Critical race theory in education is based in the idea that racism is endemic to American society and its educational system. Also, American society was formed in and still continues to function based on property rights (Ladson-Billings & Tate, 1995). In Appalachia, property and economics is the focus of discourse in the region. Because this work in economics is centered on White rurality, racial issues are made invisible (Anglin, 2002). Race is also ignored in rural education as schools are sites of normative White cultures that lead to structural racism (Groenke & Nespor, 2010).

The theory also operates under the assumption that Whiteness is a form of property. However, this functions differently in Appalachia as White people in the region have been essentialized as "white trash" (Smith, 2004). This leads to a presumed "White innocence" in Appalachians and substitutes class issues for race issues making them invisible (Scott, 2009). As the vast majority of teachers in West Virginia are White, this has ramifications for the education of Black students in Appalachia. Particularly with labor strife rampant in Appalachian education, Black students are a "neglected minority within a neglected minority" (Cabell, 1985, p. 3). Critical whiteness studies are centered in the hyper-segregation in schools and explore the race consciousness of White teachers (Jupp, Berry, & Lensmire, 2016) Using critical Whiteness studies can provide a nuanced look at White teachers of Black students.

Critical race theory and Critical Whiteness studies provide insight into the way mathematics education functions in racialized ways. Mathematics is often viewed as a neutral, universal field free from politics (Gutierrez, 2013) and can serve as a "gatekeeper" to upper levels of mathematics and higher education (Moses & Cobb, 2002). STEM education is also a form of property and capital in American society (Bullock, 2017). Mathematics education is a White institutional space (Battey & Leyva, 2016), so it is essential to use these frameworks to study students and teachers in Appalachian mathematics classrooms.

This poster provides a framework for the study of Black learners and White teachers of mathematics in Appalachia. It also provides preliminary findings in a study of Black students' experiences learning mathematics and White teachers' perspectives on teaching students of color in the region. There is ample documentation of how race functions in urban mathematics classrooms. This work is designed to illuminate racist interactions and structures that oppress Black people in mathematics education in Appalachia which can lead to the disruption and dismantling of racism in rural education.

In this poster presentation the authors share the results of surveying preservice teachers (PST's) in The United States (US) and Uruguay, with different problem types following Simic-Muller et al. (2015) framework and work. US PST's consistently showed an inclination to family background or community practice problems, and a rejection of issues of injustice problems. Uruguay PST's data is not as clear as US data, but there are some points of contact with the US results.

Keywords: Problem Solving; Social Justice; Teacher Education – Preservice.

Mathematics has long been seen as a separate tool from everyday lives of children, disconnected from social issues. Teachers need to re-discover that connection and exploit it towards the academic and non-academic success of children in and out of school. Most important, teachers need to realize and accept that as Mathematics is a "weapon in the struggle" (Gutstein, 2012), teachers themselves are political actors (Gutierrez, 2013). One effective way to help children see the connection, and help teachers explore this "new" identity, is to teach Mathematics through problem solving. Given that Mathematics it is not a "culture free" content that can be taught in a space "politics free", then teachers must acknowledge the political power of Mathematics and their own political power, specially as they teach minoritized students. The authors investigate how pre-service teachers respond to different problem types, that even though are all "real life situations", are more or less committed to show Mathematics as a political tool to understand and change the world.

The questions the authors aim to answer are:

Do elementary pre-service teachers consider using problems for which the context requires an analysis of issues of injustice that may be difficult, but that are part of children's lives?

What are the explanations pre-service teachers provide to ground their decisions in regard to what contexts are or are not acceptable for teaching mathematics in elementary school?

The authors surveyed 21 US, and 33 Uruguay elementary preservice teachers (PST) taking their first mathematics methods course. The US PST's belong to the same section on a teacher preparation program located in the South of the United States, and the Uruguayan PST's belong to the same preparation program in a urban area.

Preservice teachers have strong opinions of what is and is not appropriate for elementary school children when learning mathematics. This is usually based on their understanding of the students. However, with background so different from their students and families, it is not clear how this is helping. They assumed that children would be scared if they "introduce" mathematical contexts like family separation at the border (in the US) or feminicide (in Uruguay). They also assume apple picking and soccer would be familiar and liked by the students. Yet we know children are already scared about those difficult topics. It is imperative that the PST's understand the issues that relate and are important to their students so they can draw on those to teach mathematics. The authors consider this a pilot study, and would like to repeat this experiment with a larger audience to be able to perform statistical analysis of the data. The results also suggests that they should conduct interviews with some of the participating PST's about their choices and explanations. In addition to that, the authors also would like to consistently use cognitively guided instruction (CGI) as a way to control mathematical complexity of problems.

CONCEPTUALIZING ACCESS KNOWLEDGE FOR TEACHING MATHEMATICS

Rachel Lambert
University of California Santa Barbara
rlambert@ucsb.edu

Keywords: Equity and Diversity; Teacher Beliefs; Teacher Knowledge; Students with Special Needs

Drawing from critical approaches to disability such as neurodiversity and Disability Justice this paper focuses on developing understanding of teacher knowledge necessary for successful engagement of students with disabilities in meaningful mathematics. Students with disabilities have long been conceptualized through deficit frames within both special and mathematics education and denied opportunities to engage in sense-making (Lambert 2018). Utilizing data from a previous study (Lambert, Sugita, Yeh, Hunt, & Brophy, 2020), this paper is a call to reframe teacher knowledge in mathematics to understand the importance of *access knowledge for teaching mathematics*, knowledge about how math class and math learning feels to students with different *bodyminds* (Price 2011).

Disability Justice (Berne 2017) is an emerging political movement in the disability community that includes attention to intersectionality and embodiment. Access is understood not as not only being able to enter a space, but relational engagement within that space (Mingus 2017). The concept of access-knowledge comes from the work of Aimi Hamraie (2018) who analyzed how disabled maker culture and the founders of Universal Design redefined access-knowledge towards creative problem solving based on close understanding of user experience, as well as understanding the complexity and diversity within disability.

I define Access-Knowledge for Teaching Mathematics (AKTM) as knowledge about how math class and math learning feels to students with different bodyminds, including an approach to solving access issues for students that locates difficulties in classroom spaces, practices and school systems rather than within individual students. Solving access issues necessarily involves collaboration between the student and the teacher. Access is not just being able to enter a classroom, or be given alternative to particular forms of presentation, but also access to relationships, interaction and a feeling of safely that are at the core of student's experiences in school. This paper expands current scholarship in mathematics education teacher education by theorizing new forms of teacher knowledge necessary to include students with disabilities in meaningful mathematics.

FACILITATING MATHEMATICS TEACHER EDUCATORS' CONVERSATIONS ON INEQUITIES IN MATHEMATICS CLASSROOMS

Leslie E.J. Nielsen
Puget Sound Educational Service District
lnielsen@psesd.org

Kanita K. DuCloux
Western Kentucky University
kanita.ducloux@wku.edu

Dorothy Y. White
University of Georgia
dywhite@uga.edu

Keywords: Equity, Teacher Education - Preservice, Inservice/Professional Development

Mathematics teacher educators (MTEs) have a responsibility to prepare and support mathematics teachers to build safe cultural spaces for students to learn mathematics. This requires making teachers aware of "national, state, district, and school contexts for educating students and be[ing] ready to engage in conversations to address inequitable learning experiences" (Association of Mathematics Teacher Educators, 2017, p. 23). One method of providing this preparation is to engage teachers in conversations and experiences that enable them to recognize and address inequitable learning experiences.

We used the casebook *Cases for Mathematics Teacher Educators: Facilitating Conversations about Inequities in Mathematics Classrooms* (White et al., 2016) in our three respective contexts to foster math educators' ability to identify and address inequities and to develop MTEs' ability to engage in conversations as inequities arise or are recognized. Guided by a situative framework (Putnam & Borko, 2000) and an inquiry stance (Cochran-Smith, 2003), we sought to answer the question: *How do mathematics teachers across the teacher development continuum respond to equity-related cases and engage in conversations about inequities in mathematics education?*

This cross-site research study was situated within teacher education and professional development settings. Participants included PreK-12 mathematics teacher leaders; graduate students preparing to become university-based MTEs; and preservice mathematics teachers. After the participants read the cases, we used common prompts to explore how they grappled with, embraced, and/or resisted equity-based dilemmas. The participants' written responses, recordings of the discussions, and facilitator notes were collected and analyzed (Saldaña, 2016). Preliminary data analysis revealed that all groups were eager to engage in conversations around the cases, which enhanced their ability to notice and analyze inequitable situations.

A case titled "Who Counts as a Mathematician?" led to rich conversations across all three groups. Several participants challenged traditional assumptions regarding who can be considered doers of mathematics, allowing us to address inequitable learning contexts that may result from stereotyping and tracking. The teacher leaders often had experiences similar to those of the case authors and were ready to disrupt inequities. However, some graduate students and preservice teachers found it difficult to unpack the complexities and nuances of the dilemmas. This finding suggests the developmental nature of educators' ability to see themselves in the cases, feel empowered to disrupt inequities, and be ready to facilitate conversations with other educators.

As MTEs, we must continue to grow and develop our ability to facilitate conversations about inequities in mathematics classrooms. This study allowed us to learn collaboratively across settings and adjust our practice. Our findings highlight the need to explore how educators develop an understanding of various scenarios in order to create equitable mathematics classrooms.

MATHEMATICS IDENTITY AND SENSE OF BELONGING OF DEVELOPMENTAL MATHEMATICS STUDENTS

Francis Nzuki
Stockton University
francis.nzuki@stockton.edu

Keywords: Developmental Math, Mathematics Identity, Equity

One of the significant challenges facing higher education is narrowing the educational attainment gap between students who are academically prepared and those who are not. Although the intention of developmental education is to help support underprepared students in achieving academic success, there have been disagreements among researchers on the effectiveness of achieving this goal (Goudas & Boylan, 2012). On one hand, developmental mathematics has the capability of providing the impetus that can propel students to their overall academic success. On the other hand, the long road the students have to go through in completing mathematics requirements causes many to give up before they can finish the sequence of courses (Rosin, 2012).

This study examines how developmental students' general and mathematical experiences help to shape mathematical identities they develop and how these identities in turn hinder or enhance their successful participation in mathematics. Also examined are the factors that influence students' mathematics identities after taking a developmental mathematics course. To this end, the following research questions guided this study of first year students taking a developmental mathematics course at a mid-sized, urban public university:

1. How do developmental mathematics students describe their mathematics identities?
2. What factors coalesce to influence students' mathematical identities after taking a developmental mathematics course?

Data was collected using pre-post surveys and semi-structured interviews. The analysis reported here is based on the data from the survey instrument. The statements in the survey were grouped into five aspects of mathematics identity; self-concept, self-efficacy, motivation, and anxiety, and value of mathematics. Qualitative data from the open-ended items of the instrument was systematically analyzed using grounded theory to uncover patterns and trends in participants' responses while descriptive statistics was calculated for the quantifiable portions of the surveys. Items were compared both within surveys and across surveys to identify correlations and trends, as well as to support qualitative themes.

Analysis revealed that differences of the overall mean scores of all five aspects of mathematics identity between females and males were not statistically significant. Further, students scored the lowest on self-concept while the highest score was on their perception of the value or importance of math in their lives. As Klinger (2004) pointed out there are many students who do not particularly enjoy mathematics and report a disliking for the subject (negative affect), even though they still respect the utility and importance of math in their future lives and careers. Also, the study revealed that students' self-efficacy and self-concept increased significantly over time.

CRITICAL MATHEMATICS EDUCATION FOR SUB-SAHARAN AFRICAN YOUTH: TOWARDS EPISTEMIC FREEDOM

Oyemolade Osibodu
York University
mosibodu@yorku.ca

Keywords: Ethnomathematics, equity and diversity, first nations and indigenous cultures, informal education

I draw on the findings from one study to show how Njo (pseudonym), a Gambian youth in the study shifted towards *Epistemic Freedom* during the course of our semester long co-exploration. I argue that when multiple knowledges are valued in mathematics spaces, students are able to see themselves as capable mathematics learners. Ndlovu-Gatsheni (2018) speaks about epistemicide as the killing of indigenous peoples knowledges, that occurred during colonialism and is still in place now. Thus, he introduced Epistemic Freedom as "democratising 'knowledge' from its current rendition in the singular into its plural known as 'knowledges'." In mathematics education, epistemic freedom pushes us to make room for multiple knowledges as this shifts towards what Ndlovu-Gatsheni termed "cognitive justice."

Using African epistemologies – Sankofa, Ubuntu, and the Fela Anikulapo-Kuti Music (FAM) – I sought to co-explore with five Sub-Saharan African youth, if and how they use mathematics in understanding, challenging, and disrupting social issues related to the African context. Ubuntu (Tutu, 1999) is a Southern African philosophy emphasizing that I am because we are. Sankofa (Dei, 2012) is from the Twi people in Ghana that asserts that we must look into our past before reflecting on the future. Lastly, I coined the FAM methodology from Fela's song *Teacher Don't Teach Me Nonsense* (Anikulapo-Kuti, 1986) which has three main facets including co-learning, disruption, and joy.

The research question guiding this inquiry is "what knowledges do African youth draw upon in their investigation of social issues and how might these knowledges advance our understanding of critical mathematics education?" In the spring of 2019, I partnered with five sub-Saharan African youth in an out-of-school context. Together, we met for approximately two hours once a week using a story-telling approach. I collected audio and video data from all sessions along with WhatsApp group messages. I ensured that we collectively designed the space with the overarching goal of making sense of social issues on the African continent. I was intentional in not centering mathematics but instead was interested in seeing if mathematical ideas emerged in thinking through social issues. I analyzed the data thematically while ensuring that I was guided by the stories told (Wilson, 2008).

In the poster, I will use seven narratives that reveal Njo's journey towards epistemic freedom as she began to claim authority in her mathematics education. These narratives reveal her identity formation, disruption of colonial discourses, awareness and valuing of multiple ways of knowing, and lastly, multiple ways of knowing in mathematics. Njo's journey showed how through looking at cultural artifacts and reflecting on her own experiences, she was able to value indigenous [mathematics] knowledge. Moreover, she asserted that if young children are given the opportunity to see the multiplicity of knowledges within their communities, perhaps they will enter formal mathematics spaces with more confidence and belief in their abilities.

"YA ME CONFORME": RESISTING DOMINANT NARRATIVES IN MATHEMATICS CLASSROOMS

Kevin Pelaez
San Diego State University
kpelaez10@gmail.com

William Zahner
San Diego State University
bzahner@sdsu.edu

Keywords: Equity, Resistance, Social Justice.

Mathematics is often portrayed as an apolitical, culture- and color-blind universal language (Gutiérrez, 2013; Marin, 2009; Shah, 2017). However, Recent work in mathematics education has called for a need in exploring the intersectionality between mathematics, learning, and student identities (Gutiérrez, 2002, 2013; Shah, 2017; Zavala, 2014). This is of particular interest for multilingual students since they are a growing and diverse population (de Araujo et al., 2018) at the intersection of race, language, culture, and immigration.

In this poster, we draw from Critical Race Theory and Latinx Critical Theory (Delgado Bernal, 2002; Solórzano & Delgado Bernal, 2001) as the basis for examining patterns of resistance by Latinx multilingual students in linguistically diverse high school mathematics classrooms. Resistance is a form of agency that can be used to explore how multilingual students negotiate and struggle with structures, and use those interactions to create meanings (Solórzano & Delgado Bernal, 2001). We were particularly guided by the following research question: How do students engage in resistance that are motivated by a critique of oppression and an interest in social justice?

Similar studies have analyzed Latinx experiences in mathematics high school classrooms in more diverse settings (e.g., Zavala, 2014). However, this study includes four ninth graders from one classroom at a more racially segregated setting, City High. City High is located on the US-Mexico borderlands and has a relatively large population of recent immigrant and transnational students. The four students included in this study represent a variety of Latinx experiences, from students who recently arrived to City High from Mexico to students who have lived around City High their entire life.

Counterstories (Solórzano & Yosso, 2002) of semi-structured interviews about mathematics and identity and classroom observations are shown to illustrate how students engage in resistance. Particularly, we found that students acted in both individual and collective forms of resistance that are at the intersection of Solórzano and Delgado Bernal's (2001) transformational and conformist resistance. *Transformational resistance* includes students who are motivated by social justice and explicitly critique oppression. *Conformist resistance* includes students who are motivated by a need for social justice but do not hold an explicit critique of oppression. *Resilient resistance* lays at the intersection of transformational and conformist resistance and includes students whose actions challenge oppression, but they may not explicitly challenge the nature of the oppressive structures (Yosso, 2000). For example, students may say things like "ya me conforme" and note that race and language do not have a direct impact on their educational experiences. Yet, they may also collectively organize (e.g., assigned group roles to each other, embrace translanguaging, and engaged in collaborative group work) as a way to negotiate, struggle, and make meaning within school structures.

