievement Goals

Recently, there have been attempts to develop methods for recommending diverse and novel items beyond similarity measures. Described as a ‘long-tail recommendation’, this method recommends diverse and unpopular items in the non-mainstream area to mitigate confirmation bias and to enhance diversity in user experiences [23]. As for movie recommendations, it has been reported that the list of diverse movies positively affects viewers’ satisfaction [14]. However, a long-tail recommendation also suffers from a low accuracy in the recommendation, which necessitates some tradeoff between diversity and accuracy [23].

For learning purposes, there are numerous ways to operationally define diversity. In this study, we focus on diversity in terms of learning styles (*how learners learn*) and achievement goals (*why learners learn*). These two constructs have been well researched and established as a theoretical framework to define learner characteristics in educational research.

First, learning styles refer to the ways learners prefer to receive and process information. According to Felder and Silverman [9], learning styles are divided into four categories: (a) processing (active/reflective), (b) perception (sensing/intuitive), (c) input (visual/verbal), and (d) understanding (sequential/global). Many studies have been conducted on which learning styles are the basis for presenting effective learning methods. However, some scholars suggested two limitations about learning styles [13]. The first limitation is that the preferable way to learn and the actual effective and efficient learning method can be different. The second limitation is that the learning styles instrument showed low reliability [21]. While we are aware of such limitations, this study adopts learning styles as one of the learner-related variables for learner profiles based on the following studies. As for recommender systems, the Felder-Silverman Learning Style Model (FSLSM) has been widely used for two reasons [2, 17]. First, FSLSM can be implemented in a simple way to design personalized e-learning systems [2]. Second, the FSLSM model is appropriate to apply to mobile learning because the learning materials in mobile learning are composed of various formats such as video, text, audio, etc. [17].

Second, achievement goals refer to the aim and focus of one’s actions concerning achievement. Elliot and McGregor proposed the 2X2 achievement goal framework in terms of definition (mastery vs. performance) and valence (approach focus vs. avoidance focus). The framework includes (a) mastery-approach goal, (b)

performance-approach goal, (c) mastery-avoidance goal, and (d) performance-avoidance goal [8]. When learners have the mastery-approach goal, they strive to master learning tasks with the emphasis on learning itself and self-improvement. In contrast, learners with the mastery-avoidance goal tend to avoid misunderstanding or the failure to master a task. Regarding performance, learners with the performance-approach goal concentrate on proving their ability relative to others. They may not be interested in mastering tasks, but doing better than others is more important. On the other, learners with the performance-avoidance goal tend to avoid performing more poorly than others do.

3. RECOMMENDATION SYSTEM

To construct our RS architecture (see Figure 1), three steps were performed: Step 1: constructing the database of RS, Step 2: data analysis, and Step 3: RS evaluation (Experiment). The whole process of the research was conducted with the IRB approval from the researchers’ university.

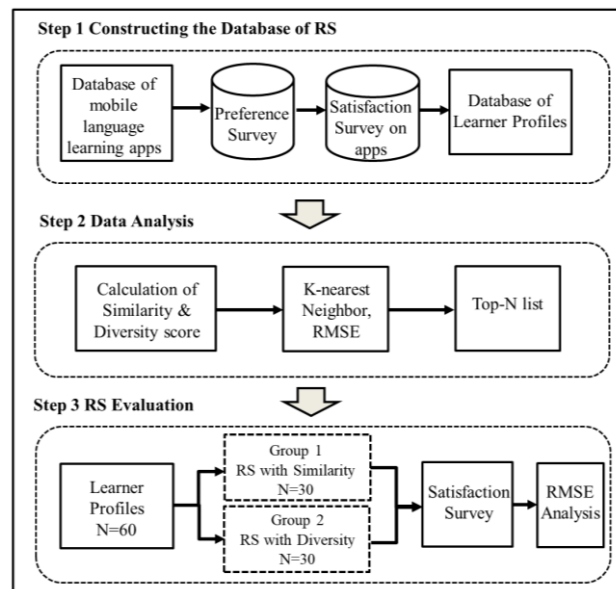

Figure 1. Proposed architecture and process

3.1 Step 1: Constructing the Database of RS

3.1.1 Database of Mobile Language Learning apps

In this study, we focused on recommending mobile language learning apps with artificial intelligence (AI) functions, which have been increasingly developed in the app market. For constructing the database of learner profiles, we chose 18 mobile apps that met five criteria: (1) an application for language learning, (2) an application with AI functions (e.g., voice recognition, adaptive learning system), (3) an application that the developer indicates the use of AI technologies, (4) an application used with no errors, and (5) an application locally available in Korea. Table 1 presents the final list of mobile language learning apps used in this study.

Table 1. List of mobile language learning apps with AI

ID	Application	ID	Application
app 1	Riid Tutor	app 10	Cake
app 2	Super Chinese	app 11	Youbot English Speaking

ID	Application	ID	Application
app 3	Plang	app 12	ELSA Speak: Accent Coach
app 4	Opic up	app 13	Bigple
app 5	Lingo Champ	app 14	Memrise
app 6	Easy Voca	app 15	Mondly
app 7	Say Voca	app 16	AI Tutor
app 8	Youbot Chinese	app 17	Rosetta Stone
app 9	Duolingo	app 18	Busuu

3.1.2 Preference and Satisfaction Survey

To construct the database of learner profiles, we recruited 100 adult learners. Among them, 82 learners fully completed the preference survey that include items about demographic information (e.g., gender, age, education, etc.), learning styles, and achievement goals. For learning styles, we used the ILS (Index of Learning style) instrument with 44 items [9]. For achievement goals, we used the 2X2 Achievement Goal Questionnaire-Revised with 24 items [20]. Then, the participants used four to six mobile language learning apps randomly assigned to them. Finally, they completed the satisfaction survey with 20 items on a 5-point Likert scale to evaluate each app they used. The satisfaction survey includes seven categories: (1) convenience, (2) personalization, (3) professionalism, (4) reliability, (5) appropriateness, (6) satisfaction, and (7) overall satisfaction. We refer to [1] to develop the items related to convenience, personalization, professionalism, and reliability and [12] for the items related to appropriateness of app use and satisfaction. We modified the items according to the context and purpose of this study.

3.1.3 Database of Learner Profiles

To construct the database of learner profiles, data from 82 learners who fully answered the surveys were analyzed based on their learning styles and achievement goals. We generated attribute values as shown in Figure 2. LS1, LS2, LS3, and LS4 refer to four dimensions of learning styles respectively: processing, perception, input, and understanding. LG1, LG2, LG3, and LG4 mean four achievement goals respectively: mastery-approach goal, mastery-avoidance goal, performance-approach goal, and performance-avoidance goal. Since each learner used 4 to 6 apps, the total data of learner profiles is 82*415 (the number of learners * the total number of applications used).

NO.	LS1	LS2	LS3	LS4	LG1	LG2	LG3	LG4
L1	1	0	1	0	4.67	3.00	4.00	1.67
L2	0	1	1	0	3.83	3.67	3.00	3.17
L3	0	0	1	0	5.00	3.00	3.17	1.67
L4	1	1	1	0	3.67	2.50	3.17	2.50
L5	0	1	1	0	4.83	4.17	4.67	1.67

Figure 2. Example of attribute values

3.2 Step 2: Data Analysis

Based on the survey results, we calculated the similarity score for RS with similarity and the diversity score for RS with diversity. The formula for calculating similarity and diversity scores for learner profiles is shown below. We measured the diversity score with Euclidean distance between two learners for learning styles and goals. For example, if the learning styles of learner A and Learner B are [1, 0, 1, 0] and [1, 1, 1, 0] respectively, the diversity score is 1. After calculation, we chose the best similarity measure and the number of K-neighbors.

$$sim(t, t')$$

$$\begin{aligned}
&= \sum_j^2 \lambda_j \cdot sim_j(t, t') \\
&= \lambda_1 \cdot sim_1(t, t') + \lambda_2 \cdot sim_2(t, t') \\
sim_i(t, t') &= diversity\ score * -1 \\
diversity\ score &= Euclidean\ distance(t, t') \\
&= \sqrt{\sum_{i=1}^n (t_i - t'_i)^2}
\end{aligned}$$

To evaluate the performance of RS, this research used Root Mean Squared Error (RMSE), which is widely used to evaluate collaborative filtering systems. From the postulation that users are satisfied with items recommended by diverse users, not just similar ones, RS with diversity returns the top N items sorted by the ascending order of the average scores of K dissimilar users. The diversity score is a negative value of the similarity score, which is the weighted sum of the learning styles similarity and the achievement goals similarity. In the following experiment in Step 3, we set K = 9 and the weights to each similarity $\{\lambda_1, \lambda_2\} = \{1.0, 1.5\}$ because the settings of K and λ show the lowest RMSE between diversity-based prediction and ground truths in training data (see Figure 3).

Figure 3. RMSE

3.3 Step 3: RS Evaluation

3.3.1 Experiment

For the experiment to compare the performance of RS with similarity and RS with diversity, we recruited 60 participants aged from 19 to 39 years old. They used the visualized RS (see Figure 4) to complete the same survey administered in Step 1. We analyzed the preference survey data to gauge their learning styles and achievement goals, and then made the recommendations of apps for each participant. We divided 60 participants into two groups with the consideration of their age, job, and gender. The first group was recommended with three apps based on the algorithm of RS with similarity. The second group was recommended with three apps based on the algorithm of RS with diversity. After using the recommended apps, the participants completed the satisfaction survey to evaluate each app they used.

3.3.2 Experimental Setup

For the experiment, we developed the mobile web-based system (see Figure 4) to simulate the real situation of using a RS for learning. The interface shows three buttons to guide learners to access

each page. In the first button ‘What is my preference?’, learners complete the preference survey about demographic information, learning styles, and achievement goals. Clicking the second button ‘Checking recommended apps’, learners see the list of recommended mobile apps for language learning. After using the recommended apps, learners move to the third button ‘What is my satisfaction?’ to complete the survey to indicate their satisfaction with the recommended apps.

Figure 4. RS Visualization

3.3.3 Data Results

We evaluated our recommendation systems with RMSE representing the difference between the predicted and actual levels of learners’ satisfaction. We chose this approach since an accuracy metric only covers the exactly matched values. We observed that RMSE values of similarity-based recommendation and diversity-based recommendation are 0.91 and 1.26 respectively. They are significantly smaller than 1.86 from the random prediction. With this, we interpret that the recommended method that considers how and why learners learn are likely to lead to higher learner satisfaction than the random recommendation. Further, RS with similarity showed a better performance than RS with diversity.

4. LIMITATIONS AND FUTURE WORK

The limitations of this research are as follows. First, the recommendation system was only evaluated by accuracy. Although it is important to predict items accurately, qualitative data such as interviews and proxy indicators (e.g., usage behaviors) should be used additionally to further test and improve the proposed RS. Second, since the data sample is rather small to build a robust model, the research findings have limited generalizability. The small sample size was due to the time and effort required for the participants to use the assigned apps and to provide valid evaluation data. In the future, we plan to recruit more users and expand the database of the apps to build a more robust model. Lastly, while this research compares two RS algorithms, developing a hybrid RS that considers the optimal level of both similarity and diversity is certainly a promising area for future research.

Despite these limitations, we believe that this research makes meaningful contributions to the existing body of literature on RS by providing empirical data that examine similarity versus diversity approaches.

A Variant of Performance Factors Analysis Model for Categorization

ABSTRACT

Many models of categorization focus on how people form and use knowledge of categories and make predictions about human categorization behaviors [19]. However, few (if any) of them implement these theories into item selection algorithms for category training. The performance Factors Analysis (PFA) model is an alternative to the Bayesian Knowledge Tracing model that tracks students' learning of knowledge components and can be implemented into adaptive practice algorithms [17]. PFA-Difficulty model has been built to select items based on their difficulty level adaptively [4]. This paper describes how we are working to incorporate categorization theories into the PFA model so that it can be used for item selection. We used experiment data of Mandarin tone categorization training to test the model and suggest the implications of the results for item selection.

Keywords

Performance factors analysis, Categorization, Similarity, Item selection.

1. INTRODUCTION

Formal models of categorization make assumptions about human psychological processes during categorization [8,19]. They specify three things in general: (1) the internal representation of the content and format of categorical knowledge, (2) the retrieval process that collects the exact information needed to make a response, (3) the response selection process about how to select a response based on the information collected [2,13]. However, categorization models do not consider individual differences in learning categories and do not track learners' learning process. Therefore, they cannot help instructional design about item selection for training because most processes of learning (other than categorization) are not characterized in the models, e.g., the benefit of active quizzing.

For example, exemplar theory assumes that subjects store each distinct stimulus and its category label in prior memory. To classify a stimulus, subjects compute the similarities between the stimulus representation and all the stored representations of exemplars, aggregate the similarities, and then make a categorical selection [13,19]. But such a strict exemplar theory is not accurate based on what we know about how the brain encodes memories [3]. Analogously, a prototype model operates by computing the similarities between the instances and a summary representation in memory.

M. Cao and P. Pavlik. A variant of performance factors analysis model for categorization. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 763–766, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

<https://doi.org/10.5281/zenodo.6852974>

The difference is that the prototype model assumes that subjects store a “prototype”, which could be a central tendency of that category instead of every exemplar [13,19]. Importantly, neither of the above models care about training sequence. More recently, Sequential Attention Theory Model (SAT-M) was developed using local context, which considers the influence of the properties of temporally neighboring items during training [5]. However, the model is built based on the Generalized Context Model (GCM) [16], a special case of exemplar models, so it still implausibly supposes a person memorizes all prior instances. Even though it captures the influence of training sequence on the stimuli representation and improves the model fit for data with different training sequences, the model does not intend to give specific suggestions about item selection. The goal of this study is to implement the categorization theories into a learner model so that it can track learners' learning of categories and provide suggestions on item selections for future training.

The Performance Factors Analysis (PFA) model is a student model that predicts individual students on knowledge components (KCs) [1] which are acquired units of cognitive function or structure (e.g., concept, fact, or skill) using counts of successes and failures on prior training trials [17,18]. The PFA model could help us develop adaptive training algorithms. Below are the formulas of the original Performance Factors Analysis model.

$$m(i, j \in KCs, s, f) = \sum_{j \in KCs} (\beta_j + \gamma_j s_{i,j} + \rho_j f_{i,j}) \quad (1)$$

$$p(m) = \frac{1}{1 + e^{-m}} \quad (2)$$

In Equation 1, i represents a student and j represents a KC. m is a logit value representing the accumulated learning of the students on KCs. β_j represents the easiness of the specific KC. s and f count the sum of cases/trials of prior successes and failures. γ and ρ are parameters scaling the effect of the observation counts. In Equation 2, the accumulated learning is converted to probability prediction.

Even though, from the results of the PFA model, we can know whether correct or incorrect responses lead to more learning gains on each KC, the result can't be used for item selection. The reason is that if the success coefficient γ is higher than the failure coefficient ρ , it implies us to select easier items that could achieve immediate success and then maximize the learning gains (the increase of m value) [4]. However, this is in opposition to some pedagogical theories, which suggest that medium-range difficulty of items promotes better learning. For example, the Goldilocks principle in cognitive science [11] and the zone of proximal development [21] suggest that the practices should be neither too simple nor too complex relative to learners' current knowledge. Kelley [12] also stated that keeping an appropriate difficulty level can make training effective. If a task is too easy, it will result in low levels of mental effort, whereas if the task is too difficult, it will be difficult to encode the experience. Both cases lead to low learning gains.

Therefore, we hypothesized that the relationship between difficulty and learning gains could be expressed as an inverted-U function (see equation 3) and incorporate it into the PFA model to build a new model called PFA-Difficulty (see equation 4) [4].

$$y = ax^2 + bx \quad (3)$$

In equation 3, x represents the difficulty of the item. y represents the effect of difficulty on learning gains. In Equation 4, instead of tracking counts of prior successes and failures, we track the effects of prior difficulty levels of successes and failures using quadratic equations.

$$m(i, j \in KCs, s, f) = \sum_{j \in KCs} (\beta_j + \gamma_2 x_{s,i,j}^2 + \gamma_1 x_{s,i,j} + \rho_2 x_{f,i,j}^2 + \rho_1 x_{f,i,j}) \quad (4)$$

We have tried to use the PFA-Difficulty model to select the item with optimal difficulty level for practice. However, the model is not the most appropriate model for categorization. It does not involve learners' categorization process like the prototype and exemplar models do. Furthermore, even though we can treat categories as knowledge components and find the optimal difficulty to learn for each category, there is no suggestion about how to select items between categories. Therefore, this study intended to build a PFA model variant that implements a categorization theory while remaining simple enough to implement for adaptive practice.

2. METHOD

2.1 Dataset

We used a dataset from a Mandarin tone training experiment [4] as a test case for the new model. Two hundred and five participants (Female = 89, Male = 116) who were Amazon Mechanical Turk workers reside in Canada or the US. Age ranged across the lifespan: 10.2% were between 18-25 years old, 34.6% were 26-34, 45.4% were 35-54, and 7.8% were 55-64 years old. Only 2.0% were more than 65 years old. The survey question for education level showed that 12.7% had a high school diploma or GED, 42.0% had some college, 38.5% had a 4-year college degree or bachelor's, and 6.8% had a graduate degree. They finished 216 trials of training in Mandarin tones in the experiment. There are four Mandarin tones (Tone 1, a high-level tone; Tone 2, a rising tone; Tone 3, a low falling-rising tone, and Tone 4, a falling tone). In each trial, participants listened to a tone sound and selected from the four options which tone it was.

2.2 Stimulus representation

The representation of stimuli could be derived from multidimensional scaling (MDS), additive clustering, and factor analysis. Based on the results of previous MDS studies of Mandarin tones [7,10] and the experiment design, we encoded the tone stimuli in 7 features. Three of them are about the F0 (fundamental frequency) direction (level, rising, and down). The other four are about the experiment variables (duration, expansion, and speaker gender).

2.3 PFA-Categorization

Based on exemplar and prototype theories, learners learn through comparing the similarity between the new instance with previous exemplars and prototypes. Here for simplification, we used a prototype mechanism where learners compare the new instance with the prototype of that category. The prototype is calculated by the average feature values of previous examples of the belonging category. According to the SAT-M model, local context is also important. Learners should also learn from comparing the

similarity between the new instance and its previous neighboring item. Therefore, the model should track two types of comparisons: the comparisons with the prototype and the local prior trial.

For the relationship between learning gains and similarity, we have a similar hypothesis to the relationship between learning gains and the difficulty level, which can also be expressed using the simple quadratic function. If the two compared objects are too similar, it will be either too difficult if they belong to different categories or too easy if they are from the same category, and vice versa. Therefore, the medium-range similarity might be optimal for practice. Then the equation of the new PFA-Categorization model can be shown as follows (see equation 5).

$$m(i, j \in KCs, s, f) = \sum_{j \in KCs} (\beta_j + \gamma_2 L_{s,i,j}^2 + \gamma_1 L_{s,i,j} + \rho_2 L_{f,i,j}^2 + \rho_1 L_{f,i,j} + \gamma_4 P_{s,i,j}^2 + \gamma_3 P_{s,i,j} + \rho_4 P_{f,i,j}^2 + \rho_3 P_{f,i,j}) \quad (5)$$

L represents the local comparisons between the current trial and its previous trial by calculating the similarities between the two items for each KC). P indicates the comparisons to the prototype by calculating the similarities between the current trial and its prototype for each KC). γ_1 and γ_2 are scaling the effects of local comparisons of prior successes. ρ_1 and ρ_2 are parameters scaling the effects of local comparisons of prior failures. Similarly, γ_3 and γ_4 and ρ_3 and ρ_4 are parameters scaling the comparisons with prototypes. In this study, for simplification, we used the Euclidean distance as an index of similarity between two items (see equation 6). Parameters p and q represent the to be compared two objects. r is the dimension of the features that range from 1 to n . p_r and q_r are the feature values of objects p and q on dimension r .

$$d(p, q) = [\sum_{r=1}^n (p_r - q_r)^2]^{1/2} \quad (6)$$

2.4 Statistical Analysis

The knowledge components in the Mandarin tone training data are four Mandarin tones. Figure 1 shows an example of the local comparisons and the prototypes' comparisons using four trials of experiment data. The bold solid arrows represent the comparisons, and the dashed arrow indicates the formation of the prototype. The thin solid arrows show the direction of the training sequence. We used the category of previous trials as covariates for the local comparisons when tracking the similarities between the current trial and the previous neighboring trial. The prototype is calculated by averaging the features of previous learned examples of that category. We then used the new PFA-Categorization model to analyze the data and computed the logit function increase or decrease as a function of similarity on each tone. All analyses were completed in R, with source code available from the corresponding author.

Figure 1. Schematic diagram of the local and prototype comparisons.

3. RESULTS

We did 5-fold cross-validations for the PFA, PFA-Difficulty, and PFA-Categorization models and calculated the mean test fold R^2 (see Table 1). An R package “LKT” (Logistic Knowledge Tracing) [18] was used to do the analysis. In all the models, we used the stimuli (Problem.Name) as the intercept. *Tone* represents the knowledge components (KCs) in the dataset. In the PFA model, *linesuc* and *linefail* track the counts of prior successes and failures of each KC. While in the PFA-Difficulty model, *diffcor1* and *diffcor2* are used to track the effects of difficulty levels of prior successes, and *diffincor1* and *diffincor2* are used to track the effects of difficulty levels of prior failures. Similarly, in the PFA-Categorization model, we used those parameters to track the effects of local similarities and similarities to the prototype. From the R^2 values of the three models, there are minor differences among them, which means they fit the data equally well.

Table 1. Results of logistic regression

Model	Predictors	Mean test fold R^2
PFA	Problem.Name: intercept, Tone: linesuc\$, Tone: linefail\$	0.1663
PFA-Difficulty	Problem.Name: intercept, Tone: diffcor1\$: difficulty, Tone: diffcor2\$: difficulty, Tone: diffincor1\$: difficulty, Tone: diffincor2\$: difficulty	0.1699
PFA-Categorization	Problem.Name: intercept, Tone: diffcor1\$: local, Tone: diffcor2\$: local, Tone: diffincor1\$: local, Tone: diffincor2\$: local, Tone: diffcor1\$: prototype, Tone: diffcor2\$: prototype, Tone: diffincor1\$: prototype, Tone: diffincor2\$: prototype	0.1648

The local comparisons are more closely related to the training sequence than the prototype comparisons. Since the training sequence of the experiment was in random order, there are 16 pairs of local comparisons (4 tones * 4 tones). We used the coefficients of the local comparisons in the PFA-Categorization model to compute the learning efficiency (learning gains divided by the time cost) [9] as a function of the distance levels. The learning gain means the increase or decrease of the m value in equation 5. Table 2 shows an example of the learning gains calculation when Tone 1 is the previous trial and Tone 1, Tone 2, Tone 3, or Tone 4 is the current trial. The distance value was normalized to be in a range of 0 and 1, which was initially between 0 and 5.76.

Table 2. The function logit change (learning gains) of distance

Local comparisons	The function logit change
Tone 1-Tone 1	$x*(0.30*x-0.30*(x)^2) + (1-x)*(-0.33*x+0.30*(x)^2)$
Tone 1-Tone 2	$x*(-0.12*x+0.20*(x)^2) + (1-x)*(-0.03*x+0.12*(x)^2)$
Tone 1-Tone 3	$x*(0.19*x-0.08*(x)^2) + (1-x)*(-0.17*x+0.18*(x)^2)$
Tone 1-Tone 4	$x*(0.21*x+0.00*(x)^2) + (1-x)*(-0.29*x+0.22*(x)^2)$

Then we plotted the learning efficiency of the local comparison pairs and found the maximum values of logit change per second given the distance between two tones. For example, Figure 2 shows the learning efficiency curves of local comparisons when Tone 1 is the previous tone, and the adjacent current tone could be Tone 1, Tone 2, Tone 3, or Tone 4. For the Tone 1-Tone 1 pair, the logit gain from trial per second is the largest when the distance between them is 0.83, and the maximal learning gain per second is 0.003. For Tone 1-Tone 2 pair, Tone 1-Tone 3, and Tone 1-Tone 4, the optimal distance values are 1, 1, and 1, and the maximal learning gain is 0.014, 0.019, 0.037, respectively. Therefore, to achieve the maximal learning gain when practicing Tone 1, we should select Tone 4 as the next learned item. Similarly, after analyzing Tone 2, Tone 3, and Tone 4 as the previous trial separately, the findings suggest that we select Tone 4, Tone 1, and Tone 3, respectively, to achieve maximal learning gain. Above findings are just the first step to build an adaptive training system since we only have a static prediction about which tone category to select. The predictions are not sensitive to learners’ performance changes due to learning. Adaptive training not only needs to consider individual differences (learning rate) but also needs to adjust the similarity between practice trials accordingly to achieve the maximal learning gain for individuals. That is the direction for future work which is out of the scope of this preliminary report.

Figure 2. Plots of logit change given the distance between two tones when Tone 1 is the previous trial.

4. DISCUSSION

In this study, we are combining categorization theories with the PFA model to track learners’ learning of categories. Instead of tracking counts of prior successes and failures as the PFA model does or effects of difficulty levels of prior successes and failures as the PFA-Difficulty model does, the new PFA-Categorization model tracks the similarities between the adjacent trials and the similarity between each trial and its prototype of the belonging category. The R^2 values showed that the performance of the PFA-Categorization model was better than the original PFA model. Even though the quantitative comparison did not reveal differences, it has useful implications for later item selection for category training. After learning a specific tone category, it may be possible to make decisions about what category and item are to be practiced next.

Many studies have examined the influence of presentation order of examples on category learning [6,14,20]. For example, Carvalho and Goldstone [6] suggest that if stimuli have high within- and between-category similarity interleaved study could result in better generalization, whereas if categories have low within- and between-category similarity, blocked presentation can lead to better generalization. However, their study used extreme examples of similarities that are either too similar or too dissimilar, which is not so often seen in regular category learning. They also have no systematic suggestion about how we should sequence the categories based on their similarity levels and learning gains. Prior studies have simple manipulations about similarity either maximize or minimize the similarity between adjacent training trials [14,15]. These methods are too general and may not fit all the category learning cases. The benefit of the PFA-Categorization model is that it could give us suggestions about what we should select next based on the analysis of the training data to achieve maximal learning efficiency.

5. CONCLUSION

This paper implemented a categorization mechanism into the PFA model to track category learning that suggests what category we should select next based on the learning efficiency curve as a function of the similarity between the two adjacent items. We plan to use a developed version of the model in an adaptive training system to select the item with optimal similarity levels for learners to achieve maximal learning efficiency.

Future work will improve the model by adding weights of features into the distance calculation since different features may have different importance for categorization. We will also test the model with more datasets since the data used in the present study did not have any manipulation of practice schedules so it may not work well for the data. For example, interleaved practice and blocked practice may have different types of local comparisons that the former is mainly between-category comparisons, and the latter is within-category comparisons. However, since the practice data we used mixed between and within category comparisons randomly it is difficult to see the cumulative effects of scheduling strategy in the data.

Selecting Reading Texts Suitable for Incidental Vocabulary Learning by Considering the Estimated Distribution of Acquired Vocabulary

Yo Ehara
Tokyo Gakugei University
ehara@u-gakugei.ac.jp

ABSTRACT

In second language acquisition, incidental vocabulary learning refers to the process by which one's vocabulary increases through activities in which increasing vocabulary is not the main goal. A typical example is extensive reading, where learners naturally expand their vocabulary by reading many texts and guessing the meanings of unfamiliar words. Selecting texts suitable for incidental learning requires a personalized and fine-grained estimation of each language learner's vocabulary. If a learner does not know sufficient words in a text, then the learner cannot read through the text to guess the meanings of unfamiliar terms, so incidental learning does not occur. In contrast, if a learner knows all the words in a text, then incidental learning cannot occur because the learner has no new words to learn. Therefore, if a learner attempts to select a text that can significantly increase their vocabulary, the risk of reading failure increases along with the possibility that no words can be guessed and learned. Therefore, learners should be presented with both the amount of vocabulary they can add and risk of failure in reading, and be allowed to select the text they wish to read. To this end, we require an algorithm that can simultaneously calculate the amount of vocabulary that can be learned and relevant risk when a text is read. This paper presents an algorithm for this purpose with preliminary experimental results. Specifically, we use findings from applied linguistics that indicate that the condition for incidental learning to occur is that the percentage of words that a learner knows in a text is above a certain threshold. By modeling the estimated size of the increase in vocabulary as a random variable, our method uses the variance of the estimated size as a measure of the risk of reading failure. This allows a learner to select the text with the lowest risk among texts that have the same estimated size of increase in vocabulary. Experimental results demonstrate that our method can significantly aid learners in selecting "efficient" texts to read by identifying a handful of such texts among a library of 500 texts. The results also demonstrate that some texts are stable and efficient for many learners.

Keywords

Second Language Vocabulary, Extensive Reading, Natural Language Processing

1. INTRODUCTION

In second language acquisition, the "incidental learning" of second language vocabulary is the incidental acquisition of vocabulary through activities in which vocabulary acquisition is not the main objective. It is a concept that is widely used in applied linguistics studies [20, 28, 11]. An example of such an activity is *extensive reading*, where readers learn vocabulary by guessing the meanings of unfamiliar words when reading various texts. In contrast to incidental learning, learning vocabulary in the context of an activity whose main goal is vocabulary acquisition is called "intentional learning" [28, 11]. An example is acquiring second language vocabulary by memorizing lists of words. Although incidental learning is less efficient than intentional learning at increasing learner vocabulary in a second language, it is believed to have many merits. It promotes a deeper understanding of how words are used in different contexts and leads to improved learner writing skills [21].

Being able to select texts of interest to each learner also improves motivation for language learning. These merits are summarized in [21] and a combination of intentional and incidental learning is desirable [21].

Incidental learning has many advantages and is used in various scenarios. In most scenarios, for successful incidental learning, it is important to select and use texts that suit the learner [21] and various technologies that support incidental learning have been studied [9, 10, 12]. New vocabulary acquisition does not occur if a text consists only of words that have already been learned. In contrast, if a learner cannot understand sufficient words in a text, then there is a high risk of *failure* in reading the text, making incidental learning difficult because the learner cannot guess the meanings of words appearing in the text. In this case, even if we allow learners to use dictionaries, they are not motivated to continue learning if there are too many words that they need to look up [27, 18]. In applied linguistics, it has been reported that if a learner knows 95% to 98% of the words (tokens) in a text, then they can learn new vocabulary through incidental learning by guessing the meanings of unfamiliar words based on their context [13]. In other words, this finding from applied linguistics suggests that unlearned words in a text can be efficiently learned incidentally if a learner knows 95% to

98% of the text’s tokens [21].

This result from applied linguistics implies that text selection for *efficient incidental learning should consider the risk of failure when reading the selected text*. Selecting a text with a small ratio of known words (i.e., a large ratio of unknown words) may increase the size of the vocabulary acquired through incidental learning, but if the ratio of known words is below a certain threshold, then learners will not be able to continue reading the text and guess the meanings of unfamiliar words. Therefore, incidental learning will not occur and the size of vocabulary acquired will not increase. Therefore, it is desirable to select texts that appear to have the largest number of unknown words while keeping the risk of learner reading failure within an acceptable range.

In this study, we mathematically formulated a strategy for increasing vocabulary through incidental learning using machine learning. Specifically, we propose a method for determining the probability distribution of the estimated size of the vocabulary acquired through incidental learning when a learner reads a text. We modelled the variance of the estimated size as a measure of the risk of reading failure. By using our method, among many texts, learners can select a text for incidental learning by considering both the number of words to be learned (i.e., estimated size of the increase in vocabulary) and risk of failure in reading the text.

2. RELATED WORK

In educational data mining and intelligent tutoring system studies, technologies for supporting incidental learning have been studied in lifelogs [9] and dictionaries [10, 12]. However, previous studies have not focused on methods that can consider both the estimated size of the increase in vocabulary and risk of reading failure. Several researchers have also proposed methods to assess second language learner vocabularies [19, 23] and tutoring systems [26]. However, to the best of our knowledge, no study has extensively addressed text selection algorithms based on the estimated increase in second language vocabulary through incidental learning.

This study focused on the task of *personalized prediction* of second language vocabulary [16, 4, 15, 29, 8, 14, 6, 7], which has been studied in natural language processing. In this task, each learner takes a vocabulary test that can be completed in approximately half an hour. Then, for a word *not on the test*, this task aims to predict whether each test taker knows the word based on their vocabulary test results. Some previous studies have used rich information other than vocabulary tests to improve accuracy, such as individual learner characteristics and word meanings [7, 4], as well as human memory lengths [25, 24].

In particular, several studies have modeled the degree of forgetting over time considering that forgetting curves are closely related to vocabulary learning [25, 24]. However, such meticulous modeling requires time-stamped records of vocabulary learning processes, which are only provided in a few datasets. We used a vocabulary test result dataset to test the applicability of our method.

3. TASK SETTING

Here, we present a motivating example for the problem considered in this study. Consider a text consisting of 4 words [a,b,c,d]. Let the frequency of the words be [93, 3, 3, 1]. Assume that the probability of knowing each word [a,b,c,d] is [0.9,0.6,0.5,0.2], respectively. In reality, these probabilities are estimated using probabilistic classifiers trained on a vocabulary test that includes *none* of a, b, c, or d. Therefore, we assume that we cannot directly test whether a learner knows these words.

According to findings from applied linguistics, if a learner knows more than 95% of the words in a text, they can learn unfamiliar words by reading the text. This percentage is called *text coverage*. Here, we enumerate the cases in an example where text coverage exceeds 95%. In this example, “a” occurs the most frequently, but knowing “a” alone does not ensure that the text coverage exceeds 95%. However, if the learner knows {a,b} and does not know {c,d}, then the coverage of the learner for the target text exceeds the threshold. If we focus only on the words that the learner knows and writes specifically, then the cases that exceed the threshold are {a,b}, {a,c}, {a,b,d}, {a,c,d}, and {a,b,c,d}.

Now, consider a case in which the learner knows words {a,b}. Because we assume that the learner does not know {c,d}, the probability of case {a,b} can be calculated as $0.9 \times 0.6 \times (1 - 0.5) \times (1 - 0.2)$. At this time, the aforementioned applied linguistics finding [20, 22] indicates that this learner can naturally acquire the unfamiliar words {c,d} by reading the text. If we focus only on unfamiliar words, we can consider this probability as *the probability that the learner can learn the words {c,d} by reading the text* ($0.9 \times 0.6 \times (1 - 0.5) \times (1 - 0.2)$) through incidental learning. Similarly, the probability that the learner knows only {a,c} can also be considered as the probability that new words {b,d} can be acquired by reading the text through incidental learning.