More importantly, the four students in this study did not have direct instruction about critiquing oppression or fostering a motivation social justice, as is with critical pedagogy (e.g., teaching math for social justice). Yet, students showed steps toward a path of transformational resistance, providing evidence for critical consciousness that students bring into the classroom.

CAPTURING THE HIGH GROUND IN LEARNING DISABLED MATHEMATICS EDUCATION RESEARCH

Thomas E. Ricks
Louisiana State University
tomricks@lsu.edu

Keywords: Equity, diversity, learning disabled, learners with difference, special education

Despite the mathematics-for-all mantra, few mathematics education (math ed) scholars have studied learning disabled (LD) students' mathematical learning (Xin et al., 2015). This extremely low number of math ed studies specifically on LD students is puzzling (considering that LD students comprise at least 5% of student populations) and unfortunate (because special education scholars—steeped in behaviorist/medical-deficiency paradigms—have dominated the research landscape and largely promulgated a dehumanizing, explicit-only instructional approach for LD students' mathematics learning that directly contradicts current reform-oriented approaches embraced by the math ed community). This special education explicit-only message is so pervasive that even mainstream reform-oriented math ed publications—like the National Council of Teachers of Mathematics' position statement on intervention (NCTM, 2011)—default to this explicit-instruction-is-best-for-LD-students belief. It is time for the field of math ed to "capture the high ground" by exerting more influence on the research narrative about what instructional methods are appropriate for LD students.

It is in this context that this mixed-methods research study investigates with fine-grained analysis the embarrassingly immature condition of math ed LD research. I examine the various tiers of math ed research publications (as defined by various authors, e.g. Toerner & Arzearello, 2012; Williams & Leatham, 2017) to describe the quantity and quality of LD math ed research by math ed scholars. For example, over the last 20 years, the two top-tier math ed journals, *Educational Studies in Mathematics* and the *Journal for Research in Mathematics Education* have only published six and five studies—respectively—on LD students' mathematics learning. Even the proceedings of the North American Chapter of the International Group for the Psychology of Mathematics Education (PME-NA) demonstrates a paltry 1.7% ratio of LD to all studies, far below the 5% minimum threshold expected based on the number of LD students in mathematics classes. I also apply Glaser's (1965) constant comparative method to develop a theoretical matrix cataloging the various types of math ed publications that include LD issues (e.g., ones that include special education statistics without separating out LD students from those with physical handicaps). I conclude with concrete recommendations for mathematics educators to capturing the high ground of LD math ed research.

A NARRATIVE INQUIRY OF *GEMS* WOMEN'S EXPERIENCE WITH STEM

Keywords: Informal Education, STEM/STEAM, Gender and Sexuality

Historically, women are underrepresented in science, technology, engineering, and mathematics (STEM) fields (Hill, Corbett, & Rose, 2010). To inspire girls to participate in STEM disciplines, many researchers have found that a variety of interventions, such as female role models, hands-on activities, and single-sex learning environments, can increase girls' interest and shape their identities in STEM areas (e.g., Chen et al., 2011; Holmes et al., 2012; Tyler-Wood et al., 2012). National efforts to engage girls in STEM disciplines have had mixed reviews. Between 1993 and 2015, the number of women in computer and mathematical sciences occupations increased by 173%. However, these fields have attracted relatively more men, whose participation increased by 239%. Thus, the overall proportion of women has declined from 31% to 26% (National Science Board [NSB], 2018). The NSB (2018) also reported that five years after receiving their highest degrees across all science and engineering areas, only 18% of females remained in these fields compared with 33% of males.

Corbett and Hill (2015) pointed out that although many studies have concentrated on factors contributing to the entry of women into STEM fields, far fewer have examined the question of why women leave these fields, often after years of preparation, and what factors could support them to remain in the fields. Through exploring the lived experiences of the women who participated in the first *Girls Excelling Math and Science* (*GEMS*) Club–an ongoing afterschool STEM program begun 26 years ago–this study will investigate the group of women's experiences with STEM. The study is guided by the research question: How have the original *GEMS* Club members' experiences in *GEMS* influenced their education, career selection, and lives, both personally and professionally? Specifically, a) How have their experiences in *GEMS* impacted their identity, including mathematics, STEM, and gender identities? And b) How have their experiences in *GEMS* influenced their sustained interest, engagement, and participation with STEM?

Given the purposes of this study, narrative inquiry is the methodology and form of analysis in the study (Clandinin & Connelly, 2000). Data is collected through a questionnaire and interviews. The questionnaire collects demographic information and experiences in the *GEMS* club from all women who have participated in the first *GEMS* Club. Respondents who have detailed memories of their *GEMS* experiences are interviewed in a sequence of three semi-structured interviews with each participant, as suggested by Seidman (2013).

Data analysis consists of both analysis of the narrative and narrative analysis (Polkinghorne, 1995) identify common themes that emerge across stories from different participants. The narrative analysis focuses on the social environment that shaped the stories, particularly from a feminist standpoint (Brooks, 2007; Harding, 1991). Using thick, rich descriptions within the three-dimensional inquiry space (Clandinin & Connelly, 2000), the study represents each participant's life story by laying out the events, configuring them into episodes, and constructing contextual explanations by drawing from common themes across each participant's story.

The findings are used to create more effective informal STEM learning environments for girls, thereby empowering women in STEM.

This paper reports an ongoing effort to address the problem of instructional capacity for high school geometry from a systems improvement perspective. In an effort to understand the system that contains the high school geometry instructional capacity problem, we identified key stakeholders and conducted preliminary interviews to learn about the problem from their perspective. We use these interview data to describe the system in more detail and to identify six major factors contributing to the high school geometry instructional capacity problem.

Keywords: Geometry and Geometrical and Spatial Thinking, University Mathematics, Teacher Education - Preservice, Systemic Change

This paper describes emerging efforts to develop a networked improvement community to address the problem of instructional capacity for high school mathematics. The capacity problem as we see it is the following: While scholars' understanding of the knowledge teachers need for teaching has progressed to a point that this knowledge base could be used to inform teacher development efforts (Ball, Lubienski, & Mewborn, 2001), the volume of aspirants to secondary mathematics teacher education has been decreasing to a point that sustaining and improving university programs for initial mathematics teacher preparation can be challenging (Sutcher, Darling-Hammond, & Carver-Thomas, 2016). Traditional efforts at instructional improvement have started from the design of policies or practices (including curriculum implementation) that are believed to have the potential to solve problems, followed by evaluation efforts that seek to achieve main effects. Following such an approach might require action at the college level, seeking both for investments in the recruitment of teachers and implementation of curricular approaches for teacher preparation focused on the knowledge teachers need. Such efforts have been underway (e.g., U-Teach, https://uteach.utexas.edu/uteach-institute-seed-grant; see also Newton et al., 2010) and may help produce some improvement. At the same time, Bryk et al. (2015) have described such approaches as problematic on account of their top-down logic of improvement, relying on developers' own understanding of the problem and conception of the solution, which usually put a premium on implementation fidelity.

Bryk et al. (2015) propose a different approach to improvement that seeks to involve all actors within the system being improved in the process of problem formulation, system mapping, and improvement design aimed at reducing variability in outcomes. This seems particularly useful in a context where improvement design and implementation is likely to cross boundaries across systems (e.g., K-12, higher education) with different existing practices and norms, where the logic that might support improvement in one system (e.g., curriculum implementation at the K-12 level) may or may not be useful in the other (viz., higher education).

[1] This work has been done with the support of NSF grant DUE- 1725837 to P. Herbst and A. Milewski. All opinions are those of the authors and do not necessarily represent the views of the Foundation.

Our paper documents an initial effort to undertake systemic improvement in secondary mathematics teaching knowledge by developing an understanding of the problem of instructional capacity for secondary geometry. While the former seems like a huge problem in general, addressing it systemically seems crucial. By this we mean understanding connections across the systems that participate in the problem, specifically university teacher preparation, K-12 teaching, and the policy level (see Figure 1). Thus, our first approximation looks at a smaller version of the problem of instructional capacity while still addressing it systemically. The choice of geometry is strategic as a way to simplify the more general problem of instructional capacity at the secondary level because geometry is largely contained in a single secondary course and is taken by almost all high school students. Likewise, most teacher preparation programs require their candidates to take a Geometry for Teachers (GeT) course. Furthermore, some progress has been made measuring mathematical knowledge for teaching geometry (Herbst & Kosko, 2014; Ko, 2019). Hence, reducing the investigation of the problem of developing instructional capacity in secondary mathematics to secondary geometry may allow us to maintain attention to systemic issues while not being overwhelmed by the sheer scale of the systems being investigated. In this paper, we outline the development of an understanding of the system that produces the current high school geometry (HSG) instructional capacity problem with the goal of further developing an inter-institutional community of university instructors of Geometry for Teachers courses.

Theoretical Framework: Systems Improvement Approach

Bryk et al. (2015) developed the concept of *networked improvement communities* by adapting an improvement science framework to the context of education research. In the early stages of the formation of a networked improvement community, Bryk et al. (2015) recommend developing a complete understanding of the "the system that produces the current outcomes" (p. 57), followed by systematic experiments in which members of the community implement small changes that have the potential to produce measurable differences in the target outcome. This requires that stakeholders identify a specific problem to be addressed and seek understanding about the larger system by asking "why" questions. Bryk et al. (2015) suggest using some diagrammatic tools to visualize who the stakeholders are and elicit their knowledge about the system to develop an accurate picture. Both a systems diagram (Figure 1), and what Bryk et al. (2015) call a fishbone diagram (Figure 2) for problem formulation are used.

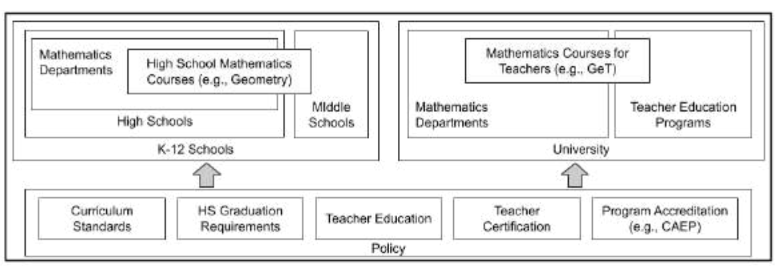

Figure 1. Schematic of the system that contains the HSG instructional capacity problem.

We developed the schematic in Figure 1 to determine who the potential stakeholders are in the problem of HSG instructional capacity. Material connections between stakeholders are indicated by overlapping rectangles. For example, the geometry courses for teachers overlap mathematics departments and teacher education programs because, while those courses are usually offered by mathematics departments, their existence relies on being required by teacher preparation programs. Students and teachers flow through the complex system: For example, high school students take geometry courses in high school; their mathematics experiences in school, for better or worse, prepare them for studying mathematics in college; those who decide to become mathematics teachers take college courses like Geometry for Teachers; if and when they get certified to teach, they are hired in K-12 districts where they might be teaching high school geometry. Likewise, some university students eventually become mathematicians who might be employed in mathematics departments and assigned to teach GeT courses. Mathematics teacher educators might also be observed in the system, inasmuch as they include former teachers and ordinarily participate in policy work such as standards development.

The *systems diagram* (Figure 1) is therefore useful as a way of identifying potential stakeholders in the problem of HSG instructional capacity. The diagram helps identify the institutional roles of people whose perspectives inform the problem. These include HSG teachers, secondary school or district leaders, HSG students, university Geometry for Teachers instructors, university mathematics department chairs, GeT students, faculty and administrators in secondary teacher education programs, recent university graduates, state or national policymakers, teacher assessment developers, and anyone making decisions about teaching certification and evaluation requirements at the state level. We surmise that improving the problem of instructional capacity for teaching high school geometry may require gathering representatives of all these institutions.

A *fishbone diagram* (Figure 2) provides a visual representation of the problem of focus for the networked improvement community (the head of the fish). Typically, these diagrams have five to six major bones, each representing a key factor that contributes to the problem, with more contributors (sub-bones) to each of those factors underneath. As our view of the HSG instructional capacity problem becomes more complex, the fishbone diagram serves as a tool to help us look for connections across stakeholders and determine potential levers for improvement.

One crucial component of a networked improvement community is a “hub” that serves to organize the information and activities of the network, including defining the system and eliciting the formulation of the problem. Our research team fills this role by gathering information from stakeholders in the system, collecting data, and disseminating the results back into the network. Members of our team have experience conducting research and teaching in secondary and higher education settings which supports our efforts to fulfill the role of network hub as well as collect and analyze the data reported in this paper.

Methods

We conducted semi-structured interviews with four sets of stakeholders from across the system in study; GeT instructors ($n = 42$), secondary school leaders ($n = 7$; 2 HS principals, 2 HS mathematics department chairs, 3 state/district instructional leaders), university mathematics department chairs ($n = 3$), and early-career mathematics teachers ($n = 3$). Recruitment and selection of participants varied by stakeholder group. The GeT instructors were already part of our project as members of an inter-institutional network made up of instructors of GeT courses located in mathematics departments at universities with teacher education programs. The secondary school leaders and early career teachers were recruited through a mass email to school leaders in a midwestern state that included an eligibility form to facilitate the screening process. We selected participants to ensure variability in administrative role, school and district size, and years of experience. The university mathematics department chairs were recruited through individual email requests from universities in a midwestern state that have a GeT course.

The interviews were conducted over video conference and recordings were transcribed for analysis. The interview protocol differed by stakeholder, but analysis of all interviews focused on connections between the data and our systems and fishbone diagrams. After the interviews had been conducted and analyzed, we reported our findings back to the network of GeT instructors through interactive online seminars.

Results

Each stakeholder group contributed to our understanding of the "hidden complexities" (Bryk et al., 2015, p. 14) within the complex system that contains the HSG instructional capacity problem. Within each stakeholder group, individual participants were able to offer insight into the particular ways in which those complexities manifested within their context. Participants vary in the number of years they have held a particular position within the system, and many of them also drew on experiences they had moving through the system (e.g., secondary school leaders that are former mathematics teachers who took a GeT course and were once students in HSG). In this section, we identify 6 main factors that contribute to the problem of HSG instructional capacity as indicated from interviews across stakeholder groups.

De-emphasizing the HSG Course

A contributing factor to the HSG instructional capacity problem is that the course has been de-emphasized by several stakeholder groups. Participants mentioned three underlying causes; (1) much of the HSG content is not needed to succeed in AP Calculus and AP Statistics, (2) HSG content is not rigorously assessed on the SAT, and (3) there is a lack of clarity on where and how HSG content should appear within the high school mathematics sequence (e.g., integrated into first- and second-year courses, as a fourth-year standalone course, etc.).

One district/state instructional leader shared that "the districts in [my] county right now are struggling with offering geometry, which is unfortunate, but they don't see an emphasis on the SAT" (CE). In addition, she identified an "importance of all students having success in Algebra 1 before they get to higher-level courses," which affords the Algebra 1 course more importance (and therefore more resources) within the high school mathematics sequence. This provides some evidence that the choice to de-emphasize HSG comes from pressure (or lack of pressure) at the school or district level. Policies at the state level may also be contributing to the deemphasizing of HSG within the system. "Messaging at the [state department of education] is that we don't have a course called geometry. Students have to demonstrate proficiency in the K-12 standards," some of which address geometry content (IF; district/state instructional leader).

There are a number of potential impacts on the HSG instructional capacity problem when schools, districts, and state education departments don't emphasize the HSG course. For example, while professional development specific to Algebra standards is frequently offered to inservice teachers, it is much less common to find Geometry-specific professional development.

HSG is not a Desirable Course to Teach

Teacher preparation programs set out to provide candidates with the knowledge, skills, and beliefs necessary to be successful secondary mathematics teachers, but multiple stakeholders identified disparities between the preparation candidates receive and the preparation they ultimately need. By far, the most common shortcoming in the preparation of HSG teachers is the overwhelming number who arrive on the job market with a lack of desire to teach geometry. Secondary school leaders at each level of administration told us, in one way or another, that "teachers don't like teaching [geometry]" (CK, Principal). One participant went so far as to say that teachers "were fearful of it" (IF, district/state instructional leader). Although there was one district that has had a steady stream of secondary mathematics teachers that view the course favorably, that was an exception to the trend.