Therefore, when considering all cases, the probability that the learner can incidentally learn each word [a,b,c,d] by reading the text is [0, 0.18, 0.27, 0.576]. If the learner does not know “a,” then they cannot read the text and incidental learning cannot occur. Therefore the probability for “a” is 0. The expected number of words that can be acquired by reading this text is $1 \times 0 + 1 \times 0.18 + 1 \times 0.27 + 1 \times 0.576 = 1.026$. In the next section, we propose a method for not only obtaining the expectation of learning (i.e., mean of the distribution), but also the entire distribution.

4. PROPOSED FORMULATION

We formulated a motivating example in the previous section. Consider a vocabulary $\{v_1, \dots, v_I\}$, where I is the vocabulary size. Let n_i be the number of occurrences of v_i (i.e., frequency of v_i in the text).

Assume that we focus on a specific learner among all J learners. We denote the probability that the learner knows v_i as p_i . Let the threshold value of text coverage be τ . In the motivating example presented in the previous section, $\tau = 0.95$. The probability of the text coverage exceeding this threshold can be expressed as follows. First, the total number of words in a text can be expressed as $N = \sum_{i=1}^I n_i$. Next, consider the following random variable Z_i , which is equal to 1 if the learner knows the word v_i and equal to zero 0

otherwise. $\{Z_1, \dots, Z_I\}$ are assumed to be independent of each other.

$$Z_i \sim \text{Bernoulli}(p_i) \quad (1)$$

Because the number of occurrences of words known to the learner in the text is $\sum_{i=1}^I Z_i n_i$, then text coverage can be expressed as $\frac{\sum_{i=1}^I Z_i n_i}{N}$. Therefore, the probability that the text coverage exceeds the threshold is $P(\sum_{i=1}^I Z_i n_i \geq N\tau)$.

The probability that the learner acquires a new word v_i through incidental learning by reading the text can be formulated as follows. For incidental learning to occur, the text must be readable, so text coverage must be above the threshold. Furthermore, for a word v_i to be learned, the learner must *not* already know the word v_i . Therefore, this probability can be expressed as $P(Z_i = 0, \sum_{i=1}^I Z_i n_i \geq N\tau)$, which is hereafter denoted as q_i .

We wished to obtain the distribution of the number of words acquired through incidental learning from a text. Therefore, we define A_i as

$$A_i \sim \text{Bernoulli}(q_i). \quad (2)$$

Here, $\{A_1, \dots, A_I\}$ are assumed to be independent of each other. The number of acquired words, which is denoted as A , can be expressed as $A = \sum_{i=1}^I A_i$. Because each A_i is a random variable, A is also distributional.

5. SOLVING THE PROBLEM

To obtain the probability desired $P(\sum_{i=1}^I Z_i n_i \geq N\tau)$, or the probability that the text coverage exceeds the threshold, and to obtain the distribution of the number of acquired words $A = \sum_{i=1}^I A_i$, we must find the probability of a random variable consisting of a sum of independent binomial distributions with *different success probabilities*. If the success probabilities of the distributions are equal, then their sum is also a binomial distribution based on the reproducing property of the binomial distribution. However, in this case, because the success probabilities are different, the sum does not follow a binomial distribution. This distribution is called a *Poisson binomial distribution*.

Regarding the second language vocabulary, in order to calculate $P(\sum_{i=1}^I Z_i n_i \geq N\tau)$, [5] proposed a method for obtaining this type of probability using dynamic programming. Based on space limitations, we do not present their algorithm in detail in this paper. Instead, we present only an outline of their algorithm. Because $\sum_{i=1}^I Z_i n_i$ is an integer, the condition that $N\tau$ or more can be attributed to the subset-sum problem. Given a target integer, the goal of the subset-sum problem is to determine if there is a subset of $\{n_1, \dots, n_I\}$ that adds up to the target integer. The subset-sum problem can be solved using dynamic programming (DP). Specifically, we can use a DP table consisting of integers that can be created using subsets of $\{n_1, \dots, n_I\}$. Additionally, we must determine $P(Z_i = 0, \sum_{i=1}^I Z_i n_i \geq N\tau)$. This is computed by applying an extension to each cell of the DP table to record the probability value of $\{Z_1, \dots, Z_I\}$. In the Poisson binomial distribution, $\sum_{i=1}^I p_i$ is the mean and $\sum_{i=1}^I p_i(1 - p_i)$ is the variance. We used this fact to obtain the mean and variance values in our experiments.

6. EXPERIMENTS

For learner vocabulary test results, [4] published a dataset based on crowdsourcing. We adopted this dataset for our experiments. According to [4], in this dataset, the vocabulary size test (VST) [1], which consists of 100 vocabulary questions, was completed by 100 learners who had taken the TOEIC test (<https://www.ets.org/toEIC>) using a Japan-based crowdsourcing service called Lancers. The VST is a multiple-choice test in which the test taker selects the appropriate paraphrase of a word *within an English sentence* from four options. To avoid questions being solved based on grammatical clues that are irrelevant to knowledge of the word such as the difference between singular and plural words, all options are designed to be grammatically correct if they are replaced with the word in question.

Using this dataset, we trained a probabilistic classifier to classify whether each learner knows a given word and used the resulting probability values as p_i in Eq. (1). Because this is a binary classification problem, a neural classifier can be used. However, because improving classification performance was not the goal of this study, simple logistic regression was used to train the classifier. For the features of the classifier, we used the frequencies from the Corpus of Contemporary American English [3] and the British National Corpus [2]. The frequencies were converted into $-\log(\text{frequency})$ values and used as features. To make personalized predictions in which the prediction results differ from learner to learner, we simply added a J -dimensional one-hot vector as a feature, where J is the number of learners considered in the model. For this purpose, we followed the method presented by [5].

The Brown corpus was used as the set of texts for selection. To ensure that the lengths of the texts did not affect the experimental results, for each of the 500 texts in the Brown corpus, the first 300 tokens of the text were used in our experiments. From these 500 texts, our goal was to select one suitable for a learner's incidental learning.

In this setting, incidental learning is likely to occur in high-performing learners because low-performing learners can read few texts from the Brown corpus. Therefore, we conducted our experiments based on the highest-performing learner, who correctly answered 96 of the 100 questions in the VST. We randomly selected a text from the Brown corpus and estimated the distribution of the vocabulary size acquired by this learner through incidental learning when reading the text shown in Fig. 1. This distribution is more informative compared to when only the mean is available.

The value and variance of the expected acquired vocabulary when reading each text are considered simultaneously in Fig. 2. Each point represents a text in the Brown corpus. For a given expected size of the acquired vocabulary, it is better for the learner to select the text with the lowest possible variance in the acquired vocabulary. This allows learners to increase their vocabulary with a lower risk of reading failure. The upper-left portion of Fig. 2 presents the most *efficient* set of texts that promotes incidental learning for this learner. Therefore, the vertical axis in Fig. 2 can be considered as the gain and the variance of the acquired vocabulary in the horizontal axis can be considered as the *risk*. Fig. 2 can be considered as a risk–return plot, which is often

Figure 1: Example of the distribution of the estimated size of the acquired vocabulary. The horizontal axis represents the number of words that the learner is expected to acquire by reading the text and the vertical axis represents the probability.

used in finance [17].

In a risk–return plot such as in **Fig. 2**, selecting the upper-left points yields the lowest risk and highest gain. Therefore, the green dashed line created by connecting the upper-left points is called the *efficient frontier*. In **Fig. 2**, among the 500 texts, 5 texts on the efficient frontier were selected. In other words, we were able to narrow down the number of texts suitable for the learner’s incidental learning by a factor of 1/100. The choice of which of these 5 texts to select depends on the degree of risk that is acceptable for learners to increase their vocabulary. Although selecting one text among 500 is difficult for a human, selecting one text among 5 is relatively easy.

An interesting question is whether there texts that are efficient for most learners. An experiment was conducted to answer this question. **Fig. 2** presents the efficient frontier for the learner with the highest score in the vocabulary test dataset. Similarly, we identified the top 30 highest-performing learners in a dataset consisting of 100 learners.

Tab. A.1 presents the results. One can see that 7 texts were selected from the efficient frontiers of more than 10 learners, with the most common text being included in the efficient frontiers of 14 learners. These results indicate that the texts included in the efficient frontiers of learners are relatively stable, even though efficient frontiers vary by learner.

Although we leave the quantitative analysis of the texts in **Tab. A.1** for future work, the following qualitative trends can be observed. The top text (first line in **Tab. A.1**) exhibits clear “contrasts.” In other words, difficult words such as “contrarities,” which many English learners presumably do not know, occur with words that they are likely to know

Figure 2: The mean (vertical) and variance (horizontal) of the estimated size of the vocabulary acquired for each text (i.e., each dot). Because our method is personalized, this figure is tailored to each learner. In this figure, we present the case of the top learner in the vocabulary test dataset as an example.

such as “belief” and “imagination.” However, because proper nouns are treated as out-of-vocabulary words, regardless of the learner, texts with many proper nouns are also likely to be listed as efficient texts by most learners in **Tab. A.1**, as shown in the second row of **Tab. A.1**. Addressing this factor is a topic for future study.

7. CONCLUSION

To select texts suitable for vocabulary acquisition through incidental learning, we proposed a method for calculating estimates of the vocabulary acquired through incidental learning for each pair of learners and texts based on the findings of applied linguistics. By considering the size of the vocabulary acquired as a type of *gain* for a learner, we introduced the concept of the *efficient frontiers* used in financial engineering for vocabulary learning. We experimentally showed that there are “efficient” texts suitable for incidental learning that are included in the efficient frontiers of many learners.

The introduction of the concept of efficient frontiers to language learning will enable vast future work in this field, including evaluation experiments over time using learning application logs, handling the aforementioned proper noun issue, and multi-text selection when reading multiple texts simultaneously. Our approach can also be used with modern portfolio theory [17] to identify the most efficient texts.

APPENDIX

A. EXAMPLES OF EFFICIENT TEXTS

Tab. A.1 lists the texts that are frequently on the efficient frontiers of the top 30 learners. The example texts were taken from the Brown corpus, which is available in the Natural Language Toolkit (NLTK, <https://www.nltk.org/>).

B. DATASET AND CODE

The dataset used in this study was published in [4]. We plan to release our code at <http://yoehara.com/> or <http://readability.jp/>. The dataset by [4] is also available for download by following the links of these websites. Further information about this paper may be found in the following website: <https://rebrand.ly/edm223info>.

C. DISCUSSION

The fact that the top 30 learners were chosen in **Tab. A.1** does not mean that, in general, our method cannot support less-skilled learners. In this case, our experiments assume a situation where the test-takers in the dataset by [4] were to conduct extensive reading on the texts taken from the Brown corpus. What matters is this combination: the Brown corpus is simply too difficult for less-skilled learners on [4], and incidental learning does not occur for them. If we use a text set easier than Brown corpus, incidental learning is more likely to occur even for low-ability learners, and the proposed method may be effective.

Identifying Explanations Within Student-Tutor Chat Logs

ABSTRACT

To improve student learning outcomes within online learning platforms, struggling students are often provided with on-demand supplemental instructional content. Recently, services like Yup (yup.com) and UPchieve (upchieve.org) have begun to offer on-demand live tutoring sessions with qualified educators, but the availability of tutors and the cost associated with hiring them prevents many students from having access to live support. To help struggling students and offset the inequities intrinsic to high-cost services, we are attempting to develop a process that uses large language representation models to algorithmically identify relevant support messages from these chat logs, and distribute them to all students struggling with the same content. In an empirical evaluation of our methodology we were able to identify messages from tutors to students struggling with middle school mathematics problems that qualified as explanations of the content. However, when we distributed these explanations to students outside of the tutoring sessions, they had an overall negative effect on the students' learning. Moving forward, we want to be able to identify messages that will promote equity and have a positive impact on students.

Keywords

Large Language Representation Models, On-Demand Tutoring, Online Learning Platforms

1. INTRODUCTION

Middle school mathematics students have been shown to benefit from on-demand support when struggling within online learning platforms [8]. These supports require time and expertise to create, which can impede the platform's ability to provide support at scale. Additionally, when attempting to personalize students' online educational experience, it is essential to have multiple supports available for the same content. There has been notable success when crowdsourcing these supports from the teachers that use the platform

E. Prihar, A. Moore, and N. Heffernan. Identifying explanations within student-tutor chat logs. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 773–777, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

[5, 6], but there are other opportunities to collect supports, including from live chat logs between students and tutors, which are an intuitive resource for generating support messages because they contain messages from a tutor explaining how to solve a problem to a student. Therefore, we propose the utilization of large language representation models to algorithmically identify support messages from live tutors that can be distributed to students at scale. At this point, we have created and evaluated a method for identifying relevant tutor messages from chat logs. However, while our method was able to identify messages that seemed equivalent to explanations already used in ASSISTments, the results of an empirical evaluation of these messages' ability to help students found that they negatively impacted learning. We are looking for critiques of our existing method and ways in which we can expand our method to account for more than just the semantic similarity between tutor messages and existing explanations in order to improve student learning outcomes.

2. METHODOLOGY

2.1 Data Collection

The student-tutor chat log data comes from the ASSISTments online learning platform [4] and UPchieve [2]. From June 9th, 2021 to November 5th, 2021, 82 students from 5 different classes had the opportunity to request help from a live UPchieve tutor within the ASSISTments learning platform. Over this time, students requested help 208 times and 8,817 messages were exchanged between students and tutors. In this work, we attempted to extract generalizable support from the live tutors' messages. Our approach relies on comparing large language model embeddings of the messages written by live tutors to the explanations already used as on-demand support within ASSISTments. Therefore, we also collected 16,130 existing explanations from the ASSISTments platform.

2.2 Identifying Generalizable Support

To identify generalizable support, we employ a four-step approach. The first step of our approach is to embed each tutor message and ASSISTments explanation using a large language representation model. We experimented with embeddings using three different pretrained large language models: BERT [3], SBERT [7], and MathBERT [9]. Due to the large number of features in these embeddings, the second step of our approach was to transform the embeddings using PCA [1] to mitigate over-fitting our subsequent supervised model. The third step was to train a logistic regression

to classify whether the embedded sample represented a tutor message or an ASSISTments explanation. The fourth step was to manually inspect the misclassified tutor messages and evaluate their generalizability and relevance. If they were deemed relevant, then they were included in the empirical study within ASSISTments. To select the number of PCA components to use for each logistic regression, a separate logistic regression was fit on 1 through n components, in order of decreasing significance, where n is the total number of components. After each logistic regression was fit, the total number of tutor messages classified as ASSISTments explanations was calculated and plotted. The plot revealed an "elbow", at which point additional PCA components had diminished effects on the accuracy of the logistic regression. Therefore, the number of components at the elbow of the graph was selected as the correct number of components to mitigate over-fitting.

2.3 Empirical Study

After candidate tutor messages were identified using the process described in Section 2.2, a randomized controlled experiment was performed within ASSISTments, in which an assignment consisting of six mathematics problems was given to middle school students. Only teachers that felt the problems were appropriate for their class allowed their students to participate in the experiment. For the 1st, 3rd, and 5th problems, students were randomized between receiving the identified tutor messages, or just the answer, as support upon their request. For the 2nd, 4th, and 6th problems, students were given a nearly identical problem with the same format and knowledge prerequisites as the previous problem. Within the assignment, the order that the students received the three pairs of problems was also randomized to eliminate bias from completing the problems in a particular order. The students' success on the 2nd, 4th, and 6th problems was used to evaluate the quality of the tutoring for each of the previous problems respectively. To determine the effectiveness of the tutor messages, an intent to treat analysis was performed in which Welch's t -tests [10] were used to compare the next-problem correctness of students that could have received the tutor messages and students that could have received the answer when requesting support, and Cohen's d was used to determine the effect size of the treatment compared to the control.

3. RESULTS

3.1 Identifying Generalizable Supports

Applying the elbow sample selection method described in Section 2.2 for each of the three different BERT models resulted in the plots shown in Figure 1. Only the first 20 PCA components are plotted because the elbow is always in the first 20 components. Based on Figure 1, MathBERT was the most accurate model and only misclassified eight tutor messages as explanations at the elbow, which is about 0.16% of all the tutor messages. To further illustrate the difference in the effectiveness of each BERT model, Figure 2 shows a two-dimensional projection of the regression boundary when fit using n PCA components, where n is determined by the elbow plots in Figure 1. Again, MathBERT has the least misclassifications. For this reason, the misclassified tutor messages from the logistic regression fit using the first eight PCA components of the MathBERT embedding were used

as candidate tutor messages for the empirical study. Of the eight messages, six were relevant enough to be used as on-demand support for the problems for which they were written. The other two messages were written about an example problem devised by the tutor, and not the original problem the student was trying to solve.

3.2 Empirical Study

The six selected tutor messages were written during discussion with students requesting support on three problems in ASSISTments. Therefore, the messages for each problem were combined into one set of on-demand support for the problem. Figure 3 shows each of the problems and the on-demand support created for them. In total, 163 students participated in the experiment. 106, 97, and 111 students were used to evaluate the supports for Problems 1, 2, and 3 respectively. Overall, there was a small, statistically insignificant negative effect from offering students tutor messages for support ($d = -0.145$, $p = 0.068$). When evaluating the effectiveness of the tutor message based supports for each individual problem, it was revealed that for the first and third problem, there was an insignificant negative effect from receiving on demand tutoring ($d = -0.094$ and -0.069 respectively, $p = 0.489$ and 0.627 respectively), but for the second problem, there was a medium-sized significant negative effect ($d = 0.406$, $p = 0.005$).

4. CONCLUSION

Although we were able to identify tutor messages that offered explanations to students on how to solve the problem they were struggling with, only 75% of the messages selected by our methodology were deemed relevant by human selection, and in an empirical study, these messages had a negative effect on real students' learning. This implies that there is more nuance to how helpful a message will be aside from how similar it is semantically to existing support messages. While this seems obvious, it is difficult to approach algorithmically filtering the tutor messages in a way that takes into account their relevance to the problem and how likely they are to benefit student learning outcomes. Moving forward, research efforts may compare tutor messages to the relevant problem, either in an embedding space or simply through phrase matching. This could help exclude tutor messages which were not relevant to the original problem but did get misclassified as supports in the embedding space. To address the negative impact that the selected tutor messages had on students' learning, we could attempt to use the students' responses in the student-tutor chat logs to identify only the tutor messages followed by student messages with positive sentiment, for example, "Thank you! I understand now". Ideally, by filtering the tutor messages this way, we would only include tutor messages that the student was happy to receive, which implies these messages would be more likely to help other students. Additionally, a metric to quantify the benefit to student learning outcomes given a problem and support would benefit our analyses of relevant tutoring logs. There are many factors to consider when improving student learning outcomes and we look forward to investigating these potential directions.

$|10 \cdot 9 \cdot 5| - 10$

We can think of a number (say, -22, or 57) as having two features:

- the magnitude of the number (which we can think of as how far away the number is from 0) and the sign of the number (whether the number is less than 0 or greater than 0).

So, the magnitude of -22 is 22 and the sign is negative. Similarly, the magnitude of 57 is 57, and the sign is positive.

The absolute value of a number is only its magnitude.

For example, the absolute value of -22 is 22, and the absolute value of 57 is 57.

The body of a 154-pound person contains approximately 2×10^{-1} milligrams of gold and 6×10^1 milligrams of aluminum. Based on this information, the number of milligrams of aluminum in the body is how many times the number of milligrams of gold in the body?

We need to divide the amount of aluminum by the amount of gold to find out how many times the amount of gold is equal to the amount of aluminum.

[Comment on this hint](#)

When we divide 6 by 2, of course we get 3. And when we divide 10^1 by 10^{-1} , we subtract the exponents.

The rule is, when you multiply two numbers with exponents that have the same base, you add the exponents. And when you divide two numbers with exponents that have the same base, you subtract the exponents.

Detecting When a Learner Requires Assistance with Programming and Delivering a Useful Hint

Marcus Messer
King's College London
marcus.messer@kcl.ac.uk

ABSTRACT

Over the last few years, computer science class sizes have increased, resulting in tutors providing more support to struggling students, and instructors having less time per-student in larger classes. Universities typically assign multiple tutors to lab sessions, especially introductory programming courses, to maximise the help available to students during their sessions. However, using multiple tutors does not help struggling students outside of official sessions. The lack of support outside official settings is especially the case for online courses and remote learning. To help resolve student frustration from not being able to get support when they need it, we propose a tool that can detect when a student is struggling with their programming task and give them a hint that gets them closer to their goal.

Keywords

computer science education, computer programs, sequence mining, learning behaviours, feedback

1. INTRODUCTION

Over the last few years, the number of students enrolled in computer science courses has increased [12] and self-directed learning is becoming more prevalent. As class sizes grow, it becomes more difficult for course leaders and assistants to assist in programming labs. This difficulty is because it takes time to solve and explain various programming issues, and instructors have less time per-student in larger classes. Multiple tutors are frequently assigned to a single lab to maximise the availability of expert assistance. However, not all students will receive assistance during their scheduled lab sessions in some circumstances, particularly approaching deadlines, when multiple requests for help occur in a single lab session. Even if a tutor is available, many students do not seek assistance when struggling to solve a problem [15]. However, if a tutor offers a student support, they will usually accept it.

Students have limited access to expert support outside of regular classes and office hours. The limited access is especially true for online courses, distance learning and students undertaking self-directed learning. The limited expert help in and outside official settings may lead to prolonged frustration, one of the leading causes of students dropping out [20].

A student could seek help for numerous programming areas, including compiler errors, logical errors, code style and best practice. Detecting code style issues and best practices are solved using various static code analysis tools, such as FindBugs and CheckStyle. FindBugs detects bad practices, performance, correctness, and “dodgy code” using pre-defined bug patterns, including common issues for novice programmers. Examples of which includes the comparison of String objects using “== or !=” and issues that cause `IndexOutOfBoundsException` [2]. CheckStyle detects various code style issues, including incorrect naming conventions and code design [7].

Some of the most challenging errors to solve are compiler errors, examples of which include “missing return statement”, “method call: parameter type mismatch”, and “method call targeting the wrong type” [16]. Understanding compiler error messages and correcting them is difficult and time-consuming for programmers of any degree of experience, especially novices [22]. Poorly written error messages could lead to a student not solving a problem for hours or days without help. Even with skilled help, an error could take several minutes to correct [13]. While compiler errors can be challenging to solve, logical errors are considerably more challenging to correct because they usually necessitate understanding the problem’s context and the student’s written work.

The proposed research will focus on detecting when a student requires assistance with compiler, logic and style errors and providing a meaningful hint on how to solve the error.

2. BACKGROUND & RELATED WORK

Previous work on detecting a struggling student has focused on other aspects than the source code. Spacco et al. used measures based on time and number of submissions to detect *flailing* students [21]. Rodrigo and Baker investigated detecting the aggregate frustration over many labs, using compilation based measures [20].

The compilation measures that Rodrigo and Baker implemented were the average time between compilations, the total number of compilations, the total number of errors, and Jadud’s Error Quotient (EQ) [20]. The EQ indicates how well a student can handle syntax errors while programming. It looks at successive pairs of compile events to see if both result in an error and if the error type is the same [9] (refined in [10]).

Recent research has investigated how EQ could be improved. Watson and Godwin created the Watwin algorithm, using consecutive compiler events to calculate a score; however, they also included checks for whether the error is on the same line and penalties for the time taken to solve each compilation pairing [23]. In addition, Becker developed the repeated error density (RED), which calculates a score based on repeated error strings, accounting for the lengths of repeated error strings in a sequence and assigning higher penalties for higher repeated error density [4].

While programming, students are given different types of feedback, the most common of which is next-step hints. After a student is stuck in a state and requires help to progress, a next-step hint will guide them to a more complete and correct version of the code [1].

There have been many implementations of next-step hints in different programming environments. Obermüller et al. have recently implemented next-step hints into Scratch. They first select a set of suitable candidate solutions using an automated test suite, then find the best matching candidate solution as the target solution. After they have the students and the target solution, they determine differences in the Abstract Syntax Tree (AST) to synthesise the hints [17]. However, this solution requires abundant candidate solutions.

There have been multiple attempts to provide hints in vast and sparsely populated spaces. Paaßen et al. produced the Continuous Hint Factory (CHF), which uses a supervised machine learning approach to provide a hint to the student. CHF uses the edit distance of the student’s current state and traces data of past students who have visited the same state in similar states to choose the edit with the lowest error as the hint [18].

While Paaßen et al.’s approach still require some trace data, Rivers and Koedinger use at least one reference solution and a test method to produce a solution space to find the next-step hint. They use a path construction algorithm to find the edit path from the current state to the solution, then finds the closest correct state within the space to find the edit that will be the basis of the next-step hint [19].

The previous approaches to next-step hint generation require trace data or a reference solution, but what if the student is the first to attempt such a task? Efremov et al. have used a reinforcement learning-based neural network hint policy to enable next-step hints for students attempting a programming task for the very first time [8].

3. PROBLEM STATEMENT

As Computer Science courses grow, the need for expert help increases; this is especially the case for online courses, remote learning and approaching coursework deadlines. Although having more tutors in regular sessions allows for more help, increasing the support offered in and out of the classroom would be beneficial.

Our research will investigate the following research questions:

- RQ1** How can traces of student code changes be used to detect struggling students?
- RQ2** After detecting a struggling student, when is the most effective time to give them a hint?
- RQ3** Can we generate next-step hints that focus on syntactic and logical errors comparable to the support offered by human tutors in these areas?

4. PROPOSED METHOD

The first phase of this project will determine whether or not a student is struggling. We will use Blackbox, a large dataset of novice programming data collected over the last eight years [6], to look for trends that could signal a struggling student. Blackbox is a large scale repository of novice programmers’ activity, including the length of programming sessions, compilation event history, and editing behaviour [6]. The editing behaviour includes a history of source code changes, allowing researchers to step through each change of a student’s code iteratively. We will explore patterns that could identify struggling students using the source code and compiler histories.

We will use existing research to detect at-risk students using compiled histories and invocations, such as the “Watwin” algorithm [23] and Repeated Error Density [5]. In conjunction with the compiler history, we will investigate the source code patterns that indicate that a student is struggling. We will use data mining approaches to derive developers’ behaviour patterns, similar to Kinnewbrew’s research into learners’ behaviour. Kinnewbrew et al. used interaction trace data from Betty’s Brain, which introduced students to a science topic (climate change). They abstracted and labelled different activities into different categories to analyse the data using differential sequence mining, identifying differentially frequent patterns across two groups of sequences [11].

We will investigate using interaction traces of source code to detect struggling students. Source code traces will allow us to examine how the student develops and any patterns in their programming and debugging practices that could indicate that they are struggling. Using source code traces could detect more struggling students than just compiler histories, as source code traces enable us to analyse more than just compiler related issues. An example pattern of a struggling student could be commenting out large chunks of code, potentially followed by uncommenting small portions to figure out which part of the code is causing their problem, which could signify that the student has trouble debugging and locating the problem. Another example may be the number of revisions made to a single code block in a given timeframe, suggesting that they are having trouble solving

a logical or syntactic mistake, depending on the compilation result.

We will use the patterns we found to detect when a student is struggling and give them a hint.

In order to give students a next-step hint, we will integrate the ideas of the Continuous Hint Factory (CHF) [18] and Evremov et al.'s research on using reinforcement learning to generate next-step hints [8]. We will use CHF as our primary method of producing hints, using Blackbox as the basis of potential candidate solutions. Blackbox contains data from opted-in users of BlueJ [14]. BlueJ is an educational IDE used worldwide by many different institutions at many different education levels. Accompanying BlueJ is a widely used textbook [3] that provides example projects and tasks, of which there are multiple solutions within Blackbox. However, there will be cases where a student is programming a task for the first time, such as new coursework. These cases are where Evremov et al.'s approach comes into effect, the ability to still provide next-step hints for the very first attempts of new programming tasks without the requirement of producing candidate or model solutions.

We will use Blackbox to learn patterns of struggling students and for elements of hint generation, as Blackbox contains both compile history and source code changes. To implement the ideas discussed in this section, we will create a plugin for BlueJ, which will run continuously in the background analysing the students' compile history and source code traces, comparing them to any patterns we have learnt from Blackbox. The plugin will include a "human-in-the-loop" process, enabling the user to give feedback to the system if the detection of their struggle was correct or if the hint helped solve their issue.

The following are the proposed steps that the system will follow:

1. While the student develops and compiles, the system will analyse the source code and compile histories for defined patterns.
2. If a pattern is detected, ask the user if they would like a hint.
 - (a) If yes, give the student a hint and ask them to rate the quality and usefulness of the hint.
 - (b) If no, log that they did not want a hint. If enough students give feedback that they do not want a hint for this specific pattern, flag it for investigation.
3. If the same pattern on the same part of the code is detected, repeat steps 2a and 2b, but with a more specific hint.
4. Repeat the steps above while the student develops.

We will conduct a series of trials to evaluate our proposed tool to determine if our system correctly detects struggling students and if the hints delivered are meaningful. Our trials could include asking students of various skills levels to

complete a set of programming tasks of increasing difficulty, with and without our proposed tool. After they complete the programming tasks, we could interview the students to determine if they thought they were offered a hint at the correct time and if the hint given was helpful. In addition to interviewing students, we may ask tutors for their feedback on whether the suggested method provided timely assistance and whether the hints assisted students in learning.

5. RISKS OF NEXT-STEP HINTS

This project aims to generate hints that will trigger a learning effect. We will have to hypothesise what area of the programming task the student is struggling with in order to generate a hint that will increase the students' understanding in that area. Using patterns of student development behaviour with next-step hint techniques could indicate which area the student is struggling with and give them a hint that increases their understanding and help them continue with their programming task.

While employing next-step hints might help students learn, there is a risk that using incrementally more specific hints can harm learning by giving students answers without teaching them how to improve. Students who abuse the hint system in this way exacerbate the risk of them not learning how to improve. We will investigate different methods to decrease the possibility of abuse in traditional hint systems, including providing a hint only when the system recognises that the student is having difficulty. However, this may not eliminate the risk, as some students will learn how to manipulate erroneous detections in order to obtain consecutive suggestions that will lead to the correct answer.

These risks lead to the pedagogical question: *Should the system give the student the answer if they have fundamental misunderstandings?* While undertaking this project, we will aim to minimise the risks discussed in this section and maximise the learning effect of the generated hints.

6. PROPOSED CONTRIBUTIONS

The proposed contributions of the above research will include:

- A method that can detect a struggling student using compiler error history and source code changes.
- Investigate when is the optimal time to hint after detecting a struggling student.
- A tool for detecting struggling students and giving them an appropriate next-step hint at the right time.

These contributions will benefit the Computer Science Education community by offering a tool to support students inside and outside formal education settings and alleviate some growing pressure on tutors of large classes.

7. CONCLUSION

We proposed the development of a tool that can detect when a programmer, mainly a novice programmer, is struggling and provide them with a next-step hint. We will look into how various pattern recognition techniques and past work on

metrics can be used to identify a struggling student based on compiler and code change histories.

A Paraphrase Identification Approach in Paragraph length texts

Arwa Al saqaabi
Dr. Craig Stewart
Dr. Eleni Akrida
Prof. Alexandra Cristea

ABSTRACT

How to measure the semantic similarity of natural language is a fundamental issue in many tasks, such as paraphrase identification (PI) and plagiarism detection (PD) which are intended to solve major issues in education. There are many approaches that have been suggested, such as machine learning (ML) and deep learning (DL) methods. Unlike in prior research, where detecting paraphrases in short and sentence-level texts has been done, we focus on the not yet explored area of paraphrase detection in paragraphs. We consider that the meaning of a piece of text can be broken into more than one sentence, this is over and above the sentences as extracted from two benchmark datasets (Webis-CPC-11 and MSRP). TF-IDF, Bleu metric, N-gram overlap, and Word2vec are used as features, then SVM is invoked as a classifier. The contribution of this paper clearly indicates that, on a commonly used evaluation set, text at the length of a paragraph is more appropriate to consider than short or long text for ML and DL approaches. Additionally, our method outperforms the existing work done on the Webis-CPC-11 dataset.

Keywords

Natural Language Processing, Machine Learning, Deep Learning, Paraphrase Identification, Paragraph Length

1. INTRODUCTION

When students submit their work, institutions have to verify if the work is free of plagiarism. To overcome the limit of human abilities in terms of scalability (e.g. time to check and consistency) machine and deep learning techniques are applied for plagiarism and paraphrase detection tasks. Plagiarism is defined as using someone's written work without giving reference to the original source, or claiming the ideas taken from the work of others [22]. In some instances, the copying of many words from the original source, regardless of the provision of a reference, is also considered an act of plagiarism [4]. The modification of sentences in such a way that the original structure of the sentences, without acknowledgment, is used by the author, also falls in the category of plagiarism. According to Ehsan et al. [14], plagiarism detection methods are divided into two main categories, which are *intrinsic* plagiarism detection and *external* plagiarism detection methods. Intrinsic methods are implemented to detect the parts of the text that are inconsistent, while external methods can match suspicious passages in a text to

the source(s), detecting exact verbatim copying and paraphrased text [23].

Bhagat and Hovy [6] define paraphrasing as a means of conveying the same meaning, but with different sentence structure and wording. This definition clearly does not include exact verbatim reproduction as a case of paraphrasing. For our purposes, let us have two different texts, A and B. If the information, ϕ , which can be derived from A, can also be inferred from B, and vice versa, then A is a paraphrase of B (Equation 1): α represents a given domain or background knowledge [8].

$$(A \wedge \alpha | = \phi) \Leftrightarrow (B \wedge \alpha | = \phi), \text{ where } A \neq B \quad (1)$$

From this definition, it is obvious that paraphrase identification (PI) is implicitly part of plagiarism detection. (PD) Both PI and plagiarism detection have assumed a tremendous importance for academic institutions, researchers, and publishers concerned for the preservation of academic integrity [3]. PI is a method that aims to measure the degree of similarity between two given texts [11, 15]. PI also helps determine whether the two texts share the same meaning, which plays a vital role in natural language applications, such as plagiarism detection, summarisation of textual material, and machine translation. Semantic similarity is also used in several other activities, such as to retrieve information [21], answer questions [5] [31,1] and clustering [7].

Attempts to solve the problem of paraphrase identification in past studies were mainly focused on comparing words in sentences [28,29], phrases in sentences [2], or sentence to a sentence [12, 24]. These studies achieved robust results. However, comparing each sentence in the suspicious document (i.e., a students' assignment), to all sentences in the source documents, is not an efficient approach for long texts. Additionally, existing studies are ignoring the fact that sentence semantics could be distributed in a paragraph as a passage-level paraphrase type, which is more complex to recognise. Thus, we aim to develop a method for recognizing paraphrasing in paragraphs, henceforth called *passage-level paraphrasing*. This approach considers a paragraph as a basic unit, avoiding comparing all sentences of the documents as separate entities.