While some stakeholders described the general phenomenon of teachers' lack of desire, some went further to identify underlying reasons for the undesirable nature of the HSG course; (1) compared to upper-level courses, HSG is not an ideal teaching assignment, (2) teachers are not comfortable with the HSG content, and (3) teachers hold an opinion that it is more difficult to plan for HSG than other mathematics courses. A district/state instructional leader shared that upper-level courses are more desirable for a number of reasons:

> There seem to be lots of people to volunteer at the upper-level courses to teach and not as many that want to teach Algebra and Geometry...I've been told those kids are easier to teach [in the upper-level courses], they come better prepared...The upper-level courses tend to have more stable classes, less kids that transfer in and transfer out...There seems to be a status thing, too, with teaching the upper-level classes where it's not seen as prestigious to teach Algebra or Geometry or an intervention class as it is to teach the upper-level classes. (ZM)

While some teachers express a desire to teach upper-level courses rather than HSG, others communicate discomfort with the content covered in HSG. A high school mathematics department chair described geometric proof as the most prominent stumbling block for teachers; "[A]s much as we can see what the process should be..., it's more difficult to teach that when it's pretty far from the other standards of math that are 'here's the process. That's it'" (RU). When one principal summarized experiences telling new hires that they would be assigned the HSG course, she said "[T]hey just cringe. They constantly tell me 'this is not my strong point.' And they try to blame it on the kids and say, 'the kids hate it'" (CI, Principal). One early career mathematics teacher even identified it as "kind of a beast to plan for—a lot of diagrams and whatnot and different notations—as far as making materials, it kind of seems overwhelming" (JL). Although none of these explanations for the lack of desire to teach HSG connect directly to university teacher preparation programs, we suggest that the structure of the system connecting universities to high schools, through the preparation and hiring of secondary mathematics teachers, may present levers for improvement.

Structure of University Teacher Preparation Coursework and Clinical Experiences

There are a number of factors that contribute to the HSG instructional capacity problem that are related to the structure of coursework and clinical experiences within university teacher preparation programs. Namely, there is wide variation in student teaching experiences, comparatively fewer opportunities to engage with geometry content, and a mismatch between the knowledge teachers gain and the knowledge they need on the job. Due to the wide variety of school contexts, teaching assignments, curriculum materials, and instructional styles, the student teaching experience often looks "wildly different, building to building, classroom to classroom, district to district" (ZM, state/district instructional leader), even for prospective teachers that come from the same program. On top of that variation in experiences, one principal reflected that "most student teachers do an Algebra [course]," and that if their mentor teacher has some sections of Geometry, "they don't really have them [take over] the geometry course until the end" (CI). If prospective teachers don't gain experience teaching Geometry in their clinical placements, they would need to rely on their university coursework for opportunities to think deeply about geometry content. If the GeT course is not required for certification, they may only have their own HSG experience to rely on. One HS mathematics department chair shared that "the most common response [to being assigned the HSG course] is 'I haven't done geometry since high school. I'm going to need to refresh on this'" (RI).

Even when prospective teachers do take a GeT course during their university coursework, the content is not always aligned to what prospective teachers feel they need when they begin teaching. Thinking back to his own university coursework, one principal shared that "there wasn't a whole lot of focus [in the GeT course I took] on what students would actually be learning in high school. It was more of exploring the higher levels of math. So I felt like there was a gap overall in my undergraduate experience of learning about subject matters that I would be teaching" (CK). One university mathematics department chair voiced support for that version of the GeT course, saying that prospective teachers "should know the subject matter a bit deeper than what their students do or what the textbooks cover" (RA). To him, that means that while HSG geometric proofs tend to be structured in two columns and contain a limited number of statements, "in a college course, they need to go one level deeper" (RA).

In addition to a focus on content that is beyond the high school curriculum, some GeT courses are taught in a style that runs counter to the instructional practices secondary mathematics teachers may be expected to enact when they are hired. An early-career mathematics teacher described the instructional style of his GeT course that was focused on spherical and hyperbolic geometry: “In the class itself, we never worked together. It was very lecture based. You sat there for an hour fifteen, got lectured to and left” (JL). This suggests that GeT courses at some universities are designed to support students’ content knowledge but do not attend to their pedagogical content knowledge. However, the secondary school leaders described the ideal qualifications for a HSG teacher in terms that blended content and pedagogical knowledge, indicating that they were not so cleanly distinct in practice. For example, a district/state instructional leader said that “we need someone who kind of has a vision of the content and what they feel is the best way to teach it” (ZM). Another described ideal applicants who are “comfortable enough with their own knowledge to be able to listen to or hear their students when their students are proposing or conjecturing and that they're flexible enough not to shut them off right away and say, no, that'll never work” (CE). The possibility that the GeT course does not prepare students to become the teachers that these leaders identify poses an issue that GeT instructors may have the power to influence. However, GeT instructors have a variety of backgrounds and visions for what the course should be.

Variability in Geometry Preparation Within Teacher Education Programs

Despite some common experiences across participants, there tends to be significant variability among GeT courses, across instructors and institutions. We have heard from many GeT instructors that the course is unique within the mathematics department offerings because of the diverse student population that enrolls. Many courses report a mix of prospective secondary mathematics teachers, mathematics majors, and students from other departments that are taking the course as an elective. The mix of students creates a tension for instructors who are not sure how to balance the rigor required for a mathematics degree with the practical needs of prospective teachers (see Milewski et al., 2019). One GeT instructor went so far as to say that prospective teachers “take the same hard math classes all the other math majors take… [but] they typically don’t like those courses. And some of them don’t see the value of it for being a teacher” (RU). Depending on the particular context of each institution, the instructor assigned to the GeT course may have a doctorate in mathematics or in mathematics education. One GeT instructor expressed that the course is “mathematically sophisticated enough that mathematicians should be teaching it” (MV), while at some institutions the mathematics department chair defers to the recommendation of a mathematics educator to determine who teaches the course. Moreover, there is not a set criteria for determining the particular instructor. According to the university mathematics department chairs, GeT instructors have been chosen depending on instructor preference (AR) or who taught it most recently (MA). Depending on which instructor is chosen, the course content can vary drastically in terms of the extent to which HSG topics are covered and pedagogical content knowledge gained. Lastly, the GeT course is not highly valued at some institutions “because this course is really not a crucial part of the mission of the math department” (DZ, GeT Instructor). As a result, fewer resources are devoted to the creation of a course syllabus and materials, and stewardship of the course is left to individual instructors. All of these factors contribute to the varied geometry preparation of prospective teachers which, in turn, adds to the HSG instructional capacity problem.

Lack of Communication Across Institutional Stakeholders

Each set of stakeholders holds responsibility for some aspects of the preparation and support of HSG teachers, but there is no single stakeholder that controls the entire system. In addition, the system does not contain structures to support communication and collaboration across groups of stakeholders. A university mathematics department chair reported that there was not direct communication between the mathematics and education departments. At his institution, an informal communication system emerged, but it was not systematic.

> Well, indirectly we get input because [an instructor] also teaches a course in the education department. And so she sort of brings us sometimes, 'no, okay—they are doing this, we might need to modify this course or something. But I don't actively ask them to. (MA)

At a different institution, a GeT instructor mentioned that "the education department and the math department don't collaborate together, as they're in separate departments—we send our students [to the school of education] to do a credential, but we are separate departments in that sense" (KC). Although that instructor seems to trust that their education department counterparts are providing the appropriate instruction in service of their shared goals, a high school principal shared that she was "not very confident with the universities" (CI) in terms of how they supported prospective teachers in gaining content knowledge.

If stakeholders did not have opinions about what could or should be occurring within other parts of the system, it would be reasonable to expect minimal communication across stakeholders. However, our interviews with secondary school leaders indicate that they have clear ideas about how their potential hires should be prepared. Looking across the levels of school or district leadership, we heard the desire for prospective teachers to have "some kind of experience with computer [based] instructional materials" (ZM; e.g., GeoGebra), to have experiences struggling with mathematics content (ZM), to take a curriculum course "where math teachers truly know the [state standards] or the common core [standards]" (CI) and how the standards build across grade levels (CK, IF), to learn strategies for teaching problem solving skills (RU), and to have support determining how geometry is used outside the classroom (CY). Without structures in place to incentivize communication across stakeholders, it is likely that efforts to better prepare HSG teachers will fall short of serving the local community's needs.

HSG Staffing Decisions Made for Subject-Generic Reasons

When hearing from the secondary school leaders, it became clear that these leaders often make staffing decisions based on generic factors rather than subject-specific considerations. For example, one district/state instructional leader shared that the choice of who teaches Geometry "doesn't seem to be about the mathematics at all. It seems to be more about the behavior management of those classes and who's got the right attitude, the growth mindset" (ZM). In addition, staffing decisions at secondary schools tend to be made by taking into consideration the preferences and requests of current mathematics teachers so that when a position opens up "there will be kind of a reshuffling in terms of who is teaching what" (CK, HS principal). Furthermore, several secondary school leaders explained that they fill open positions by posting secondary mathematics positions rather than HSG positions. This may be a result of the current teacher credentialing system: "I think as long as they have secondary mathematics credentials, then they're supposedly able to teach Geometry. So it would just be expected" (CE, district/state instructional leader). These hiring practices may be contributing to the HSG instructional capacity problem as declining instructional quality impacts high school students who then travel through the system before returning to secondary schools as mathematics teachers.

Discussion

By considering the interview data presented here in the context of the systems diagram (Figure 1), we develop a more nuanced view of the system that contains the HSG instructional capacity problem. Schools and districts post openings for secondary mathematics teaching teachers, but tend to place the new hires in Algebra 1 and Geometry courses because the current teachers within the department request to teach other courses. This means that Algebra 1 and Geometry courses tend to be taught by new hires, many of whom are just out of teacher preparation programs. Upon being hired, those new teachers will receive comparatively less geometry-specific professional development and support as a result of school, district, and state educators de-emphasizing the HSG course. In their university teacher preparation programs, these teachers were not guaranteed to have had opportunities to develop geometric pedagogical content knowledge through their coursework or clinical experiences. These connections across major bones in Figure 2 indicate that there is a need for a network that spans stakeholder groups to inform improvement efforts.

As we move forward with this work, we plan to use what we have learned from these interviews to create surveys that can be administered to a national sample within each stakeholder group. A larger sample is a critical way to address limitations to analysis that arise from making claims based on idiosyncratic experiences. We will consider how the preliminary interview data from one stakeholder group can inform efforts to craft survey questions for the other stakeholder groups. For example, secondary school leaders indicated that they sometimes look to see if applicants earned a passing grade in their GeT course, so we might like to ask how often GeT Instructors assign a non-passing grade in those courses. We are also interested in learning more about how preservice teachers' experiences in the GeT course might relate to their desire to teach HSG when they apply for jobs. In our role as the hub of this networked improvement community, we have a unique opportunity to disseminate the knowledge and perspectives of parts of the community across stakeholder groups in an effort to improve the instructional capacity of the high school geometry course.

Spatial reasoning skills are necessary to perform activities at school, at work and in everyday life, in general. Different studies indicate the importance of its development at an early age, since it allows the reading of a three-dimensional world and its interpretation in two-dimensional representations. Our research focuses on the design of activities, using the Theory of Variation, to enhance spatial reasoning skills in seven to eight year-old students. In this document, we present characteristics of the design of an activity based on the use of pentominoes (two-dimensional puzzles). The results show that spatial reasoning skills develop when the following actions are favored: comparing, overlapping, rotating, moving, visualizing, and imagining movements, positions and locations of the pentomino pieces.

Keywords: Elementary School Education, Spatial Thinking, Representations and Visualization

Introduction and background

Spatial reasoning skills are necessary in human thinking and acting. The importance of developing these skills is reflected both in everyday life and in the school environment. In everyday life, authors such as Gonzato, Fernández & Díaz Godino (2011) recognize, for example, that the development of spatial reasoning is necessary to locate, move and read maps where bi-and three-dimensional objects may be present. Research also indicates that these skills are necessary for learning advanced mathematics (Mamolo, Ruttenberg-Rozen & Whiteley, 2015; Hallowell et al., 2015) and for the development in other areas such as technology, engineering, architecture (Arıcı & Aslan-Tutak, 2015; Van den Heuvel-Panhuizen, Iliade & Robitzsch, 2015), geography, computer graphics and visual arts (Clements & Sarama, 2011; Vázquez & Noriega Biggio, 2010). In terms of the relationship between spatial thinking and STEM (Science, Technology, Engineering, and Mathematics) performance, Uttal and Cohen (2012) suggested that spatial skills strongly predict student selection for studying the STEM subjects.

Although the importance of developing spatial reasoning skills in school is recognized, a review of the literature in mathematics education (Ortiz, 2018; Ortiz, Sacristán & Sandoval, 2019), shows a lack of studies for enhancing students' competences, abilities, thinking, or spatial reasoning. Ortiz (2018) analyzed articles in 12 mathematics education journals in English and Spanish, published between 2010 and 2016. She observed that only 4.7% of the articles focus on aspects of learning and teaching geometry (in contrast to those focused on arithmetic, algebra and calculus). Of this percentage, only 13% address aspects of spatial reasoning: some describe the importance of its development, others focus on identifying difficulties and some more present activity proposals.

Research focused on analyzing the consequences of a poor development of spatial reasoning, have identified difficulties in the visualization of 2D and 3D representations (Arıcı & Aslan-Tutak, 2015); in the turning movement of 2D and 3D objects (Pittalis & Christou, 2010); in understanding the meaning of area and volume formulas (Mamolo, Ruttenberg-Rozen & Whiteley, 2015); in the construction of 2D and 3D figures (Pittalis & Christou, 2010); in relating 2D and 3D representations

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. (Dindyal, 2015); and in reading maps (Gonzato, Fernández & Díaz, 2011). These difficulties have been found to affect other disciplines and work areas that involve interpreting representations to solve tasks (Francis & Whiteley, 2015).

In relation to the design of activity proposals, the research recognizes objectives categorized by educational level: in preschool and elementary school, students are expected to recognize two-dimensional representations (drawings) of real objects (Hallowell, Okamoto, Romo & La Joy, 2015; Van den Heuvel-Panhuizen, Iliade & Robitzsch, 2015); in secondary school, students are expected to manipulate 3D objects, either with dynamic geometry or tangible materials (Arıcı & Aslan-Tutak, 2015; Gómez, Albaladejo & López, 2016), and be able to draw conjectures of events related to a specific context.

There are also few longitudinal studies focused on describing what type of materials, activities, or teaching/learning proposals promote the development of spatial reasoning skills. As Davis, Okamoto and Whiteley (2015) point out, further research is required in this regard.

In this sense, the study on which this document is based, investigated how to provide, through the design of activities involving 2D and 3D representations, learning opportunities for 7 to 8 year-old students to develop their spatial reasoning skills. To answer this, we designed six activities based on the Theory of Variation (Marton & Pang, 2006), which were implemented in a public school located in a marginalized area of Mexico City.

This document presents the design of the first activity that involves isometric movements in the plane, using puzzles with pentomino pieces. Next, we describe some elements of the Theory of Variation on which we based the activity design; we then provide a brief analysis of how this design can promote the development of students' spatial reasoning.

Theoretical perspective: Variation as a tool for the design of the activities

In the Theory of Variation (Marton & Pang, 2006; Ling-Lo, 2012) learning happens when a difference is experienced between two things or between two parts of the same thing (Marton & Pang, 2006), that is, when the learner manages to *discern characteristics* and *critical aspects* of some *learning object* (Orgill, 2012; Runesson, 2005). An object of learning is "a specific insight, skill, or capability that the students are expected to develop" (Marton & Pang, 2006, p.194).

Ling-Lo (2012) distinguishes the critical aspects of a learning object from its critical characteristics: "a critical aspect refers to a dimension of variation, whereas critical feature is a value of that dimension of variation" (p. 65). This can be better understood through an example: if the learning object is the cube, some critical aspects to discern can be the dimensions of the *shape* or *number of its faces*; and it has, as critical characteristics (the values of the dimensions), the fact that *each face is a square (congruent between themselves)* and the fact that *it has exactly six faces.*

Methodology

In our study, we carried out a teaching experiment framed in the research design paradigm (Cobb & Gravemeijer, 2008). A teaching experiment involves a cyclic process of design, implementation, and analysis of a sequence of activities (Steffe & Thompson, 2000) to improve and refine it. Derived from the literature review and the Theory of Variation, the following aspects were considered for the design of the sequence: the use of different manipulatives (pentominoes, blocks, SOMA Cube, Lego pieces) and digital technologies (Lego Designer); construction activities with dimension variation (starting with 2D, continuing with 2D-3D dimension changes); and variation in the characteristics of the representations in the printed materials (number of divisions in the different pentominoes, and colors or grayscale for the representations of 3D objects). The first activity is described in detail in the following section.

Our study had two cycles: in the first one, we designed a sequence of six activities to be carried out in 13 sessions; we analyzed the results of its first implementation for improving the design in the second cycle, in which we had the same number of activities but implemented in 15 sessions.

In both implementations, 7-8-year-old students participated. In the first cycle, we had eight participating students and in the second, 26 (a complete group of third grade). For the data collection, we used two video cameras to record what happened during each class, complemented by field notes. These records were used to plan subsequent sessions, as well as to perform a retrospective analysis of the experiment. In the second implementation, the first author of this paper acted as teacher-researcher, and together with the students, they agreed on the organization of the activities: student autonomy, materials to use (manipulatives and worksheets –with brief and clear guidelines on the activity) and ways of working (individual, in pairs, teams or as a whole group). When managing her class, the teacher-researcher carried out different actions: she did a recap of the aim of the previous session, mentioned the objective of the current session, asked questions and clarified doubts to the teams, specified the mathematical vocabulary used to describe spatial actions, and coordinated the closing plenary discussion with the entire group.

In order to analyze the development of spatial reasoning as a result of the implementation of the sequence of activities, we used a diagnostic pre and post test, as well as observations of the cognitive and movement actions of the students during the activities.

Description of some of the activities

In our design, and according to the Theory of Variation, each activity has a specific *learning object* and is made up of two or three tasks. An assignment can be carried out in one or two class sessions. *Variants* and *invariants* of this learning object are required for each task. *Critical aspects* and *characteristics* describe those elements of spatial reasoning that students are expected to develop. Next, we present the design of the first activity –which focuses on recognizing, visualizing and performing isometric movements in the plane using two-dimensional representations (puzzles)–; we describe the elements of the Theory of Variation involved in it and then analyze some results of the activity implementation.

An activity focused on isometric movements of two-dimensional representations

The *learning object* of this activity is rotation and translation (isometric movements) in the plane and in space, when using pentominoes (12 pieces; see Figure 1.a).

a. b.

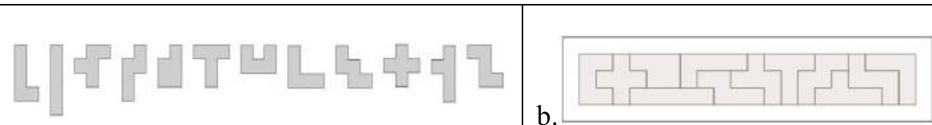

Figure 1: a. The pentomino pieces. b. Rectangle made up of pentomino pieces.

Students have to solve *different* puzzles (the *variants*) formed with the *same* pentomino pieces (the *invariants*); this requires promoting the ability to discern that, even though the shape and perimeter change, the area is conserved. In this activity there are four *critical aspects*: comparison and visualization, localization, turns, and organization of the pieces. The *critical characteristics* related to each critical aspect are presented in Table 1.

Table 1: Description of the critical characteristics

Critical aspects	Critical characteristics
Comparison and visualization	• Recognizing the shape of each piece. • Comparing the shapes of the pieces in order to assemble them. • Recognizing, in the 2D representation, the pieces that make up each puzzle (whether they are explicit or implicit). (Ideas of congruence through immediate perception and superposition). • Imagining what the union of the pieces represents in the given configuration. (The whole).
Localization	• Locating, in the 2D representation, the location of each piece. • Describing the relative position of each piece using terms of proximity (near, far) and direction (up, down, right, left).
Turns	• Rotating and flipping pieces to complete a given setup.
Organization of the pieces	• Organizing the pieces to achieve the requested configuration. • Dividing the puzzle into sections. • Assemble the pieces that make up a section.

This activity has two tasks (T1 and T2). In T1, each student has 12 pieces of pentomino to assemble them on a rectangular frame of 3 × 20 units, in such a way that it covers it completely, without overlapping pieces (see Figure 1.a). In this task, students need to recognize the shape of each piece of the pentomino and compare them.

In order to promote the use of language, in the assembly of the puzzles, students are encouraged to interact and support each other with ideas or suggestions, with the restriction of only giving verbal indications or gestures. And at the end of the T1 task, a group discussion is carried out, with the following guiding questions: *¿Do all the puzzles have the same number of pieces? ¿Are the pieces themselves, different or the same? ¿Why are they different or the same? ¿How could we differentiate them?*

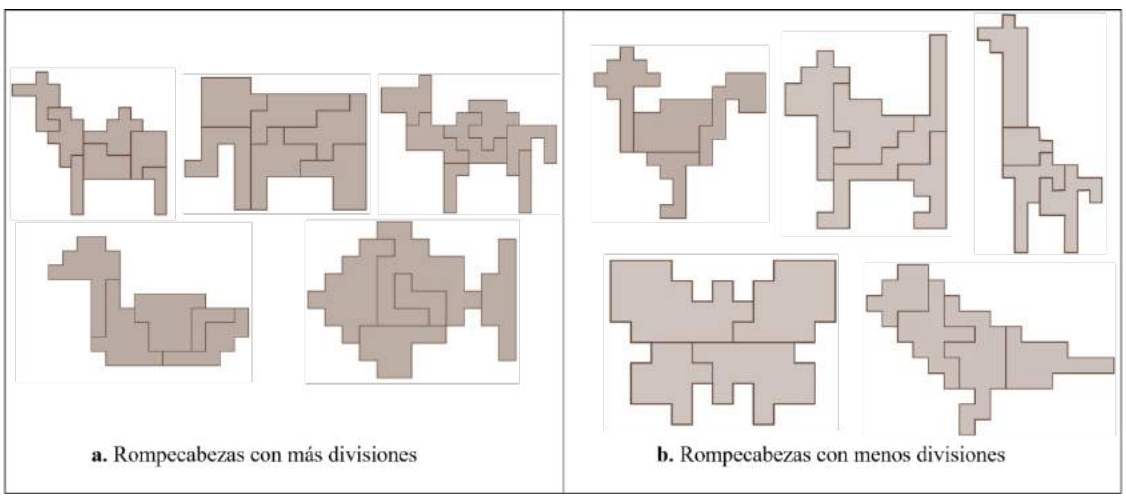

Figure 2: Representations of the puzzles to assemble, as given to the students in T2.

In task T2, each student must assemble an assigned puzzle in the shape of an animal (see Figure 2), for which clues are given regarding the shape of the pieces that compose it: some puzzles (Figure 2.a) show some subdivisions congruent to the pentomino pieces; while in others, only four divisions are shown, none of which is congruent to any part (Figure 2.b). Students put together the puzzles with the most divisions and then the puzzles with the least divisions. In this sense, different levels of cognitive difficulty are considered (from more guided to less guided).

Results of Activity 1

In the implementation of T1, the students worked for two hours and all managed to *recognize the shape of the pentominoes* and identified how they fit into the rectangular frame, without any leftover or missing space.

For T2, two sessions were required, each lasting two hours. In the first of these sessions, students put together the puzzles with more divisions; students who had difficulties, were given a sheet with a printed replica of the assembled puzzle, showing the pieces in real size (in a 1:1 scale) (see Figure 3.a). The intention was for all students to recognize the shape of each pentomino piece, its location and position in the puzzle. In the second session, students put together puzzles with fewer divisions. Those who finished first helped their teammate (see Figure 3.b); to do this, they used the assembled puzzle (scale 1:1), and gave instructions to their partner regarding the orientation and position of each piece.

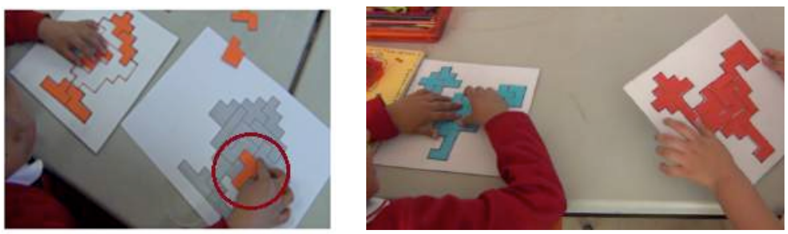

Figure 3: Examples of student work during task T2.

From overlapping pieces to visualizing spaces

During T1 and T2 we identified three strategies for assembling the puzzles: overlapping, trial-and-error, visualization-and-imagination. When they used the replica to assemble the puzzle, the most common way was to overlap the pentomino pieces unto the congruent spaces on the replica (see the part indicated in Figure 3.a) to later transfer (carry out a translation) of the pieces unto the puzzle.

When assembling the puzzles with more divisions, initially students used *trial-and-error* to place the pieces (see Figure 4.a); later, they *visualized* if any of the pieces had the shape of a section in a space of the puzzle that still needed to be completed (see Figures 4.b and 4.c).

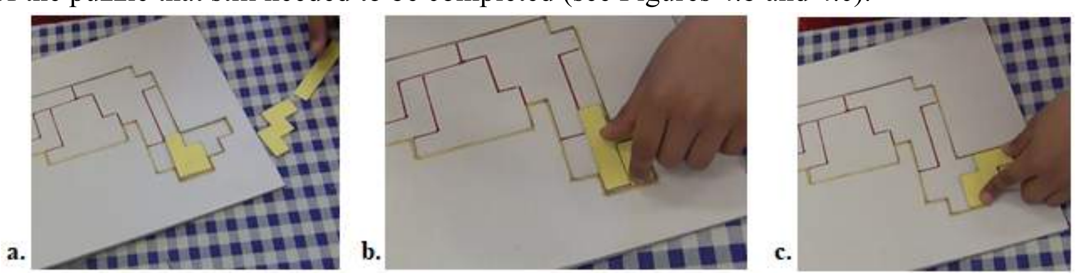

Figure 4: Location of the pentominoes by trial and error.

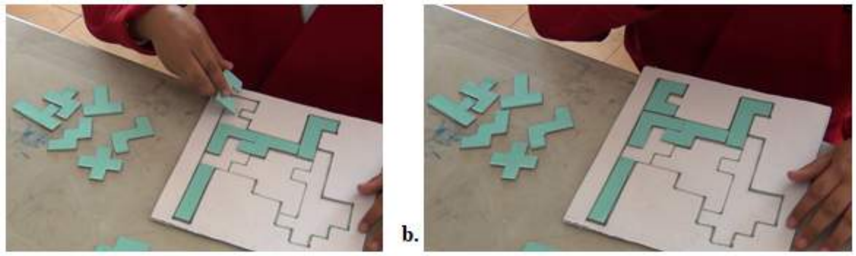
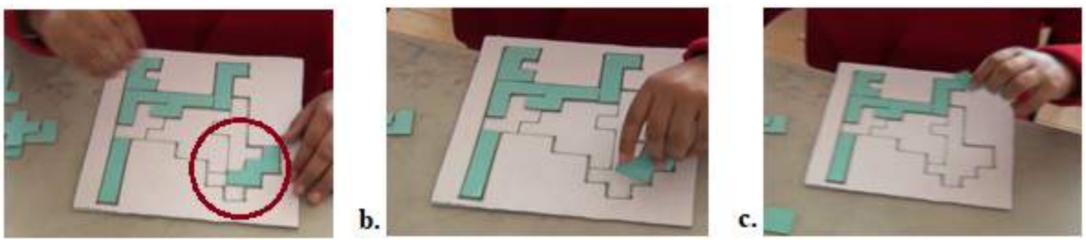
For putting together the puzzles with fewer divisions, the students generated a strategy: to *first locate the pentominoes at the edges of the puzzle*, since it was easier to recognize the congruence of the shape of the edges with the shape of some of the pentomino pieces (see Figure 5); thus, they postponed placing the pieces of the center of the puzzle.



a. b.

Figure 5: Assembling puzzles with fewer divisions in T2.

In putting together these puzzles, not only was it necessary to match the shape of the pentomino pieces with those of the puzzle, but also to compare the missing shapes of the puzzle with the remaining pentomino pieces. For example, Figure 6 shows that the student placed a pentomino in a space (marked section in Figure 6.a,), because its shape partially coincides with that of that space in the puzzle; however, since he did not find another piece that would complete the space, as can be seen in Figures 6.b and 6.c, the student discarded the piece that he had initially placed.



a. b. c.

Figure 6: Matching puzzle pieces in T2.

Identifying the locations of the pentomino pieces and the different ways in which they fit into the puzzles, allowed a refinement of strategies. At first it was a trial-and-error activity; and it was through the comparison between the remaining spaces of the puzzle and the shape of the pieces. that students could *imagine-and-visualize* the congruence between the divisions of the puzzle and the assembly of pentomino pieces.

Critical aspects of isometric movements: from translation and rotation, to turn

In T1 and T2, students were able to locate, immediately or not, a pentomino piece in the puzzle depending on whether the orientation of the piece and the congruent space were the same or different. When it was the same, the students moved (*translated)* the piece without difficulty (see Figure 7).

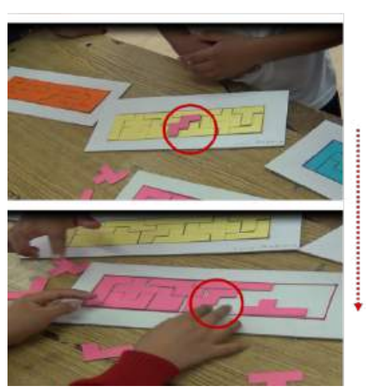


Figure 7: Translation movement.

In the case where the orientation of the piece and the missing space were different, students *rotated* the pieces, with no apparent difficulty, through a movement carried out on the plane (see Figure 8).

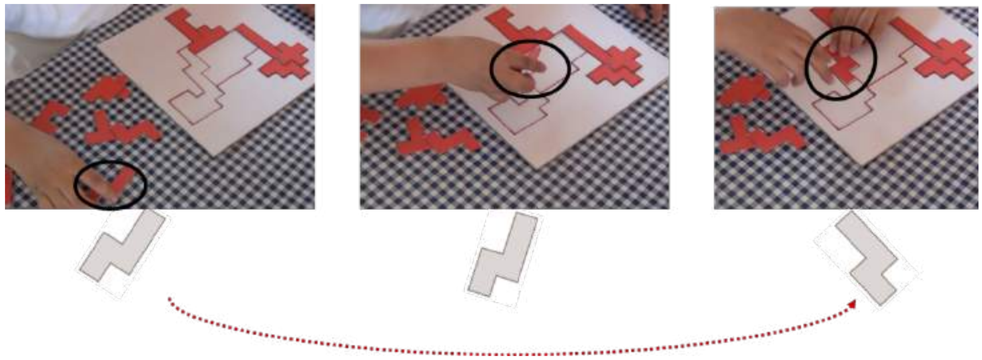

Figure 8: Rotation movement in the plane.

A challenge for the children was the action of turning. If the location of a piece in the puzzle required a *rotation* movement in space, and if a student did not immediately recognize how to locate it, he would first rotate it in the plane and then *visualize* whether, with a turn of the piece in the 3D space, it would fit into the puzzle (see Figure 9).

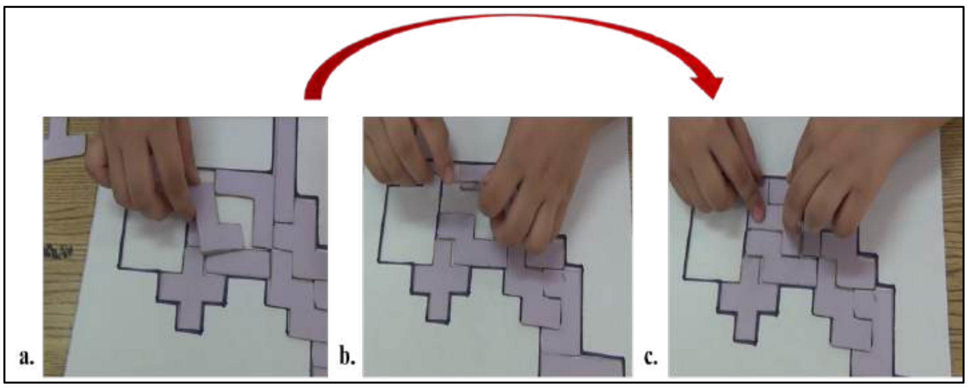

Figure 9. Rotation movement in space.

All of the students, through rotation and translation movements, achieved the required assembled puzzles. Experimenting in putting together these puzzles allowed them to *identify subconfigurations* (one figure contained in another) and *visualize* the congruence of a composite shape (a union) formed by joining several pentomino pieces (the parts). It should be noted that the movement actions, when locating a piece, are not linear. In the examples presented in this section, we illustrate how students, in order to place a piece in the puzzle, perform a combination of the following actions: they manipulate the piece to *translate* it, *visualize* its *orientation*, *rotate* and/or *turn* it, in order to finally *locate* it in the empty space in the puzzle.

The implementation of this activity reflects a development of the spatial reasoning of the students, since, thanks to an activity design that included a *variation of the puzzles, a variation of the positions and orientations of the pentomino pieces,* and an *invariance in the number and shape of the pieces*, they went from *locating the pieces by trial and error*, to *visualizing* the location of the pieces in the puzzles. The two tasks led the students to *rotate* and *translate* the pieces of the pentomino, find a *correspondence* of each of the pieces according to the shape that they identified in the drawing, *compare* the remaining spaces with the unused pieces, and *visualize* and imagine the composition. Furthermore, they recognized that there are several puzzle shapes that can be put together using the same number of pentomino pieces.