Existing work investigated paraphrasing that is accrued at sentence level [16, 30]. Additionally, prior works count exact and quasi-exact sentences as a paraphrased text [2, 25]. To the best of our knowledge, this study is the first to allow for passage-level paraphrasing (beyond sentence-only) text length. We have chosen to focus on passage-level paraphrasing, as we argue that it is a common and naturally occurring way to consider paraphrasing, more so than the previously studied sentence-level paraphrasing. In addition, we analyse how the text length affects machine learning (ML) model accuracy. For this purpose, we compare ML approaches that are mainly based on handcrafted features, as well as state-of-the-art deep learning sentence representation models, such as word2vec.

A. A. Saqaabi, C. Stewart, E. Akrida, and A. Cristea. A paraphrase identification approach in paragraph length texts. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 782–788, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

For further research, constricting a new dataset is required to consider the text length and paraphrasing type. For purpose of this research, we provide the following definitions:

- a. *Sentence level paraphrasing*: the meaning of one sentence is paraphrased into exactly one other sentence (example: data in the MSRP dataset);
- b. *Passage level paraphrasing*: the semantics of a piece of text of multiple sentences are paraphrased into a potentially different number of sentences without a one-to-one mapping between sentence semantics (example: data in the Webis-CPC-11 dataset);
- c. *Sentence-length level*: represents a **short text** length, which is less than 50 words;
- d. *Paragraph-length level*: represents a **mid-text** length, which consists of about 100 words, this is the average length of a paragraph [20].
- e. *Passage-length level*: **long text** which consists from more than a paragraph (containing 150+ words).

Hence, our main research questions (RQ) are:

RQ1: How does the length of a piece of text affect the efficiency of the paraphrase identification approach used?

RQ2: What type of features are more effective for the problem of paraphrase identification on sentence - and passage level of paraphrasing, respectively?

RQ3: How effective are current state-of-the-art paraphrase identification methods for the problem of paraphrase identification in long text (paragraph) and (passage-level paraphrase)?

2. RELATED WORK

Machine learning (ML) and deep neural networks (DNN) attract the PI researchers and a lot of efforts have been devoted in this area. In these works, features are extracted by considering N-gram overlap features, metrics like Bleu, syntactic features, and semantic features from external knowledge such as WordNet or pretrained word embedding.

Cordeiro et al. [9, 10] implemented experiments that extract features from text, by applying a variety of metrics such as Bleu, edit distance which calculates how many character or word insertions, deletions, and replacements are required to change one string into the other, and Sim, Word Simple N-gram Overlap. They evaluated the experiments on the MSRP and the Knight and Marcu Corpus (KMC), where the paraphrased sentence is a shortened or summarized version of the original one. The Sim metric present the highest accuracy after removing the equal and quasi-equal samples from the dataset. For more investigations on the metrics' efficiency, they defined two types of paraphrasing, which are *symmetrical paraphrasing* (SP) and *asymmetrical paraphrasing* (AS). Symmetrical sentence pairs contain the same information, while in the asymmetrical paraphrasing, at least one sentence has more information. The result shows that the Sim metric is efficient for AS, while the Logisim metrics, based on the theory of exclusive lexical links between pairs of short text, is better for SP. Rather than implementing a specific threshold value to do binary classification, these metrics also were fed as text features extracted from the Webis-CPC-11 dataset, which has longer text samples, to a classifier such as SVM and k-nearest neighbours [8]. Regardless of the accuracy of these models, the Sim metric is suitable only for short texts, because of its demands on computing time.

Ferreira et al. [16] evaluated different ML algorithms, namely RBFNetwork, BayesNet, C4.5, and SMO on short text. They measured the lexical features from a Bag of Words (BOW), which breaks a text into all of its unique words and counts the number of times each word appears, syntactic and semantic features from the Resource Description Framework (RDF) based on dependence tree graphs. It mainly tackled two specific issues: sequences with the same meaning, but different terms, and the word-order problem. The results of the RBFNetwork and BayesNet algorithms outperform others, with accuracies of 75.13 and 74.08, respectively, both of which are measures of performance discussed in more detail in Section 3.3. Despite the fact that it did not improve overall outcomes, it significantly recognized the meaning of sentences that shared the same words but in a different order.

Wan et al. [29] designed an approach that considered 17 syntactic dependency features, to examine their effects on the accuracy of different machine learning algorithms, namely Naive Bayes learner, C4.5 decision tree, support vector machine, and K-nearest neighbour, to indicate dissimilarity between a pair of sentences. They claimed that dependency and N-gram features enhanced the classifier to recognise falsely paraphrased cases. In addition, avoiding lemmatisation was shown to keep the signs of differences in meaning and focus between sentences. However, more of the correctly paraphrased cases were identified as a negative, decreasing the overall accuracy of the approach. Moreover, they evaluated their experiment on a partial MSPC, because some cases led to stopping the parsing script. To leverage the limitations of this study, Ji and Eisenstein [18] considered the same features of Wan et al. [29] and implemented them on the whole MSRP corpus. Additionally, they developed a metric that computed the discriminability of features between sentences, called Term Frequency Kullback Leibler Divergence (TF-KLD). It counted the probabilities that appeared on paraphrased and non-paraphrased sentences, to re-weight features before factorisation, to obtain latent representations of the text. It clearly outperformed TF-IDF by 4% in accuracy and 1% in F1 score on MSRP. Moreover, they combined other features, such as unigram and bigram, overlapping fine-grained features, which raised the accuracy from 72.75 to 80.41. TF-KLD improved discriminatively distributional features while reducing others.

From another perspective, Vrublevskiy and Marchenko [28] extracted dependency tree, IDF and Bleu features from natural language. They concatenated word embedding with dependency tree features, to show that this combination can be useful to detecting paraphrase. However, this model did not outperform the state-of-the-art in that area [18].

Ji and Eisenstein [18] and Wan et al. [29] noted the need for more investigating on another dataset, also considering long text, such as a paragraph, where these studies examined only the MSPC corpus, where the maximum length of a sentence is 36 words [13]. In addition, using parse trees to solve problems restricted an approach to single sentences [19]. Also, BOW was unable to consider word order which is a vital textual feature in PI [30].

Nguyen et al. [24] developed an algorithm based on external knowledge and word embedding. It takes name entities (e.g., US) and rewrites them in words (e.g., United States). Additionally, they have applied the continuous bag of words CBOW and Skip-Gram models to extract interdependent features based on pre-trained word embedding. CBOW predicts a target word based on its context and Skip-Gram does the opposite, predicting context words according to the target word. As a part of the methodology, more features were also included that help to measure semantic relatedness based on external knowledge resources such as WordNet.

Features extracted from sentences with and without pre-processing. Then Support Vector Machine SVM is involved for classification task. It examined on MSRP, SemEval and P4PIN datasets achieving high accuracy 84.17, 83.73, and 95.22 respectively by considering features based on the external-knowledge resource. Unfortunately, they didn't report other evaluation metrics like F1 score, precision, and recall.

The above-mentioned work considered words or sentences as a mean unit of calculating semantic similarity in text segments. In addition, methods like SVM and BOW fall short of delivering a high-quality solution for extracting the semantics meaning of natural language. Particularly, SVM works better when integrated with deep learning models for recognizing paraphrased sentences [32].

Several academics have recently used deep neural networks to model sentence pairs to leverage the shortness of non-deep learning methods. Vrbanec and Meštrović [26, 27] conducted two studies on different models of sentence semantic representation such as word2vec, Glove and Fast-Text. The experiments were done on three datasets namely MSRP, Webis-CPC-11 and C&S. Because of the pairs of sentences that are semantically unrelated and very similar lexically, no specific model outperforms others on all datasets, however, USE provides high accuracy and F1 score. They also compare similarity metrics with two types of word embedding deep learning models: word2vec and Fast-Text [27].

Kenter and De Rijke [19] focused on word2vec and Glove semantic sentence representation. They extract word level and short sentence level features by word alignment and word embedding beside the saliency weighted semantic graph. This approach is corpus-based hence no use of external knowledge source is needed. It measures the semantic similarity on sentence level ignoring the importance of the word order in PI downstream task. Although applying word alignment to extract syntactic and semantic relations between words of the sentence and feeding them into SVM model as features showed the significance result on PI task, it needs to be examined on paragraph level. The authors show that classifiers which trained to predict semantic similarities between short texts can benefit from saliency-weighted semantic networks. In addition, concatenating of pre-trained word embedding models obtain better scoring than WordNet-based approaches.

Although these studies were done on more than one of public paraphrase dataset, they did not take into account the verity of numbers of words on each sample, nor the type of paraphrase have been done on different datasets. More importantly, they consider typical samples as paraphrased cases that do not state the paraphrase definition.

To overcome the limitation with sentence representation models that are based on a unidirectional encoder, Devlin et al. [12] proposed Bidirectional Encoder Representation from Transformers (BERT), which uses a masked language model and next sentence prediction, and is fine-tuned with one additional output layer. BERT has been demonstrated to achieve state-of-the-art outcomes on a wider array of sentence-level and token-level NLP tasks. Specifically in the PI task, it evaluated on MSRP with 89.30 percent of accuracy. This high accuracy raises the machine prediction accuracy to be closer to human performance.

As we see, BERT as a transformer learning model outperforms other sentence representation models because it generates a context vector representation that can discriminate word meaning in different contexts rather than giving the same weight for each word wherever it occurs [12].

Deep learning techniques have attracted a lot of attention in different research fields regarding to its impressive performance. In the PI field, researchers employ deep learning models to detect semantic similarity mainly in short text. In a way to show the efficiency of deep learning models over machine learning on PI task. Hunt et al. [17] compared the accuracy of two machine learning models with three different deep neural network models. Results illustrate that all DL models' accuracy outperforms LR and SVM models. The lowest accuracy is obtained by Siamese NN (~62) while the best accuracy is (~82) from LSTM RNN on the PI task.

3. METHODOLOGY

Prior research has investigated the efficiency of pre-processing techniques such as removing stop words and word lemmatizing [29], similarity metrics such as cosine, soft cosine and Euclidean [27] and using pre-trained word embedding models [26] on the PI downstream task. Here we examine how the length of text affects the model's accuracy in determining the appropriate number of words that could provide enough semantic information for machine models. Specifically, do short texts (sentences), mid length texts (paragraphs), or long texts (passages and paragraphs), provide sufficient semantic detail for the models? What type of features are most appropriate to use when attempting to identify paraphrases in sentence or paragraph texts? More importantly goal is that how to measure semantic meaning in paragraph length level to enhance other fields such as plagiarism detection, summarization, and text matching. Additionally, how the state-of-the-art autoregressive method advance the PI task?

3.1 Dataset

3.1.1 Microsoft Paraphrase Corpus (MSRP)

Dolan et.al. [13] presented separated sets of sentence pairs for training and evaluation. MSRP contains 4076 pairs of short text for train and 1725 for evaluation, taken from news sources on the internet. Human reviewers have then determined if each pair has a semantic equivalence. Each sentence pair is then labelled by 0 or 1, which represent negative and positive labels respectively.

3.1.2 Webis Crowd Paraphrase Corpus 2011 (Webis-CPC-11)

Burrows et.al. [8] provided 7859 possible text paraphrases pairs by Mechanical Turk crowdsourcing. The corpus consists of 4067 acceptable paraphrased pairs (meaning that one piece of text is a paraphrase of the other) and 3792 non-paraphrased pairs.

Most of the existing PI experiments are done on MSRP, which contains sentence-level paraphrases, so the existing results measure sentence similarity, whereas the most common and natural paraphrase is at the passage-level as seen in Webis-CPC-11. Another point of comparison between these corpora is the length of text which is vital for our study. The maximum sentence length in MSRP is 36 words while in the Webis-CPC-11 it is about a thousand words. This variety of document lengths in the Webis-CPC-11 dataset enables us to study how the text length can affect the ML model's results and to determine the best length of text that could be applied for ML and DL models.

3.2 Features Extracted

Based on the purpose of this study, we select the most important features in the PI task that represent text into numeric values. Each work discussed in Section 2 has implemented at least one feature of TF-IDF, Bleu, dependency tree, N-gram overlap or Word2vec [9, 10, 17, 18, 19, 24, 26, 27, 29]. However, most of these works

are done on the MSRP dataset which represents sentence level paraphrase, whereas we present a study on passage level paraphrase as seen in the Webis-CPC- 11 dataset.

4. EXPERIMENT

As we aim to study how the length of a text can affect the accuracy of using a specific or a combination of features in ML and DL models, we use MSRP as it focuses on short text length and Webis-CPC-11 as it contains a variety of text length samples. Therefore, we clean, then divide the samples from Webis-CPC-11 into three subsets based on the text length after removing the empty samples containing no text. Firstly, we remove identical sample texts from the Webis-CPC-11 dataset to satisfy the requirements of the paraphrase definition mentioned in the introduction, see equation (1). So, given a text pair (text 1, text 2), text 1 must be different from text 2 but carrying the same meaning. We call the resulting new dataset Webis-CPC-21, following the trend of the original dataset naming where 11 refers to 2011, the year of creation. However, we perform our experiments on the Webis corpus both with and without these identical samples to compare our results to state-of-the-art literature where possible. Secondly, we split the Webis-CPC-21 into three sub corpora: short text, where the maximum length of samples is 50 words; mid text represents the paragraph length (51-150 words) as the average length of a paragraph in English consists of 100 words [20]; long text containing samples of 151-500 words. We keep MSRP in its original form, as its samples consist of short text length (less than 40 words). Each dataset has numbers of negative and positive labelled samples. Positive and negative label refer to pair of text that are paraphrased and non-paraphrased respectively.

Table 1. The experiment's result, bold font represents the highest accuracy and f1 in each feature

Dataset	Bleu		TF-IDF		Sen2vec		Ngram_overlap		All Features	
	Acc	F1	Acc	F1	Acc	F1	Acc	F1	Acc	F1
Webis-CPC-11	57	72	87	82	64	63	56	68	66	65
Webis-CPC-21	77	87	78	87	80	88	83	90	79	88
Short text	77	82	78	87	79	88	77	82	79	88
Mid length	81	89	83	90	84	91	85	91	85	91
Long text	73	84	73	84	75	89	78	86	75	85
MSRP	67	80	71	80	72	82	69	81	71	81

4.4 Result and Discussion

Our result in table 1 outperforms the baseline system of Webis-CPC-11 dataset which is the main dataset for this study, thanks to its variety of text length and the paraphrase type that is applied on its samples. Our accuracy and F1 are 80 and 88, respectively, which outperform baseline results by 3% in terms of F1 score on Webis-CPC-21 for Sen2Vec feature set. While the result on WebisCPC-11 is more by 3% for accuracy and less by 3% F1 with implementing one feature which is TF-IDF, rather than using 10 different metrics as the baseline system did. In addition, the efficiency of the ML and DL models could be improved when the length of the text is neither short nor long. Thus, the features engineers have to consider also must include the text length when extracting these features from text segments.

Our results on each feature on MSRP are worse than the ones achieved on the short text category, which potentially indicates that the good results we have achieved on Webis-CPC-21 are because the length of the samples in MSRP is even shorter than the short text category of Webis-CPC-21. Various previous studies

4.1 Pre-Processing

The data cleaning process includes removing irrelevant punctuation and stop words, which are commonly used words such as 'a', 'in' and 'the'. There isn't a single list of stop words that applies to every NLP task; we use the stop words list constructed by NLTK (Natural Language Toolkit) in python. Additionally, the process involves converting all letters to a lower case, then lemmatizing each word.

4.2 Feature sets

Since we're interested in how different features perform on different categories of text length, we carry out experiments per feature (TF_IDF, Bleu metric, sen2vec and N-gram overlap) and with combinations on the original dataset, modified dataset, and the sub-datasets that consist of different text sample lengths.

4.3 Baselines

The ground truth on Webis-CPC-11 dataset is determined by [8], where the Precision (P) is 81, Accuracy (Acc) is 84, and Recall (R) is 90. Although F1 is not reported, we calculate it by equation (2), which results in a value of 85 for F1. These results are obtained in [8] by feeding 10 different metrics as features to the k-nearest neighbour machine learning algorithm.

$$F1 = \frac{2PR}{P+R} \quad (2)$$

applied a pre-trained word2vec with cosine similarity or soft cosine on MSRP [27]. In this work, we convert each piece of text into one vector by summing up all word vectors in the text. This means we consider the semantic substance of the text to represent the overall text meaning. This clearly brings high accuracy and F1 results on Webis-CPC-21. In general, the Sen2vec yields the highest F1 score on most of the categories and surprisingly N-gram overlap performs much better than expected.

5. CONCLUSION

In this study, we answered RQ1 and RQ2 by investigating how the length of a text effects the model results in terms of measuring the semantic similarity of two different texts and which features work better with sentence, paragraph, and passage length levels. From the present experiment's results, we show that paragraph length level can convey the semantic meaning of natural language text better than sentence or passage length levels.

Based on the results, we plan to build a new passage-level- paraphrasing dataset that consist of a paragraph-length level to

achieve our contribution. Then involve the state-of-the-art transformer models to detect paraphrasing.

Title: A Paraphrase Identification Approach in Paragraph length texts

I mainly work on Paraphrase identification downstream task as it important for other tasks such as plagiarism detection. These tasks could be solved by machine learning and deep learning approaches. The existing work done on sentence-length level and sentence-level paraphrasing while I focused on paragraph text length and passage-level paraphrasing.

In this year (1st year of my PhD), I implemented a study on how the length of text impact the model's results and submitted as a short paper for this conference. The experiment's results clearly show that the paragraph length level provides semantic meaning better than sentence or passage length levels. To expand my research and contribution, I plan to construct a dataset considering the text length and paraphrasing type to be in paragraph length level and passage-level paraphrasing as the existing dataset represent sentence-level paraphrasing.

I am seeking behind your recommendation, comment, opinion, and advice such on how to expand my research and What tool or approach I have to consider.

Investigating learners' Cognitive Engagement in Python Programming using ICAP framework

ABSTRACT

Introductory programming courses suffer a fate of high failure. Also, research has shown a significant relationship between engagement and academic success. Therefore, reliable and real-time engagement measures could help identify students who need help and provide them with personalised instruction. The present methods of measuring engagement rely primarily on self-reports that have reliability issues due to self-bias and poor recall and, at the same time, do not provide real-time and high granularity data. Interestingly, the online environments allow for real-time capturing of fine-grained interactions, which could be used to measure students' engagement and overcome the issues of self-report measures. The focus of our work will be cognitive engagement, which is a less explored dimension of engagement. To achieve this, we have developed an online learning environment called PyGuru for teaching-learning of Python. We propose to collect learner interaction data, classify these actions into different levels of cognitive-engagement, and study the impact of these different levels on their learning. We present the initial work done in this direction regarding the system developed and the data collected. We intend to seek advice on the validity and reliability of our approach to measuring cognitive engagement.

Keywords

Programming, Cognitive Engagement, PyGuru

1. INTRODUCTION

Research has demonstrated a significant relationship between engagement and educational outcomes like persistence, completion and achievement [7, 9, 18]. While student engagement is crucial to any learning experience, it is particularly important for domains like computer programming since introductory programming courses suffer a fate of high failure and dropouts and engagement as a construct can help in addressing this [2, 21].

D. Singh and R. Rajendran. Investigating learners' cognitive engagement in Python programming using ICAP framework. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 789–794, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

<https://doi.org/10.5281/zenodo.6852960>

The construct “engagement” has multiple unique conceptualisations. Kuh (2007) defines engagement as “participation in educationally effective practices, both inside and outside the classroom, which leads to a range of measurable outcomes” . Krause and Coates (2008) define it as “the extent to which students are engaging in activities that higher education research has shown to be linked with high-quality learning outcomes” [13, 14].

Engagement as a construct not only requires involvement but also feelings and sense-making [15] as a result, many theorists argue for a multidimensional definition of engagement. In literature, the various dimensions of engagement include academic, behavioural, emotional, affective, psychological, social, cognitive, and agentic dimensions [4, 8, 9, 11]. The focus of our work will be Cognitive Engagement(CE), because of two reasons. Firstly, as it has established research and a theoretical base that supports its significance in learning [3, 9, 10]. Secondly, CE has been less explored in the domain of computer programming [12]. Cognitive engagement is defined as the extent to which students are willing to invest in working on the task [5], and how long they persist [17, 19]. Similarly, as per Fredricks et al.(2004) “*cognitively engaged students would be invested in their learning, would seek to go beyond the requirements, and would relish challenge.*” [9].

Our research uses the framework developed by Chi & Wylie (2014). This framework classifies students' overt behaviours (like taking notes, asking questions etc.) into four different modes of engagement, namely interactive, constructive, active, and passive(ICAP)[3]. ICAP model, which was initially developed for classroom learning, has been extended to online learning as well [6, 16, 20, 22]. However, most of the existing studies in the online environment explore components such as video watching, DF, in pieces (i.e. they apply ICAP to only one of the online learning components like video watching, discussion forums, etc). This implies a lacuna of studies in a Computer-Based Learning Environment (CBLE) that study all these components together and hence, lacks an understanding of how students' behaviour in CBLE is related to their CE. Also, most studies that explore engagement in computer programming mainly focus on the motivational and behavioural aspect and not the cognitive aspect of engagement[12]. Hence, there is a need of analysing actions learners' perform in CBLE with all the existing components to better understand cognitive engagement and its impact on learning .

To fill the above gaps, we developed a CBLE called PyGuru for teaching-learning of Python programming that consists of four components: book-reader, video player, Integrated Development Environment(IDE), and discussion forum. This learning environment captures fine-grained data related to learning like highlights and annotations in the book-reader. Play, pause and seek behaviour and response to in-video questions in a video player. Views, comments, and likes in the discussion forum and their performance in IDE using test cases for each program.

In our research, we propose to use the interaction data generated to classify students' actions into different modes of cognitive engagement, namely Interactive, Constructive, Active and Passive (ICAP). We will then study the impact of these different engagement levels on students learning of computer programming. These results will help us develop models to measure learners' cognitive engagement and provide them feedback to prevent failure and dropouts.

In this paper, Section II presents the background and related works. The description of the learning environment and study design are provided in section III. Section IV offers a proposed solution, and the closing section contains questions for which we intend to seek advise.

2. BACKGROUND AND RELATED WORK

To analyze learners' interaction in the system, we will be using the ICAP framework developed by Chi Wylie (2014). This section consists of two subsections. The first one provides a brief introduction to the ICAP framework and the second subsection involves the related works that use the ICAP framework.

2.1 ICAP Framework

ICAP is a hierarchical framework that defines engagement in terms of students' overt behaviours and tries to distinguish these overt behaviours into four modes of engagement, namely interactive, constructive, active and passive[3].

They define passive mode as *"learners receiving information without overtly doing anything related to learning"* (Chi Wylie, 2014, p. 221). In this mode, learners simply attend to the information (without performing any actions like note-taking) and store it in episodic form rather than integrating it with prior knowledge.

Active engagement occurs when the learner's information acquisition is accompanied by certain physical or motoric actions that support their learning. This includes taking notes in the classroom, pausing and recap of the videos being watched or highlighting the text while reading.

The cognitive process involved during active engagement demands the activation of prior knowledge and integrating the new information into the existing one. Constructive engagement happens when the learners attempt to produce some artefacts using their prior knowledge and the information available in the environment. The characteristic feature of these artefacts is that they use information that goes beyond the available information. This includes "elaborating, comparing and contrasting, generalizing, reflecting on, and explaining how something works" (Chi Wylie, 2014, p. 228).

Interactive engagement occurs when learners engage in interaction, and during these interactions, both partners must be constructively engaged and there must be sufficient turn-taking.

2.2 Studies based on ICAP

Yogev et al. (2018) examined students' CE in reading material using Nota Bene annotation platform[22]. They firstly analyzed CE anchored in the text by manually labelling students' annotations and then developed an interactive decision tree to automate this process. They found that different sections of the text elicit different levels of CE. For instance, low CE corresponds to definitions provided in the text. They also developed a visualization tool to show the distribution of varying levels of CE over the reading material.

Acknowledging the absence of a framework for active viewing(active learning to describe students' behaviours while learning from video), Dodson et al. (2018) developed a framework to classify students' different video watching behaviours as per the ICAP framework which classified behaviours as passive(playing video content), active(replay, pause, seek specific information), constructive(taking notes, highlighting), and interactive (cooperating and collaborating with others) [6]. To fully support video-based learning, they used ViDeX in this study which supported a broader set of behaviours, as mentioned previously.

Wang et al. (2015) investigated students' contributions in the discussion forum participating in a MOOC[20]. They studied the relationship between the kind of posts students write and their learning gain. For this purpose, they considered each post as a sampling unit and coded each post into nine categories: active (note-taking, repeat, paraphrase), constructive (compare or connect, ask novel questions, provide justification or reason), and interactive (building on partner's contribution, acknowledging partner's contribution, defend or challenge). Their study shows a significant association between the discourse in the discussion forum and learning gains.

The study by Atapattu et al. (2019) tried to automate this process of classifying the post in the discussion forum into the active and constructive modes of engagement[1]. Their research included finding semantic similarities between each post and related course materials using cosine similarity. The posts significantly different from the learning materials were classified as constructive, and the more similar ones were labelled as active.

To summarise, we have presented how ICAP is used in book-reader, video-watching and discussion forums. These studies have influenced the design of our system PyGuru. Moreover, the results presented in these studies are promising and indicate a strong link between students' CE and their performance. It is, therefore, crucial to investigate how overall learning behaviour (actions in book reader, video player etc.) impact students' performance in Python programming. To understand this, we present PyGuru- a learning environment for learning Python programming capable of logging the user actions. The following section offers details about the system, study design, and the proposed solution.

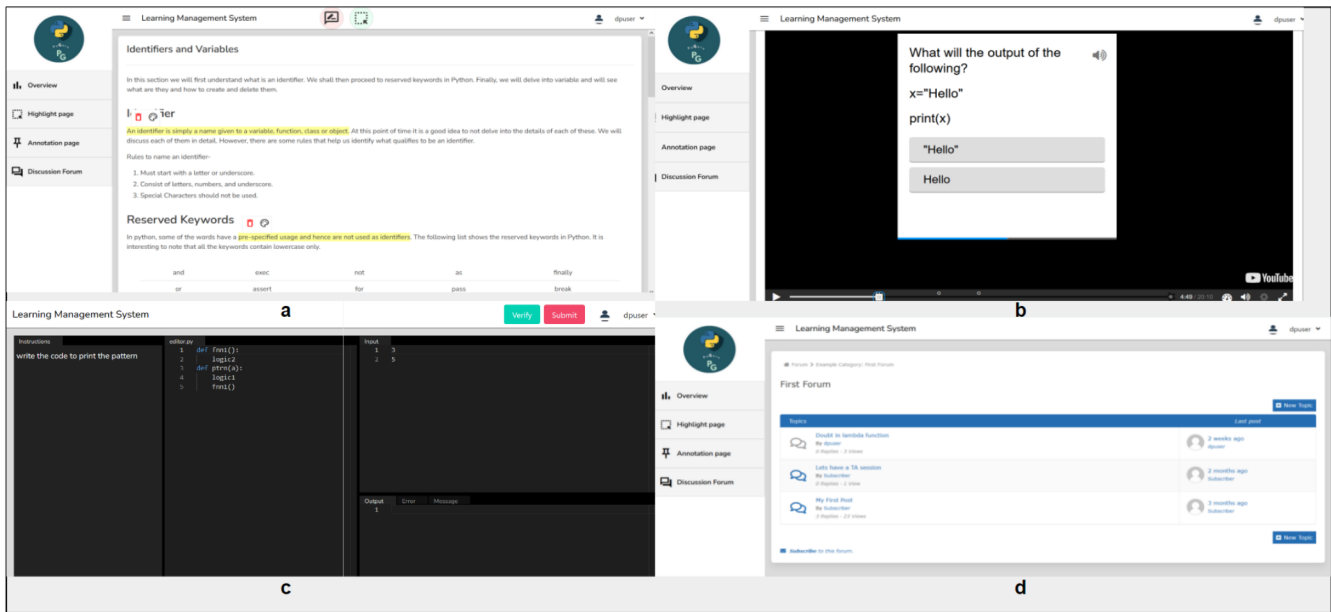

Figure 1: PyGuru Environment (a) Book Reader (b) Video Player (c) IDE (d) Discussion Forum

3. LEARNING ENVIRONMENT

PyGuru¹ is a computer-based learning environment for teaching and learning Python programming skills. PyGuru has four major components: 1) Book Reader 2) Video Player 3) Integrated Development Environment (IDE) 4) Discussion Forum.

A book reader (shown in Fig 1. a) in PyGuru allows readers to highlight and annotate the text. Highlight in the digital context consists of selecting a text and colouring it. The annotating feature in the learning environment comprises selecting a text, commenting on that text, and providing a tag to that text.

PyGuru has an interactive video watching platform (Fig. 1.b). The students can interact with the video using basic video player features like enhancing the speed of the video and performing other actions like play, pause and seek. More advanced interactive features are embedded into the system that allows the instructor to add questions within the video. The video automatically stops and waits for the learner's response.

We also have integrated an IDE (Fig 1. c) in PyGuru. Currently, the IDE evaluates the learners' code against the test cases. The "verify" button in the IDE allows learners' to check their program for errors and test cases before submitting. The IDE consist of four panels 1) Instruction Panel -To provide details about the problem or algorithm 2) Input Panel - To provide the test cases for the problem, and these test cases are tested against these inputs 3) Coding Panel - The coding panel is where the student is expected to write the code, and the instructor can present some partial codes as well 4) Output Panel - To display the output once the program is run and provide information about the number

¹<https://tinyurl.com/2p8h6zpw>

of test cases passed and failed.

PyGuru has a discussion Forum (Fig 1.d). The learners can use this discussion forum to put forth their queries which the instructor or their peers can then answer. They can also respond and hit like on the post made by their peers or instructor.

4. METHODOLOGY

The study is focused on investigating learners' cognitive engagement in a CBLE, designed for teaching and learning of Python programming. We decided to use ICAP framework not only to design the system but will also use it to analyze learners' interactions in PyGuru. The aim is to answer the following questions: 1.1 Is there a relationship between log data of student activity in CBLE and self-reported student engagement survey scores? 1.2 Is there a relationship between actions that are believed to represent higher cognitive engagement and learning gains? 1.3 How do learners' actions having different learning gains differ in a CBLE while learning computer programming?

4.1 Study Design

The study participants will be students from undergraduate colleges or diploma colleges located in developing countries (India and Malaysia). The duration of the study will be 3-5 weeks. During this time the learners will be interacting with the system to learn programming by reading content, watching videos, and coding on IDE. One week prior to the study, learners will be introduced to the system. Along with this a consent form, demographic survey and a pre-test will be administered. This pre-test will be designed by the instructor and on similar lines a post-test will be designed to measure learning gains. Student engagement will be measured using the 7-item activity-level student engagement survey (Henrie et al. 2016). From this survey,

we will only consider items corresponding to cognitive engagement. Log data from the PyGuru will be collected for all participants. The log data consists of the user id, session id, timestamp, page id, and other details like the action performed (e.g. highlighted or annotated) and the context information (the text highlighted).

4.2 Proposed Solution

We propose to investigate cognitive engagement in CBLE using log-data. At this point, there are two directions. One is to do a correlation analysis with the engagement scores obtained through engagement surveys and identify whether the data captured from logs could be used as a proxy for cognitive engagement. The second one is to use a data-driven approach to identify the characteristics of students with higher learning gains using descriptive and diagnostic analytics. Further, using the findings obtained from descriptive and diagnostic analytics to develop regression models to measure cognitive engagement.

5. ADVICE SOUGHT

Q1. Are the system's design and the data captured suitable for measuring engagement?

Q2. Since we plan to develop regression models for measuring engagement using learning gains. Is this proposed approach valid? Also, what are other ways to validate our measures other than self-report or teachers' ratings?

Q3. What are the general suggestions regarding the study design in terms of duration of the study, the data collected from the environment, etc.?

6. ACKNOWLEDGMENTS

I would like to thank Ashwin TS, Deepak Pathak and Ruma Pathan for useful discussions and their support. This paper is based upon work supported by the grant from Council of Scientific and Industrial Research(CSIR).

Supervisor: [Prof. Ramkumar Rajendran](#)

Title: Measuring learner's Cognitive Engagement in Python Programming using log-data

Introduction: I am Daevesh Singh, a third year research scholar at the Educational Technology Department, IITB. My research area is educational data analytics. All my research work till now has been focused on using log-data from learning environments and their analysis. Some of my published works include-

1. Nishane, I., Sabanwar, V., Lakshmi, T. G., **Singh, D.**, & Rajendran, R. (2021, July). Learning about learners: Understanding learner behaviours in software conceptual design TELE. In *2021 International Conference on Advanced Learning Technologies (ICALT)* (pp. 297-301). IEEE.
2. Satavlekar, S., Nath, D., Priyadarshini, R., Prasad, P., **Singh, D.**, & Rajendran, R. (2021, July). Unraveling Learner Interaction Strategies in VeriSIM for Software Design Diagrams. In *2021 International Conference on Advanced Learning Technologies (ICALT)* (pp. 308-310). IEEE.

About Thesis: My PhD thesis is focussed on measuring cognitive engagement using log-interaction data. The domain includes introductory programming. The study will involve diploma or undergraduate students that are learning Python as a part of their curriculum from the Indian Subcontinent (Mostly India and Malaysia) . For this purpose, we have developed a Computer Based Learning Environment called PyGuru. PyGuru consists of four components, namely the book-reader, video-player, Integrated Learning environment(IDE), and discussion Forum and the environment logs all the interactions made by the learner. We plan to use this data to come-up with meaningful measures of cognitive engagement.

EDM researchers:

1. Neil Hefferman - Neil's research involves computer-based learning environments and engagement.

2. Tanja Mitrovic - Tanja's work in active video watching could be helpful since my environment also has an interactive video player.
3. Sharon Hsiao - Sharon's work includes the use of learning analytics in the domain of computer programming.