Discussion and final remarks

In the design of the activity reported here, three elements were considered in order to develop spatial reasoning in the students: i) The use of the same pentomino pieces, in different puzzles; ii) a gradual change in the level of difficulty of the puzzles (from more to fewer divisions); and iii) the difficulties, reported in the literature, when putting together puzzles (e.g., turning in the 3D space).

Through the first element, students were given the opportunity to recognize that, even when the puzzles were different, they could always be assembled using the same number of pieces; they noted also that the location, orientation and direction of the pentomino pieces varied. The variation of puzzles and invariance of the pentomino pieces could assist these students in creating meanings for the concept of area, which according to Mamolo, Ruttenberg-Rozen and Whiteley (2015), is a common difficulty for students.

The gradual increased complexity of the activities promoted the development of visualization processes through the composition of pieces. When students assembled puzzles with more divisions, they could see the *congruence* of remaining puzzle spaces with the pentomino pieces. But when they had to put together puzzles with fewer divisions, they had to *discern* which of the pieces, when put together, would complete a section of the puzzle divisions. In this process, we found that children *developed construction strategies,* such as: starting the assembly by identifying and locating the pieces at the edges that is, going from the outside in); and assembling the puzzle in sections according to the divisions.

Both in the design and in the development of the activities, possible difficulties were anticipated that a 7-8-year-old student could face, as reported in the literature (Arıcı & Aslan-Tutak, 2015; Gonzato, Fernández & Díaz, 2011). If students did not identify the pentomino pieces that would go in a certain section, a replica was provided to help them in solving the puzzle. This helped the children to *establish congruences* between pentomino pieces and *perform isometric transformations such as rotation and translation* with the pieces.

The previous results show the potential of activities using 2D representations to support the development of spatial reasoning skills in 7-8-year-old children. The use of tangible material, in accordance with what is mentioned by Gutiérrez (1991), allowed students to experiment and recognize the movement and shapes of the pentomino pieces and two-dimensional puzzles. In addition, identifying the position and orientation of the pentominoes in the puzzles required students to *compare, overlap, rotate, translate, visualize,* and *imagine* the shapes of the pieces in the various puzzles.

Gonzato, Díaz-Godino and Neto (2011) have found that, if these experiences are provided in the first years of schooling, children acquire greater abilities to build constructions and mentally manipulate figures in the plane and in the 3D space. Therefore, we consider that these types of experiences that promote cognitive actions (visualizing, imagining) and movement (comparing, overlapping, rotating, translating), allow students to make sense and understand a world presented through two-dimensional representations in different areas of knowledge and in daily life.

Las habilidades de razonamiento espacial son necesarias para desempeñar actividades en la escuela, en el trabajo y en la vida cotidiana en general. Diferentes estudios señalan la importancia de su desarrollo en edades tempranas, pues permite la lectura de un mundo tridimensional y su interpretación en representaciones bidimensionales. Realizamos un estudio enfocado al diseño de actividades, usando la Teoría de la Variación, para potenciar habilidades de razonamiento espacial en estudiantes entre siete y ocho años. En este documento presentamos características del diseño de una actividad basada en el uso de pentominós (rompecabezas bidimensionales). Los resultados muestran desarrollo en habilidades de razonamiento espacial cuando se favorecen acciones como comparar, superponer, rotar, trasladar, visualizar e imaginar movimientos, posiciones y ubicaciones de las piezas del rompecabezas.

Palabras clave: Educación primaria, pensamiento espacial, representaciones y visualización.

Introducción y antecedentes

Las habilidades de razonamiento espacial son necesarias en el actuar y el pensar del ser humano. La importancia del desarrollo de dichas habilidades se refleja tanto en lo cotidiano como en el ámbito escolar. En la vida cotidiana, autores como Gonzato, Fernández y Díaz Godino (2011) reconocen, por ejemplo, que el desarrollo de razonamiento espacial es necesario para ubicarse, desplazarse y leer mapas donde objetos bi- y tridimensionales pueden estar presentes. En relación con lo escolar, investigaciones señalan que estas habilidades son necesarias para el aprendizaje de matemáticas avanzadas (Mamolo, Ruttenberg-Rozen y Whiteley, 2015; Hallowell et al., 2015) y el desenvolvimiento en otras áreas como tecnología, ingeniería, arquitectura (Arıcı, y Aslan-Tutak, 2015; Van den Heuvel-Panhuizen, Iliade y Robitzsch, 2015), geografía, computación gráfica y artes visuales (Clements y Sarama, 2011; Vázquez y Noriega Biggio, 2010). En términos de la relación entre el pensamiento espacial y el rendimiento en STEM (por sus siglas en inglés, correspondientes a Ciencia, Tecnología, Ingeniería y Matemáticas), Uttal y Cohen (2012) exploraron y sugirieron que las habilidades espaciales predicen fuertemente la selección de estudiantes para estudiar las áreas STEM.

Si bien se reconoce la importancia de desarrollar habilidades de razonamiento espacial en la escuela, una revisión de la literatura en educación matemática (Ortiz, 2018; Ortiz, Sacristán, Sandoval, 2019) refleja una falta de estudios para potenciar competencias, habilidades, pensamiento o razonamiento espacial. Ortiz (2018) analizó artículos en 12 revistas en inglés y español de educación matemática, publicados entre 2010 y 2016. Observó que solo el 4.7% de los artículos se enfoca en aspectos del aprendizaje y enseñanza de la geometría (en contraste con los enfocados a aritmética, álgebra y cálculo). De este porcentaje, solo el 13% aborda aspectos de razonamiento espacial: unos describen la importancia de su desarrollo, otros se centran en identificar dificultades y algunos más presentan propuestas de actividades.

Las investigaciones centradas en analizar las consecuencias del poco desarrollo del razonamiento espacial han identificado dificultades en la visualización de representaciones 2D y 3D (Arıcı y Aslan-

Tutak, 2015); en el movimiento (giros) de objetos 2D y 3D (Pittalis y Christou, 2010); en la comprensión del significado de fórmulas de área y volumen (Mamolo, Ruttenberg-Rozen y Whiteley, 2015); en la construcción de figuras en 2D y 3D (Pittalis y Christou, 2010); en la conexión entre representaciones 2D y 3D (Dindyal, 2015); y en lectura de mapas (Gonzato, Fernández y Díaz, 2011). Se ha encontrado que estas dificultades inciden en otras disciplinas y áreas de trabajo que implican interpretar representaciones para resolver tareas (Francis y Whiteley, 2015).

En relación con el diseño de propuestas de actividades, en la investigación se reconocen objetivos por nivel educativo: en preescolar y primaria se pretende que los estudiantes reconozcan representaciones bidimensionales (dibujos) de objetos reales (Hallowell, Okamoto, Romo y La Joy, 2015; Van den Heuvel-Panhuizen, Iliade y Robitzsch, 2015); en secundaria se pretende que manipulen objetos tridimensionales, ya sea con geometría dinámica o material tangible (Arıcı y Aslan-Tutak, 2015; Gómez, Albaladejo y López, 2016), y, de esa manera, logren conjeturar sucesos relacionados con algún contexto determinado.

También son pocos los estudios longitudinales enfocados en describir qué tipo de materiales actividades o propuestas de enseñanza/aprendizaje propician el desarrollo de habilidades de razonamiento espacial. Como lo precisan Davis, Okamoto y Whiteley (2015) se requiere mayor investigación al respecto. En este sentido, el estudio en el que se basa este documento investigó ¿cómo proporcionar, a través del diseño de actividades que involucran representaciones bi- y tridimensionales, oportunidades de aprendizaje a estudiantes de siete a ocho años de edad para el desarrollo de habilidades de razonamiento espacial? Para responder a este cuestionamiento, se diseñaron seis actividades con base en la Teoría de la Variación (Marton y Pang, 2006), que se implementaron en una escuela pública ubicada en una zona marginada de la Ciudad de México.

En este documento se presenta el diseño de la primera actividad que involucra movimientos isométricos en el plano, mediante el uso de rompecabezas con piezas pentominó. A continuación se describen elementos de la Teoría de la Variación en los que se basa el diseño de la actividad; posteriormente, se realiza un breve análisis de cómo este diseño promueve el desarrollo del razonamiento espacial de los estudiantes.

Perspectiva teórica: La variación como herramienta para el diseño de actividades

En la Teoría de la Variación (Marton y Pang, 2006; Ling-Lo, 2012) el aprendizaje sucede cuando se experimenta una diferencia entre dos cosas o entre varias partes de una misma cosa (Marton y Pang, 2006), es decir, cuando el aprendiz logra *discernir características* y *aspectos críticos* de algún *objeto de aprendizaje* (Orgill, 2012; Runesson, 2005). Un objeto de aprendizaje, en esta teoría, es "una idea introspectiva (insight), una habilidad o una capacidad específicas que se espera que los estudiantes desarrollen" (Marton y Pang, 2006, p.194).

Ling-Lo (2012) distingue los aspectos críticos de un objeto de aprendizaje, de sus características críticas: "un aspecto crítico se refiere a una dimensión de la variación, mientras que una característica crítica es un valor de esa dimensión" (p. 65). Esto se puede entender mejor mediante un ejemplo: si el objeto de aprendizaje es el cubo, algunos aspectos críticos a discernir pueden ser las dimensiones de *forma* o *número de sus caras*; y tiene como características críticas (los valores de las dimensiones) que *cada cara es un cuadrado (congruentes entre sí)* y que *tiene exactamente seis caras*.

Metodología

En nuestro estudio se llevó a cabo un experimento de enseñanza enmarcado en el paradigma de investigación de diseño (Cobb y Gravemeijer, 2008). Un experimento de enseñanza implica un proceso cíclico de diseño, implementación y análisis de una secuencia de actividades (Steffe y Thompson, 2000) para mejorarla y refinarla. Derivado de la revisión de la literatura y de la Teoría de la Variación, para el diseño de la secuencia se consideraron los siguientes aspectos: uso de diferentes manipulables (pentominós, bloques, Cubo SOMA, piezas de Lego) y tecnologías digitales (Lego Designer); actividades de construcción con variación en la dimensión (comenzando con 2D, continuando con cambios de dimensión 2D-3D); y variación en las características de las representaciones en los impresos (cantidad de divisiones en los diferentes pentominós, y colores o escala de grises para las representaciones de objetos 3D). En el siguiente apartado se describe con detalle la primer actividad.

Nuestro estudio tuvo dos ciclos: en el primero se diseñó una secuencia de seis actividades llevadas a cabo en 13 sesiones; se analizaron los resultados de su primera implementación y los resultados sirvieron para mejorar el diseño en el segundo ciclo, terminando con el mismo número de actividades pero implementadas en 15 sesiones. En ambas implementaciones participaron estudiantes entre los siete y ocho años. En el primer ciclo participaron 8 estudiantes y en el segundo, 26 (un grupo completo de tercer grado). Para la toma de datos se utilizaron dos cámaras de video y se registraron en notas de campo lo sucedido durante cada clase. Estos registros se usaron para planear las sesiones posteriores, así como para realizar un análisis retrospectivo del experimento. En la segunda implementación, la primera autora de este escrito fungió como profesora-investigadora y junto con los estudiantes acordaron la organización de las actividades: autonomía de los alumnos, material a utilizar (manipulables y hojas de trabajo –con indicaciones breves y claras sobre la actividad) y formas de trabajo (individual, en parejas, equipos o grupo completo). En la gestión de la clase, la profesora-investigadora realizó diferentes acciones: recapituló el objetivo de la sesión anterior, mencionó el objetivo de la sesión, hizo preguntas y aclaró dudas en los equipos, precisó el uso de vocabulario matemático para describir acciones espaciales y coordinó la discusión plenaria de cierre con todo el grupo.

Para analizar el desarrollo del razonamiento espacial a raíz de implementar la secuencia de actividades, se usó una prueba diagnóstica aplicada como pre y post test, así como observaciones de las acciones cognitivas y de movimiento de los estudiantes durante las actividades.

Descripción de algunas actividades

En nuestro diseño, cada actividad tiene un *objeto de aprendizaje* determinado y está conformada por dos o tres tareas. Una tarea puede realizarse en una o dos sesiones de clase. Para cada tarea se precisan *variantes* e *invariantes* de dicho objeto de aprendizaje. Los *aspectos* y *características críticas* describen aquellos elementos del razonamiento espacial que se espera desarrollen los estudiantes. A continuación se presenta el diseño de la primera actividad –la cual se centra en reconocer, visualizar y realizar movimientos isométricos en el plano usando representaciones (rompecabezas) bidimensionales—, se describen los elementos de la Teoría de la Variación involucrados en ella y se analizan algunos resultados de su implementación.

Una actividad centrada en movimientos isométricos de representaciones bidimensionales

El *objeto de aprendizaje* de esta actividad está enfocado en movimientos isométricos en el plano (rotación y traslación) y en el espacio, al usar pentominós (12 piezas; ver Figura 1a).

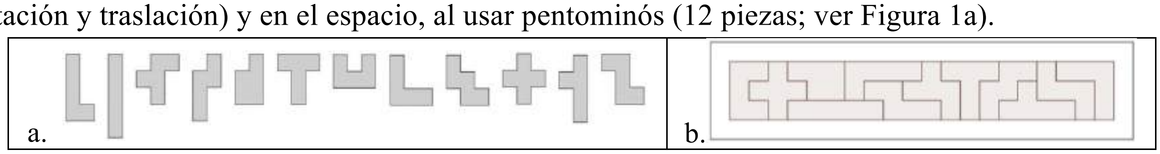

Figura 1: a. Las piezas pentominó. b. Rectángulo formado por piezas pentominó.

Los alumnos resuelven *diferentes* rompecabezas (las *variantes*) armados con las *mismas* piezas de pentominó (las *invariantes*); esto supone promover el discernimiento de que, aunque cambia la forma y el perímetro, hay conservación del área. En esta actividad son cuatro los *aspectos críticos:*

comparación y visualización, localización, giros y organización de las piezas. Las *características críticas* relacionadas a cada aspecto crítico se presentan en la Tabla 1.

Tabla 1. Descripción de las características críticas

Aspectos críticos	Características críticas
Comparación y visualización	Reconocer la forma de cada pieza. Comparar las formas de las piezas para ensamblarlas. Reconocer, en la representación 2D, las piezas que componen cada rompecabezas (estén explícitas o implícitas). (*Ideas de congruencia por percepción inmediata y superposición*). Imaginar lo que representa la unión de las piezas en la configuración dada. (*El todo*).
Localización	Ubicar, en la representación 2D, el lugar de cada pieza. Describir la posición relativa de cada pieza usando términos de proximidad (cerca, lejos) y de dirección (arriba, abajo, derecha, izquierda).
Giros	Rotar y voltear piezas para completar una configuración determinada.
Organización de piezas	Organizar las piezas para lograr el ensamble solicitado. Dividir el rompecabezas en secciones. Ensamblar las piezas que conforman una sección.

Esta actividad tiene dos tareas (T1 y T2). En T1 cada estudiante tiene 12 piezas de pentominó para ensamblarlas sobre un marco rectangular de 3 unidades × 20 unidades de tal manera que lo cubra completamente, sin sobreponer piezas (ver Figura 1a). En esta tarea los estudiantes necesitan *reconocer* la forma de cada pieza del pentominó y *compararlas*.

Para favorecer el uso del lenguaje, se promueve la interacción entre los estudiantes para apoyarse en el armado de los rompecabezas con ideas o sugerencias, con la restricción de sólo dar de indicaciones verbales o gestos. Y en el cierre de la tarea T1 se hace una socialización para responder las siguientes preguntas guía: *¿Todos los rompecabezas tienen el mismo número de piezas? ¿Las piezas entre sí, son diferentes o iguales? ¿Por qué son diferentes o iguales? ¿Cómo las podríamos diferenciar?*

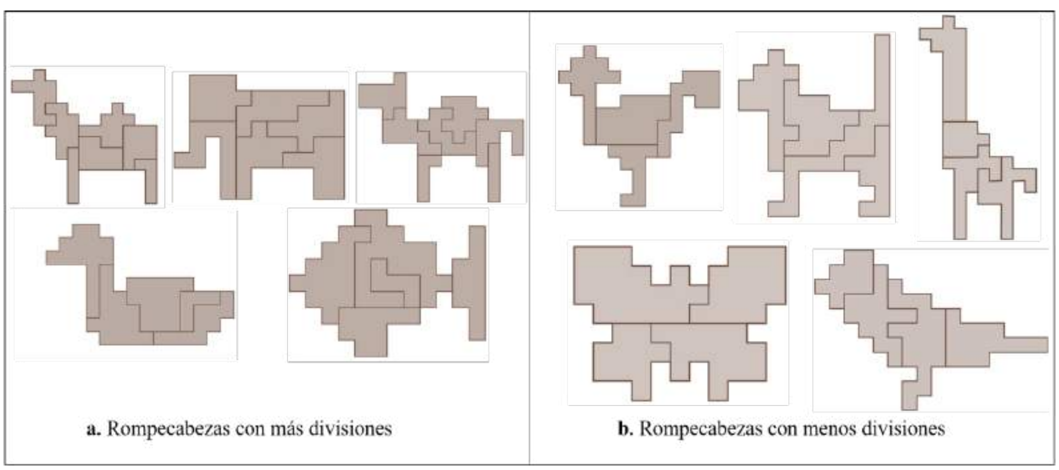

Figura 2: Representaciones, dadas a los alumnos en T2, de los rompecabezas a construir.

En la tarea T2, cada estudiante debe armar un rompecabezas asignado con la forma de un animal (ver Figura 2), para el cual se dan pistas respecto a la forma de las piezas que lo componen: unos rompecabezas (Figura 2.a) muestran algunas subdivisiones congruentes a las piezas pentominós; mientras que en otros, solo se muestran cuatro divisiones, ninguna de las cuales es congruente a alguna pieza (Figura 2.b). Los estudiantes arman primero los rompecabezas con más divisiones y después aquellos con menos divisiones. En este sentido se consideran diferentes niveles de dificultad cognitiva (de más guiado a menos guiado).

Resultados de la Actividad 1

En la realización de T1 los estudiantes trabajaron durante una sesión de dos horas y todos lograron *reconocer la forma de los pentominós* e identificaron cómo se encajaban en el marco rectangular, sin que sobrara o faltara algún espacio.

Para T2 se requirieron dos sesiones, cada una de dos horas. En la primera de estas sesiones, los alumnos armaron los rompecabezas con más divisiones; a quienes se les dificultaba, se les proporcionaba una hoja con una réplica del rompecabezas ya armado, mostrando las piezas en tamaño real (escala 1:1) (ver Figura 3.a). La intención era lograr que todos reconocieran la forma de cada pieza pentominó, su ubicación y posición en el rompecabezas. En la segunda sesión, los estudiantes armaron rompecabezas con menos divisiones. Quienes terminaron primero ayudaron a su compañero (ver Figura 3.b); para ello, usaron el rompecabezas armado (escala 1:1), y dieron indicaciones a su compañero respecto a la orientación y posición de cada pieza.

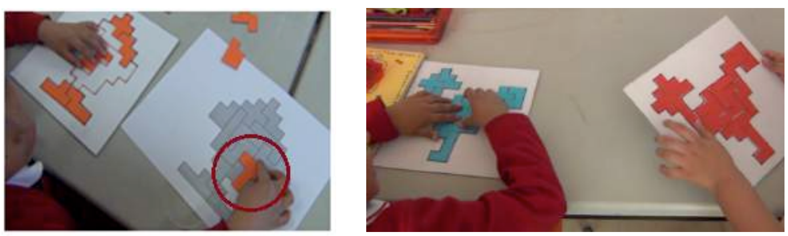

Figura 3: Ejemplos del trabajo de los estudiantes durante la tarea T2.

De la superposición de piezas a la visualización de espacios

Durante T1 y T2 identificamos tres estrategias para el armado de los rompecabezas, superposición, ensayo-y-error, visualización-e-imaginación. Cuando usaron la réplica para el armado del rompecabezas, lo más usual fue hacer uso de la superposición de las piezas de pentominó en los espacios congruentes sobre la réplica (ver parte señalada en la Figura 3.a) para, después, trasladar dichas piezas al rompecabezas.

Al armar los rompecabezas con más divisiones, colocaron las piezas de pentominó, por *ensayo-y-error* inicialmente (ver Figura 4.a); y luego, fueron *visualizando* si alguna de sus piezas tenía la forma de alguna sección en un espacio del rompecabezas que faltaba por armar (ver Figuras 4.b y 4.c).

a. b. c.

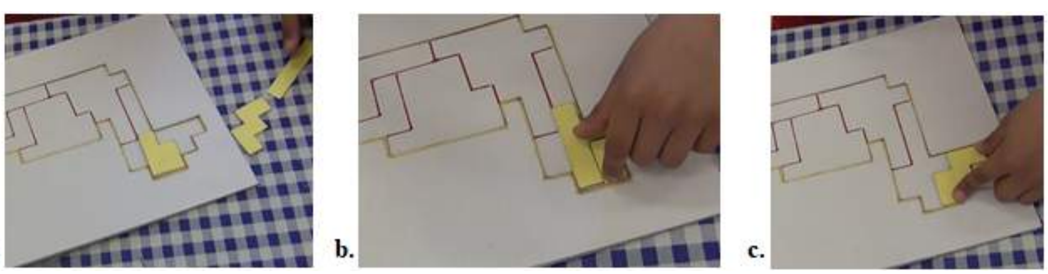

Figura 4: Ubicación de los pentominós por ensayo y error.

Para el armado de rompecabezas con menos divisiones los estudiantes generaron una estrategia: *ubicar primero los pentominós de los bordes del rompecabezas*, pues era más fácil reconocer la congruencia de la forma del borde con algunas formas de las piezas pentominó (ver Figura 5); así posponían la colocación de las piezas del centro del rompecabezas.

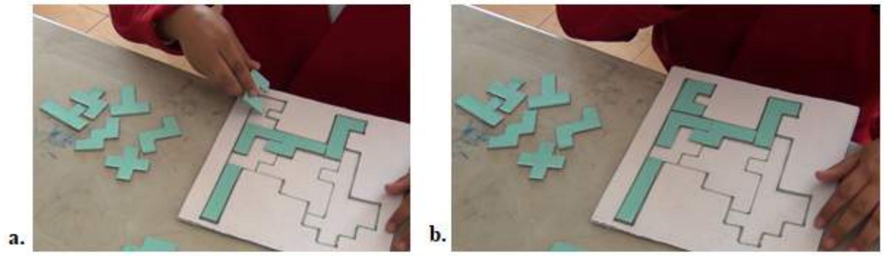

Figura 5: Armado de rompecabezas con menos divisiones en T2.

En el armado de estos rompecabezas no solo era necesario hacer corresponder la forma de las piezas pentominó con las del rompecabezas, sino comparar las formas faltantes del rompecabezas, con las piezas restantes de pentominó. Por ejemplo, en la Figura 6, se puede observar que el estudiante ubicó en un espacio (sección señalada en la Figura 6.a,) una pieza pentominó, porque su forma coincide parcialmente con la de ese espacio del rompecabezas; sin embargo, como no encontró otra pieza que completara el espacio, en las Figuras 6.b y 6.c se aprecia que el estudiante descarta la pieza colocada inicialmente.

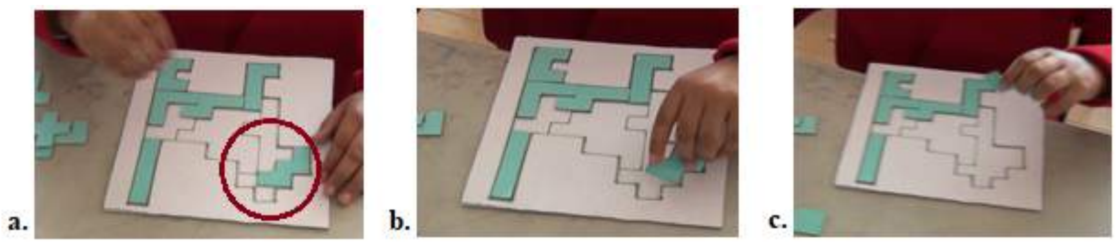

Figura 6: Haciendo corresponder las piezas en el rompecabezas en T2.

La identificación de la ubicación de las piezas pentominó y las diferentes maneras como éstas encajaban en los rompecabezas permitió el refinamiento de estrategias. Al principio fue una actividad de ensayo-y-error; y fue a través de la comparación entre los espacios sin armar del rompecabezas y la forma de las piezas, que los estudiantes fueron *imaginando-y-visualizando* la congruencia entre las divisiones del rompecabezas y la unión de piezas pentominó.

Aspectos críticos de movimientos isométricos: de la traslación y la rotación, al giro

En T1 y T2 los estudiantes ubicaban en el rompecabezas una pieza pentominó inmediatamente o no dependiendo de si la orientación de la pieza y del espacio congruente era igual o diferente. Cuando era igual, los estudiantes *trasladaban* la pieza sin dificultad (Figura 7).

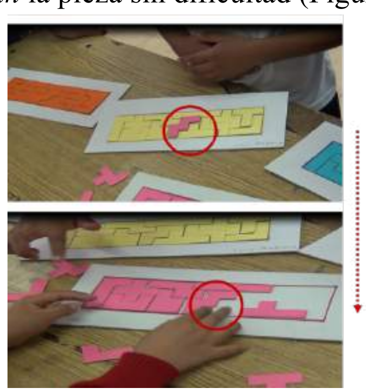

Figura 7: Movimiento de traslación.

En el caso de que la orientación de la pieza y el espacio faltante fueran diferentes, *rotaban,* sin dificultad aparente, las piezas con un movimiento realizado sobre el plano (ver Figura 8).

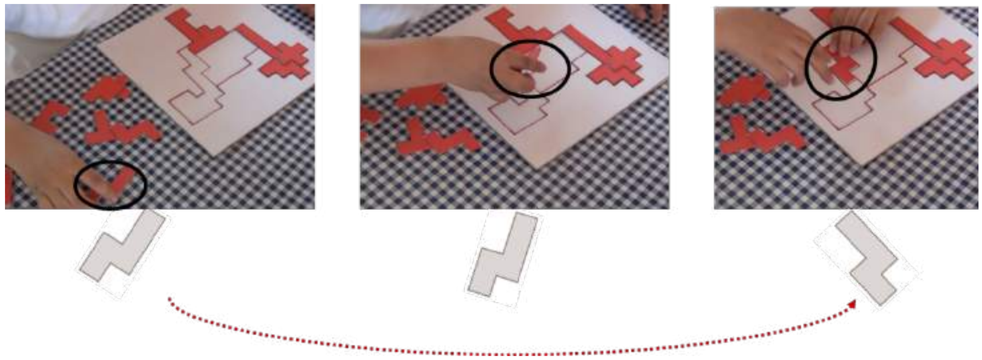

Figura 8: Movimiento de rotación en el plano.

Un reto para los niños fue la acción de girar. Si la ubicación de la pieza en el rompecabezas requería realizar un movimiento de *rotación* en el espacio, y si algún estudiante no reconocía de inmediato cómo ubicarla, primero la rotaba en el plano y luego *visualizaba* si con un giro de la pieza en el espacio le permitía encajarla en rompecabezas (ver Figura 9).

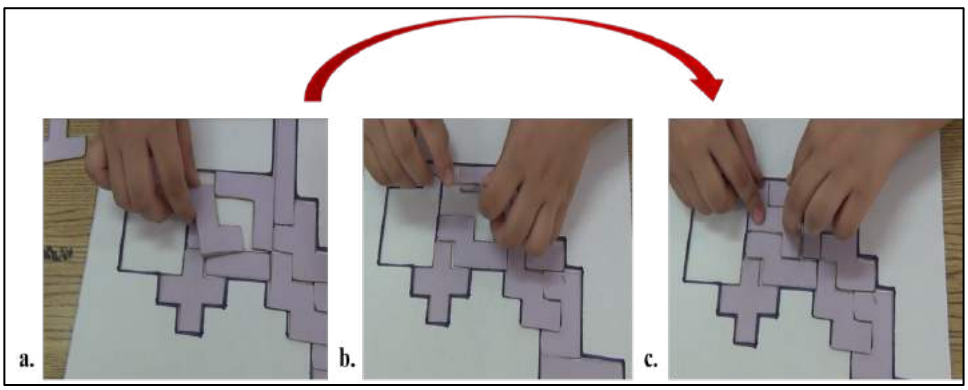

Figura 9. Movimiento de rotación en el espacio.

Todos los estudiantes, a partir de movimientos de rotación y traslación, lograron los ensambles solicitados. Experimentar con el armado de estos rompecabezas, les permitió *identificar subconfiguraciones* (una figura contenida en otra) y *visualizar* la congruencia de una forma compuesta (un ensamble) obtenida al unir piezas de pentominó (sus partes). Cabe señalar que las acciones de movimiento, al ubicar alguna pieza, no son lineales. En los ejemplos presentados en este apartado ilustramos cómo los estudiantes, para colocar en el rompecabezas alguna pieza, realizan una combinación de las siguientes acciones: la manipulan para *trasladarla*, *visualizan la orientación* de la pieza, la *rotan* y/o *giran* para finalmente *ubicarla* en el espacio vacío del rompecabezas.

La implementación de esta actividad refleja un desarrollo del razonamiento espacial de los estudiantes, pues, al incluir en el diseño de las actividades: la *variación de rompecabezas, variación de posiciones y orientaciones de las piezas* pentominó, e *invariancia en el número y forma de las piezas*, pasaron de *ubicar las piezas por ensayo y error,* a *visualizar* la ubicación de las piezas en los rompecabezas. Las dos tareas llevaron a los estudiantes a que *rotaran* y *trasladaran* las piezas del pentominó, *correspondieran* una a una las piezas dadas con la forma que identificaban en el dibujo *compararan* los espacios faltantes con las piezas sin usar y *visualizaran* e imaginaran su composición. Además, reconocieron que hay varias formas de rompecabezas que se pueden armar con la misma cantidad de piezas pentominó.

Discusión y reflexiones finales

En el diseño de la actividad reportada aquí, se consideraron tres elementos a fin de desarrollar razonamiento espacial en los estudiantes: i) El uso de las mismas piezas de pentominó en diferentes rompecabezas; ii) un cambio progresivo en el nivel de dificultad para armar el rompecabezas (de más a menos divisiones); y iii) las dificultades reportadas en la literatura para armar los rompecabezas (e.g., girar en el espacio 3D).

Con el primer elemento se proporcionó a los estudiantes la oportunidad de reconocer que, aun cuando los rompecabezas fueran distintos, siempre podían ser armados con el mismo número de piezas; además, notaron que la ubicación, orientación y sentido de las piezas pentominó también variaban. La variación de rompecabezas y la invarianza de las piezas pentominó podrían ayudarle a estos alumnos en la compresión del significado de área, que según Mamolo, Ruttenberg-Rozen y Whiteley (2015), es una dificultad común en los estudiantes.

El cambio gradual en la complejidad de las actividades promovió el desarrollo de procesos de visualización a través de la composición de piezas. Al armar rompecabezas con más divisiones, los estudiantes podían *ver la congruencia* de espacios faltantes del rompecabezas con las piezas de pentominó. Pero cuando armaban rompecabezas con menos divisiones, ellos debían *discernir* cuáles de las piezas, al unirlas, completaban una sección de las divisiones del rompecabezas. En este proceso, encontramos que los niños *generaron estrategias de construcción* tales como: iniciar el armado identificando y ubicando las piezas de los bordes (es decir, yendo de afuera hacia adentro) y armar el rompecabezas por secciones según las divisiones.

Tanto en el diseño como en el desarrollo de las actividades se previeron posibles dificultades a las que un estudiante de 7-8 años podía enfrentarse, según lo reportado en la literatura (Arıcı y Aslan-Tutak, 2015; Gonzato, Fernández y Díaz, 2011). Si el estudiante no identificaba las piezas de pentominó que debían ir en determinada sección, se le proporcionaba una réplica que le ayudara en la resolución del rompecabezas. Esto ayudó a los niños en el *establecimiento de congruencias* entre piezas pentominós y la *realización de transformaciones isométricas como rotación y traslación* de las piezas.

Los resultados anteriores muestran el potencial de actividades con representaciones bidimensionales para apoyar el desarrollo de habilidades de razonamiento espacial en niños con edades entre 7-8 años. El uso de material tangible, en concordancia con lo mencionado por Gutiérrez (1991), permitió a los estudiantes experimentar y reconocer el movimiento y las formas de las piezas de pentominó y los rompecabezas bidimensionales. Además, la identificación de la posición y orientación de los pentominós en los rompecabezas requirió que los estudiantes *compararan, superpusieran, rotaran, trasladaran, visualizaran* e *imaginaran* las formas de las piezas con los distintos rompecabezas.

Gonzato, Díaz-Godino y Neto (2011) han encontrado que, de darse estas experiencias desde los primeros años de escolaridad, los niños adquieren mayores capacidades para hacer construcciones y manipular mentalmente figuras en el plano y en el espacio. Por lo que, consideramos que este tipo de experiencias que promueven acciones cognitivas (visualizar, imaginar) y de movimiento (comparar, superponer, rotar, trasladar), permiten a los estudiantes la lectura y comprensión de un mundo presentado a través de representaciones bidimensionales en distintas áreas de conocimiento y en el cotidiano.