Improving Automated Assessment and Feedback for Student Open-responses in Mathematics

Sami Baral
Worcester Polytechnic Institute
sbaral@wpi.edu

ABSTRACT

Advancements in online learning platforms have revolutionized education in multiple different ways, transforming the learning experiences and instructional practices. The development of natural language processing and machine learning methods have helped understand and process student languages, comprehend their learning state, and build automated supports for teachers. With this, there has been a growing body of research in developing automated methods to assess students' work both in mathematical and non-mathematical domains. These automated methods address questions of two categories; closed-ended (with limited correct answers) and open-ended (are often subjective and have multiple correct answers), where open-ended questions are mostly used by teachers to learn about their student's understanding of a particular concept. Manually assessing and providing feedback to these open-ended questions is often arduous and time-consuming for teachers. For this reason, there have been several works to understand student responses to these open-ended questions to automate the assessment and provide constructive feedback to students. In this research, we seek to improve such a prior method for assessment and feedback suggestions for student open-ended works in mathematics. For this, we present an error analysis of the prior method "SBERT-Canberra" for auto-scoring, explore various factors that contribute to the error of the method, and propose solutions to improve upon the method by addressing these error factors. We further intend to expand this approach by improving feedback suggestions for teachers to give to their students' open-ended work.

In the past decade, development in artificial intelligence and machine learning methods have led to advancements in online learning platforms, transforming learning experiences and teaching practices. From personalized learning to augmenting teaching processes through automated assessment methods [8, 2, 4, 14, 11, 1], the benefits of these platforms have been significant. With this, several prior works have leveraged machine learning methods and natural language processing-based techniques to automate the assessment of students' work, both in mathematical [10, 6] and non-mathematical domains [13, 15]. As these methods and models of student learning become deeply integrated into normal instructional and educational practices, it becomes increasingly important to understand the strengths and weaknesses in their application. Within this, it is important to not only identify areas where existing methods under-perform, but it is also important to develop methods to improve such models to alleviate risks to fairness.

In the domain of mathematics there have been several works to automate assessment and provide constructive feedback to students, to further increase the efficiency of teaching and help teachers guide their focus to students in need. These works address problems of two categories: close-ended and open-ended problems. For close-ended problems, that have a finite number of correct answers, these auto-scoring methods can apply simple matching techniques to compare the student answer with the list of correct answers and consistently achieve near-perfect accuracy. However, open-ended problems are subjective with multiple accepted correct answers and are mostly given in the form of natural language. For these types of responses teachers commonly assess students based on an explicit or implicit rubric that pinpoints key aspects that must be included in a student response to sufficiently demonstrate their understanding. In addition, these types of student responses in mathematics often are a combination of language, images, tables, or other mathematical expressions, equations, and terminologies, which poses a challenge in developing automated methods of assessment for these problems. Due to the numerous challenges that this poses to automated assessment, existing methods commonly apply natural language processing (NLP) to build a high-dimensional representation of student responses that is then combined with various machine learning approaches (e.g. [13, 15, 3, 5]).

In this paper, we observe one such prior works on automated assessment model of student open responses in mathemat-

ics based on sentence-level semantic representation of the student open responses: "SBERT-Canberra" method. With the goal of exploring the limitations and further improving the method for assessment, we discuss our prior study that applies an exploratory error analysis to identify the areas of improvement that may be addressed by future iterations of these methods. We further propose a simple solution to improve upon the SBERT-Canberra method for automated assessment by addressing one of these error factors, that is the presence of mathematical terms and expressions in student answers. Additionally we seek to explore and address other factors of error to further improve the SBERT-Canberra method for auto-scoring. Finally we also intend to improve and expand this work towards feedback recommendations for student open-responses in mathematics.

2. PRIOR WORK

For this research, we observe one of the prior works on automated assessment of student open-responses in mathematics: the "SBERT-Canberra" model. This method follows a simple similarity-ranking procedure to generate the score predictions based on Sentence-BERT (SBERT) [12]. When suggesting a score for a given student response, it first applies SBERT to generate a high-dimensional feature embedding that describes the response as a whole. The intuition behind this is to capture semantic and syntactic meaning within this embedding, such that similar responses would be mapped closer within the embedding space. The SBERT embedding for this new student response is then compared to SBERT embeddings corresponding to a pool of historic labeled student responses utilizing the canberra distance measure [9]. In the final step the score for the historic response corresponding to the smallest distance (i.e. the most similar response) is used as the score prediction. The intuition behind this method is that similar answers to the a problem would have the same score.

3. CURRENT WORKS

3.1 Error Analysis of Auto-Scoring Method

With the goal of exploring the limitations of the SBERT-Canberra approach in order to identify the areas where the model does well and where it may yet improve through future iteration, we conducted an exploratory error analysis of the method. The dataset for the analysis was collected during the pilot testing of a teacher-augmentation tool designed to aid the assessment of open-responses within the ASSISTments[7] online learning platform. This tool, called QUICK-Comments used the SBERT-Canberra model to predict the scores for student open-responses in mathematics. Toward the error analysis, we observe two regression models that observe absolute model error as a dependent variable. The absolute model error here is the absolute difference between the score predicted by the SBERT-Canberra model and the teacher assigned grade for a particular student answer.

3.1.1 Uni-level linear model

For the uni-level model we explore characteristics of student answers in the context of this modeling error. These answer-level features are composed of length of answer, average character per word in the answer, total nos. of numbers, and operators in the answer text, percentage of mathematical expression in the answer text, and presence of images.

The results of the error analysis are presented in Table 1. It is found that the uni-level linear model with student answer level features explains 38.6% of the variance of the outcome as given by r-squared. Out of the six student answer-level features, nearly all were found to be statistically reliable predictors of model error. However, only two of these variables: Equation Percent and Presence of Images were found to have more meaningful coefficient as compared to other features. This suggested that the presence of mathematical expressions and images(unsurprisingly) both correlate with higher prediction error.

3.1.2 Multi-level linear model

Similarly, we then apply a multi-level model to observe which of student-, problem-, and teacher-level identifiers most explains any observed modeling error. In regard to this, accounting for student, problem, and teacher identifiers each as random effects, we see that the inclusion of these level-2 factors explains some of the impact of the fixed effects (Table 1). It is worth noting that the level-2 variables account for 55.5% of the variance of the outcome. This suggests that a majority of the modeling error can be explained by the factors external to the student answers. Looking at the variance of the random effects, it can be seen that the problem level identifiers contribute most in terms of explaining the variance of the outcome.

3.2 Improving the Auto-Scoring method

With the results from the error analysis of the SBERT-Canberra method for auto-scoring, next we seek to improve this approach addressing for the factors that contributed to the modeling error. We know from the error analysis that one of the limitations of the SBERT-Canberra method in predicting the scores is in the presence of mathematical terms and equations in the student answer. To address this limitation, we propose the "Math Term Frequency" (MTF) model, drawing inspiration from assessment methods applied for close-ended problems. The goal of this method is to learn about the mathematical terms present in student answers and supplement this method to the previously developed SBERT-Canberra model through ensembling. For this, first we identify non-linguistic terms in students answers, and then identify the most frequently-occurring terms for each possible integer score to learn a kind of rubric. These most frequently occurring non-linguistic terms are then used to develop the features for this method. These features indicate whether a newly-observed student response contains any of the most frequent terms most commonly associated with each given score. They are finally used in a multinomial logistic regression (treating each score as an independent category), trained separately for each problem.

The score predictions from the MTF model are then ensembled with the SBERT-Canberra predictions using another logistic regression model, referred to as the SBERT-MTF model; to clarify, this ensemble regression model observes ten features corresponding to the probability estimates produced for each of the five possible scores for each of the two observed models. The goal of this is to combine the semantic representation captured by the SBERT method, while taking advantage of the non-linguistic term matching from the MTF method.

Table 1: The resulting model coefficients for the uni-level linear regression model and random and fixed effects of the multi-level linear model of absolute error for auto-scoring method.

	Uni-level Linear		Multi-level Linear	
	Variance	Std. Dev.	Variance	Std. Dev.

4. FUTURE WORKS

In this research, we have identified areas where more advanced methods of image processing and natural language processing (or math language processing), may lead to further improvements in the existing methods for automated assessment. We have proposed a simple solution to address the limitations of current scoring method in presence of non-linguistic terms in student answers. While this proposed solution is an initial step towards addressing mathematical terms in these NLP based methods, we intend to explore more advanced methods based on Mathematical language processing and MathBERT to address such issues in future.

Further, we believe this method can be extended to recommend feedback messages in addition to suggesting numeric scores. With this, the next steps in our research is to expand the existing methods in suggesting and generating directed feedback to these student answers. We believe that the proposed MTF method combined with SBERT-Canberra can be extended as a prediction task in predicting whether given student responses are similar or not. This could be further beneficial in finding similar answers to math open-ended questions and thus utilizing this in improving the feedback recommendation task.

While the current works are based on textual open-ended responses, there are other forms of open-ended responses in mathematics including drawn diagrams and graphs, hand written formulas and expression uploaded as images, and other forms of audio and video responses. We seek to expand this research to these other forms of student open-ended responses, and further study the feasibility in deploying these automated methods in a computer-based learning environment.

ABSTRACT

Online learning has been spreading with the increasing availability and diversity of digital resources. Understanding how students' cognitive load and affect changes when using learning technologies will help us decipher the learning process and understand student needs. In this research, we focus on modeling learner's cognitive load and affect using real-time physiological reactions. We explore what affect modeling contributes to the modeling of cognitive load, and how real-time cognitive load changes alongside learning activities. We want to further investigate if cognitive load modeling helps diagnose learner knowledge and facilitates improvement. We have designed two case studies: one where students are learning python with an e-learning system and another where they are practicing literacy skills with a web-based learning game. To collect learner data, we have implemented a sensing prototype consisting of an eye tracker and a wireless wristband.

Keywords

Student modeling, Cognitive load, Affect, Online learning.

1. INTRODUCTION

The cognitive processes that underpin information processing and knowledge construction in learning have gained increasing attention from educational researchers. Prior studies have found cognitive load has a complex relationship with learning performance [22]. Models like cognitive load theory (CLT) [24, 33] have been used to explain the learner's cognitive process. How student cognitive load reacts when dealing with an abundance of information is a key component of learning performance. While previous research has shown the impact of cognitive load on learning outcomes, the exploration of its real-time changes when learners use online educational technologies has not yet been fully conducted. Moreover, the diversification of how learning materials are presented and changes in the corresponding learning methods suggest a need to explore their impact on learner cognitive load.

Although CLT effectively represents learner processing, some have argued that it fails to fully explain learning performance [21, 24]. Recent research has suggested people's affective reactions might contribute to changes in their cognitive load during learning given the role that affective states seem to play in learning [10]. Neuroscience research has suggested that the brain mechanisms

M. Cai and C. D. Epp. Modeling cognitive load and affect to support adaptive online learning. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 799–804, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

<https://doi.org/10.5281/zenodo.6853020>

underlying affect and cognition are not fundamentally different [18]. The potential interactivity between affect and cognitive load [9, 11, 16] suggests that there may be value in jointly modelling these constructs.

Previous learner modeling studies using cognitive load mostly focused on supporting adaptation (e.g., feedback [6], problem selection [17]) to improve student performance. We argue that by including learner affect alongside their cognitive load, learner modeling has the potential to help improve learner's experiences while supporting effective learning.

In this thesis project, we explore the potential of modeling students' real-time cognitive load when using online educational tools to support adaptive learning experiences. We highlight a learner's affective reactions and their contributions to cognitive load, as one of the areas that has not been sufficiently considered in previous student modeling studies. Based on recent research in cognitive processes in learning, we believe a learner's cognitive load is affected by the difficulty of tasks and the sequence of learning units so it can change alongside the learning process.

To achieve our goal, user studies across different educational domains will be conducted. The online learning environments include one that supports learning to program in python and an edu-game for supporting literacy development. A sensing platform has been built to collect and synchronize different types of learner physiological data. Multimodal analysis will be conducted to detect learner cognitive load and affect. The modeling of cognitive load will be used for predicting the learner's knowledge in each domain.

2. RELATED WORK

2.1 Cognitive Load and Affect

CLT is widely used. Its application in educational design to enhance instruction has supported the learning of children, teens [35], and older adults [23, 38] in a wide variety of domains. CLT is grounded in an understanding of the human cognitive architecture that is supported by previous research on working memory models [2] and mental effort [31].

There are three types of cognitive load. Intrinsic load (IL) is the inherent difficulty of what needs to be learned and should be managed so it does not exceed the capacity of working memory. Extraneous load (EL) is unnecessary load that does not support learning [20, 34]. It is usually caused by specific learning activity or system designs. The third kind is germane load (GL) which refers to the mental resources devoted to acquiring and automating schemata.

CLT can help understand student's learning patterns and provide guidance for adaptive learning design. However, we expect that it will not be enough to model the cognitive load of students since recent neuroscience research has shown the interconnectedness of

affect and cognition despite earlier theories that posited the processes were separate [26]. Studies suggest that cognitive and affective behaviors have rich interactions and some argue that emotions arise from the same general cortical system that processes cognition [18]. These findings support the joint inclusion of affect and cognitive load within learner models.

While research on the connection of affect and learning has been performed for a long time [37], many studies have explored affect without considering its implication on cognitive load. For example, previous research on negative emotions argued students experiencing longer periods of boredom tended to have lower scores than those experiencing positive emotions [7]. However, the type of negative affect is important; students might have better learning performance when given erroneous examples even though those examples produced confusion and frustration [5].

While some argue the interrelatedness of affect and cognition, there is no consensus on how to incorporate affect into cognitive load modeling. Some argue affect could increase extraneous cognitive load because emotion regulation may add non-task-related processing that consumes extra cognitive resources [12]. Others have suggested that affect could be considered beneficial as it can foster motivation so that learners invest more cognitive effort [14]. Even negative emotions could motivate learners to turn to learning for shifting their attention away from their negative emotional states [4]. In this thesis project, we would like to recognize a student's affective reactions in the context of computer-supported online learning and seek to investigate how affect contributes to learner cognitive load in these settings.

2.2 Measurement of Cognitive Load & Affect

To achieve our goal, appropriate data collection and modeling approaches must be selected. Commonly used methods include subjective rating scales as well as task- and performance-based methods. According to Paas and van Merriënboer's work, cognitive load can be assessed using aspects of mental load, mental effort, and performance [25]. Subjective rating scales have been widely used and are grounded in a belief that people can reflect on their cognitive processes and report the amount of mental effort expended. The NASA task load index (NASA-TLX) is one instrument that attempts to capture this type of information [13]. However, it might not be able to measure unconscious and automatic processes. Task-based and performance-based methods have also been commonly used to measure cognitive load by measuring reaction time or accuracy on a secondary task. Although monitoring such tasks itself requires few cognitive resources, their use may interfere with the primary task when a reaction is necessary [8].

As the nature of questionnaires and performance evaluation implies, the above two methods rely on data collection after an experiment, which fails to support continuous monitoring. Brain-activity-based methods such as electroencephalography (EEG) have been used for identifying changes in cognitive load [1]. This measurement approach requires wearing complex instruments that are obtrusive to users. More recently, with advances in sensing technologies, physiological-data-based methods have presented the potential to address this issue. Eye-tracking technology is one of these sensors that can now be worn like a pair of glasses. This sensor provides information about pupillary response, which is considered a reliable source that enables the investigation of cognitive processes. One project found that pupil diameter changes indicated visual presentations that induced lower cognitive load in a math-education context [15]. More generally, increased cognitive load has been associated with increases in pupil diameter due to

decreasing parasympathetic activity in the peripheral nervous system [3].

In addition to estimating cognitive load through dynamic pupillary information, research has shown that user's gaze trajectory data can be reliable for quantitatively measuring reading behavior. For example, eye-gaze data has been used to infer user cognitive style in reading activities [28] and the impact of distractions on surgeons' intraoperative performance [32]. Such visual information is the key to investigating learner attention patterns and strategic processes.

In the context of affect measurement, three groups of tools are commonly used: psychological (i.e., self-reported), physiological, and behavioral [39]. While psychological methods often depend on respondents' ability to consciously process their affective responses, physiological methods allow researchers to capture non-conscious aspects. Physiological arousal data, such as Electrodermal activity (EDA) and skin temperature, are considered to provide robust signals for measuring affect [29].

In this thesis project, we incorporate questionnaires and physiological tracking including eye-tracking data, cardiovascular responses, and EDA data for cognitive load and affect measurement.

3. RESEARCH QUESTION & APPROACH

Considering the research problem mentioned above, the overall goal of this thesis is to *model students' cognitive load and affect across instructional domains*. To address this goal, case studies will be conducted to collect learner data, including their performance and reactions to learning activities. Models will then be developed using the collected data. Across this work we will answer the following questions.

- Q1 What does affect modeling contribute to the modeling of cognitive load in online learning settings?
- Q2 How does learner affect and cognitive load change alongside their learning when interacting with educational systems?
- Q3 Can affect and cognitive load help in identifying a learner's knowledge state and trajectories?

To answer these questions, we have designed and will conduct lab-based case studies. Two case studies will be performed with different educational technologies: one is used to teach undergraduate students how to program and the other helps students improve their reading comprehension.

3.1 What does affect modeling contribute to the modeling of cognitive load in online learning settings?

We would like to investigate the added benefit, if any, of jointly modeling affect and cognitive load so we can determine what affect contributes to learner cognitive load modeling.

Considering the dynamic, sequential nature of cognitive load, we will use hidden Markov models (HMM) to model learner's cognitive load. An HMM approach demands that the system has observable evidence that suggests the value of a hidden state. We will use the physiological reactions as observable signals to estimate the hidden cognitive load state.

We will compare the performance of estimating intrinsic and extraneous cognitive load using physiological features, i.e., pupil dilation (PD) and heart rate against the performance of estimating

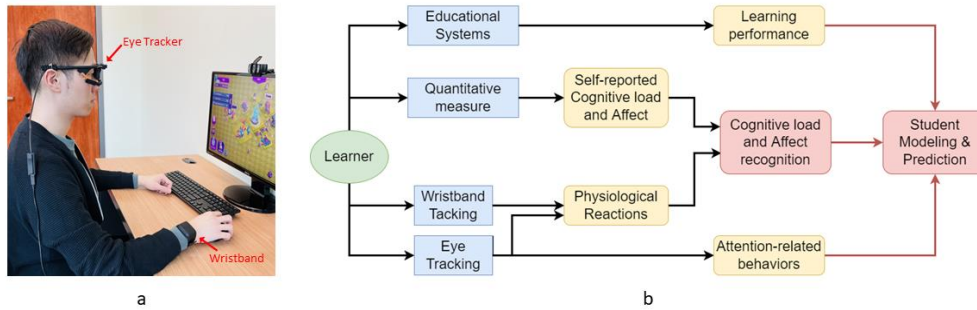

Figure 1. Study Overview: (a) shows the device set up and (b) shows the overall process

these loads when also including EDA data. Participant responses to affect and cognitive load scales will be used as a reference.

For the pupil data, we will use changes in PD instead of its absolute value as a feature to eliminate the influence of individual differences on model training. In a preprocessing step, we will calculate PD values as proportion change, by dividing pupil size by the grand mean PD size during the baseline period averaged across all attempts.

3.2 How does learner affect and cognitive load change alongside their learning when interacting with educational systems?

We will investigate the dynamics of cognitive load and affect across learning activities with a focus on what contributes to changes in cognitive load and affect. We are especially interested in understanding how the learning activity sequence and user interface design contribute to these latent states.

We would like to compare the continuous reactions of cognitive load and affect with information from learner behaviors and performance with educational technologies. Learner's interaction and learning performance information (i.e., score, task completion) will be extracted from the learning systems. Learner behavior data will come from two sources: the learning system's logs (i.e., keyboard input, buttons clicked, questions answered) and eye tracking (i.e., gaze point and trajectory).

We will investigate what kinds of information contributes to increasing cognitive load or changes in affect by comparing the eye information actions obtained by students at critical moments (the moment when cognitive load or affect change).

Ideally, we will compare the cognitive load and affect levels of students who had similar achievements. This analysis will be done across their learning session(s) to explore whether there is a specific pattern among them.

3.3 Can affect and cognitive load help in identifying a learner's knowledge state and trajectories?

We will use the models developed under section 3.1 and 3.2 to help predict a learner's knowledge and how it changes during learning. To answer this question, initial experiments will be conducted to predict a learner's knowledge level. The prediction of this information can be important for providing suitable learning materials and learning sequences. As an initial step, we will evaluate two approaches: one heuristic with collaborative filtering (CF) and the other machine learning (ML) using engineered features. Based on

the initial results, further experiments will be performed to identify changes in learner knowledge or mastery.

4. PROGRESS TO DATE & PLAN

So far, we have implemented our sensing platform and designed two case studies. The proposed case studies have been approved by our institutional Research Ethics Board (REB), and we have begun piloting the first.

4.1 Sensing System

In our literature search, we noticed there is no integrated sensing system to allow us to easily collect multiple types of learner physiological data. In this project, we choose multimodal analysis to support the recognition of cognitive load and affect. Thus, we need a sensing platform that enables us to collect and synchronize a learner's physiological features automatically. This generates databases of learners' physiological reactions that can be used to extract their cognitive load and affect characteristics. Our approach focuses on modeling with two dimensions of real-time physiological information: pupil dynamics collected by an eye tracker and cardiovascular and EDA data from non-invasive wearable sensors. As mentioned in Section 2, previous studies have shown the possibility of using pupil dynamics and electrodermal activity to investigate the continuous monitoring of cognitive load. These types of data have also been used to recognize state-based affect.

We developed our sensing platform that allows subjects to remain relatively comfortable (Figure 1-a). The platform consists of two non-invasive sensors and a software system that facilitates the synchronization of data from different channels. The first sensor is an open-source eye tracker (Pupil Core, Pupil Labs), which records dual eye movements at 200 Hz and includes gaze tracking and pupillometry. It is worn like normal glasses and consists of a scene camera that records what the user sees. The second sensor is a wireless wristband (E4, Empatica Inc.), which is worn as a wristwatch and connected via Bluetooth. The wristband includes photoplethysmography (PPG), electrodermal activity (EDA), skin temperature, and accelerometer sensors. The PPG sensor is used to measure blood volume pulse (BVP) which can then be used to calculate heart rate.

As these time series data come from different sources, they need to be synchronized to enable analysis. For this purpose, we have developed a system based on an open multi-model recording framework – Lab Streaming Layer (LSL). This system will be used to support real-time data streaming, synchronization, and recording with a laptop.

4.2 Case Studies

According to what we discussed in Section 3, our case studies will collect three types of learner data (Figure 1-b): (a) physiological

data from the sensing system, (b) self-report measures, and demographic information from questionnaires, and (c) learner interaction and performance from the learning system.

4.2.1 Experiment procedure

The experiment will take approximately 90 minutes. Sensor calibration will follow consent. Participants will interact with a specific e-learning system for approximately 60 minutes. Sensors will be used to collect learner data as they perform learning tasks in the system. Self-report instruments for measuring affect and cognitive load will be administered every 5-10 minutes. Demographics will be collected at the end.

4.2.2 Learning environments (LE)

The first study (S1) will be conducted when students are learning programming using the Mastery Grids e-learning system within our lab (Figure 2). This system visualizes learner progress and provides multiple types of interactive learning activities. An explicit, visually rich representation with social comparison helps students track their activities alongside those of their peers. Interactive learning content with feedback helps students practice and makes them aware of the knowledge they are expected to learn.

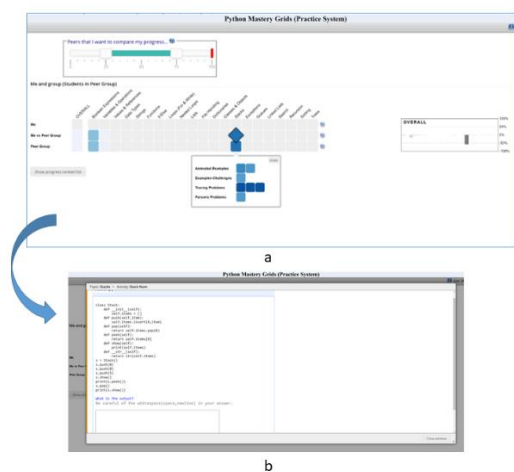

Figure 2 Online learning portal for python learning: (a) visualization of individual learning progress and social comparison (comparing the percentage of attempted units) and (b) a programming task with feedback.

Figure 3 In the strengthening of their role in the virtual game world, learners are motivated to solve reading tasks with appropriate difficulty levels: (a) game interface, (b) a passage, and (c) an English-language arts question.

The second study (S2) will be conducted when learners are using a web-based online learning game (Figure 3). It engages players to enhance literacy skills for English learning using a popular base-building game design. Players pretend to be in the realm of dreams and are tasked with defending their virtual home from invading “reveries” (in-game creatures). The game combines the strategy and engagement of the game factors with passage reading and comprehension tasks to create an interactive learning experience.

4.2.3 Participants

Different people will be recruited for each case study. The target participants in S1 will be 35 undergraduate students registered in an introductory computer science course that teaches how to program in python. The target participants in S2 (n = 35) will be students registered in an English as an additional language course.

4.2.4 Self-reported measures

In this project, self-report information will be used as verification of our sensor-based measurement. We follow the definition of CLT [33], dividing cognitive load into three types: intrinsic, extraneous, and germane. Based on prior work [19], we developed Likert-scale items to measure all three types of cognitive load.

Affect has been defined in many different ways, and no generally agreed upon definition has emerged [26, 27]. We follow Russell’s model [30] that describes affect in two dimensions – arousal and valence. We adopt an established scale – the international positive and negative affect schedule short-form (I-PANAS-SF) [36] to measure both the positive and negative affect of learners.

We will collect participants’ demographic information using a questionnaire at the end of the study session. In addition to basic information (e.g., age, gender) we will collect information about participants’ programming background for S1 and language-learning background (e.g., mother tongue, IELTS/TOEFL scores) for S2.

4.3 Future Work

In conclusion, we have implemented the sensing prototype and designed the case studies that will collect learner data for student modeling. We will conduct the case studies and perform the modeling work.

If modelling cognitive load and affect better explains student learning trajectories, we will incorporate these models so that they inform system adaptation, thus optimizing student learning experience and performance.

5. ACKNOWLEDGEMENTS

This work is supported in part by funding from the Social Sciences and Humanities Research Council of Canada and the Natural Sciences and Engineering Research Council of Canada (NSERC), [RGPIN-2018-03834].

ABSTRACT

We present a new dataset which captures the sentiment and thoughts of applicants to an industrial IT training course in relation to *technology careers* and in relation to *technology usage*. The dataset is live and capturing over 2,000 new applicants' data each week, from 12 countries, and contains a wide range of diversity information such as *gender*, *ethnicity*, and *sexuality*. The applicants are almost all a similar age, career status and education status, thereby limiting the demographic variables in the dataset.

This dataset has been created in collaboration with a technology consulting firm for use in this PhD research into increasing diversity and equity in technology careers and training. Research into how people from different demographics think about technology careers and technology usage and these topics side-by-side will be facilitated by this dataset. It is intended that relevant findings from the research will be applied at the technology consulting firm to increase equity and diversity.

The data are anonymised during the upload to the dataset and the data provenance is achieved through each upload being controlled, audited and fully repeatable.

It is the intention that a version of this dataset will be made public.

Keywords

Diversity, technology careers, public dataset.

1. INTRODUCTION

The substantial research into the low uptake of technology careers amongst underrepresented groups agrees that the representation of these groups in technology careers remains too low and has changed little despite considerable effort to try to affect change[6, 20, 25]. Use of technology such as internet and smartphones is now widespread across all demographics in society[27]. Research has shown that the diversity of users of technology has evolved, and, in the USA and Europe, we are in the third phase of the Digital Divide[27].

We have observed from working with the graduates who join the technology consultancy's training programme that they show confidence with and ownership of their technology, whether

mobile phone or Personal Computer (PC). This is often at odds with the lack of confidence with which they speak about the prospect and challenge of being active in creating and building technology.

This research will use ML/AI, sentiment analysis and Natural Language Processing (NLP) to understand patterns in the sentiment of different groups in society, including underrepresented demographic groups, to technology use and to technology careers and investigate whether this contributes to the continued absence of diversity in people in technology careers. Our focus will be an application of these ML/AI, sentiment analysis and NLP techniques and tools to the dataset gathered from the recruitment process of a global technology consultancy and enhanced with free text responses. The dataset will be extended by ~100,000 rows each year through the normal volume of applications for the training programme. Alongside analysing data patterns in sentiment across different groups in relation to both technology usage and technology careers, we will also examine the evolution of sentiment amongst graduates who are undertaking the consultancy's training for a career in technology.

This paper describes the **Graduate Technology Applicant Dataset (GTAD)** which contains the applicants' diversity data as well their free text responses to questions related to their thoughts on *technology usage* and *technology careers*. The diversity data includes, but is not limited to, *gender*, *ethnicity*, *age*, *school type*, *sexual orientation*, and whether the applicant was the *first in their family to go to university*. The questions have been designed to allow the respondent to write freely about their thoughts at the time of application. Growing at around 2,000 records per week and covering applicants from 12 countries, GTAD also receives around 2,000 responses to the free text questions each week.

This paper describes how the data provenance is maintained and gives some preliminary research findings using statistical methods, sentiment analysis and text analysis tools. The paper outlines a version of GTAD which could be made publicly available in the future.

RQ: Are there differences in perception of technology careers and technology usage for different demographic groups (e.g., women compared to men, 'pale and male' respondents compared to everyone else) which can be modelled?

To be able to address this question, the following objectives (Ox) have been defined:

O1: Create GTAD, collecting long text perceptions on technology careers and usage. As the related research shows, there is an absence of such datasets in the literature. In this paper, we mostly focus on objective O1 and how we create this dataset.

O2: Design experiments related to the demographics targeted, using the dataset created in O1. Preliminary results of some initial experiments are also outlined in this paper.

2. RELATED RESEARCH and WORK

The lack of gender diversity in technology careers has been an active area of research for many years[17, 21, 24], wherein it is agreed that the composition of the technology workforce does not reflect the diversity in society[6, 20]. The findings of Spertus [17] in 1991 in relation to women in IT, such as lack of role models, male-dominated work culture, and lack of workplace flexibility, were repeated in many of the 213 entries in Trauth’s Encyclopedia of Gender and IT[22] in 2006 and are found in Vainionpää’s work [23] in 2021, with much of the literature reporting findings from interviews and surveys of modest sized groups of people from specific, common demographics. Our research adopts a new approach of researching technology career perceptions using analysis of a large, tailored dataset of long text responses from multiple demographic groups.

Van Dijk notes that research into the digital divide doesn’t agree on a model but does agree that the digital divide is changing and his research agrees with Marler and the Office for National Statistics that the uptake and use of technology has diversified considerably and is more widespread [10, 19, 27]. This suggests that perceptions of technology usage have evolved, unlike perceptions of technology careers, which is why we are collecting perceptions on both topics for side-by-side research.

In terms of methodology useful for researching demographic perception diversity in technology careers, there is substantial research into NLP and sentiment analysis to analyse large bodies of data as described in the comprehensive survey by Pang and Lee in 2008[11] and in the scholars’ introduction to the subject by Liu in 2010[8]. Recent relevant research by Yu[4] has included sentiment analysis of attendees of a technology training course. Another recent research used statistics and tools such as Linguistic Inquiry and Word Count (LIWC)[14] to analyse emotional, structural, and cognitive components of long text datasets to comparing gender differences in the way people worry about COVID-19[26]. This research contains results of experiments on data in the Real-World Worry Dataset (RWWD) gathered from 2,500 respondents who wrote their thoughts on COVID-19. They demonstrated differences in the way men and women thought about COVID-19 at that time. The paper concluded that longer statements were more relevant and accurate than short tweets and called for more publicly available high-quality datasets rather than relying on social media datasets. Therefore, our research has created a new, long text dataset, specifically designed for capturing diverse perceptions in relation technology *careers* and *usage* and we propose to apply these techniques and tools to that dataset to look for patterns and themes.

3. CREATION OF THE DATASET

3.1 The Need for GTAD

As shown in section 2, a new dataset is necessary, with as many responses as possible, from a wide diversity of applicants commenting on their thoughts about technology careers and technology usage.

Creating a dataset using similar ‘long text’ responses as used in the RWWD but containing questions on *technology usage* and *technology careers* could replicate some of this methodology to examine whether there are statistically significant differences in

responses – women compared to men, white respondents in relation to people of colour, *pale and male* respondents compared to everyone else. A dataset with as many diversity data points as possible could lead to multiple options for comparison in the future and can be made publicly available.

3.2 GTAD Methodology

Digital Divide research is the main area focus of our literature review in relation to IT usage. More than half the research into the Digital Divide comes from USA and most of the research originates in English-speaking developed and (relatively) rich countries[27]. This correlates with the origination of the majority of the work in relation to diversity in tech careers and, for these reasons the focus of our research is on the UK and USA[15]. There is not, to the best of our knowledge, a publicly available database containing data such as the data in GTAD.

GTAD’s main purpose is to capture free text responses on how the applicants feel about technology usage and technology careers. The data is collected from the technology consultancy’s Applicant Tracking System (ATS) and contains diversity related data such as *gender, ethnicity, sexuality, first to go to university, disability*. GTAD also contains data related to the *application process* and the *outcomes* of that process such as whether the candidate was rejected or withdrew and at what stage of the process.

Data collection started on May 22nd, 2018, from USA, Canada, UK, Germany, Poland, China, Hong Kong, Singapore, Australia, Ireland, South Africa, Luxemburg, Netherlands. Although the focus of this PhD research is UK and USA, the data for all other geographies will also continue to be captured to make GTAD as rich as possible for future research.

The free text questions were added to the system on August 1st, 2021, replicating the long word format from the RWWD paper[26], and replacing “*the Corona situation*” with our research topics of *technology careers* and *technology usage* as shown below:

Question 1 (**careers**):
“Write in a few sentences how you feel about **starting a career in technology/IT** at this very moment. This text should express your feelings at this moment.”

Question 2 (**usage**):
“Write in a few sentences how you feel about **using technology/IT** (e.g., smartphone/PC/Wi-Fi) at this very moment. This text should express your feelings at this moment.”

On the same ATS screen, alongside the questions, it is made clear that the data is to be used for research into diversity in technology careers, will be anonymised and has no bearing on the candidate’s application.

GTAD is populated with secondary data and is anonymised from the original dataset so has limited relevance in terms of data privacy. Nonetheless, approval was sought and gained from the Executive of the consultancy for the data to be used for research. Approval from the Ethics review board of Durham University for the use of GTAD for research was sought on February 15th, 2022.

It is the intention that a subset of this dataset, less any commercially sensitive information, will be made public for other researchers to use. An early instance of this proposed public dataset has been used for MSc level experiments at Durham University.

3.3 GTAD Population

For the GTAD dataset defined below, at least 91% of UK applications are from university graduates. All are at a similar stage in their career and considering a career and training in technology, with 91.1% of the current population who provided their age are aged 18-30. This limited variation in the dataset population could be classified as bias. At the same time, the similarities could ensure that the effect of different diversity characteristics are more pronounced. Combined with the various diversity data fields, GTAD could be a useful research asset when made public.

For the period up to January 1st, 2022, GTAD comprised:

- 565,937 applications from candidates, over 44,000 of which were received since the questions were added to the application form.
- 25,243 long text questions answers, spread 12,242 and 13,001 across *usage* and *careers* respectively.
- A corpus of 1,243,578 words.

The growth of GTAD has been constant throughout the period with an average of 2,000 applications per week, of which around 1,000 applicants are currently answering the free text questions, giving 2,000 answers and 100,000 words each week.

This growth rate trajectory to the end of this research (January 2027) suggests that the GTAD population could be substantial with over a million applications, over half a million free text questions answers and a corpus of over 27 million words.

3.4 Data Provenance

Via a series of initial data uploads from September 16th, 2021, to December 22nd, 2021, the upload process was tested and refined incrementally. The process is now controlled and repeatable and the scripts and code used to perform the uploads, as well as data manipulation and enrichment scripts, are stored and controlled using source code control tools and processes as prescribed by the technology consultancy's ISO-27001 compliant[3] IT policies and practices.

It is important that any information related to the status of the application is a **final** status i.e., at the end of the recruitment process as this relates to outcomes of the process. For example, Did the candidate withdraw? Were they successful in their application? If they were rejected, at what stage was this? The recruitment process lasts a maximum of 4 weeks and so, only data older than 5 weeks was included an initial GTAD upload of February 24th, 2022, covering the period, May 1st, 2018, to January 1st, 2022. Incremental uploads and will be repeated monthly, five weeks in arrears, following the subsequent upload of March 15th, 2022.

3.5 Data Enrichment and Optimisation

Some applicants to the training programme apply more than once and so the ATS contains multiple applications from some applicants. Where this is the case, the applicant may answer the questions in different ways for different applications. They may also elect to complete different elements of the diversity data in different applications. So, for example, they might enter no data in their first application. They then provide gender and ethnicity in the second application. In their third and final application they may choose to provide their sexuality and their education information. The uploads of the dataset include logic to ensure that the superset of all diversity related data for that applicant is

captured for each application. By capturing every individual application for every applicant, GTAD contains all responses to the technology questions at different times.

3.5.1 Future Enrichment

3.5.1.1 Predicting Gender and Ethnicity

The primary database (ATS) contains the names of applicants. It is intended to use the first name to enrich the data during the process of the upload and create derived attributes of ethnicity and gender, initial research into which is described later in this paper.

3.5.1.2 Anonymisation

Although the data is anonymised *en route* to GTAD by the removal of the identifying fields which are used in the ATS such as surname and date of birth, identifying data does appear in the dataset occasionally. One of the main ways in which this happens is when a contributor uses their name in their free text response. It is intended to use automated tools to anonymise the data during the upload to GTAD.

4. RESEARCH

4.1 Initial Research

Initial experiments were conducted on the data, some of which are summarised here.

4.1.1 Recruitment Process Outcomes Analysis

A comparison of the 10 of the most relevant recruitment process outcomes (from a total of 48 outcomes) such as 'Rejected After Assessment Day', 'Rejected After Video/Phone Interview' and 'Invited to Video/Phone Interview', in the UK revealed statistically significant patterns in the outcomes for different diversity groups. The recruitment process is reviewed and certified annually as fair by a 'Big Four' consultancy firm and so these differences in outcomes for specific demographic groups was an unexpected outcome.

4.1.2 Gender Prediction

A dataset was created according to the method described here with the added step that the applications' first name was retained. For the non-NULL values, the `genderizeR`[28] and `Nltk`[9] libraries were used to predict gender and the former was found to be most effective. Globally, `genderizeR` was 86% accurate and for the USA and UK, 89% and 88% respectively (see Table 1. Gender Prediction Performance). Figures 1,2 show the respective confusion matrices for these countries.

Table 1. Gender Prediction Performance

Methodology	Accuracy	Precision	Recall	F_1 Score
GenderizeR (USA)	89%	0.88	0.94	0.91
GenderizeR (UK)	88%	0.86	0.93	0.90
GenderizeR (Global)	86%	0.85	0.79	0.88
Nltk (Global)	67%	0.75	0.69	0.70

Figure 1. GenderizeR Performance UK

Figure 2. GenderizeR Performance USA

4.1.3 Sentiment Analysis

Sentiment analysis was conducted using the Flair Python library[7, 18], returning a sentiment category (positive, negative, neutral) and a score. This analysis revealed mostly positive sentiment (*career*: 96.63% and *usage*: 89.69% positive). There was no neutral sentiment and entries from ‘not disclosed’ applications made up 30% of *career* and 68.4% of *usage* responses classed as negative.

4.1.4 K-means Clustering

K-means clustering was performed using the scikit-learn library[13]. The optimal number of clusters was found by the elbow method to be 3. Features resulted in the highest score of 0.878 were *location*, *ethnicity*, and *stream* (i.e., technical training course) chosen by the applicant.

4.1.5 LIWC Analysis

LIWC 2015[14] analysis was performed on the applicants’ long text responses, comparing the results for different groups to the results from the most dominant group in technology careers, white males. Non-parametric Kruskal-Wallis was used to determine differences which were statistically significant, and Cohen’s *d* was used to determine the magnitude of the differences.

There were differences between other groups and white males for *usage*, but these were not as pronounced as the differences in the responses related to *careers*. In the latter, white men focus more on professional aspects, by being more analytical and touching on subjects such as *time*, *money*, *numbers*, *power*, and *work*. Whereas other groups tend to share more personal thoughts speaking about *feelings*, *drives*, *family* and showing an emotional tone. White men also use more words per sentence

when speaking about *careers* and are more authentic, speaking about *certainty* whereas the other groups seem to share personal experience, speaking about *affect*, *affiliation*, and *rewards*.

4.1.6 Top2Vec Analysis

Topic modelling of questionnaire responses was performed, facilitated through Top2Vec[2]. This approach seeks to identify dense clusters of document vectors using hierarchical clustering techniques[5]. Based on an analysis of all responses to question 1 of the questionnaire, 16 distinct topics were identified from the topic modelling approach, shown with the first 5 words in each in Figure 3. These require a manual qualitative analysis when defining a topic label, with the topics demonstrating responses relevant to *fast-paced work environments*; *educational background*; and *career growth* when manually analysed and labelled (topic ids 0, 1, 6 respectively). This demonstrates the initial feasibility of the approach, which may be subsequently investigated further with the aims of identifying more coherent topics from the data.

		MOST PREVALENT WORDS - decreasing frequency with higher number					
		0	1	2	3	4	5
TOPIC ID	0	evolving	constantly	fast	change	excites	exciting
	1	university	computer	science	coding	degree	programming
	2	forward	looking	apply	real	problems	look
	3	if	not	but	much	know	just
	4	projects	coding	apply	eager	programming	professional
	5	pandemic	we	our	covid	important	becoming
	6	growth	industries	their	companies	innovation	society
	7	wanted	feeling	long	company	get	ve
	8	solving	problem	enjoy	skills	challenging	challenge
	9	important	our	becoming	society	therefore	we
	10	professional	gain	am	passionate	looking	fdm
	11	challenges	new	forward	ready	challenge	eager
	12	cloud	computing	technical	related	interested	data
	13	us	keep	solutions	improve	lives	environment
	14	ready	challenge	put	new	pursue	challenges
	15	forward	looking	moment	feeling	ready	start
16	confident	put	strong	start	fdm	technical	

Figure 3. Top2Vec Topic Clustering

4.2 Future Research

The immediate focus of the research is on the enhancement and enrichment of GTAD as the baseline for the analysis and experimentation. Further analysis of the enhanced dataset plus qualitative analysis, through interview and workshops with the consultancy’s recruiters, will be used to research the clustering of outcomes for different groups in the technology consultancy’s recruitment process. Derived ethnicity attribute via ethnicolr[16] will be further researched as well as anonymization of data using tools such as Anonymate[1].

Sentiment analysis and textual analysis tools will then be tested against the data for patterns in the text across diverse groups and the LIWC analysis could be tuned and improved using the latest version of the tool. Improvements in the Top2Vec topic modelling performance could be researched and analysis of the frequencies of demographic groups within specific topics may help in the identification of attitudes towards questionnaire responses and may aid in future works.

Since the researcher’s relationship with both the dataset and the recruitment processes is not passive, we intend to experiment with causal inference[12] and interventions in the process and data.

5. CONCLUSION AND OUTLOOK

There was a consistent rate of response to the questions on *technology usage* and *technology careers* from applicants to the technology consultancy’s training course, both in terms of numbers of applicants responding and length of responses. This

suggests that GTAD will continue to grow, both in size and richness, and could be used for research including research into the PhD hypotheses of the author.

This work is at an early stage and any feedback or ideas on the paper would be highly welcomed. Particularly of interest would be comments on what research and analysis could be performed using the data, and thoughts on the wider distribution of the non-commercially sensitive dataset.

6. ACKNOWLEDGMENTS

We acknowledge the contribution of Stuart Brown from the IT consultancy's technology team for his advice on database design and his implementation of the data extraction code for GTAD.

Effect of Q-matrix Misspecification on Variational Autoencoders (VAE) for Multidimensional Item Response Theory (MIRT) Models Estimation

Mahbubul Hasan, Lih Y Deng, John Sabatini, Dale Bowman, Ching-chi Yang, John Michael Hollander

ABSTRACT

Deep generative models with a specific variational autoencoding structure are capable of estimating parameters for the multidimensional logistic 2-parameter (ML2P) model in item response theory. In this work, we incorporated Q-matrix and variational autoencoder (VAE) to estimate item parameters with correlated and independent latent abilities, and we validate Q-matrix via the root mean square error (RMSE), bias, correlation, and AIC and BIC test score. The incorporation of a non-identity covariance matrix in a VAE requires a novel VAE architecture, which can be utilized in applications outside of education such as players performance evaluation, clinical trials assessment. Moreover, results show that the ML2P-VAE method is capable of estimating parameters and validating Q-matrix for models with a large number of latent variables with low computational cost, whereas traditional methods are infeasible for data with high-dimensional latent traits.

Item Response Theory, Deep Generative Model, Interpretable Neural Network, Cognitive Diagnostic Model, Educational Assessment

1. INTRODUCTION

Item Response Theory (IRT) is a popular model for the understanding of human learning and problem-solving skill and to predict human behavior and performance. Since the 1950s [21], thousands of researchers have used IRT in fields, e.g., education, medicine, and psychology, and this includes many critical contexts such as survey analysis, popular questionnaires, medical diagnosis, and school system assessment.

More recently, computer-assisted open-access learning has gotten more popular worldwide, e.g., Khan Academy, Coursera, and EdX have developed a new challenge to handle large-scale student and trace performance [15].

M. Hasan, L. Y. Deng, J. Sabatini, D. Bowman, C.-C. Yang, and J. Hollander. Effect of q-matrix misspecification on variational autoencoders (VAE) for multidimensional item response theory (MIRT) models estimation. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 811–815, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

In the deep learning domain, a revolution in deep generative models via variational autoencoders [12] [14], has demonstrated an impressive ability to perform fast inference for complex MIRT models. In this research, we present a novel application of variational autoencoders to MIRT, explore independent and correlated latent traits in the MIRT model via simulated data, and apply them to real-world examples. We then show the impact of Q-miss (wrong Q-matrix) when mixed compared with the original Q-matrix (Q-true).

Specifically, in this paper, we have explored two research questions as follows: first, how to use variational autoencoder in the estimation of MIRT models with large numbers of correlated and independent latent traits? Second, how are the effects of various factors such as the percentage of misfit items in the test and item quality (e.g., discrimination) on item and model fit in case of misspecification of Q-matrix?

Most closely related to the present work, Converse [2] utilized variational autoencoders (VAE) to estimate item parameters with correlated latent abilities and directly compared ML2P-VAE with traditional methods. Curi [1] introduces novel variational autoencoders to estimate item parameters with independent latent traits. Guo [16] explored the neural network approach and compared the outcome with the DINA model. Converse [3] compared outcomes between autoencoders (AE) and variational autoencoders (VAE). Wu [21] investigated the novel application of variational inference and incorporated IRT in the model via simulated and real data. Different from Converse [2], and Curri [1], we use both independent and latent traits in the VAE model. Moreover, we have explored the effect of Q-matrix misspecification in MIRT parameter estimation via different fit statistics, e.g., RMSE, BIAS, AIC, & BIC score measures.

The Multidimensional Logistic 2-Parameter (ML2P) model gives the probability of students answering a particular question as a continuous function of student ability [14]. There are two types of parameters associated with each item: a difficulty parameter b_i for the item i , and a discrimination parameter $a_{ik} \geq 0$ for each latent trait, k quantifying the hierarchy of ability k required to answer the item i correctly. The ML2P model gives the probability of a student j with latent abilities answering an item i correctly as

$$P(u_{ij} = 1 | \Theta_j; a_i, b_i) = \frac{1}{1 + \exp[-\sum_{k=1}^K a_{ik}\theta_{jk} + b_i]} \quad (1)$$

2. VARIATIONAL AUTOENCODERS

The variational autoencoder (VAE) is a directed model that uses learned approximate inference and can be trained purely with gradient-based methods [12]. It is similar to auto-encoders but with a probabilistic twist. VAE makes the additional assumption that the low-dimensional representation of data follows some probability distribution $N(0, I)$, and fits the encoded data to this distribution.

The main use of a VAE as a generative model, VAE generates X to \hat{X} after training and feed-forward through the decoder. By Bayes' rule, we can write the unknown posterior distribution. In our case, we generalized VAE as $N(\mu, \Sigma)$. In order to keep both P and Q distribution similar, Kullback-Liebler divergence $D_{KL}(P \parallel Q)$ plays a key role in the neural network loss function. The KL-Divergence is given by as follows:

$$KL[q(\Theta | x) \parallel f(\Theta | x)] = E_{\theta \sim q(\Theta | x)} [\log q(\Theta | x) - \log f(\Theta | x)] \quad (2)$$

As shown by Kingma and Welling [12] that minimizing Eq. 2 while still reconstructing input data is equivalent to maximizing.

$$E_{\theta \sim q(\theta | x)} [\log P(X=x|\Theta) - KL[q(\Theta|x) \parallel f(\Theta)]] \quad (3)$$

Next, the VAE is trained by a gradient descent algorithm to minimize the loss function. In this case, L_0 is the cross-entropy loss function and λ is a regularization hyperparameter.

$$L(W) = L_0(W) + \lambda KL[q(\Theta | x) \parallel f(\Theta)] \quad (4)$$

Root mean squared error (RMSE): RMSE criterion reflects the average magnitude of the bias between the true item parameters and their associated estimates. A smaller RMSE suggests higher estimation accuracy. Moreover, we also looked into Akaike information criterion (AIC), and Bayesian information criterion (BIC) score to explore MIRT model estimation when using Q-Miss.

First, we have incorporated the independent and correlated latent traits via the ML2P-VAE model proposed by Curi [1], and Converse [2]. We have extended this work by validating Q-matrix based on root, mean, square, error (RMSE), BIAS, and Correlation score.

We made modifications to the architecture of the neural network to allow for the interpretation of weights and biases in the decoder as item parameter estimates, and activation values in the encoded hidden layer as ability parameter estimates. As we know, sometimes researchers call neural networks are usually uninterpretable and function as a black-box model. However, following the addition of Q-matrix in the second from the last layer will make NN more interpretable.

The required modifications are as follows. The decoder of the variational autoencoder has no hidden layers. The non-zero weights in the decoder, connecting the encoded distribution to the output layer, are determined by a given

Q-matrix [19]. Thus, these two layers are not densely connected. The output layer must use the sigmoid activation function as follows:

$$\sigma(z_i) = \frac{1}{1 + e^{-z_i}} \quad (5)$$

When latent traits are assumed to be correlated, a full correlation matrix must be provided for the ML2P-VAE model. However, a correlation matrix is not required when latent traits are assumed to be independent. This corresponds to the fixed covariance matrix Σ_1 . ML2P-VAE can estimate ability, discrimination, and difficulty parameters, but it does not estimate correlations between latent traits.

Also, the input to our neural network consists of n nodes, representing items on an assessment. After a sufficient number of hidden layers of sufficient size, the encoder outputs $K + K(K + 1)/2$ nodes. The architecture for correlated latent traits is more complex than we think (See Visualization of Deep-VAE architecture for two correlated latent traits and ten input items model via this link [tinyurl.com/aied22]).

2.1 Q-Matrix and Misspecification of Q-matrix

Specification of Q-matrix is mainly criticized because of its subjective nature [17]. Misspecification in the cognitive diagnostic model (CDM) mostly occurs because of the types of the attributes, construct of the attribute, Q-matrix, or selected cognitive diagnostic model [6]. In this experiment, we utilized only a misfit source because Q-matrix misspecification was examined, and no changes were made in students' responses. In the study, the Q-matrix was misspecified by a mixed approach, and misfit items used in this study are presented in Table 1 (See misfit items table in Appendix 2: tinyurl.com/aied22). When the Q-matrix was misspecified, one attribute was translated from 1 to 0, and another attribute was translated from 0 to 1, but the number of measured attributes didn't change, which is referred to as mixed.

In the architecture of the model ML2P-VAE, we train the neural network with the ADAM optimizer (pure stochastic gradient descent). A simulated assessment with six latent abilities used two hidden layers of sizes 50 and 25. The largest network we used was for an assessment of 20 latent abilities, which utilized two hidden layers of sizes 100 and 50.

3. THE DEEP-Q ALGORITHM

For convenience, we are calling this algorithm the Deep-Q algorithm. The steps of the Deep-Q algorithm are as follows-

- Step 1:** Use the variational autoencoder and multidimensional item response theory (ML2P-VAE) model [2] to estimate students' ability and item parameters based on Q-True and the response data.
- Step 2:** Compute all items' via RMSE, BIAS, and Correlation test score values based on Q-True and the student's ability and item parameters estimated at Step 1. We also use AIC and BIC scores to compare Q-true and Q-miss.
- Step 3:** Randomly misspecify Q-true by 10% and 20% to change Q-True.

Table 1: Q-matrix validation measures via RMSE, BIAS and Correlation score for discrimination (a), difficulty (b), and ability θ parameters with correlated latent traits

Data	Miss	Method	a.RMSE	a.BIAS	a.Corr	b.RMSE	b.BIAS	b.Corr	θ .RMSE	θ .BIAS	θ .Corr
		Q_{True}	0.1465	0.0100	0.9427	0.0750	0.0100	0.9988	0.8120	0.0476	0.5815
N=18000	10% $_{Miss}$	Q_{Miss}	0.2297	0.0195	0.8562	0.0993	0.0083	0.9986	0.8398	0.0637	0.5486
	20% $_{Miss}$	Q_{Miss}	0.2621	0.0466	0.7984	0.1684	0.0268	0.9962	0.8684	0.1660	0.5351
		Q_{True}	0.1007	0.0259	0.9094	0.2098	-0.0186	0.9984	0.5614	-0.0013	0.8686
N=60000	10% $_{Miss}$	Q_{Miss}	0.2525	0.0654	0.8430	0.2881	0.0129	0.9926	0.7288	0.0037	0.6859
	20% $_{Miss}$	Q_{Miss}	0.2200	0.0367	0.8777	0.2191	0.0243	0.9952	0.6561	0.0166	0.7551

Step 4: Repeat step-1 with Q-miss (Q-miss, Step 3).

Step 5: Compare Q-True(top row, boldface) with Q-miss. Q-true should yield a small RMSE/BIAS and a strong correlation score, AIC, and BIC score for difficulty, discrimination, and ability parameters.

4. METHODOLOGY

We ran experiments on two data sets: (i) 6 traits, 35 items, and 18000 students, and (ii) 20 traits, 200 items, and 60,000 students. It is also important to mention here that true parameter values, for both students and items, are only available for simulated data. When simulating data, we used the Python's SciPy package to generate a symmetric positive definite matrix with 1s on the diagonal (correlation matrix) and all matrix entries non-negative. All latent traits had correlation values between 0,1. We assumed that each latent trait was mean-centered at 0. Then, we sampled ability vectors to create simulated students. We generated a random Q-matrix where each entry $q_{ij} \sim \text{Bern}(0.2)$. If a column for each element after sampling from this Bernoulli distribution, one random element was changed to a 1. Discrimination parameters were sampled from a range so from 0.25 to 1.75 for each item i , and difficulty parameters were sampled uniformly from - 3 to 3. Finally, response sets for each student were sampled from the ML2P model using these parameters.

5. RESULTS

All experiments were conducted using TensorFlow for R and the ML2Pvae package [4] on an iMac computer with a 3.1 GHz Intel Core i5 via Google Colab Premium, 12 GB NVIDIA Tesla K80 GPU.

Table 1 presents the estimation accuracy of Q under Q-True and Q-miss. The range of values for each criterion is provided in the second and third row of Table 1, and the numbers in bold denote better performance in the associated criterion for the corresponding method, e.g., Q-Miss.

Overall, Table-1 indicates that the Deep-Q method yields a better fit statistic score and strong correlation score than the Q-miss situation when using a wrong Q-matrices. This result is corroborated by the correlation plots between the

true discrimination parameters and the weights of the decoder, displayed in Fig. 1 and 2 (see Appendix for larger view).

In addition, Q-matrix validation measures via AIC, BIC score for discrimination (a), difficulty (b), and ability θ parameters with correlated latent traits remain consistent with Table-1 outcome (see AIC and BIC scores in the Appendix).

In Fig 1(A and B), the correlation plots of discrimination parameter estimate for data with items and latent traits. Each color represents discrimination parameters relating to one of each latent skill. In the ability parameter, each color in the plot represents discrimination and ability parameters associated with each latent trait. Difficulty parameters are on the item level, not the latent trait level. So in each item, I have exactly one difficulty parameter b_i , regardless of the number of latent skills. The interpretation is similar for independent latent traits, as described in figure 1(A). Plots show correlated latent traits and show better outcomes compared to independent latent traits.

6. DISCUSSION AND CONCLUSION

An incorrect Q-matrix can lead to a significant change in the assessment outcomes when applied to CDMs. As a result, a Q-matrix validation strategy to reduce assessment error is becoming increasingly important. Several approaches, including EM-based and non-parametric methods, have shown the ability to identify and create an acceptable Q-matrix. However, to the best of the authors' knowledge, their experiment utilizes traditional IRT parameter estimation where they utilize low-dimensional latent traits and students' responses. However, the Deep-Q algorithm is most useful with high and low-dimensional data.

Moreover, Converse's [2] study shows that MIRT parameter estimation results via the ML2P-VAE model are competitive compared to traditional IRT parameter estimation methods. Our study used a Deep-Q algorithm, a deep learning-based algorithm, to identify and validate a Q-matrix for small and large-scale latent traits. Deep-Q could be useful for large-scale assessments, e.g., PISA and TIMSS.

ML2P-VAE is a novel technique that allows IRT parameter estimation of independent and correlated low and high-

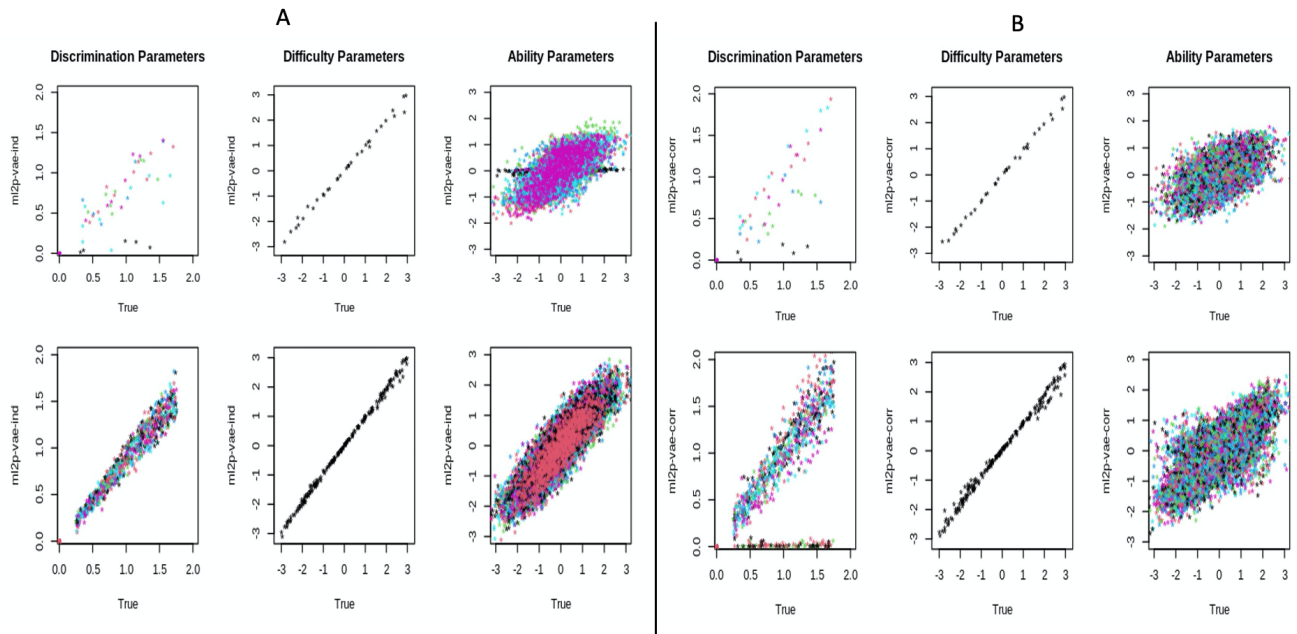

Figure 1: (A) Discrimination, Difficulty, and Ability Parameter Estimates with Independent Latent Traits (B) Discrimination, Difficulty, and Ability Parameter Estimates with Correlated Latent Traits.

dimensional latent traits. Ultimately, it can be said that the Deep-Q algorithm succeeds in detecting misfit items in both large and small sample cases. ML2P-VAE methods and Deep-Q are most useful on high-dimensional data, but even when applied to smaller data sets where traditional techniques are feasible, the results from current methods are competitive.

ABSTRACT

Data Mining (DM) currently represents a key element for improving the acquisition of knowledge and for providing proper feedback in educational environments. In this field, as well as in others, psychomotor skills represent a unique way to advance in the knowledge of human behaviours. Our research apply in two equally promising, but different domains. On one hand, we would be able to improve the learning of psychomotor skills at educational level with the use of different DM techniques. This may includes learning martial arts or supporting the acquisition of locomotor abilities. On the other hand, we would like to expand our DM research far beyond the basis of the aforementioned educational field. Thus, we can evaluate other users, such patients, with the aim of improving the re-learning of motor capabilities during recovery processes on rehabilitation, or even to detect cognitive impairments, analysing slight psychomotor alteration: at early stages using DM. The latter includes gait analysis, which are currently used for screening, but not so much for predicting purposes. Although our research is still at early stages, we are following the principles set on previous researches, such those included in our intelligent Expertise Level Assessment (iELA) method.

Keywords

Educational Data Mining, Personalised Learning, Psychomotor Skills, Active Ageing and Education

1. INTRODUCTION

In order to properly apply state-of-the-art DM techniques for personalised learning, we have developed the following taxonomy, distinguishing between *mutually-exclusive* and *non-mutually-exclusive* movements [31]. This differentiation is particularly relevant for psychomotor activity analysis, since learners should be modelled according subtle details, which

are not often obvious. In the first *mutually-exclusive* group we can find most of the Human Activity Recognition (HAR) systems, which basically use DM and Machine Learning (ML) techniques to analyse human movements, that cannot be executed at the same time (running, walking, sleeping, etc). In our case, it is extremely pertinent to be able to analyse *non-mutually-exclusive* movements, meaning distinguish different behaviours which are similar. This is the case of analysing distinct personal gait registries or matching several gaits gathered from different users or patients. For recognising the specific *non-mutually-exclusive* human movements, we can use inertial sensors, where the information is often collected in form of Time-Series (TS), like the ones depicted in Fig. 1.

Figure 1: Inertial data recorded representing human activity. On the left side we have the three axis (x, y, z) gathered using an accelerometer. On the right side we have the three axis (x, y, z) gathered using a gyroscope [31].

Fig. 2 depicts another method suitable for breaking down *non-mutually-exclusive* human movements, in this case utilising AI-based video analytics.

Many other different controllers may be used for the purpose of gathering information related to *mutually-exclusive* and *non-mutually-exclusive* human movements, such Microsoft Kinect sensor [29] or LIDAR¹ sensor [20]. Whether the method and sensors used, the aim of the research disclosed on this paper is to analyse, with different DM techniques, several data sets gathered from the execution of human movements, to anticipate psychomotor learning behaviours supporting appropriate feedback or analysis.

This research may also have a specific impact on achieving well-being through active ageing, since the correct execution of certain movements at certain ages allows us to take care

¹Acronym of LIght Detection And Ranging.

Figure 2: Multi-person Pose Estimation with OpenPose [30].

of ourselves properly. Therefore, the use of DM techniques, which allow us to automatically assess whether we perform certain motor movements correctly or if we preserve certain psychomotor skills, is essential for our comfort and well-being.

2. RELATED RESEARCH

The first steps for our research relies on the iELA method disclosed in [31], which uses *quaternions*, a specific group of hyper-complex numbers, to fuse the transformed inertial data, gathered during the practice of different martial arts. iELA uses DM to provide an innovative method to infer performance level, showing its relevance assisting psychomotor learning and educational systems. iELA follows the principles set in [34], which details how the use of different sensors, together with a specific methodology, to support psychomotor learning processes in educational environments. These foundations are also used in [35, 12, 9, 18] since motor tasks can be consolidated into memory through repetitions, creating a long-term neuromuscular memory for specific tasks.

Other intelligent tutoring system related with psychomotor skills can be found in [24], although in this case the authors use physiological sensors. Regarding video analysis, [28] introduce the design, development, deployment and evaluation of video games to support locomotor acquisition in a classroom setting. Other examples are related with the learning of playing piano [8], practising martial arts [33], performing dance step movements [33, 16] or improving sport technique [7], among others.

Some researches, as in [25, 37, 36, 15], use video analysis techniques for human pose estimation, in contrast, iELA foundations analyse inertial data gathered with the use of IMU² sensors, as in [22, 32, 13, 5, 21]. iELA analyses the data collected in form of TS, as in [40] but using two different approaches: extracting features, as in [3, 4], and using Convolutional Neural Networks (CNNs), as in [19, 14], taking into account that TS have practically the same topology than images, as mentioned in [6]. Other researches use another DM techniques [23], machine learning methods [26] or neural networks [39, 2, 11].

The use of various methods to estimate accurately the hu-

²Acronym of Inertial Measurement Unit

man pose is also common, as in [27, 38, 12] which use two different types of data, the one provided by the IMU and the one gathered from video footage.

In addition to the analysis of psychomotor activities in Educational DM systems, the detection and analysis of the human pose in other research areas, can also take advantage of the different DM techniques described above. Thus, [1] provides automated movement assessment for stroke rehabilitation using video analysis. At this point it is important to denote how pre-dementia stages (motor cognitive risk syndrome) are characterised in some cases by slow gait, as disclosed in [10]. Consequently, this research has an impact on other areas related to psychomotor aspects and, therefore, could also provide tools to promote innovation in active and healthy ageing, increasing healthy life expectancy³.

3. EXPECTED CONTRIBUTION

In aspects exclusively related to the detection of the human pose in educational environments, in addition to iELA, neither of the examples described above, evaluate the level of performance. As iELA is setting up the principles for evaluating the level of performance of complex movements in martial arts, our aim is to extrapolate iELA to other domains, including educational or health behavioural. The use of *quaternions* to fuse inertial information, with the addition of other sources, such as those provided by video footage, may provide innovative mechanisms on educational and non educational environments that require the analysis of psychomotor skills.

Although one of the desired goals is to merge information coming from different sensors, including video footage, we carefully need to deal with one of the main drawbacks of using a video-based approach for human activity classification purposes, which are the issues in terms of privacy [17]. This will be particularly relevant for fulfilling IDEA (inclusion, diversity, equity, and accessibility) approaches, as well as for satisfying the guidelines for a trustworthy AI, including transparency, explainability, fairness, robustness and the aforementioned privacy.

On this research, we will also consider the analysis of the affective state of the participants within data gathering and in relation to the execution of the movements under our study.

4. RESEARCH QUESTIONS

The affirmative answer to the iELA research question carried out in the Master Thesis [31]:

RQ-1 *Can we use these DM driven analysis (iELA) to automatically classify practitioners according their expertise level?*

represents the starting point for defining the next research question to be carried out in the on going Doctoral Thesis:

RQ-2 *May we use DM approaches to assess the level of expertise accomplished while performing motor activities on*

³<https://ec.europa.eu/social/main.jsp?langId=en&catId=1062>

different psychomotor learning schemes (from martial arts techniques to physical movements to benefit active ageing) thus achieving a domain transfer?

which will be the main objective of this research.

5. PROPOSED METHODOLOGY

Our proposed methodology is based on iELA, a DM method for an intelligent expertise level assessment which analyses high volumes of inertial data. In this case, when breaking down inertial data, without fusing it into *quaternions*, we cannot clearly distinguish whether the representation corresponds to an expert user, which may be extrapolated to a patient without a pathology, who performs certain motor activity, as depicted in Fig. 3. When fusing this information into *quaternions*, see Fig. 4, we can clearly have information about how the motor activity was performed. On the other hand, if we analyse the same movement executed by a beginner user, which may be also extrapolated to a patient with a pathology, then we can obtain a different depiction, as in Fig. 5.

This approach is based in analysing quality datasets gathered while executing human psychomotor activities. The DM analysis of this data will follow iELA approaches, and may include the use of CNNs and the examination of the extracted features from TS.

6. CONCLUSIONS

Research in the analysis of psychomotor skills represents an important challenge, overall when we are going far beyond the distinction of the *mutually exclusive* movements disclosed alongside this article. At this stage we are looking forward for feedback to support our research with the aim of demonstrating how our iELA method provides a top-notch approach in the treatment and analysis of different psychomotor behaviours on educational, learning or even on health scenarios.

The use of the DM techniques developed in this research may have different fields of application at educational level, but also can be useful for achieving the benefits of active ageing.

7. ACKNOWLEDGMENTS

The work reported is framed in the project "INTELLIGENT INTRA-SUBJECT DEVELOPMENT APPROACH TO IMPROVE ACTIONS IN AFFECT-AWARE ADAPTIVE EDUCATIONAL SYSTEMS" (INT2AFF) led by Dr. Santos at UNED and funded by the Spanish Ministry of Science, Innovation and Universities, the Spanish Agency of Research and the European Regional Development Fund (ERDF) under Grant PGC2018-102279-B-I00, specifically within the scenario "SC4-motor skills", which focuses on analysing the influence of emotions in motor skills learning.