INTERPRETIVE MODEL OF THE CONCEPTUALIZATION OF THE CONGRUENCE OF POLYGONS (MICP)

MODELO INTERPRETATIVO DE LA CONCEPTUALIZACIÓN DE LA CONGRUENCIA DE POLÍGONOS (MICP)

Cristian Andrey Peña Acuña

Mirela Rigo-Lemini
Cinvestav
mrigolemini@gmail.com

The document presents a set of categories for the analysis of the conceptualization of the congruence of polygons - a central theme in school mathematics - and details the application of the analytical tools used, derived from Grounded Theory, in this construction. This set of categories is called 'Interpretive Model of the Conceptualization of Polygon Congruence' (MICP). This model emerged from the interpretive analysis of empirical data recollected during the investigation. The MICP categories can be used by teachers or researchers to cover different didactic objectives (e.g., interpret the resolution of tasks with congruence content; prepare student profiles or identify their difficulties. See Peña, 2019) and it is relevant because it does not seem to exist in the literature a similar model that covers the previously stated objectives.

Key words: Geometry, research methodologies.

Problem formulation and research question

The criteria of congruence and the notion of congruence are important and fundamental subjects for geometry, both for the geometry taught from the basic levels of education and for geometry as a branch of mathematics. In different versions of Euclidean geometry - proposed by Euclid, Legendre or Hilbert and which present a deductive organization with different degrees of formalization - the notion of congruence and the criteria of congruence emerge from the beginning of axiomatization. In the case of Euclid's *Elements,* according to the Heath (1908) version, the notion of congruence is introduced in Common Notion 4 (Heath, 1908) and the 'criteria of congruence of triangles' are found in propositions I.4; I.8 and I.26 (Heath, 1908). In the case of Legendre geometry (Legendre, 1984), congruence is discussed at the beginning of axiomatization and the congruence criteria for triangles are shown in propositions VI, VII, and XI. Something similar occurs in the formalization of the geometry proposed by Hilbert (1996) where the congruence criteria are also included at the beginning of the work. This allows us to suppose that in disciplinary geometry, particularly in the different versions of euclidean geometry, it is required from the beginning of axiomatization to make use of the notion of congruence and the criteria of congruence of triangles.

Just as the notion of congruence and the criteria of congruence are necessary for disciplinary geometry, they are also essential in school mathematics education. To verify this statement, curriculum for Mexico and Colombia were reviewed. In Mexico, the Secretary of Public Education (SEP, 2017) introduces in its study plans the notion of congruence and the criteria of congruence of triangles from the third year of primary - where it is requested to compare geometric figures and establish uniqueness (p.314) -, up to the third year of secondary -level at which the triangle congruence criteria are expected to be determined and used (p.315). In Colombia, the Ministry of National Education (MEN, 2006) proposes "to recognize the congruence of figures" (p.80) in the 1st and 3rd grade; "Identify and justify the congruence between figures" (p.82) between 4 ° and 5 °; make use of figure congruence to solve problems for 6th and 7th (p.84) and study the properties of congruence for 8th and 9th (p.86). All of this basically refers to the congruence of triangles.

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

Given the weight and scope that congruence has not only in disciplinary geometry but also in school geometry, tools are required to cover a series of didactic objectives related to this concept, among others: interpret the task resolutions, with congruence contents, produced by the students; elaborate student profiles and identify some of their conceptual difficulties regarding this notion; analyze the statements of the tasks and develop didactic sequences on the subject. However, in the mathematics education literature, no studies were found that provide these analysis tools for the case of triangles, and even less so for the congruence of polygons, which is the central theme of the research presented here.

When the authors of this writing did documentary research on mathematical education studies focused on polygon congruence issues, didactic proposals were found for teaching the topic (e.g. Carbó and Mántica, 2010; Piatek-Jimenez, 2008; Zakiz & Leron, 1991 to name a few). However, these works lack, for example, a systematic analysis of the possible difficulties in learning and teaching aspects related to the congruence of polygons; they also lack theoretical support that could justify the order of exposition of topics in a didactic sequence on congruence and that allow outlining possible profiles that account for the level of understanding that students have of this concept.

This document sets out a set of categories - which has been called the 'Interpretive Model of the Conceptualization of the Congruence of Polygons' (MICP) (Peña, 2019) - which is intended to help cover (albeit preliminary) the shortcomings mentioned above.

Methodology and application of the analytical tools used

For the construction of the MICP, some of the principles that rule the Grounded Theory (GT) were followed in the version by Corbin and Strauss (2015), although the study was not intended to achieve the ultimate objectives of the GT (i.e., build theory). What follows is an outline of the category construction process and some central ideas of that construction process.

In GT interpretive categories are based on empirical data collected during research and do not emerge from a theoretical framework given in advance (Corbin & Strauss, 2015). Following this general principle of the GT, the construction of the MICP was carried out, always taking care that the categories were oriented by empirical data.

Initially, the empirical data was fractured, from which patterns were constructed based on which conceptual labels were generated. In a return to the empirical domain, the authors verified that these conceptual labels adequately represented the data. Then a comparative analysis was made between the conceptual labels. From a synthesis process carried out in the conceptual domain, categories were generated. Constant comparisons, asking questions and preparing memos and diagrams, analytical tools that are part of the TF methods, were involved in all these processes (Corbin & Strauss, 2015). At a later time - which Birks and Mills (2011) call 'intermediate coding' - each of the categories was deepened and subcategories were defined and processes of logical ordering were carried out synchronously between them, making use of the idea or reification proposed by Sfard and Linchevski (1994) (paragraphs below the authors explain this point).

Subsequently, a theoretical sampling was carried out (Corbin & Strauss, 2015) that allowed to provide new properties and dimensions to the constructed categories. At a subsequent stage, these categories were confronted with the levels proposed by the researchers Van Hiele (trad. in 1984). Finally, and with the support of some of the reification ideas proposed by Sfard and Linchevski (1994) and by Wenger (2001), modifications were made at the conceptual level. This gave rise to the MICP that is exposed in this document, which has properties of a conceptual order according to the definition given by Corbin and Strauss (2015).

Literary references

As it was told, for the construction of the MICP some of the ideas proposed by Wenger (2001) and by Sfard and Linchevski (1994) were used. Wenger (2001) expresses that, to signify their daily actions and practices and their experience in the world, the members of the communities carry out reification processes. The idea of reification is generally used by Wenger to refer to the process of shaping our experience by producing objects that translate this experience into one thing (p.84). For example, writing a law, creating a recipe for a cake, or proving a theorem are reification processes in which a certain social, gastronomic, or mathematical experience is shaped or "materialized." Thus, in these processes of objectification, some aspects or characteristics of a practice become objects - the law, the cake or the theorem - objects that can be treated as if they were material and concrete elements, even when they are not. Once these objects are constituted, we perceive them as if they existed in the world, as if they had a reality of their own. This is very clear with mathematical concepts and scientific structures. They are usually seen as if they had (and as if they had always had) an independent existence.

Reification, Wenger (2001) argues, can refer to both a process, or a practice, and its product, that is, the object that results from and reflects that practice. In fact, these objects are the basis for new processes, which will give way to new objects. This consideration, applied to the field of epistemology -consideration according to which in the construction of individual and historical knowledge there is an iteration of processes that give rise to objects, which are part of new processes- underlies the organization of the categories that exposed in this document.

Sfard and Linchevski (1994) retake the ideas of reification theory for the analysis of the construction of algebraic knowledge, both historically and at the student level. In particular, they propose that, starting from a set of processes A, a first object A is generated, from which another set of processes B is carried out, in order to build an object B, which serves to carry out a set of processes C that give rise to an object C. This development allows to build increasingly abstract objects.

Wenger's ideas of reification and the interpretation made by the aforementioned authors of these ideas, based on constructivist positions, are part of the philosophical framework of the authors of this writing. This philosophical framework guided the interpretive work and the methodology from which the empirical data recovery methods were derived. However, in this work, these literary references were included in advanced stages of the analysis, when there was already a set of categories that described the data. With these literary references we worked only at the conceptual level: the categories were reorganized and renamed, assigning them much more eloquent and appropriate names, thus gaining generality, systematization, and abstraction. Peña (2019) describes the use of literary references in the construction of the MICP and details of its construction.

Methods of collecting empirical data

Eleven third-year high school students (14 to 15 years old) from a public school in Mexico City participated in the research. These students had already studied the topic of triangle congruence. Four questionnaires were applied. For questionnaire 1 and 2, the first two work sessions were arranged. The objective was to provide students with tools to work on the concept of geometry congruence (congruence as superposition, geometric constructions, basic notions of geometry). For the solution of questionnaire 3 and 4, 4 class sessions were arranged; the objective in these questionnaires was to collect information on the way in which the students understood the congruence criteria for triangles and polygons. His empirical ideas on congruence were used as empirical data for the construction of the MICP. In Peña (2019) a detailed description of the battery of questionnaires is presented.

Results

In the following, the MICP is presented and each of its phases is exemplified.

Table 1. Interpretive Model for the Analysis of Polygon Congruence

Process	Object
Phase 1. Empirical intrafigural idea of congruence	
Process	Object
	In this phase, triangles, some of the components of the triangle (sides, angles, base, area, perimeter) and an idea of congruence seen as a property of the components of a triangle have been conceptualized; the conceptual object in this case is the intrafigural notion of congruence. In this phase it is usual to see representations of equilateral or isosceles triangles since in this type of triangles there are sides and angles congruent to each other.
Phase 2. Empirical interfigural idea of congruence. Congruence as a property of triangles	
Process	Object
In this phase pairs of triangles are compared to determine their possible congruence. To do this, the congruence between the components of the triangles is used (a process supported in the previous phase). To determine the interfigural congruence, empirical processes are performed such as the superposition of the triangles (where the decomposition of the figure into its parts is not necessary), or the comparison of measurements of pairs of sides or corresponding angles in the triangles.	In this phase the congruence relations occur between two specific triangles. The conceptual object in this Phase is an interfigural notion; In this phase, the students do not yet take it as an object of reflection. Although there is an idea of congruence, it only makes sense when associated with specific triangles. In this phase the congruence has a purely applicative character and is not an object of reflection as such, i.e., the student's reflection does not appear to be deliberately directed toward congruence as such. The notion of congruence grammatically functions as a predicate.
Phase 3. Initiation of congruence as an object of reflection	
Process	Object

In this phase, the processes and actions carried out respond to a need to consider triangles in a general way and not only as concrete cases. In this context, students carry out cognitive processes in which they reflect directly on the congruence related to these generic objects. In this phase, they change the focus of attention: from the concrete triangles they direct their interest towards congruence as an object of reflection; in these processes they seek to characterize the congruence of triangles by appealing to their components (sides, angles, base, area ...). Although the interest or need of the students in this phase is to get rid of the concrete cases, the lack of conceptual tools leads them to return to the use of empirical methods of representation and verification of congruence; however, unlike the previous phase, the specific triangles they use are considered by the student as general representations of the triangles.	In this phase the student begins to conceive of congruence as an object on which the student reflects and with which he associates properties. In this Phase, for example, there are those answers where the student makes explicit reference to some characterization of the congruence. In this phase two sub-phases are distinguished: If the properties with which students seek to characterize the congruence are not mathematically relevant to define it, the answer is located in Phase 3.1. In this case, the characterizations that the students make of the congruence of triangles are unsystematic, inconsistent, and usually made with atypical components (base, height, perimeter, area). If the characterizations about congruence are relevant, the answer would be in phase 3.2. In this case, these characterizations are usually coherent and systematic, and usually typical components are used (sides and angles). Grammatically, in this phase, congruence already plays the role of noun.
Phase 4. Reflection on properties of congruence as an object of reflection	
Process	Object
In this phase, reflection processes occur that no longer focus only on congruence but on the properties associated with congruence (which emerged in the previous phase). It is usual to find processes where sufficient conditions (or minimum conditions) are discriminated (either correctly or incorrectly, from the mathematical point of view) to guarantee congruence. This is done by the student with the understanding that it is possible to limit, depending on certain conditions or reasons, the number of components to establish the congruence of two triangles. In the case in which sufficient conditions that are correct are chosen, they coincide with what in school mathematics is known as the congruence criteria (SSS, SAS and ASA).	In this phase, sufficient conditions are associated with congruence, which are based on a definition of congruence that occurred in the previous phase. These are new properties related to this conceptual object, which make it much more general and more solid, although in this Phase it is still tied to empirical considerations. Two sub-phases are also identified in this phase: If the characterizations that the students carry out are erratic or inconsistent (e.g. when there are cases of consistency criteria such as AA, SSSA, SSSAA) it is associated with Sub phase 4.1. On the other hand, if the minimum conditions proposed by the students to guarantee consistency are mathematically correct (e.g. the consistency criteria), it is in Sub phase 2
Phase 5. Processes of deductive support.	
Process	Object
Students use deductive processes, based on definitions and general properties, to answer the why of certain properties of congruence (e.g., sufficient conditions for congruence of polygons) and other properties of congruence that they can conjecture or anticipate.	The mathematical concept of congruence is consolidated, as a general and abstract concept, by supporting some of its properties in deductive arguments.

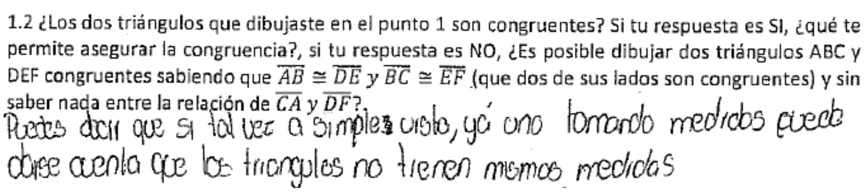
To exemplify the phases of the MICP, in the following some productions of the students are presented. Although examples of each phase are offered, the categorization of the students' responses was not carried out considering these responses in isolation. In the interpretation of each answer, the response patterns identified in the course of each student's production were taken into account as an analysis criterion.

Phase 1. Empirical intrafigural idea of congruence

Figure 1. Student response 2 to question 1 of questionnaire 3

The answer of figure 1 is located in this phase since the student shows to be aware that the triangle can be separated into components (sides); proof of this is that he names the sides and gives them a measurement. In this case, the congruence relations that are observed are only intra-figural, which can be verified in the fact that he only directs his gaze towards the congruence of sides that are part of the first triangle (side A and side C).

Phase 2. Empirical inter-figural idea of congruence. Congruence as a property of triangles.



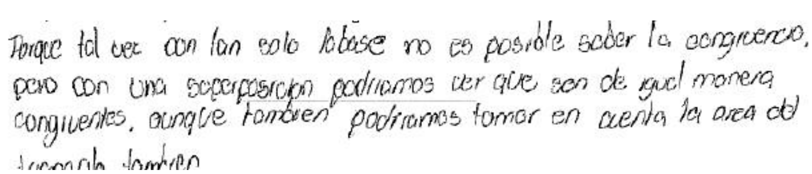
1.2 ¿Los dos triángulos que dibujaste en el punto 1 son congruentes? Si tu respuesta es SI, ¿qué te permite asegurar la congruencia?, si tu respuesta es NO, ¿Es posible dibujar dos triángulos ABC y DEF congruentes sabiendo que $\overline{AB} \cong \overline{DE}$ y $\overline{BC} \cong \overline{EF}$ (que dos de sus lados son congruentes) y sin saber nada entre la relación de $\overline{CA}$ y $\overline{DF}$?

Puedes decir que si tal vez a simple vista, yá uno tomando medidas puede darse cuenta que los triangulos no tienen mismas medidas

Figure 2. Student response 1 to question 1.2 of questionnaire 3

The answer in figure 2 is found in phase 2 since the student explicitly shows that he is thinking of two particular triangles; this is seen when the student says "by taking measurements you can see that the triangles have the same measurements". Furthermore, he evaluates congruence through an empirical comparison method, which he calls “at a glance”.

Phase 3. Reflection on consistency.

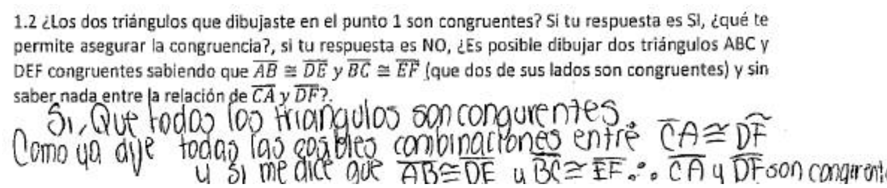


Porque tal vez con tan solo la base no es posible saber la congruencia, pero con una superposición podriamos ver que son de igual manera congruentes, aunque tambien podriamos tomar en cuenta la area del triangulo tambien

Figure 3. Student 1 response to question 1.4b of questionnaire 3

Figure 3 presents a student's answer to the following question: what other minimum data should we have to ensure the congruence of two triangles if we already have a pair of corresponding congruent sides? As a result, the student does not seem to propose sufficiency criteria (as expected); on the contrary, he proposes a way to characterize congruence in terms of necessity, the latter being a constant in many of his other responses. On the other hand, it seems that the student lacks conceptual tools to support his hypothesis, so he must resort to a known field, the superposition, even when he tries to characterize the congruence far from the empirical verification methods. In this case, the student was in subphase 3.1, since his characterizations turn out to be atypical (since he makes use of the base of the triangles).