ABSTRACT

Knowledge space theory (KST) is a mathematical framework for modeling and assessing student knowledge. While KST has successfully served as the foundation of several learning systems, recent advancements in machine learning provide an opportunity to improve on purely KST-based approaches to assessing student knowledge. As such, in this work we compare the performance of an existing KST-based adaptive assessment to that of a newly developed version—with this new version combining the predictive power of a neural network model with the strengths of existing KST-based approaches. Using a cluster randomized experiment containing data from approximately 140,000 assessments, we show that the new neural network assessment engine improves on the performance of the existing KST version, both on standard classification metrics, as well as on measures more specific to the student learning experience.

Keywords

Adaptive assessment, neural networks, knowledge space theory

1. INTRODUCTION

Combining elements of probability theory and combinatorics, knowledge space theory (KST) is a mathematical approach to the modeling and assessing of student knowledge [12, 15]. KST-based adaptive assessments focus on identifying the set of topics that are most likely to be known by a student, with many such implementations having been developed over the years [6, 7, 18, 20]. The particular system at the center of this work is ALEKS, an adaptive learning system covering subjects such as math, statistics, and chemistry. The foundation of the system is an *initial assessment* that is given to a student at the beginning of an ALEKS course, with the information from this assessment being used to guide their subsequent learning in the system. The current version of the initial assessment engine uses a KST-based model that employs many features and concepts described in the

KST literature (informative summaries of these ideas can be found in [13] and Chapter 13 of [15]).

Several works have evaluated the validity and reliability of KST-based assessments, with the results indicating that such assessments are both accurate and valid [5, 6, 10, 28]. However, current innovations in machine learning and, in particular, neural network models provide an opportunity to improve on purely KST-based approaches to adaptive assessments. As such, a newer version of the ALEKS initial assessment was recently developed and released into production for testing. By augmenting the KST-based adaptive assessment approach with a neural network model that can better leverage the years of accumulated ALEKS user data, we hope to make improvements to the accuracy and efficiency of the initial assessment. Thus, in the current study we evaluate this new assessment engine by analyzing the results from a randomized experiment—or, A/B test—comparing the performance of the two different versions of the ALEKS initial assessment.

2. BACKGROUND

In this section, we give a brief background of the ALEKS system and the two versions of its initial assessment engine. Within the ALEKS system, a *topic* is a problem type that covers a discrete unit of an academic course—Figure 1 contains a screen capture of an example math topic titled “Introduction to solving an equation with parentheses.” A *knowledge state* is a collection of topics that, conceivably, a student can know at any one time. The collection of knowledge states is known as the *knowledge space*. Based on the knowledge space, the topics in an ALEKS course contain many *prerequisite* relationships. That is, topic *a* is a prerequisite for topic *b* if *a* contains certain core material that must be mastered before learning the material in *b*.

In order to ensure students are learning the most appropriate topics, the initial assessment is given at the start of an ALEKS course, with the purpose of this assessment being to measure the student’s incoming knowledge. In this assessment, a student is presented topics from the course, and for each topic they can either submit a response—which is then graded as either correct or incorrect—or they can click on the “I don’t know” button if they are unable to answer the question. This assessment is adaptive, in that it selects the current question based on the responses to the earlier questions in the assessment. At most 30 questions are asked, which balances the need to acquire information on the stu-

dent’s knowledge state with the possibility of overwhelming the student.¹ After each question, a probability is computed for each topic in the course, with this probability estimating how likely it is that the student knows the topic. At the end of the assessment, based on both these probability estimates and the prerequisite relationships in the knowledge space, the ALEKS system partitions the topics in the course into the following three categories.

- Topics that are most likely known
- Topics that are most likely unknown
- All remaining topics (uncertain)

The student’s knowledge state consists of the topics in the known category.² Due to the enormous numbers of possible knowledge states, KST-based assessments typically use simplifications in order to model the relationships between topics. Perhaps the most common approach is to focus solely on identifying the prerequisite—or, topic to topic—relationships when developing the knowledge space; these are variously known as partial order or ordinal knowledge spaces [8, 9, 11, 15]. While adaptive assessments using these approaches have been successful [6, 7, 10, 20], there is an inherent loss of information when mainly focusing on the pairwise relationships between the topics. Although methods have been outlined for moving beyond pairwise relationships and looking at larger groups of topics simultaneously, the computational complexity grows substantially with each added topic, and research has thus far been mostly limited to small groups of at most three or four topics [11].

Motivated by this issue, the new version of the ALEKS assessment engine is powered by a neural network model that, for each topic, estimates the probability of a correct answer. The advantage of a neural network is that it has the flexibility to model more complex relationships between the topics—that is, it can go beyond focusing on specific relationships between pairs or very small groups of topics. However, for both practical and theoretical reasons, it’s desirable that the neural network model work within the existing KST framework of the ALEKS system. While other attempts have been made at applying neural networks to ALEKS data [21, 22, 24], none of these previous models took into account the specific details of the knowledge spaces. As such, the distinguishing feature of the neural network used for the initial assessment is that it applies a specially designed architecture to output probabilities consistent with the knowledge space—in particular, this architecture ensures that the probability estimates follow the prerequisite relationships among the topics. Thus, the neural network can leverage the vast amounts of ALEKS data to make accurate predictions, while simultaneously respecting the set of knowledge states and thereby ensuring these predictions are pedagogically sound. Notably, similar ideas have been successfully applied in knowledge tracing models, where it’s been shown that leveraging prerequisite relationships can be done effectively through the loss function of a neural network [2], or by utilizing dynamic Bayesian networks [19].

¹See [23] for evidence of a ‘fatigue effect’ experienced by students towards the end of an ALEKS assessment.

²The distinction between the unknown and uncertain topics is mainly relevant for the student’s learning in the system, with these categorizations determining the amount of work required before a topic is considered to be mastered.

Solve for x .

$$2(3x - 6) = 12$$

Simplify your answer as much as possible.

Figure 1: Screen capture of the ALEKS topic “Introduction to solving an equation with parentheses.”

3. EXPERIMENTAL SETUP

Neural network models were trained for eight ALEKS products: middle school math courses 1-3 (in the U.S., these correspond to grades 6 through 8); general chemistry A and B (the first and second semesters of college-level general chemistry, respectively); and three college-level math classes (pre-calculus, college algebra, and college algebra with trigonometry). Although we do not have access to specific demographic information for the students in our data, we can say that the majority of the middle school users are from U.S. public schools, while the higher education users come from both community colleges and four-year institutions, again mainly from the U.S. We began evaluating the new assessment engine in mid-December of 2021, using A/B testing to compare its performance to that of the existing version of the assessment, with data being collected through February of 2022. For the aforementioned products, we used a cluster randomized design to assign the two versions of the assessment at the class level, an approach commonly used for educational studies [14, 27, 29]. Specifically, each class was randomly assigned to receive either the new assessment or the old assessment, whereupon all the students in that class then received the same version of the assessment.

For the middle school and chemistry products, the neural network models were trained with the exact data sets that were used to build the models for the existing version of the ALEKS assessment engine; as such, our analyses on these products are the most informative when trying to precisely estimate the differences in performance between the two engines. In comparison, rather than being restricted to a certain time period, the college math neural network models were trained on all the available data. Thus, from the purely scientific perspective of measuring the differences between the assessment engines, comparing the results on the college math courses is perhaps less useful. However, from the more practical standpoint of understanding the (possible) gains from updating existing ALEKS products with the new engine, we believe this analysis to be informative. That is, there are currently many older ALEKS products that haven’t been updated over the past several years; thus, if these products were updated with the new neural network assessment engine, they would stand to gain from both the application of the neural network *and* the extra data used to train the model. As such, we believe this analysis gives some insight into the potential benefits from converting these older ALEKS products to the new assessment engine.

Table 1: Summary statistics for the three groups of ALEKS products.

Product	Type	Total		Average number of topics	Extra problem correct rate
		Classes	Assessments		
Middle school math	KST	5,311	19,480	433.6	0.334
	NN	5,407	19,313	436.4	0.330
Chemistry	KST	360	16,315	158.0	0.264
	NN	381	18,812	155.2	0.257
College math	KST	1,247	33,207	258.2	0.317
	NN	1,202	30,785	253.9	0.311

4. ANALYSIS

In order to compare the performance of the two assessment models, in what follows we make use of an *extra problem* that is asked during each initial assessment. This extra problem is chosen uniformly at random from the topics in the course and presented to the student as an assessment question. However, the answer to the extra problem does not affect the results of the assessment—instead, the information from the extra problem is used to evaluate and improve the ALEKS system. In Table 1 we show summary statistics after partitioning the products into three distinct groups—middle school math (middle school math courses 1–3), chemistry (general chemistry A and B), and college math (precalculus, college algebra, and college algebra with trigonometry)—and also the two treatment arms of our analysis—the KST-based assessment, and the neural network assessment (NN). In addition to showing the total numbers of classes and initial assessments taken, we also show the average number of topics used by each class, weighted by the number of assessments per class.³ Finally, in the last column we display the average correct answer rate to the extra problem.

Our first analysis compares the performance of the two assessment models by treating them as binary classifiers, where we consider a positive outcome to be a correct answer to the extra problem, while a negative outcome is either an incorrect or “I don’t know” response. We compare the assessment engines using three metrics: area under the receiver operating characteristic curve (AUROC), point biserial correlation (r_{pb}), and accuracy score. AUROC is frequently used to evaluate probabilistic classifiers, and it is known to perform well even with some class imbalance [16]. The point biserial correlation is a special case of the Pearson correlation coefficient in which one variable is dichotomous (the student response) and the other variable is continuous (the probability estimate from the assessment).⁴ While the actual probabilities are used in the computations of AUROC and the point biserial correlation, for the accuracy calculation we

assume any probability at or above 0.5 is a positive prediction, with anything below 0.5 then being considered a negative prediction. We should clarify that while this assignment of prediction labels is a standard procedure used to evaluate binary classifiers, it does not necessarily correspond to the actual classifications made by the ALEKS system—we look at these ALEKS-specific classifications in more detail later.

As students are grouped—or, “clustered”—into classes, to compute confidence intervals around the point estimates we use the following bootstrap procedure, applied separately to each product and assessment engine pair. That is, we apply this procedure a total of six times: once for the middle school products using the KST engine, then for the middle school products using the neural network engine, then for the chemistry products with the KST engine, etc. The first step in the procedure is to resample our data using the *cluster bootstrap*, a modified version of the standard bootstrap that specifically works with clustered data [17]. For our analysis, classes are randomly sampled with replacement from our original data set, until we have a sample of classes equal to the number in our original data set. Then, we combine all the assessments from these selected classes to generate one bootstrap sample—note this means that some classes, as well as the associated assessments, appear multiple times in the sample. Next, we compute our statistics for this bootstrap sample, and we then repeat this entire procedure until we’ve generated 20,000 bootstrap samples in total. Finally, since each resulting bootstrap distribution turns out to be symmetric and centered at the original values of the statistic—i.e., the value of the statistic computed from our original set of data—we compute each confidence interval by simply taking the 2.5th and 97.5th percentiles.

The results are shown in Table 2. For the middle school products, we can see that the neural network engine performs better according to each of the metrics, even after taking into account the confidence intervals. Next, the results for the chemistry products are less conclusive. Although the point estimates are all higher for the neural network engine, based on the confidence intervals in the third column there’s uncertainty with the signs of these differences. Finally, for the college math products the neural network engine again has much stronger performance compared to the KST-based assessment—we reiterate that this is expected, as the college math neural network models had access to more recent data in comparison to the corresponding KST models.

While the results for the middle school and college math

³While each course has a default set of recommended topics, the instructor is free to add or remove topics from this set.

⁴The Matthews correlation coefficient (MCC) [25] is a related statistic that is regarded as being an informative measure for evaluating binary classifiers [1, 3, 4, 26]. As the MCC is mathematically equivalent to the Pearson correlation coefficient of two dichotomous variables—also known as the phi coefficient—the only difference from computing the point biserial correlation is that the MCC requires we dichotomize the probability estimates. However, since this would result in some loss of information, we prefer to use the point biserial correlation for our current evaluations.

Table 2: Comparison of the two assessment engines, using the area under the receiver operating characteristic curve (AUROC), point biserial correlation coefficient (r_{pb}), and accuracy score. Numbers in parentheses represent the 95% confidence intervals computed from 20,000 cluster bootstrap samples.

Product	Metric	Assessment type		Difference
		KST	NN	NN–KST
Middle school math	AUROC	0.875 (0.870, 0.881)	0.894 (0.889, 0.899)	0.019 (0.011, 0.026)
	r_{pb}	0.624 (0.612, 0.635)	0.674 (0.664, 0.684)	0.050 (0.035, 0.065)
	Accuracy	0.811 (0.805, 0.817)	0.831 (0.825, 0.836)	0.020 (0.012, 0.028)
Chemistry	AUROC	0.871 (0.861, 0.881)	0.880 (0.873, 0.888)	0.009 (-0.003, 0.022)
	r_{pb}	0.610 (0.585, 0.634)	0.629 (0.613, 0.646)	0.019 (-0.010, 0.049)
	Accuracy	0.837 (0.829, 0.845)	0.838 (0.827, 0.849)	0.001 (-0.013, 0.014)
College math	AUROC	0.861 (0.856, 0.867)	0.898 (0.893, 0.902)	0.036 (0.029, 0.043)
	r_{pb}	0.599 (0.589, 0.610)	0.674 (0.664, 0.684)	0.075 (0.060, 0.089)
	Accuracy	0.814 (0.807, 0.821)	0.838 (0.833, 0.843)	0.024 (0.015, 0.032)

products are encouraging, the performance of the chemistry neural network models is slightly unexpected. Based on our previous evaluations when training the neural network models, we expected a larger performance improvement over the KST-based assessment for the chemistry products—in comparison, the performance of the middle school and college math neural network assessments are consistent with our expectations. A possible concern is that there are differences between the chemistry student populations using the two different assessment engines—while not conclusive, some of the statistics in Table 1 are suggestive of such a difference. To start, although there are over 35,000 total assessments taken for the chemistry products, the number of unique classes is low in comparison to the other products—for example, the number of chemistry classes (741) is a small fraction of the number of middle school classes (10,718). This is important, since in a cluster randomized experiment such as ours, the number of clusters is typically more restrictive than the overall sample size [29], and such designs have a higher risk of non-equivalence between the experimental groups [14, 27]. Additionally, for the chemistry products the neural network group has about 15% more assessments taken than the KST group, which is possibly another sign of non-equivalence between the groups. While these differences aren’t conclusive, they at least suggest that the student populations may differ in some respect. Thus, in the next section we analyze the chemistry products further in order to obtain a better understanding of the results.

5. REANALYZING THE CHEMISTRY ASSESSMENTS

To investigate the possibility that the student populations are not equalized across the chemistry experimental groups, we take advantage of the fact that an ALEKS assessment can be “replayed” on an assessment engine different from the one that was originally used. For example, suppose a student takes an assessment using the KST-based engine. Once this assessment is completed, we can feed the questions and responses to the neural network engine—taking care to remove the extra problem from this process—generate probability estimates, and then evaluate the probability for the extra problem in the original assessment. The main

drawback to this approach is that the engine used for the replay assessment won’t be able to choose the questions that are given to the student, which could theoretically bias the results somewhat. However, the advantage of this approach, and the reason we employ it here, is that it allows us to directly compare the assessment engines on the same sets of data, removing any concerns about the non-equivalence of the experimental groups.

To that end, using the data from the 16,315 chemistry assessments originally taken with the KST engine, we feed the questions and responses to the neural network models and generate probability estimates. We then take these probabilities and compute our evaluation metrics on the extra problems. Next, we repeat the same procedure in the other direction—that is, using the data from the 18,812 chemistry assessments that originally used the neural network engine, we take the questions and responses from each assessment and feed them to the KST-based engine. As before, we use the resulting probabilities to compute our evaluation metrics on the extra problems.

Table 3: Comparison of the replayed assessments on the chemistry products. Numbers in parentheses represent the 95% confidence intervals computed from 20,000 cluster bootstrap samples.

Metric	Assessment type		Difference
	KST	NN	NN - KST
AUROC	0.856	0.889	0.033
	(0.847, 0.866)	(0.881, 0.898)	(0.020, 0.046)
r_{pb}	0.581	0.651	0.070
	(0.561, 0.602)	(0.630, 0.671)	(0.041, 0.099)
Accuracy	0.824	0.844	0.021
	(0.812, 0.835)	(0.836, 0.853)	(0.007, 0.035)

The results are shown in Table 3, where we can see a large difference in performance between the two assessment engines. In contrast to the results from Table 2, on the replayed assessments the neural network engine does much better, while the performance of the KST assessment engine has dropped noticeably. As such, the contrast in performance between the assessment engines is clearer, with

the 95% confidence intervals for the differences (third column) all bounded away from zero. So, it does appear likely that there are underlying population differences between the groups of students using the two assessment engines. Thus, arguably the fairest comparison is to use both the actual assessment data and the replayed assessment data, and then compare the assessment engines based on this combined data set. The results are shown in Table 4, where we can see a relatively clear performance gap between the two engines, albeit not quite as large as in Table 3.

Table 4: Combined comparison of the two assessment engines on the chemistry products, including data from both the original and replayed assessments. Numbers in parentheses represent the 95% confidence intervals computed from 20,000 cluster bootstrap samples.

Metric	Assessment type		Difference NN - KST
	KST	NN	
AUROC	0.863 (0.856, 0.870)	0.885 (0.879, 0.891)	0.022 (0.012, 0.031)
r_{pb}	0.594 (0.578, 0.610)	0.639 (0.626, 0.653)	0.045 (0.024, 0.067)
Accuracy	0.830 (0.823, 0.837)	0.841 (0.834, 0.848)	0.011 (0.001, 0.021)

6. ALEKS KNOWLEDGE STATES

While the previous analyses have compared the performance of the assessment engines assuming they are standard binary classifiers, in this section we compare the models based on measures more specific to the ALEKS system. In what follows, we restrict our analyses to the middle school data, as we believe this data set gives the most balanced and fair comparison between the two assessment engines.

Recall that the purpose of the initial assessment is to identify the topics in a student’s knowledge state—that is, the topics in the known category. Since the ALEKS system uses this information to determine what a student is ready to learn, inaccurately measuring a knowledge state would negatively affect the student’s learning experience. For example, giving a student credit for many topics that aren’t justified could cause the student to start their learning with topics for which they aren’t prepared, possibly leading to frustration. On the other hand, not giving a student enough credit for topics they know has an opposite effect, as the student may start with topics that are too easy, causing boredom.

To start, in Figure 2 we show a relative frequency histogram of the number of topics classified as known after each assessment is completed. The striped (blue) bars represent the 19,313 assessments from the neural network engine, while the solid bars show the proportions for the 19,480 assessments from the KST engine. The mean and median are 112.5 and 98, respectively, for the neural network engine; in comparison, these values are 106.9 and 85 for the KST engine. Depending on whether we use the mean or median to describe the outcome of a “typical” assessment, the knowledge states from the neural network assessment engine are larger by either 5.2% (mean) or 15.3% (median). Furthermore, the first and third quartiles for the neural network

engine are 52 and 159, respectively, with these values being 42 and 152 for the KST engine. These differences possibly indicate that the advantages of the neural network engine apply to a diverse sample of students, rather than only those in a specific part of the distribution. Moreover, it’s encouraging that the gains are larger for the students in the first quartile, as the relative benefit of the additional topics is greater for students with smaller knowledge states.

Figure 2: Relative frequency histogram of the number of known topics for the middle school products.

While the knowledge states from the neural network engine tend to be larger, it’s important that they are also accurate; assigning more topics to the known category is of limited use if the topics aren’t actually known by the students. As such, in our next analysis we look at how often students answer correctly to the extra problem based on the classification (or, categorization) of the ALEKS system—either known, unknown, or uncertain. The results are shown in Table 5. Starting with the known category, we can see that students answer correctly more often with the neural network engine compared to the KST engine—0.792 vs. 0.788. Additionally, the neural network classifies the extra problem as being known more often than the KST model—0.271 vs. 0.259—which is consistent with the results in Figure 2. Next, note that while we want a high rate of correct answers to the topics in the known category, for topics in the unknown category we want the opposite—that is, a low correct answer rate to the unknown topics indicates the classifications are accurate. We can see that the unknown topics for the neural network engine have a lower correct answer rate in comparison to those from the KST engine—at the same time, the proportions of topics labeled as unknown are comparable. Finally, the neural network engine has a lower proportion of topics in the uncertain category, showing that overall it’s more aggressive in labeling topics as known or unknown.

In this last analysis we’d like to get a different perspective on the performance of the models. In particular, both assessment engines rely on the same underlying knowledge spaces, which means the prerequisite relationships between the topics are the same. Furthermore, when a topic is answered correctly during an assessment, the ALEKS system uses these prerequisite relationships to classify topics as being known—specifically, if a topic is answered correctly, that topic, as well as all of its prerequisites, are classified as known. Since

Table 5: Statistics for the assessment engines, partitioned by the classification of the extra problem.

Classification		Assessment type	
		KST	NN
Known	Proportion	0.259	0.271
	Correct rate	0.788	0.792
Unknown	Proportion	0.573	0.574
	Correct rate	0.106	0.088
Uncertain	Proportion	0.168	0.154
	Correct rate	0.412	0.421

Figure 3: Precision-recall curves for the extra problems that are not directly classified by the prerequisite relationships.

this behavior is the same for each assessment engine, we want to remove these classifications and obtain a more nuanced view of the differences in performance. Additionally, these “prerequisite” classifications tend to be the easiest ones for the assessment engines to make, and so by removing them we can evaluate the engines on a more challenging subset of the data. To that end, we remove any extra problem that (a) also appeared as a regular assessment question and was answered correctly, or (b) is a prerequisite of a topic that was correctly answered during the assessment—this leaves us with 16,122 and 15,963 extra problems for the KST and neural network engines, respectively. Since the performance of the ALEKS system depends on the assessment’s ability to correctly classify the topics in a student’s knowledge state (i.e., precision), while simultaneously identifying as many such topics as possible (i.e., recall), for these data points we plot the precision-recall curves, as we can then compare the performance of the assessment engines across a range of thresholds. The results are shown in Figure 3, where we can see that the neural network curve dominates for the vast majority of the recall values, with the precision values being substantially higher in many places. Overall, it’s informative to see the strong performance of the neural network assessment engine on this specific subset of the data.

7. DISCUSSION

In this work we presented and analyzed the results of a randomized experiment—or, A/B test—comparing two differ-

ent versions of the ALEKS initial assessment engine. The purpose of this analysis was to validate the neural network assessment engine and verify it improves upon the existing version that’s based on knowledge space theory (KST). While an initial analysis indicated strong improvement for the middle school and college math products, the difference was less clear for the chemistry products. To investigate further, we reanalyzed the chemistry assessments by “replaying” each of them with the competing engine. This analysis suggested that the student populations in the two experimental groups for the chemistry products were not completely equivalent, confounding the comparison. Thus, we adjusted for the non-equivalence of the student populations by combining the data from both the replayed and actual assessments, with the results indicating that the neural network assessment outperformed the KST-based version. Finally, we evaluated the assessment engines on metrics more specific to the ALEKS system—in these analyses, we saw that the neural network assessment gave students credit for knowing more topics, while simultaneously being more accurate.

The chemistry results were interesting and somewhat surprising. Given the large numbers of students in the two experimental groups, it was unexpected that, as suggested by the replay results, these groups would be dissimilar. However, since many of the chemistry students are from large universities, the class sizes also tend to be large—thus, as seen in Table 1 the number of distinct classes is relatively small. (In comparison, the middle school products have a higher number of “independent” users—e.g., homeschooling/home education students, or individual students seeking extra help—resulting in smaller average class sizes.) In experimental designs with multilevel structure such as ours, the number of clusters—represented by the student classes in our data—is typically more important than the overall sample size in ensuring the baseline equivalence of the experimental groups [14, 27, 29]. As such, our experience highlights the fact that the use of cluster randomized designs, while desirable in education research for several reasons, can lead to difficulties with the statistical analysis of the results, and that this can be an issue even with seemingly large samples of data.

Overall, we found the performance of the neural network assessment engine to be promising, in that it has the potential to benefit students in multiple ways. For example, the fact that it returns larger knowledge states in comparison to the KST engine—and, importantly, without a drop in accuracy—means that students do not have to spend as much time working on topics they may already know. Thus, students can learn more efficiently and spend more time working on completely new material, hopefully allowing them to progress further in the course. Yet another possible benefit pertains directly to the initial assessment itself. User feedback from both students and teachers has informed us that there is a desire for a shorter initial assessment, one that asks fewer questions and takes less time to finish. Given the gain in performance, it seems plausible that the neural network assessment could still improve on the KST-based assessment even if fewer questions are asked. We are currently looking at this possibility in detail, with the hope of shortening the initial assessment and improving the student experience within the ALEKS system.

Mining Artificially Generated Data to Estimate Competency

Robby Robson¹, Fritz Ray², Mike Hernandez³, Shelly Blake-Plock⁴, Cliff Casey⁵, Will Hoyt⁶, Kevin Owens⁷, Michael Hoffman⁸, Benjamin Goldberg⁹

ABSTRACT

The context for this paper is the *Synthetic Training Environment Experiential Learning – Readiness* (STEEL-R) project [1], which aims to estimate individual and team competence using data collected from synthetic, semi-synthetic, and live scenario-based training exercises. In STEEL-R, the *Generalized Intelligent Framework for Tutoring* (GIFT) orchestrates scenario sessions and reports data as experience API (xAPI) statements. These statements are translated into assertions about individual and team competencies by the *Competency and Skills System* (CaSS). Mathematical models use these assertions to estimate the competency states of trainees. This information is displayed in a dashboard that enables users to explore progression over time and informs decisions concerning advancement to the next training phase and which skills to address.

To test, tune, and demo STEEL-R, more data was needed than was available from real-world training exercises. Since the raw data used to estimate competencies are captured in xAPI statements, a component called DATASIM was added. DATASIM simulated training sessions by generating xAPI statements that conformed to a STEEL-R *xAPI Profile*. This facilitated testing of STEEL-R and was used to create a demo that highlighted the ability to map data from multiple training systems to a single competency framework and to generate a display that team leaders can use to personalize and optimize training across multiple training modalities.

This paper gives an overview of STEEL-R, its architecture, and the features that enabled the use of artificial data. The paper explains how xAPI statements are converted to assertions and how these are used to estimate trainee competency. This is followed by a section on xAPI Profiles and on the xAPI Profile used in STEEL-R. The paper then discusses how artificial data were generated and the challenges of modeling longitudinal development and team in these data. The paper ends with a section on future research.

1. INTRODUCTION

The research reported in this paper relates to the US Army *Synthetic Training Environment* (STE) initiative that “brings together live and virtual training environments, aiming to deliver accessible exercises that mimic the full complexity of the physical world” [2]. To support this initiative, the initiative is developing infrastructure and a suite of *Training Management Tools* (TMT) that permit diverse training systems – including desktop game-based, mixed reality, virtual reality, augmented reality, and sensor-instrumented live training – to be rendered and integrated in a single training environment and training to be optimized within this environment.

The goal of the *STE Experiential Learning – Readiness* (STEEL-R) project is to support the STE TMT with software that collects evidence from training scenarios and uses this to estimate team and individual competency and performance probabilities, recommend training interventions, and inform the design of training scenarios. Research to date has focused on US Army battle drills [3], i.e., short tactical team scenarios intended to train individuals and teams to an automated response level. These include cognitive, psychomotor, and affective skills and behaviors that can be trained in a series of training systems that progress from first-person shooter game-like environments such as Virtual Battle Space 3 [4] (*synthetic* in this paper), to mixed reality and augmented reality environments (*semi-synthetic*), and field exercises in which trainees are instrumented with sensors (*live*). Traditionally, observer controllers / trainers (OC/Ts) are present and can alter conditions on the fly to change difficulty or add stressors. A goal of the STE TMT is to accelerate development and skill retention by using data-driven automation and the capabilities of intelligent tutoring systems to support assessment and facilitate personalized coaching.

The training addressed by STEEL-R is *experiential*, meaning that learning and mastery require repeated deliberate practice under varied conditions. To support experiential skill acquisition, the underlying competency and predictive models in STEEL-R must take longitudinal data and progression into account. This type of training also heavily involves team tasks and *team dimensions* such as cohesion, communication, and backup behaviors [5]. This adds further complexity to the underlying models and places further requirements on the data that must be collected to generate and test these models. Since the demand for such data is too large to be met by small trials, and since it is important that STEEL-R demonstrate good results prior to deployment in high-stakes real-world training, we saw *artificial data* as the best way to proceed in the early and middle stages of our research. We use the term *artificial* rather than *synthetic* in this paper to avoid confusion with synthetic training.

This paper focuses on the use of artificial data, on the use of xAPI Profiles and DATASIM to produce artificial data, on the challenges encountered, and on the results obtained. We start with an overview of the STEEL-R architecture and its critical features, which is next.

2. STEEL-R ARCHITECTURE

Three systems play a central role in the STEEL-R architecture, shown in green in Figure 1. The first is the *Generalized Intelligent Framework for Tutoring* (GIFT) [6], which orchestrates scenario sessions. It connects to and collects data on trainee actions from training systems via connectors. GIFT examines these actions and assesses whether specified tasks, activities, and expected behaviors are performed or demonstrated at, below, or above expectations.

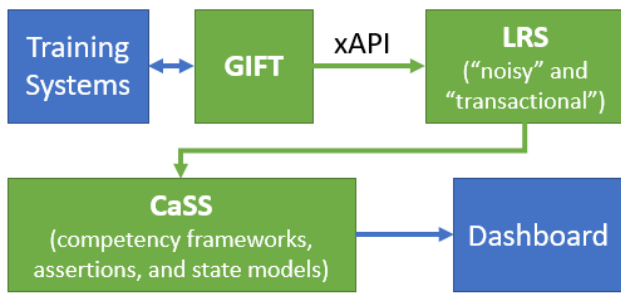

Figure 1: STEEL-R Component Architecture

The second core component is a set of two *Learning Record Stores* (LRSs). Every time an assessed performance state changes, GIFT reports the state and associated session data to a “noisy” LRS via experience API (xAPI) [7] statements. This noisy LRS captures everything that is happening in a session. A second “transactional” LRS filters noisy LRS data, retaining only the overall assessment of each trainee in a session. Data from the transactional LRS is polled by an instance of the *Competency and Skills System* (CaSS) [8], the third core component.

CaSS stores *competency objects* that represent the individual and team tasks, skills, knowledge, attitudes, and behaviors that a given instance of STEEL-R is intended to train and track. These are stored in *competency frameworks* that include relations among the skills, competencies, and behaviors these objects represent. As STEEL-R runs, CaSS collects xAPI statements and formulates *assertions*. An assertion is a statement to the effect that a trainee or team has or has not demonstrated competency based on identified evidence under specified conditions [9].

A GIFT performance assessment generated can generate multiple assertions about multiple competency objects. As explained in Section 3, CaSS computes competency states from these assertions using mathematic models. Competency states and other data are sent by CaSS to a Dashboard that can be used to view states, track progress, and make informed training decisions. Throughout this process, the chain of evidence is preserved so an OC/T can review and audit it. Dashboard data can be traced back through CaSS, the LRS, and GIFT to trainee actions that can be replayed in a GIFT “gamemaster” interface.

A crucial feature of this architecture is that the data from all training systems is filtered through GIFT, where it is referenced against a common set of competency objects. Data from desktop games, mixed reality simulations, and live exercises can thus be combined to estimate and track the state of each single skill and competency.

2.1 STEEL-R Implementation

STEEL-R uses a Multiple Open System Architecture (MOSA) that integrates GIFT and the US Advanced Distributed Learning (ADL) initiative’s Total Learning Architecture (TLA) [10] [11]. Most components (including GIFT and CaSS) are customized versions of open-source software. The LRSs are instances of the Yet Analytics SQL LRS [12], and all components are hosted on a hybrid container-based platform (Docker™). Since STEEL-R is intended to support field operation, it is designed for offline use and the entire system can be deployed on a mid-range rugged laptop. In field deployments, STEEL-R collects data in offline mode and forwards it to a cloud hosted instance when it comes back online. The mechanisms that permit offline operation enable STEEL-R to assemble data received from multiple sources at different times into

a coherent sequence of events along a single timeline. This feature turned out to be crucial, as will be discussed in Section 5.2.

3. ESTIMATING COMPETENCY

The current version of STEEL-R considers three competency states – *untrained*, *practiced*, and *trained* – and three training phases – *crawl*, *walk*, and *run*. The three states are derived from US Army doctrine, while the training phases roughly correspond to synthetic, semi-synthetic, and live training. The Dashboard component of STEEL-R informs OC/Ts how an individual or team is progressing from untrained to practiced to trained within each training phase and how ready they are for the next training phase, i.e., to move from crawl to walk and walk to run. In future Army versions, an *expert* state may be added, and different states and phases may be used for different application domains.

3.1 The Math Model

CaSS populates the STEEL-R Dashboard with longitudinal data about the competency state of each individual or team. These states are estimated using a mathematical model (the “math model”) that involves a *repetition function*, an *evidence function*, and *rollup rules*. The repetition function represents the number of times a skill or competency has been trained, weighted by a forgetting function and a function that accounts for the value of spaced repetition. Similar methods are used in ACT-R [13] and the work of Jastrzembski and others on predicting future training performance [14]. The evidence function assigns a score between -1 and 1 that is derived from the history of performance assessments, taking skill decay, the trustworthiness of the evidence, and performance on related skills and competencies into account. Rollup rules allow performance on related skills and competencies to contribute to an evidence function and allow dependencies on performance under varied conditions and on the states of sub-skills to be added. More details model can be found in [15].

3.2 The Role of CaSS Assertions

The raw data used to evaluate the repetition and evidence functions comes from *assertions*. Assertions are a fundamental data type in CaSS that expresses conclusions drawn from evidence in a uniform way. An assertion can identify its source, the on which the source relied, the source of the evidence, the person or team and the CaSS competency object about which the assertion is made, a timestamp, a decay function, and a parameter that indicates the confidence its source has in the assertion [15]. Assertions can assert that a skill or competency was or was not demonstrated or is or is not possessed. Assertions can also identify the conditions under which the evidence was gathered e.g., difficulty factors and stressors.

CaSS computes the repetition and evidence functions from data in assertions. For example, if a competency object represents the ability of a team or person to perform a task, CaSS examines all assertions about their performance on that task and uses these to determine when and how often and with what results the task was attempted under varied conditions. This information is used to compute the repetition and evidence functions, which are in turn used to estimate whether they are untrained, practiced, or trained within the crawl, walk, and run phases.

3.3 Generating Assertions from xAPI

GIFT does not directly make CaSS assertions. Instead, it assesses actions, activities, and expected behaviors based on data from a training system and emits xAPI statements that require translation into CaSS assertions. CaSS does this with a *decoder*. The decoder has a lookup table that maps activities to competency objects and specifies how the three states reported by GIFT (at, above, and

below expectations) translate into positive or negative assertions about these objects. At present, this lookup table is hard-coded based on subject matter expert (SME) input.

3.4 The Need for Data

The math model and decoder have weights and parameters that can be set in a STEEL-R instance and control competency estimates. As STEEL-R develops, these will be used to compute performance probabilities and to recommend interventions and scenario designs. The system is designed so that its weights and parameters can be machine-learned, but at this stage they are manually set based on experimentation guided by theory. This requires significant data, and machine learning will require even more.

The best data would be data from real-world training exercises. Unfortunately, there are limited opportunities to deploy STEEL-R in such exercises, and since many involve high-stakes training, STEEL-R must be thoroughly stress-tested and shown to produce reasonable results before deployment can be considered. For these reasons, we took the approach of generating artificial data.

Referring to Figure 1, there is a choice as to where artificial data is inserted. One choice is to inject it into CaSS in the form of assertions. This can be used to test the math model, and early on we developed a small web app to do this, see Section 5. This allowed us to check formulas and code and to demonstrate how evidence affected competency estimates, but it was not sufficient to test the entire architecture. As a result, we decided to generate artificial xAPI statements that mimicked those generated by GIFT. This involves xAPI profiles, which are explained next.

4. XAPI PROFILES

The experience API (xAPI) is a mechanism for reporting and retrieving learner activities in an *actor – verb – object – context – results* format [7], [16]. xAPI *statements* in this format are sent to an LRS where they can be retrieved by other systems with appropriate permissions. xAPI statements are usually generated by an education or training system such as an LMS, simulation, or intelligent tutoring system, but statements can come from another LRS, as is done in the STEEL-R handoff between the noisy and transactional LRS. This ability enables multiple LRSs at the edge of a network to feed a central LRS, which improves scalability. The xAPI specification, which includes specifications for LRSs, was first developed by the ADL and is now undergoing more formal standardization in IEEE [16].

The xAPI specification is intended to be usable in any education or training ecosystem. To maintain flexibility, it does not specify the context or semantics of xAPI statements. In implementations it is necessary to add definitions and place restrictions on the format and elements in statements to ensure that data is properly reported and interpreted. This is done via *xAPI Profiles* [17].

xAPI Profiles define concepts, templates, patterns, and extensions for use in forming xAPI statements. *Concepts* define the vocabulary and attributes that may appear in xAPI statements, including verbs and activity types, and specify rules for how and when they can be used. *Templates* provide rules for constructing statements. *Patterns* are collections and sequences of templates that describe the actions associated with a task, performance, or learning path. *Extensions* enable new (externally defined) attributes to be used in statements. Together, these rules and definitions enable xAPI statements to be properly formed and interpreted. The xAPI profiles specification [18] establishes rules for serializing profiles in JavaScript Object Notation (JSON) and in JSON for Linked Data (JSON-LD). Using

JSON-LD, vocabulary can link to the same or similar terms in other profiles, creating a semantic web of xAPI statements.

4.1 Designing the STEEL-R xAPI Profile

A critical factor in designing any xAPI Profile is creating concepts, statement templates, and patterns that are flexible enough to be used in many different scenarios but restrictive enough to enable data to be reported and understood in use cases of interest. The challenge for STEEL-R is that STEEL-R is meant to support many types of experiential learning. Even in relatively narrow domains, it may be necessary to track and capture data on hundreds (or more) tasks, activities, and behaviors. Profiles could be created that specify the names of tasks and performance levels for each domain, but a more flexible approach is enabled by exploiting the capabilities of GIFT.

4.2 The STEEL-R xAPI Profile

As a scenario session unfolds, GIFT determines if performance on tasks, activities, and behaviors stored in a Domain Knowledge File (DKF) exceeds, meets, or is below expectations [19]. At present, CaSS only uses summative assessments at the session level, but GIFT generates a formative assessment each time a performance state changes and can record information about the exercise, such as the conditions under which performance was assessed.

The xAPI profile designed for STEEL-R uses statement templates that enable tasks, activities, and behaviors to be referenced from the DKF and that report results on the GIFT three-step scale. This simplifies the form of statements, leaving the list of specific activities to GIFT. The STEEL-R templates also allow scenario conditions to be reported and include extensions for linking a GIFT assessment to a recording of the session segment that produced it.

To form a complete chain of evidence, STEEL-R xAPI statements can capture current performance states, changes in performance state, the factors that changed, and the conditions present when the state changed. Of particular interest to our future research is the ability to identify stressors and difficulty factors, both of which can be dynamically altered mid-session. Stress and difficulty are now being included in xAPI statements as discrete variables that are evaluated by GIFT and that CaSS can use in its math models.

Patterns represent the lifecycle of trainee participation in a training session. The templates in these patterns are populated by system events such as starting or joining a session, interactions within the session that could result in changes to a trainee's psychomotor, cognitive, or affective state, and GIFT's conclusions about a learner's overall performance with respect to specified tasks. Event data reported by GIFT is used to select the appropriate template and to filled in the template based template rules.

5. GENERATING ARTIFICIAL DATA

For testing purposes, artificial data was generated in two ways. The first was through a small app that was purpose-built to test and demonstrate the math model. This app allows users to apply hard-coded assertions about competency objects in a framework and displays how the repetition and evidence functions, competency state, and performance probabilities change with each statement.

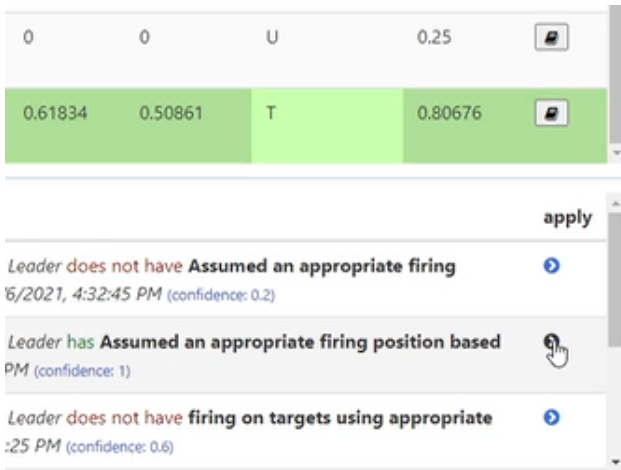

Figure 2: User applying a competency assertion

A second screen shows how the estimated probability of successful performance varies over time as both positive and negative assertions are activated. This visualization proved useful for both demonstrating and validating the math model.

Figure 3: Display showing how applying assertions changed the estimate of performance probability as evidence accumulated.

5.1 DATASIM

The second method used to generate artificial data used an open-source component of the ADL's TLA reference implementation [11] called the *Data and Training Analytics Simulated Input Modeler* (DATASIM) [20]. DATASIM can produce xAPI datasets that conform to one or more xAPI Profiles at small scale (tens to thousands of statements) and large scale (over a billion statements). DATASIM is controlled by a *simulation specification* that a user defines via a user interface. Each simulation specification includes an xAPI Profile, the actors in the simulation, and parameters that specify the involvement of each actor in each type of activity as well as start and stop times, a seed value, and the maximum number of xAPI statements to be generated.

Within a given simulation, DATASIM generates a pseudo-random autoregressive moving average (ARMA) time series (called the

common time series) and a pseudo-random ARMA time series for each actor, each determined by the seed value. An actor generates an xAPI statement whenever their time series graph crosses the common time series graph [21]. When that happens, a Gaussian that is weighted by parameters in the simulation profile is sampled for each possible pattern and the pattern with the highest value is used. The same is then done to select templates in the pattern, statements in each template, and concepts in each statement.

5.2 Applications to STEEL-R

We used DATASIM to benchmark and stress-test STEEL-R, which was the original purpose of DATASIM [21]. By using the same actors, we could simulate multiple successive training sessions across each training phase and by referencing the same competency objects in the CaSS decoder, we could generate assertions about same competencies, skills, and behaviors at each stage. This let us validate system operation and benchmark performance at every point and for every component downstream of GIFT. It did not, however, give us the desired level of realism.

Although xAPI profiles enable DATASIM to generate data that statistically reflects the right mix of training events and outcomes at the macro level, DATASIM has no mechanism that allows a given actor to develop competency as they engage in successive activities and no mechanism to realistically correlate individual and team behavior. Thus, if DATASIM is used to simulate people performing a series of tasks, it will produce about the right number of successful and unsuccessful task completions but cannot alter its parameters during a simulation so that a person who successfully completes the early tasks will be more likely to successfully complete later ones. Similarly, if one of the actors is a team, DATASIM, the probability of team events cannot be changed based on the activities of team members during a simulation. Since longitudinal data and developmental progression are fundamental to experiential learning, we needed a way to reflect individual development and team dynamics.

We did this by running series of micro-simulations instead of one large one and by manually set parameters between runs. Each micro-simulation produced data for the same actors in a small time slice. This gave us greater control over the progression of outputs and implied team dynamics. STEEL-R treated these as offline data, automatically stringing them together to create a sequence of activities along a single timeline. This produced enough data to test and tune STEEL-R and to implement the use case described next.

5.3 A Use Case and Implementation

In November of 2021 we used DATASIM to implement and demo a use case in which a small team underwent three days of training. Our goal was to highlight how team competency improved and progressed from crawl to walk as interactions with multiple training systems activated cognitive, psychomotor, and affective skills.

On day one, the team trained on Army battle drill 6 (BD6) [3] in a synthetic game-based environment. This was done in multiple sessions with under varied conditions and with varied difficulty levels. DATASIM micro-simulations were manually configured to show performance improvement over the course of day one. On day two, BD6 training continued in a mixed reality environment that activated psychomotor skills. The data from day one showed that the team knew what to do, so day two provided opportunities to apply that knowledge in a safe controlled environment with more realistic interactions. The data generated by DATASIM represented exposure to numerous scenarios and showed further performance improvement. At the start of day three the team leader looked at the

Dashboard (Figure 4) and noticed that the team was progressing well on BD6 but there were potential skill decay issues with a related task trained in a previous battle drill. As a result, the team leader initiated training of this previous battle drill. The third day of training activated some of the same skills as the first two days and resulted in improvements in skills that seemed to have decayed.

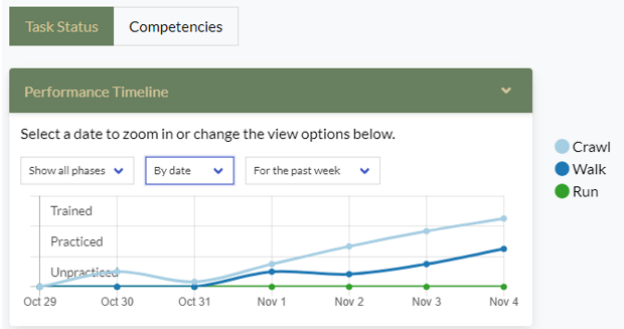

Figure 4: Part of the Dashboard, showing progress on reported by CaSS and derived from artificial data.

6. CONCLUSION

The use case we implemented and demonstrated with artificial data showed the art of the possible. It showed a team leader using competency estimates derived from multiple and varied training environments to personalize a training plan and the potential to optimize training time by leveraging multiple training modalities within a given training cycle. The ability to mine artificial data enabled us to stress-test and benchmark STEEL-R and permitted us to visualize the effects of parameters in the formulas and models used to estimate competency. This served as an excellent tool for debugging, tuning, and demonstrating the models, and we continue to take this approach as we make changes and add features.

We note that as of November of 2021, neither difficulty or stress levels were reported by GIFT or used by CaSS. These are critical factors that can be manipulated during training sessions and that should be used when determining whether an individual or team is trained and ready to advance. GIFT is now reporting difficulty and stress levels in xAPI statements, and we are incorporating difficulty and stress into the decoder, math model, and Dashboard.

Finally, our work with DATASIM exposed the need to model the progress of simulated individuals and to correlate individual and team behaviors. We did this with manually manipulated micro-simulations, which is labor intensive and will not scale. In this regard, we are exploring two further research directions. The first is to implement ways to dynamically alter the parameters used to generate artificial data during a single simulation. The second is to enable the parameters that control these alterations to be machine-learned. These will create a virtuous cycle wherein artificial data are used to test and tune new features and models, these features and models are used to improve real-world training, and real-world training data are used to improve the generation of artificial data.

7. ACKNOWLEDGEMENTS

This work was supported by U.S. Army Research Laboratory contract #W912CG20C0020. It is dedicated to Tom Buskirk who contributed to this project as a software developer and who died suddenly in 2021 at the age of 47. He was a joy to work with, was a talented developer, and is dearly missed by the STEEL-R team.

“Closing the Loop” in Educational Data Science with an Open Source Architecture for Large-Scale Field Trials

ABSTRACT

Ten years after the announcement of the “rise of the super experiment” at Educational Data Mining 2012, challenges to implementing “internet scale” educational experiments often persist for educational technology providers, especially when they seek to test substantive instructional interventions. Studies that deploy and test interventions, when informed by data-driven modeling, are often described as “close the loop” studies. Studies that close the loop attempt to link improvements in statistical and machine learning models of learning to real-world learning outcomes. After first considering challenges to internet scale experiments, we review several educational data science/mining studies that close the loop between data-driven modeling and learning outcomes. Next, we describe UpGrade, an open source architecture that, when integrated with educational technologies, helps overcome challenges to large-scale field trials (or internet scale experiments) that close the loop between data-driven work and real-world learning outcomes. In addition to describing preliminary randomized experiments that have been conducted and will soon be conducted using the architecture in two educational technology platforms, we end with a “call for contributors and integrators.” UpGrade contributors and integrators will be researchers and developers who seek to drive continuous, data-driven improvements in real-world settings where learning with technology occurs.

Keywords

A/B testing, closing the loop, educational technology, large-scale field trials, experimentation, open source software.

1. INTRODUCTION

At Educational Data Mining 2012, Stamper et al. [18] described “the rise of the super experiment” and the Super Experiment Framework (SEF), which conceptualizes data-driven educational experimentation at the lab scale, school scale, and internet scale. Lab scale experiments may have sample sizes in the range of 1-100; school scale experiments range in sample size between tens of learners and thousands of learners, and internet scale experiments may have sample sizes ranging from thousands of learners to

S. Fancsali, A. Murphy, and S. Ritter. “closing the loop” in educational data science with an open source architecture for large-scale field trials. In A. Mitrovic and N. Bosch, editors, *Proceedings of the 15th International Conference on Educational Data Mining*, pages 834–838, Durham, United Kingdom, July 2022. International Educational Data Mining Society.

millions of learners. Experiments at each scale have benefits and drawbacks, and there are important ways in which experiments at each scale can inform the design and implementation of experiments at the other scales. The authors’ presentation of the SEF concludes by laying out several key challenges for internet scale experiments. We briefly present their four posited challenges and review several (types of) educational data science/mining (EDS/EDM) studies that “close the loop” before describing the UpGrade open source architecture for conducting experiments in educational technologies at any of the SEF’s scales and how UpGrade helps educational technology developers address these challenges.

2. CHALLENGES FOR INTERNET SCALE EXPERIMENTS

Stamper et al. [18] lay out four key challenges for internet scale educational experiments. The first challenge is attracting a large user-base to the learning platform on which one would like to conduct such experiments. While an important issue, we leave the much broader discussion of large-scale adoption of educational technologies and software for learning for another day and assume that a researcher seeking to “close the loop” already is satisfied that they have a sufficiently large and diverse user-base to answer their research questions.

The second challenge they suggest, in the context of an educational game deployed via the Brainpop.com platform, is “instrumenting software for generating data logs that measure player performance, learning, and engagement” [18]. This is another broad, general challenge for developing software for learning, whether an educational game, intelligent tutoring system (ITS), or other type of learning software. Well-instrumented learning software provides insights about learners and their learning process, behaviors, engagement, and related facets of their learning experience that are the purview of nearly all work published at Educational Data Mining and related venues. We assume that readers and platform developers already recognize the importance of generating meaningful data from their learning platforms if they seek to run studies that close the loop or similar internet scale educational experiments.

Features of UpGrade target the third and fourth challenges raised by Stamper et al. [18]. The third challenge they pose is “the configuration of the software to allow for experimental designs” [18]. Being able to run experiments within a piece of software requires that different variants or instances of elements within an application’s design space can be instantiated and deployed in software, abstracted in such a way that the software can deliver

users to particular experiences based on their condition assignment. The software must also have some way of assigning users to particular experimental conditions. While variants within a target application's design space must still be created, UpGrade serves as an enabling technology to make experimental management (e.g., handling complexities of random assignment and tracking of users' condition assignments) less onerous for technology developers. One way of viewing UpGrade is as an enabling technology that makes A/B testing or experimentation a relatively simple matter of instrumenting target applications by implementing appropriate application programming interface (API) "hooks" to UpGrade rather than having to implement complex experimental management logic within the target application itself. Just as learning software developers increasingly understand the importance of instrumenting their software for high quality learning data collection, UpGrade may serve to further the goal that basic instrumentation in learning software will allow for rigorous learning engineering, involving experimentation and testing of new content, software features, instructional approaches, and other factors of interest to both researchers and technology developers.

The fourth challenge is two-fold, as Stamper et al. [18] note that "researchers increasingly face the challenge of making use of tens of thousands of subjects in an efficient manner" while also pointing out that some experiments may create inconsistent user experiences. While the authors view inconsistent user experiences as a potential catalyst for reducing overall participation, we take inconsistent user experiences as a more fundamental potential barrier to delivering internet scale experiments. Educational technology providers might reasonably refuse to deploy experiments at all if there are potential scenarios in which unsatisfying, inconsistent, or disengaging user experiences are likely to result.

Enabling technologies for large-scale educational experiments like UpGrade ought to deliver flexible options and capabilities to researchers and developers to deploy complex, substantive experiments and experimental designs in ways that still maintain high quality, consistent learning experiences. By illustrating practical examples of how studies that "close the loop" based on EDS/EDM insights might noticeably affect (or not) the learning experiences of real K-12 students and teachers, we motivate how UpGrade helps to meet many of the challenges raised by internet scale experiments.

3. "CLOSING THE LOOP"

We consider two kinds of potential "close the loop" studies drawn from literature in EDS/EDM and ITS research to provide a simple illustration of the types of considerations educational technology providers might make in delivering internet scale field trials or experiments to users in settings like K-12 classrooms. One case is intended to illustrate a situation in which a relatively simple, user-level random assignment study is unlikely to raise any concerns about consistency of learner experience while the other illustrates some potential concerns about consistency that might arise. In the section that follows, we describe important features and affordances of the UpGrade architecture in more detail to show how it enables researchers and educational technology developers to deploy experiments that address these concerns about consistency as well as provide other options for delivering high quality experiments for learning engineering.

The overarching goal of "closing the loop" with experiments is to evaluate whether observed improvements in (usually statistical) outcomes like prediction accuracy of particular models translate

into improved learning outcomes for students in a target system. Learning outcomes of interest in target systems might include efficiency of practice, time to skill mastery, or gains in performance from a pre-test measure to a post-test measure, among others.

Our example "close the loop" studies are related to how data-driven modeling of learner performance informs the specification and parameterization of so-called knowledge component (KC; or skill) [10] cognitive models frequently used within ITSs like Cognitive Tutor/MATHia [14] or in tutors built with tools like the Cognitive Tutor Authoring Tools [2].

A bevy of research in EDS/EDM and related areas (e.g., [3, 15, 19]) consider different approaches to fitting the parameters of KC models deployed in ITSs, typically within the four-parameter framework of Bayesian Knowledge Tracing [6], holding the set of KCs that appear to a learner during the learning experience fixed.

Contrast (1) studies that close the loop by contrasting *two or more sets of parameter estimates for the same KC model* with (2) studies that contrast two or more *different specifications of a KC model*, of which there are several examples in the literature (e.g., [11]). The second type of experiments are typically supported by semi-automated, data-driven techniques (e.g., Learning Factors Analysis [5]), various types of task analysis (e.g., [4]), or more recent multi-method approaches for "design loop adaptivity" [1, 8]. These techniques are used to re-evaluate the underlying KC model that drives the ITS's adaptive learning and determine how the specification of the KCs themselves might better represent what a student is learning (not just the performance parameters related to their learning) as they practice in the ITS.

In the first "parameter estimation" experiment in an ITS like MATHia, one or more experimental conditions and a control condition each have the same "skillometer" or dashboard display for students to see their progress toward KC mastery. Similarly, the same KCs or skills reported to teachers in their classroom analytics. The only difference in a parameter estimation experiment is likely to be exceedingly subtle, in that there are different parameters for subsets of KCs in each condition. In the latter "specification" experiment, the control condition and one or more experimental conditions vary in what KCs constitute the set of KCs used to drive adaptation for the topic as well as *what is displayed to students and their teachers*.

In the hypothetical parameter estimation study, individual random assignment is likely to be a reasonable choice for the researcher running the experiment. If the ITS, for example, implements some form of mastery learning (e.g., [17]), then students will be accustomed to receiving different amounts of practice on KCs they encounter within different topics in the ITS. Different parameterizations for different students in the same classroom are *not likely to lead to drastically different perceptions of the learning experience* for students. Nevertheless, if the experiment is successful, one or more parameterizations may lead to more efficient practice or provide students with additional practice that they need to achieve mastery. Teachers' experience of using analytics and reports are likely to be nearly indistinguishable across the different parameterizations.

Though perhaps still subtle, KC model specification studies are more likely to create inconsistencies in K-12 learners' and instructors' experiences in an ITS if they were to be deployed within, for example, the same classroom, or even to all of the classrooms of the same teacher. Changes in the KC model specification may also be accompanied by design differences in the

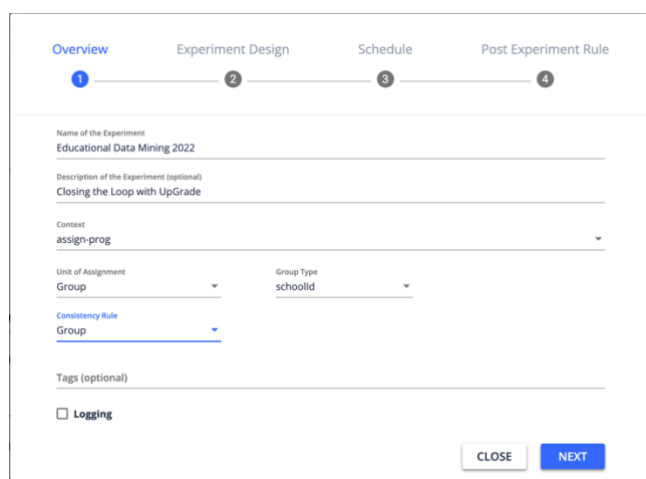

tasks presented to students (e.g., as in [8, 18]), presenting further opportunities for noticeable differences in learner experiences to emerge.

Generally, the contrast we seek to illustrate is between any type of relatively “stealthy” experiment with more “conspicuous” and/or visually salient experiments. More stealthy examples, like the hypothetical experiment that only manipulates parameter estimates, are those in which differences in the learner experiences are subtle and likely to be unnoticed between conditions. Experiments are likely to be more conspicuous when they seek to test substantive differences in learning experiences and may have more easily-discernable variations, as in the “specification” experiment.

More conspicuous differences might reasonably be evaluated between instructional methods, encouraging students to adopt different problem-solving strategies for the same topic, and contrast along any number of a wide variety of instructional decisions content designers must make [9]. Many such differences between experimental conditions are easily perceived by students and teachers. If condition assignment is not thoughtfully considered (e.g., by considering a group-level assignment), students may realize that they are receiving a different experience compared to other learners in their classrooms, leading to unanticipated changes in learning patterns. Teachers might easily become overwhelmed by the need to support different learning experiences for the same topic, keep track of differences in analytics and reporting, and other potential inconsistencies. In what follows, we describe how the UpGrade platform can help educational technology developers and researchers not only deploy internet scale educational experiments but also do so in ways that handle many of the challenges that arise in such deployments in real world settings in which learning takes place.

4. UPGRADE

UpGrade¹ [16] is an open source software architecture (available via GitHub²) intended to lower barriers to learning engineering and enable internet scale experiments (also sometimes referred to as “A/B tests” or randomized field trials) that test substantive changes to learning experiences in settings like K-12 classrooms while preserving consistent, high-quality learning experiences for end-users.

The screenshot shows the 'Overview' step of a four-step process for creating a new experiment. The steps are: Overview (1), Experiment Design (2), Schedule (3), and Post Experiment Rule (4). The 'Overview' step is currently active. The form includes the following fields and options:

- Name of the Experiment: Educational Data Mining 2022
- Description of the Experiment (optional): Closing the Loop with UpGrade
- Context: assign-prog (dropdown menu)
- Unit of Assignment: Group (dropdown menu)
- Group Type: schoolid (dropdown menu)
- Consistency Rule: Group (dropdown menu)
- Tags (optional):
- Logging
- Buttons: CLOSE and NEXT

Figure 1. Screenshot of the “overview” of an experiment in the UpGrade user interface for creating a new experiment

We consider several of the major affordances provided by UpGrade, several of which are illustrated in the screenshot of Figure 1 that shows the preliminary “overview” of an UpGrade experiment as it is being specified. Group random assignment, consistency rules, post-experiment rules, and user segmentation are features of experiments that help to ensure that consistent learning experiences are delivered during experiments. Researchers determine how best to set these options as a part of designing experiments in UpGrade.

4.1 Group Random Assignment

While UpGrade has logic for assigning experimental conditions on an individual-student or user basis, the ability to randomly assign conditions by group (e.g., at the level of classrooms within a K-12 school) enables researchers to conduct internet scale experiments in educational software products that are both deployed at scale and used in authentic classroom contexts. In educational settings, it may be undesirable for students within the same group (e.g., by class, teacher, school district, or some other grouping) to be assigned different conditions within the same experiment, particularly if such conditions involve conspicuous or salient visual changes (e.g., different “skillometers” displays and teacher analytics in the KC model specification experiment illustrated in §3) or substantively different models of instruction. UpGrade manages coherence of learning experiences by group as well as anomalies that may arise in group membership, enabling researchers to specify how an experiment should behave if a student switches classes or is in multiple classes simultaneously.

4.2 Consistency Management

The second way in which UpGrade helps deliver consistent experiences is via associating deployed experiments with consistency rules that govern how users are treated for inclusion/exclusion in an experiment who have already encountered pieces of instructional content or other design features that are included in experiments. This is particularly useful when instructional content is delivered via adaptive software in which self-paced progress is often a crucial feature of the learning experience; in such software students may reach the content of interest at different times. If a student in a class encounters the content of interest earlier (or later) than their fellow students, consistency management can specify whether condition assignment binds more strongly to group membership or individual students.

4.3 Post-Experiment Rules

A “post-experiment rule” is a parameter that manages delivery of experimental conditions once an experiment has stopped running, but students may still interact with the target content in the educational application. Researchers may wish to have a “winning” condition be delivered to subsequent students who encounter the content of interest, or may wish to maintain the condition assignment weighting even if the experiment has ended. For example, if a study using UpGrade runs from September-November of a school year, but a student goes back to review content in preparation for an end-of-semester exam in December, a post-experiment rule can specify whether that student should receive the same experimental condition they were originally assigned, or whether they are permitted to experience a default or other condition.

4.4 User Segmentation

Another challenge when conducting internet-scale experiments in real-world classrooms is that researchers may not necessarily want or need to target all members of a population. Segmentation and the ability to pre-define include/exclude lists empowers researchers to target experimental interventions to groups of interest, at the level of interest: e.g., middle schools, 7th grade, specific districts, or even geographic regions. Similarly, districts or schools can fully “opt-out” and join a global exclude list without impacting research at scale conducted by an educational technology company.

While learning platforms often do not automatically collect data about individual learner demographics, when such data are available (or when such data are available at an aggregated level like that of particular schools), user segmentation is likely to also play an important role in better understanding what works for particular sub-populations of students, helping researchers close the loop in ways that promote inclusion and equity across diverse populations of learners.

4.5 Monitoring Metrics

UpGrade enables researchers running experiments to monitor their progress with respect to “enrolled” users (i.e., those users who have encountered relevant content and been assigned to a condition) as well as those who have been excluded. In addition, APIs are available for target learning applications to send specific metrics (e.g., time to complete a particular piece of content) of interest to UpGrade’s monitoring dashboards for real-time progress monitoring of experimental progress. The screenshot in Figure 2 illustrates a particular case of an experiment with two conditions in the UpGrade platform, displaying enrollment data over time and by experimental condition.

Figure 2. Screenshot of monitoring dashboard in UpGrade, showing enrollment metrics over time and by condition, for two experimental conditions, entitled “ddi_control” and “pre_ddi_variant,” where “ddi” stands for “data driven improvement” of particular content in Carnegie Learning’s MATHia platform.

4.6 Support for Diverse Experimental Designs

UpGrade currently supports relatively simple experimental designs, including weighted random assignment to two or more conditions (see “weight” column near the bottom of the screenshot in Figure 2) as well as within-subject, factorial, and partial-factorial designs. UpGrade developers have a roadmap for implementing additional designs including multi-arm bandits and stepped-wedge designs in the near future. More sophisticated designs and those

incorporating adaptive experimentation could be valuable contributions from the EDM and allied communities. This leads to our call for contributors and integrators.

5. CALL FOR CONTRIBUTORS & INTEGRATORS

Our goal in the present paper has been to introduce UpGrade to the EDM community. We hearken back to the “rise of the super experiment” and seek to build awareness of challenges often raised by internet scale, experimental “close the loop” studies and how UpGrade presents a solution that can be integrated within an existing or emerging educational technology product to help overcome those challenges. Efforts at the intersection of EDS/EDM and the emerging field of learning engineering rigorously seek to establish causal links between data-driven insights that inform improvements in educational technologies and practical learning outcomes resulting from the use of these technologies. We applaud efforts like E-TRIALS [12], MOOClets [13], and Terracotta³ that aim to provide similar support for rigorous experimental or A/B testing of learning innovations within particular contexts (e.g., E-TRIALS within ASSISTments [7], TerraCotta within the Canvas Learning Management System). UpGrade can be integrated into existing or new learning applications and technologies to similarly drive rigorous data-driven improvements to learning platforms.

Educational technology developers must still (as ever) address challenges to attracting large and diverse user-bases, instrumenting their technology to capture rich learning data, and appropriately abstracting features and content in their systems so that different learning experiences can be delivered to learners (Challenges #1-2 and part of the third challenge described by [18]). However, UpGrade removes many of the barriers imposed by the challenges of large-scale experimental management in real-world learning settings. The educational technology developer need only implement software instrumentation that calls UpGrade’s API to determine which alternative learning experience (if any) ought to be delivered to a particular user, given characteristics of that user that the target system “knows” about (e.g., via communication with a rostering system) such as the class or school in which the user is learning. The target system for experimentation can also implement UpGrade’s API to provide metrics for monitoring experiments as they proceed. UpGrade handles complex logic of managing condition assignments and dealing with real-world complexities that inevitably arise in settings like K-12 schools.

As an open source platform, developers can contribute new functionality and features to the codebase for the future benefit of all integrators and researchers using platforms that integrate with UpGrade. For example, code might be contributed to build connections to deliver A/B tests in different LMSs and implement appropriate APIs to have metrics for monitoring delivered to UpGrade. Support for new types of experimental designs and algorithms for adaptive experimentation are also a natural place for future development. We welcome such new contributions from the EDM community as well as from the broader educational technology and learning engineering communities.

UpGrade has already been used to deliver experiments to tens of thousands of learners in a math game similar to that targeted in the paper that introduces the SEF [18]. A number of experiments are currently deployed in Carnegie Learning’s MATHia, and new experiments will be deployed in the coming months using

³ <https://terracotta.education/>

UpGrade. These experimental field trials will close the loop between data-driven improvements to facets of learning experiences like KC models as well as personalization and motivational features, and we look forward to presenting those results in the near future. We encourage educational technology developers to consider integrating UpGrade into their platforms to enable rigorous, iterative learning engineering improvements and platform-enabled educational research.

Estimating the causal effects of Khan Academy MAP Accelerator across demographic subgroups

Phillip Grimaldi, Kodi Weatherholtz, and Kelli Millwood Hill
Khan Academy
Mountain View, CA, USA
efficacy-team@khanacademy.org

ABSTRACT

As educational technology platforms become more and more commonplace in education, it is critical that these systems work well across a diverse range of student sub-groups. In this study, we estimated the effectiveness of MAP Accelerator; a large-scale, personalized, web-based, mathematics mastery learning platform. Our analysis placed a particular focus on students from historically under-resourced groups. Our sample comprised 181K students in grades 3-8 from 99 school districts across the United States, 52% of whom attended schools where the majority of the students are eligible for free or reduced price lunch (a proxy for high-poverty schools). Using a combination of system logs/platform telemetry data, standardized assessments, and publicly available school/district data, we estimated the causal effect of a year-long supplemental math intervention on students' standardized mathematics growth outcomes via a quasi-experimental design with controls and a modification of the difference-in-differences framework. Students who used the platform as recommended (30+ min/wk) during the (COVID-19 disrupted) 2020-2021 school year had math growth scores 0.26 standard deviations higher on average than similar students who used the platform for <15 min/week. Further, positive benefits of the platform were observed across all genders, race/ethnic groups, and school poverty levels, but were not as large for districts with greater than 20% English language learners. Further analysis revealed that these students were predominantly Hispanic, and tended to make less progress on fewer skills than their peers given the same amount of practice time. We discuss the implications of these findings, and potential avenues to ensure more equitable outcomes for these students in the future.

Perhaps the most natural question to ask concerning any educational intervention is “does it work?” Indeed, the *What Works Clearinghouse* has reviewed over 11,000 studies evaluating the efficacy of various programs and technologies [26]. Overwhelmingly, these studies are concerned with establishing how well the intervention works *in general*. Of course, the results are inherently limited to the student population in the study, and generalizing the results is not always straightforward. In the U.S., student populations are becoming increasingly diverse [13], with students coming to the classroom with differing skills, backgrounds, and needs. Moreover, there is a growing awareness of educational inequities across the student population coupled with concerns about systemic bias. Even if a study sample is representative of national norms, it is unreasonable to expect that the expected effect would work the same for every subgroup within the sample. Thus, it is critical that we move from asking only “does it work?” to a more specific “for whom does it work?”

In this study, we estimated the effectiveness of Khan Academy's MAP Accelerator, a large-scale, personalized, web-based, mathematics mastery learning platform. Like many other such studies, we used performance on a standardized test, NWEA MAP Growth™, to measure the impact of the intervention. We utilized statistical controls to rule out the influence of confounding variables when possible, and applied difference-in-differences to control for unobserved confounding as well. Critically, we also repeated the analyses across a variety of student sub groups (grade, gender, ethnicity, socioeconomic status, English language proficiency) in order to determine whether the software worked equally well for these groups.

2. BACKGROUND

2.1 NWEA MAP Growth

MAP Growth is a computerized, adaptive, standardized assessment designed to measure and track student mathematics, reading, language usage, and science [18]. For the purposes of this report, we are primarily interested in the mathematics assessment. MAP Growth is designed to be used as an interim assessment, allowing educators to monitor progress and tailor instruction in advance of a summative assessment. The assessment is typically administered three times per year—Fall, Winter, and Spring—with an optional summer administration. During the Fall 2020 administration, the MAP Growth test was completed by nearly 4.4 million students in the United States [14].

Figure 1: Screenshot of MAP Accelerator unit page. Students can learn, practice, quiz, and view mastery states from this page.

MAP Growth is based on the Rasch Model [2], which measures latent student ability on the tested domain. The assessment provides a “RIT” score (short for “Rasch Unit”), which is a linear transform of the θ estimates from the Rasch model. RIT scores typically range from 100 to 350. Given the adaptive nature of the assessment, the RIT scale is not grade dependent. Instead, a student’s RIT score improves incrementally across school years, affording the ability to track progress longitudinally. RIT scores can be categorized into different “bands”, which describe the expected range for students at that grade level. Scores are also offered for four high level subscales: 1) Geometry, 2) Number & Operations/The Real & Complex Number Systems, 3) Operations & Algebraic Thinking, and 4) Measurement & Data/Statistics & Probability.

2.2 MAP Accelerator

MAP Accelerator is a web-based supplemental math learning tool designed to be used in schools that are also using the MAP Growth assessment. At the beginning of the school year, a student’s subscores from their fall MAP Growth assessment are sent to MAP Accelerator, which then constructs for them a set of supplemental instruction and practice content. For example, if a student’s RIT score for Geometry was in the 176-188/Grade 3 range, their lessons in Geometry would be aligned to that level.

A full description of MAP Accelerator’s functionality is beyond the scope of this paper. However, the key take away is that students can learn, practice, or quiz on content of their choosing (see Figure 1). Learn refers to study activities such as explanatory videos, worked examples, and articles. Practice refers to solving interactive math practice problems on specific skills[8]. Practice opportunities typically provide hints to students, as well as immediate elaborative feedback[21] after failed attempts. Quizzing is similar to practice, except provides an opportunity for students to self-test in a mixed skill environment.

MAP Accelerator also implements concepts from *mastery*

learning [15]. The idea behind mastery learning is that students should work at their own pace to master content before advancing on. MAP Accelerator monitors student performance on practice blocks, quizzes, and mastery challenges and provides feedback on their estimated level of mastery (attempted, familiar, proficient, or mastered). While MAP Accelerator allows students to choose their own path, the mastery feedback allows for easy selection of topics that need the most help.

Importantly, MAP Accelerator is intended to be used as a supplement and not a primary source of instruction. Teachers are encouraged to have their students use MAP Accelerator for at least 30 minutes of focused learning time per week—a dosage level that is meant to be reachable with one dedicated class period per week.

2.3 Impact of COVID-19 Pandemic

MAP Accelerator was first broadly released during the 2020-2021 school year. This was the peak of the COVID-19 pandemic and prior to wide spread availability of vaccines. Nearly two-thirds of U.S. students were enrolled in distance learning formats during the Fall 2020 school year [13]. In addition to academic life, home life was disrupted as well. Many parents were losing their jobs or shifting to at home work. Thus, many students had to complete the school year jockeying for internet access and a quiet place to study. Of course, the degree of disruption would obviously depend on socioeconomic-status of the household and available resources.

Given the extreme disruption to academic and home life, it is not surprising then that student achievement measures would drop. Lewis et al. [17] reported that overall Math RIT scores in Fall of 2020 were considerably lower than pre-pandemic levels. Moreover, the amount of growth from Fall 2020 to Spring 2021 was lower than historical averages. Thus, not only did students start the school year behind where they should have been, they grew at a slower pace than they would have been expected to pre-pandemic.

Lewis et al.[17] also found that the negative effects of the pandemic were not observed equally across all ages or demographic groups. First, younger students (grades 3-5) were more negatively affected than older students (grades 6-8). Second, pandemic related declines were more pronounced in students that attended schools with a high proportion of students on free or reduced lunch. Finally, students from historically under-served groups (e.g., Hispanic/Latino, Black-/African American, American Indian/Alaskan Native) were more negatively affected than White and Asian students. In sum, the pandemic appears to have hit vulnerable populations the hardest, and exacerbated pre-existing inequities and achievement gaps.

3. METHODS AND RESULTS

3.1 Data and Sample Summary

In the sections below, we describe some of the data that was available to us, as well as any feature engineering we did. Data from Khan Academy and NWEA MAP Growth tests were privately shared with the researchers for this study. We also made use of publicly available government data from the

National Center for Education Statistics (NCES). All data and analyses are limited to U.S. Schools that adopted MAP Accelerator for the 2020-2021 school year, and to students who took both a Fall and Spring administration of the test. A summary table of the data is available in Appendix A.

Several measures were taken to protect the privacy of students and teachers in this study. All data were deidentified, and personally identifiable information was removed and replaced with electronically encrypted hashed fields. Key files to decrypt the hashed fields were not shared with the researchers. Deidentified data was stored on encrypted and password protected servers. Only researchers directly involved with the project were permitted access to the data. Finally, all data was used in accordance with MAP Accelerator Supplemental Terms and Conditions, which was agreed to by participating districts.

3.1.1 School Data

For each student, we were provided with `district_name`, `school_name` (school the student started the year enrolled in), and `math_teacher` (unique math teacher identifier).

Using this information, we were able to merge publicly available school level variables from the NCES. For each school, we obtained the percent of students reported to be on Free or Reduced Price Lunch (FRL), a commonly used indicator of socioeconomic status[25]. From this, we created a `school_frl_level` variable by binning schools into one of four groups: High FRL ($\geq 75\%$), Med FRL ($> 25\%$, $< 75\%$), Low FRL ($\leq 25\%$), or Unknown. We also obtained the percent of English Language Learners at the district level (ELL). From this we created a `district_ell_level` variable by binning into four groups: High ELL ($\geq 20\%$), Med ELL ($\geq 5\%$, $< 20\%$), Low ELL ($< 5\%$), and Unknown.

The key point to note about the school level data is that 52% of the sample came from High FRL schools. The overall sample skews more towards high poverty schools than would be expected from a random sample of US schools (24%)[24].

3.1.2 Demographic Data

For each student, we were provided with their `gender` (Male, Female), `grade` (3 - 8), and `ethnic_group` (American Indian or Alaska Native, Asian, Black or African American, Hispanic or Latino, Native Hawaiian or Other Pacific Islander, White, Multi-ethnic, Not specified or Other).

A key point to note about the demographics of this sample (see Appendix A) is that the ethnicity breakdown is much different than national averages. In particular, Hispanic or Latino students are just as prevalent in the study sample as White students. Nationally we would expect around 47% White and 27% Hispanic or Latino [13].

3.1.3 MAP Accelerator Usage

For each student we obtained a summary of their total minutes using MAP Accelerator, filtered to the time period between when they took their Fall 2020 and Spring 2021 MAP Growth assessments. Further, only “on task” (i.e., not navigation) minutes working with math content specifically was used. Because the duration of the period between tests varied across students, we then divided the total minutes by

the number of weeks between the two assessments. Lastly, we created a categorical `usage_group` variable by binning the total minutes per week into four groups: *No use*, *< 15 min/wk*, *15-30 min/wk*, or *30+ min/wk*.

Only 5% of students reached the recommended level of 30+ min/wk, and only 9% reached the next highest level of 15-29 min/wk (see Appendix A for full table). We conducted an exploratory analysis to examine how much school level factors predicted an individual students level of usage. We fit a multi-level regression model predicting students’ total learning minutes on MAP Accelerator based on a single population-level intercept (global mean) and random intercepts for teacher, school and district. The random effect variance estimates are shown in Table 1. The intraclass correlation coefficient (ICC) indicated that 57% of the variance in students usage is explained by the environmental factors of teacher, school and district [12].

Table 1: Variance estimates from a multi-level regression model predicting users’ learning minutes on MAP Accelerator.

	Variance	Proportion of variance
math_teacher	38741.12	0.22
school_name	25034.16	0.14
district_name	35668.95	0.20
Residual	74729.04	0.43

^a ICC = 0.57

3.1.4 MAP Growth Data

NWEA provided several measures for each student, the critical ones being: `baseline_test_rit_score` (Fall 2020 RIT score), `endline_test_rit_score` (Spring 2021 RIT score), `subject` (Math or reading), and `conditional_growth_index` (population-normalized fall to spring gains).

The *Conditional Growth Index* (CGI) will be our primary outcome variable of interest, thus it warrants additional explanation. CGI is essentially a z-score of a students simple Fall to Spring growth relative to all other test takers. However, unlike a standard z-score, which is based on the population mean and standard deviation, the calculation is conditioned on the student’s starting RIT score, grade, and total instructional time between test events. CGI is then interpreted as the standard deviation change in RIT, relative to all other students who also started with the same RIT score (see [23] for more information on CGI calculation). An interesting aspect of CGI in the context of this study is that it utilizes pre-pandemic national norms. This means that CGI contextualizes a students’ observed growth relative to their expected growth prior to the pandemic. Concretely, a CGI of 0 does not mean that the student did not grow, but rather that they grew at a rate that would be expected for a similar student pre-pandemic.

We use CGI over simple growth for several reasons. The first is that it is a standardized metric that is easier to interpret without knowledge of the RIT scale. The fact that it is standardized against pre-pandemic norms also provides added context for interpreting the results for a COVID dis-

rupted school year. The second reason has to do with the unique properties of the RIT scale. In particular, typical growth rates are not consistent across grades[18]. Students in earlier grades tend to gain more from Fall to Spring than students in later grades. Even within a grade, students with higher RIT score may actually be expected to grow less than students with a lower starting RIT score – which is not a typical or intuitive pattern[5]. Moreover, the logic of the difference-in-difference framework hinges on the “parallel trends” assumption [11] which is that the treatment group should be expected to follow the same trend as the untreated group if no treatment had taken place. The fact that expected growth depends on Fall 2020 starting values means that examining only raw scores would likely violate the parallel trends assumption. Standardization with CGI overcomes this issue.

3.2 Design Overview

In general, this study will use a quasi-experimental, pretest-posttest nonequivalent groups design with controls. We leverage the natural variations in usage to infer the impact of using MAP Accelerator on gains in CGI, while controlling for covariates. Even with statistical controls, this design has the potential for confounding from unobserved variables. For example, students who received more parental support during the pandemic may have been more likely to succeed academically[10, 3] and more likely to use MAP Accelerator[19]. We account for unobserved confounding by using the logic of Difference-in-differences (DID)[6].

Difference-in-differences is a causal inference technique that compares an outcome measure before and after an intervention against a counterfactual. For example, the impact of a new traffic law could be evaluated by comparing traffic accidents before and after passing of the law both in the state that passed the law and in a neighboring state that did not. The logic is that the counterfactual (i.e., neighboring state) affords the ability to account for any changes in traffic accidents that could be attributable to other factors, such as bad weather. In our case we compare a low usage group (<15 min/wk) to a recommended usage group (30+ min/wk) on test scores before and after the intervention. We take the logic a step further by comparing the DID of two outcome measures, math and reading. Because MAP Accelerator is designed as a math intervention, we expect effects to be observed primarily in math outcomes. However, an unobserved confound such as parental support should also influence reading performance. DID provides a framework for removing the influence of these confounds. Finally, we add one more layer to DID by conducting a similar analysis across demographic subgroups in order to infer the effects within each of those groups.

3.3 Analysis 1

First we modeled `conditional_growth_index` for both math and reading using mixed effect regression models. We used the following fixed effects: `usage_group`, `gender`, `ethnic_group`, and `baseline_test_rit_score`. We also included the following random effects: `district_name`, `school_name`, `math_teacher`. Math and reading were modeled separately. The critical results are shown on Figure 2, which shows the corrected marginal means of CGI for each of the usage groups.

As we see on Figure 2, there was a positive relationship between usage levels of MAP Accelerator and math CGI. Students in the *No use* group showed the lowest CGI scores, and CGI improved with each usage level. Interestingly, we also see a similar pattern for reading. Given that we did not expect substantive effects of a math supplement on reading performance, this pattern is problematic as it suggests the existence of unobserved confounding in the usage groups. However, we do note that the estimated effects of MAP Accelerator usage were larger for math than for reading. Notably, students in the *30+ min/wk* group showed growth that was approximately 0.23 standard deviations higher than expected for math, but slightly below expected levels for reading. Thus, while there may be a degree of confounding, it does not fully explain the relationship between MAP Accelerator usage and performance. Nevertheless, it does make it difficult to determine how much of the true causal effect can be reasonably attributed to MAP Accelerator.

Figure 2: Estimated Conditional Growth Index as a function of MAP Accelerator usage group and test domain. Error bars are 95% CI.

3.4 Analysis 2

In order to account for unobserved confounds, and to estimate the effects across demographic subgroups, we applied the DID approach as previously discussed. We fit a mixed effect regression model using the `lme4` package in R[1] and the specifications on Listing 1. The interaction terms model the various DID effects. The overall main effect was modeled as a two-way `usage_group * subject` interaction. Similarly, the effects for individual subgroups were modeled as three-way interactions (e.g., `usage_group * subject * grade`). The three-way interactions allow us to estimate the causal effects of MAP Accelerator across subgroups.

After fitting the model, we conducted post-hoc contrasts to extract the DID effects of interest, using the `emmeans` package[16]. We focus on contrasting the two highest usage groups (*30+ min/wk*, *15-29 min/wk*) against the lowest usage group (*<15 min/wk*), and excluded the *No use* group from further analysis. On the surface, the *No use* group seems a natural reference point, however we noted fairly large differences in pre-intervention measures between the *No use* group and other groups, in some cases exceeding

Listing 1: Full model specification for difference-in-differences effects.

the maximum standardized mean difference recommended by the What Works Clearinghouse [27]. Moreover, the total lack of usage may signal a substantive difference in and of itself. For example, students in the *No use* group may have faced technological barriers, such as limited computer or internet access, that prevented them from using the tool in the first place. Note that overall usage in the <15 min/wk group was very low (Median 1.7 Hours over the entire year). Thus, we would not expect usage at these levels to have meaningful benefits on growth over an entire school year.

The critical results are shown on Figure 3. We will focus first on the overall effect, as it provides a nice explanation of how the DID are calculated. The panel A of Figure 3 shows the marginal means of CGI for each of the usage groups on both math and reading. Presented this way, we see a clear interaction – CGI improves incrementally with each usage group, but the improvement is larger for math than reading. The main DID is shown on panel B of Figure 3. These estimates are the less-contaminated causal effects of using MAP Accelerator on math CGI. The effect was larger for the *30+ min/wk* group than the *15-29 min/wk* group (+0.26 vs. +0.15). The direction of this difference is consistent with a causal effect of using MAP Accelerator.

The panel C of Figure 3 shows the DID effects broken down by various subgroups. In general, the pattern of *30+ min/wk* students showing larger effects than *15-29 min/wk* students held across most of the groups. However, while the magnitude of these gaps did fluctuate, so too do the confidence intervals, ultimately preventing any firm conclusions to be drawn regarding the relative effectiveness of 30+ min/wk vs. 15-29 min/wk within each group. Regardless, both usage levels were consistently positive and greater than 0 across subgroups. In particular, there were no meaningful differences across grades, gender, ethnicity¹, or school FRL.

Figure 3 did reveal that students from high ELL districts did not experience the same benefits from their use of MAP Accelerator as their peers. We conducted some post-hoc ex-

¹We did not report results from Am. Indian/ Alaska native due to having too small a sample sizes. Not specified/other and multi-ethnic were also excluded because these labels were not specific enough for the results to provide practical utility.

ploratory analyses to learn more about these students. High ELL districts were demographically distinct from the overall sample, with a higher proportion of Hispanic or Latino students (64%), consistent with national norms[13]. The vast majority of MAP Accelerator usage in High ELL districts was in English (99.7%). Using additional MAP Accelerator data, we computed a rough estimate of learning efficiency by estimating the proportion of skills leveled up over the school year. Students from high ELL districts tended to level up an average of 5.3 (SE = .06) skills per hour, compared to 7.2 (SE = .03) for mid ELL and 8.9 (SE = .07) for low ELL.

4. DISCUSSION

We applied difference-in-differences with controls to estimate the causal effect of MAP Accelerator on NWEA MAP Growth assessment across a wide range of student subgroups. In general, we observed positive effects of MAP Accelerator, with an overall effect size of +0.26 for students who used at the recommended levels of usage. Effect sizes of that magnitude are fairly common in educational technology research [22, 9]. These results provide additional support for mastery learning and the importance of tailoring instruction to students ability levels[15]. In future analysis, we plan to conduct more targeted analyses to determine which specific features of MAP Accelerator resulted in the most benefits.

While the finding that use of MAP Accelerator improved MAP Growth scores is good news, such effects would be less welcomed if it only helped some students. Fortunately, the benefits of MAP Accelerator appeared mostly consistent across grade, ethnicity, and school FRL. These results are important, especially given the context of COVID-19 and known existing equity gaps. As noted earlier, Lewis et al. [17] found that the pandemic more negatively affected the change in MAP Growth scores of younger students, students from high FRL schools, and Black and Hispanic or Latino students. Here we see indication that the pattern was halted, at least for students who used MAP Accelerator at recommended levels. An exception was that students from high ELL schools did not appear to benefit as much from their use of MAP Accelerator as other students.

Why didn't students from High ELL districts benefit from their use of MAP Accelerator? Prior research on ELL students has shown that learning new content in a language other than their primary language can be a source of cognitive overload [20]. The fact that these students also progressed on MAP Accelerator at a slower pace is consistent with this explanation. Other research has found that programs that allow students to receive instruction in their primary language is more effective relative to comparison groups[4]. Interestingly, students had the option to switch MAP Accelerator to their preferred language, but this was extremely rare. Students may have not been aware of this feature, or were instructed not to use it. Unfortunately, ELLs have long been under-served in U.S. schools, and policies for the instruction of ELL students are not always guided by evidence [7]. Nevertheless, these findings are relevant for other ed tech tools planning implementation in areas with a high concentration of ELLs.

While positive benefits of using MAP Accelerator at recommended levels were observed in the majority of subgroups

Figure 3: Difference-in-differences effects across subgroups. Error bars are 95% CIs.

that we analyzed, it is important to point out that a low proportion of students actually met this threshold. Exploratory analysis found that usage was mostly predicted by District/School/Teacher factors. This suggests that the degree of class level integration was the largest determinant of whether an individual student would reach recommended usage levels. We can only speculate as to why so many classrooms seemed to not use MAP Accelerator, and the context of the pandemic makes the question even more difficult to address. However, low levels of ed tech usage seems to be a common occurrence [28], suggesting that this challenge is not specific to MAP Accelerator.

4.1 Limitations

There are several limitations of this study that must be addressed. First, although we implemented several statistical and methodological controls, this was still an observational study and does not provide the same quality of causal ev-

idence as a randomized control trial. Our DID approach can only control for unobserved confounds that affect general academic performance, not math specific ones. Second, the study took place during a COVID-disrupted school year. Whether these results will hold post-pandemic is uncertain and yet to be seen. Finally, the results from FRL and ELL analysis leveraged school and district level data, rather than the preferred student level data. Just because a student was in a High ELL group does not mean that they themselves were an ELL.

5. ACKNOWLEDGMENTS

We want to thank Robert Berry, Emma Brunskill, Philip Oreopoulos, and Bi Vuong for their guidance and feedback on this report. We also thank the NWEA research team for their helpful suggestions on an earlier version of our main analysis.

The Third Workshop of The Learner Data Institute: Big Data, Research Challenges, & Science Convergence in Educational Data Science

Vasile Rus
University of Memphis
vrus@memphis.edu

Stephen E. Fancsali
Carnegie Learning, Inc.
sfancsali@carnegielearning.com

1. WORKSHOP SUMMARY

The Third Workshop of the Learner Data Institute (LDI) builds on the success of two previous, virtual workshops (at EDM 2020 & EDM 2021) and seeks to bring together researchers working across disciplines on data-intensive research of interest to the educational data science and educational data mining communities. In addition to welcoming work describing mature, data-intensive or “big data” research and emerging work-in-progress that spans traditional academic disciplines, the workshop organizers welcome case studies of interdisciplinary research programs and projects, including case studies of learning engineering efforts pursued by universities, learning technology providers, and others (both successful and unsuccessful), as well as position papers on important challenges for researchers harnessing “big data” and crossing disciplinary boundaries as they do so.

We convene researchers and developers from diverse fields who seek to “harness the data revolution” in educational data science and “grow convergence research,” aligning with (at least) two of the U.S. National Science Foundation’s “10 Big Ideas” for emerging research and development opportunities. “Convergence builds and supports creative partnerships and the creative thinking needed to address complex problems” [1], and we expect that bringing together highly experienced researchers, as well as students and early-career researchers, will stimulate substantial growth and interest in state-of-the-art, data-intensive, transdisciplinary or “convergent” approaches to solving vexing societal problems related to education. We also seek to explore the big data and learning engineering frameworks that will enable convergent solutions.

2. WORKSHOP AGENDA

The half-day workshop will begin with an introductory talk presenting a summary report of the work of the LDI and situating its progress within the goals of LDI and the broader notion of convergence research for educational data science. Next, Richard Baraniuk (C. Sidney Burrus Professor of Electrical and Computer Engineering, Rice University & Founder and Director, OpenStax) will deliver a keynote talk (including a question-and-answer period and time for discussion). Workshop organizers aim to include four

to six peer-reviewed contributed research papers (“short” 4-6 page papers, as submitted and informed by peer-review decisions) generally concerned with state-of-the-art big data methodology, applications, and research in educational data science and learning engineering, ideally with an emphasis on science convergence, and 1-3 shorter position papers on similar topics, with an eye toward where future research *should* be directed and/or laying out compelling *challenges* for these areas of research. Each contributed paper presentations will be followed by a question-and-answer session. If there is time, a panel discussion will afford the opportunity for keynote speakers and invited guests to interact with workshop attendees, addressing issues related to convergence research and the future of big data in educational research.

3. WORKSHOP ORGANIZERS

ABSTRACT

The increasing impact of machine learning and algorithmic decision making on education has brought about growing opportunities and concerns. Evidence has shown that these technologies can perpetuate and even magnify existing educational and social inequities. Research on fair machine learning has aimed to develop algorithms that can detect and, in some cases correct, bias, but this effort within the educational data mining community is still limited.

FATED 2022 hopes to spur discussion around algorithmic fairness and bias detection as specifically applied in an educational context. Submissions and panels will be invited to discuss: (a) collection and preparation of benchmark datasets for bias detection and correction tasks, (b) evaluation protocol definition and metric formulation appropriate for bias and fairness in educational tasks, and (c) countermeasure design and development for biased and unfair circumstances. These specific topics will be complemented by a more general discussion of the education-specific challenges for fair machine learning in education, bringing together perspectives from both industry and academia. This workshop builds on the FATED workshop held at EDM 2020, and we expect the workshop to make connections among already interested researchers and provide a foundation for those who want to engage in this area.

Part of the vision of creating adaptive educational technologies and building machine learning systems for education is reducing inequality (e.g., [2]), and data-driven practices are often viewed as a way to make education more equitable (e.g., [1]). While some interventions have been found to decrease achievement gaps (e.g., [4]), there is increasing concern that these systems may instead increase achieve-

ment gaps and perpetuate existing inequities [10, 12]. For example, such systems might make targeted support more available only to students with greater access to technology, or be associated with lower learning gains in more disadvantaged schools (as seen in [11]).

In this workshop, we hope to bring an education-specific lens on broader questions related to fair ML by spurring discussion around:

- **Data Set Collection and Preparation.** By spurring discussion about what educational datasets are particularly ripe for use as benchmarks for detecting and/or correcting bias and what characteristics of an educational dataset make it most useful for measuring or detecting algorithmic bias, this workshop aims to increase awareness about what datasets are available and encourage future research to include results on benchmark datasets.
- **Evaluation Protocol and Metric Formulation.** This workshop encourages discussion about what evaluation protocols and metrics are most suitable for empirical research on fairness and bias across common types of educational machine learning and EDM tasks.
- **Detection and Countermeasure Design.** FATED 2022 provides a forum for discussion about what features of the questions that we address in educational machine learning and the datasets that we use pose particular challenges for detecting and/or addressing algorithmic bias. Further, the workshop will provide an opportunity for researchers to share their work on algorithmic bias detection and correction specifically in education-related context.

Around these themes, FATED 2022 will showcase papers that focus on datasets, evaluation protocol, research, reproducibility, and recently published work (encore papers). By stimulating these discussions, the organizers hope to build community among researchers in this area, including interested EDM researchers who are not yet involved in these topics and fair ML researchers who may wish to engage with the field of education. Surrounding literature from the workshop organizers focuses on educational technology [3, 20, 6, 13, 15], student behavioral patterns [7, 8], algorithmic fairness [19, 18, 5], explainability [17], and responsible analytics for social good [14, 9, 16].

ABSTRACT

Computing is an increasingly fundamental skill for students across disciplines. It enables them to solve complex, real and challenging problems and make a positive impact in the world. Yet, the field of computing education is still facing a range of problems from high failure and attrition rates, to challenges in training and recruiting teachers, to the under-representation of women and students of color.

Advanced learning technologies, which use data and AI to improve student learning outcomes, have the potential to address these problems. However, the domain of CS education presents novel challenges for applying these techniques. CS presents domain-specific challenges, such as helping students effectively use tools like compilers and debuggers, and supporting complex, open-ended problems with many possible solutions. CS also presents unique opportunities for developing learning technologies, such as abundant and rich log data, including code traces that capture each detail of how students' solutions evolved over time.

These domain-specific challenges and opportunities suggest the need for a specialized community of researchers, working at the intersection of AI, data-mining and computing education research. The goal of this 6th Educational Data Mining for Computer Science Education (CSEDM) is to bring this community together to share insights for how to understand and support learning in the domain of CS utilizing CS educational data and AI. This field is nascent but

growing, with researching in computing education increasingly using data analysis approaches, and researchers in the EDM community increasingly studying CS datasets. The objective of the CSEDM workshop is to facilitate a discussion among this research community, with a focus on how data mining can be uniquely applied in computing education research. Researchers, faculty and students are encouraged to share their AI- and data-driven approaches, methodologies and experiences where data is transforming the way students learn Computer Science (CS) skills.

We invite researchers who are interested in further exploring, contributing, collaborating and developing data- and AI-driven techniques for building educational tools for Computer Science to submit their papers on any of these topics.

The workshop is a half day workshop. It consists of paper presentations, discussions to facilitate collaboration. Interactive sessions include multiple parallel, short presentations, where participants can float around to the presentations they are interested in, similar to a poster session.

Finally, the workshop celebrates the winners of the 2nd CSEDM Data Challenge. The Data Challenge is an IEDMS and SOLAR-sponsored competition in which researchers compete to develop the best model for a student modeling problem with a CS dataset, including snapshots of student code. Winners are invited to give presentations on their models, followed by discussion of where the challenge focuses in subsequent years.

ABSTRACT

In standardized testing, the assumption is that assessing all students on the same content under standardized conditions would provide evidence of what students learned and were able to do. However, some facets of standardized testing pose major challenges for students with disabilities (SWDs). We would not expect students with vision impairment, for example, to complete a paper-and-pencil test or a student with learning disabilities to complete a test within the same time limit as students without such disabilities. Thus, to truly include all students, assessment barriers that prevent SWDs, English language learners (ELLs), or other non-traditional students from achieving their best must be removed.

In recent years, technological advances have made computer-based and digitally based assessments (DBAs) more mainstream, especially for large-scale evaluations like the National Assessment of Educational Progress (NAEP). These new DBAs implement technologies to improve accessibility for all participants with different learning backgrounds, especially those with disabilities, using the universal design (UD) framework. UD rests on the idea that in designing tests the full range of students who will participate must be kept in mind from the beginning. By using UD, assessments are expected to become more accessible to and equitable for all students.

Inclusion, diversity, equity, and accessibility (IDEA) is a broad topic and can tap into various areas. Potential topics we would like to cover in our workshop include:

1. Use of different data sources (e.g., large-scale assessments, massive open online courses (MOOCs), games, collaborative chats) to address specific IDEA questions
2. Use of different features and variables, with a special focus on process data (e.g., performance indicators, tool use, accommodation assignments) common and uncommon within IDEA research
3. Special focus on populations, general students with disabilities (SWDs), students with specific disabilities (e.g., autism), English language learners (ELLs)
4. Identification of students who may benefit from IDEA assistance but did not receive it (e.g., students who may need extra time but were not provided extra time)
5. Dissemination and reporting of IDEA results to public audiences for better transparency and inclusion
6. Application of EDM techniques and methods to explore IDEA data (e.g., propensity score matching, machine learning, process mining).

What we hope to accomplish in this workshop is a better understanding of the ways in which research on inclusion, diversity, equity, and accessibility benefit from recent advances and improvements in education and policy (e.g., consistent accommodation procedures), education technology (e.g., digital tests), and emerging research methodologies. Through this workshop we plan to highlight and discover the various approaches and methods through which IDEA research is conducted. Specifically, we aim to explore ways to support this wide research area through data-driven findings.

Causal Inference in Educational Data Mining

Third Annual Half-Day Workshop

Adam C. Sales, Neil T. Heffernan
Worcester Polytechnic Institute
asales@wpi.edu
nth@wpi.edu

ABSTRACT

The goal in crafting intelligent tutoring systems, educational games, MOOCs, and other computerized learning tools, is to improve student learning. To that end, EDM research typically focuses on methods to identify, measure, and predict learner behaviors or outcomes. Causal research seeks to estimate the impacts of different factors on these behaviors or outcomes—not only predicting who will wheel-spin, experience frustration, or successfully learn a new skill, say, but determining causes these? Causality lies at the heart of both learning science, which seeks to understand how inputs in an educational system affect the system's outputs, and of policy, which seeks to design educational systems that improve learning.

The field of causal inference, which spans statistics, philosophy, economics, computer science, and other more traditional academic disciplines, has itself experienced rapid and exciting developments in the recent past. The new science of causality encompasses new ways of estimating effects under challenging circumstances, such as possible confounding, but also new questions—how do impacts vary between learners? What mechanisms drive causal effects? How may we construct optimal individualized policies for specific learners?

This workshop is intended to raise awareness of the ubiquity and importance of causal questions in EDM, some of the exciting methods available to address those questions, and some of the open questions of causal inference in EDM. It will include invited discussions of ongoing projects addressing causal questions, and short talks about relevant work in progress, including work in any stage of development.

Lastly, the workshop will give an opportunity for EDM researchers to submit open problem related to causality in EDM research. In five minute presentations, researchers will briefly present problems they have encountered in research, or that they just think are interesting, but that they do not yet know how to solve. Each presentation will be followed by an open-ended discussion among the workshop participants, hopefully suggesting ways to solve, or at least better refine the problem. This sub-workshop will hopefully give the presenting researchers constructive suggestions, and spur collaborations. In general, the workshop will be organized to stimulate discussion among participants, including, hopefully, constructive suggestions for open problems.

This workshop will be the third annual EDM workshop of its type—now jointly hosted along with International Conference on Artificial Intelligence in Education. It will follow a similar structure to the previous two workshops, but with all new material.

Tutorial: Using the Open Science Framework to promote Open Science in Education Research

Stacy T. Shaw, Adam Sales
Learning Sciences and Technologies
Worcester Polytechnic Institute
sshaw@wpi.edu, asales@wpi.edu

ABSTRACT

Within the past 10 years there has been increasing momentum of the open science movement to make research more open, transparent, and reproducible. However, the adoption of open science practices in education lags behind other fields. In this hybrid tutorial, we will begin by providing a brief overview of open science practices, benefits and workarounds, as well as how the statistical foundations of open science, including the benefits for inference and hypothesis testing. In the second part of the workshop, we will provide a hands-on tutorial of how to use the Open Science Framework to make projects, invite collaborators, preregister studies, share data, code, and materials. Participants in this workshop will gain a better understanding of open science practices, the reasons motivating their adoption, and how to use the Open Science Framework to make their research more open.

Keywords

open science, open access, preprints, preregistration

1. BACKGROUND

The adoption of open science practices— such as preregistration, open data, open code and materials, preprints, and open access— has become increasingly normative across various scientific disciplines, yet attitudes and adoption of these practices remain lagging in education science [1]. While some sub disciplines of education have begun to pioneer the open science movement in education (e.g. special education research, [2]; gifted education, [3]) remaining subfields, such as those related to educational data mining, have not seen widespread adoption. There are many reasons that education scientists may not have adopted open science practices, whether from a lack of training, to general concerns about what can and cannot be shared [4]. Despite the reason, there is a greater need for education about what open science is, how it can be leveraged, as well as guidance on how to use existing resources to make education research more open and transparent.

In this tutorial, we will cover the basics of open science practices, discuss the specific challenges associated with education research (e.g. protecting participant anonymity), and provide a step-by-step tutorial of how to use the Open Science Framework to preregister a study, post open data, code, and materials, and post preprints. We will also discuss further open science activities such as registered reports that might be relevant for participants, and how to use other

tools to identify opportunities to publish open access (e.g. directory of open access journals, sherpa romeo, etc.).

2. FORMAT AND TIMELINE OF TUTORIAL

The proposed tutorial will be offered in a hybrid fashion, and focuses on open science in education research, and using the Open Science Framework to preregister studies, share data and code, and post preprints. An outline of this workshop can be found below.

- First, we will provide a brief overview of some of the problems of conducting science and research, how open science practices are being used to overcome some of these issues, as well as the myths and workarounds of these practices.
- Second, we will discuss the statistical foundations of open science, including the benefits for inference and hypothesis testing. This discussion will include information about which aspects of data analysis may themselves depend on the data—and hence do not need to be pre-registered, and which phases may not.
- For the third part of this tutorial, we will lead a hands-on tutorial on how to navigate the OSF website, make an account, create projects, invite contributors to join projects, and how to post projects for the public. Afterwards, the presenter will give a step-by-step guide on how to create a preregistration, discuss best steps for preregistration, and identify how to create an embargo on a given preregistration. Other features, such as how to create anonymous versions of projects for blind peer-review will be shown.