Phase 4. Reflection on properties of congruence as an object of reflection



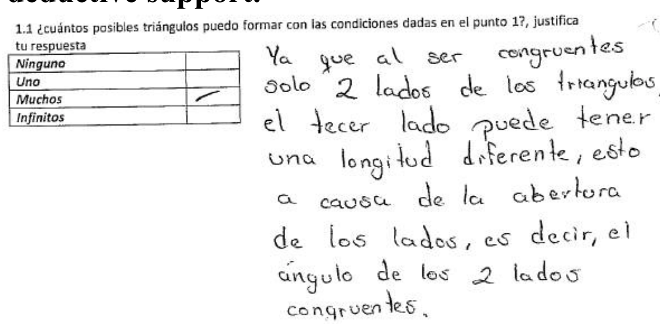
1.2 ¿Los dos triángulos que dibujaste en el punto 1 son congruentes? Si tu respuesta es SI, ¿qué te permite asegurar la congruencia?, si tu respuesta es NO, ¿Es posible dibujar dos triángulos ABC y DEF congruentes sabiendo que $\overline{AB} \cong \overline{DE}$ y $\overline{BC} \cong \overline{EF}$ (que dos de sus lados son congruentes) y sin saber nada entre la relación de $\overline{CA}$ y $\overline{DF}$?

Si, Que todos los triangulos son congruentes.
Como ya dije todas las posibles combinaciones entre $\overline{CA} \cong \overline{DF}$
y si me dice que $\overline{AB} \cong \overline{DE}$ y $\overline{BC} \cong \overline{EF}$ ∴ $\overline{CA}$ y $\overline{DF}$ son congruent

Figure 4. Student response 6 to question 1.2 of questionnaire 3

The answer of figure 4 corresponds to this level since the student shows to have characterized certain sufficient criteria for polygon congruence, although in this particular case those criteria are erroneous. The student shows to believe that it is possible, having $\overline{(AB)} \cong \overline{(DF)}$ and $\overline{(BC)} \cong \overline{(EF)}$ ensure that $\overline{(CA)} \cong \overline{(DF)}$, this shows that he understands, at least in one level basic, the sufficient conditions, i.e., is aware that it is possible to exclude components in the congruence of triangles and still continue to ensure congruence.

Phase 5. Processes of deductive support.



1.1 ¿cuántos posibles triángulos puedo formar con las condiciones dadas en el punto 1?, justifica tu respuesta

Ninguno	
Uno	
Muchos	✓
Infinitos	

Ya que al ser congruentes solo 2 lados de los triangulos, el tecer lado puede tener una longitud diferente, esto a causa de la abertura de los lados, es decir, el ángulo de los 2 lados congruentes.

Figure 5. Student response 7 to question 1.1 of questionnaire 3

The answer in figure 5 is in phase 5 since the student presents a deductive argument that supports the congruence criterion for SAS triangles.

Comments and conclusions

The MICP is a preliminary model. It is hoped, in future works, to be able to further refine the model by adding properties to the phases. In future works, the authors of this document will seek to identify the types of arguments presented in each phase. The MICP is considered to be a model that can be useful for teachers, researchers and people involved with education in mathematics, since it allows analyzing the productions of students, their possible profiles in relation to performance in congruence tasks (Peña, 2019), in addition to suggesting hypotheses about possible trajectories of the construction of the concept of "congruence" in the classroom.

The authors of the document have considered important to detail the process of construction of the MICP categories, because that constructive process allows readers to get a closer look at the construction of conceptual categories, whose details are often omitted in the research literature in mathematics education. The authors of the writing are aware that the work involved in the construction of the categories is sometimes enormous, that the data is often overwhelming and that there will be many moments when the researcher (in training and already trained) must reformulate and discard ideas that had already developed. However, even with all the problems involved in constructing theoretical models or conceptual categories, the process that this entails leads, from our point of view, to basically understanding what it involves doing a certain type of research.

MODELO INTERPRETATIVO DE LA CONCEPTUALIZACIÓN DE LA CONGRUENCIA DE POLÍGONOS (MICP)

INTERPRETIVE MODEL OF THE CONCEPTUALIZATION OF THE CONGRUENCE OF POLYGONS (MICP)

Cristian Andrey Peña Acuña
Cinvestav

mrigolemini@gmail.com

En el documento se presenta un conjunto de categorías para el análisis de la conceptualización de la congruencia de polígonos -tema central en la matemática escolar- y se detalla la aplicación de las herramientas analíticas empleadas, provenientes de la Teoría Fundamentada, en esa construcción. A ese conjunto de categorías se le llama 'Modelo interpretativo de la conceptualización de la congruencia de polígonos' (MICP). Este modelo surgió como resultado de la interpretación de datos empíricos recuperados durante la investigación. Las categorías del MICP pueden ser empleadas por profesores o investigadores para cubrir distintos objetivos didácticos (e.g., interpretar la resolución de tareas de contenidos de congruencia; elaborar perfiles de estudiantes o identificar sus *dificultades. Ver Peña, 2019) y resulta relevante porque no parece existir en la literatura un modelo semejante que cubra los objetivos antes planteados.*

Palabras clave: Geometría, metodologías de la investigación.

Planteamiento del problema y pregunta de investigación

Los criterios de congruencia y la noción de congruencia son temas importantes y fundamentales para la geometría, tanto para la que se enseña desde los niveles básicos de educación como para la disciplinar. En distintas versiones de la geometría euclidiana -propuestas por Euclides, Legendre o Hilbert y que presentan una organización deductiva con distintos grados de formalización- la noción de congruencia y los criterios de congruencia surgen desde los inicios de la axiomatización. En el caso de *Los Elementos* de Euclides, conforme a la versión de Heath (1956), la noción de congruencia se introduce en la Noción Común 4 y los 'criterios de congruencia de triángulos' se encuentran en las proposiciones I.4; I.8 y I.26. En el caso de la geometría de Legendre (Legendre, 1984), se habla de la congruencia en los inicios de la axiomatización y se muestran los criterios de congruencia para los triángulos en las proposiciones VI, VII y XI. Algo similar ocurre en la formalización de la geometría propuesta por Hilbert (1996) en donde también se incluyen los criterios de congruencia al inicio de la obra. Lo anterior permite suponer que en la geometría disciplinar, particularmente en las diferentes versiones de la geometría Euclidiana, se requiere desde los inicios de la axiomatización hacer uso de la noción de congruencia y de los criterios de congruencia de triángulos.

Así como la noción de congruencia y los criterios de congruencia resultan necesarios para la geometría disciplinar, de igual forma resultan imprescindibles en la educación matemática escolar. Para verificar esta afirmación se revisaron planes de estudio de México y de Colombia. En México, la Secretaria de Educación pública (SEP, 2017) introduce en sus planes de estudio a la noción de congruencia y los criterios de congruencia de triángulos desde tercero de primaria -donde se solicita comparar figuras geométricas y establecer unicidad (p.314)-, hasta tercero de secundaria -nivel en el que se espera que se determinen y usen los criterios de congruencia de triángulos (p.315). En Colombia, el Ministerio Nacional de Educación (MEN, 2006) propone "reconocer a la congruencia de figuras" (p.80) en el 1° y el 3° grado; "identificar y justificar la congruencia entre figuras" (p.82) entre 4° y 5°; hacer uso de la congruencia de figuras para resolver problemas para 6° y 7° (p.84) y el estudio de las propiedades de la congruencia para 8° y 9° (p.86). Todo esto hace referencia básicamente a la congruencia de triángulos.

Dado el peso y el alcance que la congruencia tiene no solo en la geometría disciplinar sino en la geometría escolar, se requieren herramientas que permitan cubrir una serie de objetivos didácticos relacionados con ese concepto, entre otros: interpretar las resoluciones de tareas de contenidos de congruencia elaboradas por los alumnos, elaborar perfiles de estudiantes e identificar algunas de sus dificultades conceptuales sobre esa noción; analizar los enunciados de las tareas mismas y elaborar secuencias didácticas sobre el tema. No obstante, no parecen haber trabajos en investigación en educación matemática que brinden estas herramientas de análisis para el caso de los triángulos, y menos aún, para la congruencia de polígonos, que es el tema central de la investigación que aquí se expone.

Al hacer investigación documental sobre reportes de estudio de educación matemática centrados en temas de congruencia de polígonos, solo se encontraron propuestas didácticas para la enseñanza del tema (Carbó y Mántica, 2010; Piatek-Jimenez, 2008; Zakiz y Leron, 1991 por citar algunos). Estos trabajos carecen, por ejemplo, de un análisis sistemático de las posibles dificultades en el aprendizaje y la enseñanza de temas afines a la congruencia de polígonos; carecen también de sustentos teóricos que pudieran justificar el orden de exposición de tareas en una secuencia didáctica sobre la congruencia y que permitan delinear posibles perfiles que den cuenta del nivel de comprensión que los alumnos poseen de este concepto.

En este documento se expone un conjunto de categorías -al que se le ha llamado 'Modelo interpretativo de la conceptualización de la congruencia de polígonos' (MICP) (Peña, 2019)- que tiene la intención de ayudar a cubrir (aunque sea de manera preliminar) las carencias antes planteadas.

Metodología y aplicación de las herramientas analíticas empleadas

Para la construcción del MICP se siguieron algunos de los principios que rigen la Teoría Fundamentada (TF) en la versión de Corbin y Strauss (2015), si bien el estudio no tenía como propósito alcanzar los objetivos últimos de la TF (i.e., hacer teoría). En lo que sigue se esboza el proceso de construcción de las categorías y algunas ideas centrales.

En la TF las categorías interpretativas se basan en los datos empíricos que se recolectan durante la investigación y no emergen de un marco teórico dado de antemano (Corbin & Strauss, 2015). Siguiendo este principio general de la TF, se realizó la construcción del MICP cuidando siempre que las categorías estuvieran orientadas por los datos empíricos.

En un primer momento se fracturaron los datos empíricos, a partir de lo cual se construyeron patrones con base en los cuales se generaron etiquetas conceptuales. En un regreso al dominio empírico, se comprobó que dichas etiquetas representaran a los datos. Enseguida se hizo un análisis comparativo entre las etiquetas conceptuales. A partir de un proceso de síntesis llevado a cabo en el dominio conceptual, se generaron categorías. En todos estos procesos estuvieron involucradas las comparaciones constantes, el planteamiento de preguntas y la elaboración de memos y diagramas, herramientas analíticas que forman parte de los métodos de la TF (Corbin & Strauss, 2015). En un momento posterior -que Birks y Mills (2011) denominan de 'codificación intermedia'- se profundizó en cada una de las categorías y se definieron subcategorías y sincrónicamente se realizaron procesos de ordenamiento lógico entre ellas, haciendo uso de las ideas propuestas por Sfard y Linchevski (1994).

Posteriormente, se realizó un muestreo teórico (Corbin & Strauss, 2015) que permitió dotar de nuevas propiedades y dimensiones a las categorías construidas. En una etapa subsecuente, estas categorías se confrontaron con los niveles propuestos por los investigadores Van Hiele (trad. en 1984). Finalmente, y con apoyo de algunas de las ideas de cosificación propuestas por Sfard y Linchevski (1994) y por Wenger (2001), se realizaron modificaciones a nivel conceptual. Esto dio lugar al MICP que se expone en este documento, el cual posee propiedades de un ordenamiento conceptual de acuerdo con la definición que dan Corbin y Strauss (2015).

Referentes Literarios

Para la construcción del MICP se usaron algunas de las ideas propuestas por Wenger (2001) y por Sfard y Linchevski (1994). Wenger (2001) expresa que, con el fin de significar sus acciones y prácticas cotidianas y su experiencia en el mundo, los miembros de las comunidades llevan a cabo procesos de cosificación. La idea de cosificación la emplea Wenger de manera general para referirse al proceso de dar forma a nuestra experiencia produciendo objetos que plasman esta experiencia en una cosa (p. 84). Por ejemplo, redactar una ley, crear una receta para un pastel o demostrar un teorema son procesos de cosificación en los que se da forma o se 'materializa' una cierta experiencia social, gastronómica o matemática. Así, en estos procesos de cosificación se convierten en objetos -la ley, el pastel o el teorema- algunos aspectos o características de una práctica, objetos que pueden ser tratados como si fueran elementos materiales y concretos, aún y cuando no lo sean. Una vez constituidos esos objetos, los percibimos como si existieran en el mundo, como si tuvieran una realidad propia. Esto es muy claro con los conceptos matemáticos y las estructuras científicas. Se suelen ver como si tuvieran (y como si siempre hubieran tenido) una existencia independiente.

La cosificación, sostiene Wenger (2001), puede hacer referencia tanto a un proceso, o una práctica, como a su producto, es decir, al objeto que resulta y es reflejo de esa práctica. De hecho, esos objetos son la base para nuevos procesos, mismos que darán paso a nuevos objetos. Esta consideración, aplicada al terreno de la epistemología -consideración conforme a la cual en la construcción del conocimiento individual e histórico se da una iteración de procesos que dan lugar a objetos, que forman parte de nuevos procesos- subyace a la organización de las categorías que se exponen en este documento.

Sfard y Linchevski (1994) retoman las ideas de la teoría de la reificación para el análisis de la construcción de conocimientos algebraicos, tanto a nivel histórico como a nivel del estudiante. En particular, ellas proponen que, partiendo de un conjunto de procesos A, se genera un primer objeto A, a partir del cual se realiza otro conjunto de procesos B, para así construir un objeto B, mismo que sirve para realizar un conjunto de procesos C que dan lugar a un objeto C. Este desarrollo permite construir objetos cada vez más abstractos.

Las ideas de cosificación de Wenger y la interpretación que hacen las autoras antes citadas de esas ideas, basadas en posturas constructivistas, forman parte del marco filosófico de los autores de este escrito. Ese marco filosófico orientó el trabajo interpretativo y la metodología de la cual se desprendieron los métodos de recuperación de datos empíricos. Sin embargo, en este trabajo esos referentes literarios se incluyeron en fases avanzadas del análisis, cuando ya se contaba con un conjunto de categorías que describían los datos. Con esos referentes literarios se trabajó sólo a nivel conceptual: se reorganizaron las categorías y se renombraron, asignándoles nombres mucho más elocuentes y adecuados, con lo que se ganó generalidad, sistematización y abstracción. En Peña (2019) se describe el empleo de los referentes literarios en la construcción del MICP y detalles de su construcción.

Métodos de recolección de los datos empíricos

En la investigación participaron 11 estudiantes de tercero de secundaria (14 a 15 años) de una escuela pública de la ciudad de México. Estos alumnos ya habían estudiado el tema de congruencia de triángulos. Se aplicaron cuatro cuestionarios. Para el cuestionario 1 y 2 se dispusieron las dos primeras sesiones de trabajo. El objetivo fue brindar a los estudiantes herramientas para trabajar sobre el concepto de congruencia de geometría (congruencia como superposición, construcciones geométricas, nociones básicas de la geometría). Para la solución del cuestionario 3 y 4 se dispusieron 4 sesiones de clase, el objetivo en estos cuestionarios era el recolectar información sobre la manera en la que los estudiantes entendían los criterios de congruencia para triángulos y polígonos. Como datos empíricos para la construcción del MICP se utilizaron sus ideas sobre la congruencia. En Peña (2019) se presenta una descripción detallada de la batería de cuestionarios.

Resultados

En lo que sigue se presenta el MICP y se ejemplifican cada una de sus fases.

Tabla 1. Modelo Interpretativo para el análisis de la Congruencia de Polígonos

Fase 1. Idea empírica intrafigural de congruencia	
Proceso	Objeto
	En esta fase se han conceptualizado los triángulos, algunos de los componentes del triángulo (lados, ángulos, base, área, perímetro) y una idea de la congruencia vista como una propiedad de los

	componentes de un triángulo; el objeto conceptual en este caso es la noción intrafigural de la congruencia. En esta fase es usual ver representaciones de triángulos equiláteros o isósceles ya que en este tipo de triángulos hay lados y ángulos congruentes entre sí.
Fase 2. Idea empírica interfigural de congruencia. la congruencia como una propiedad de triángulos	
Proceso	Objeto
En esta fase se comparan parejas de triángulos para determinar su posible congruencia. Para ello se recurre a la determinación de la congruencia entre los componentes de los triángulos (proceso que se respalda en la fase anterior). Para la determinación de la congruencia interfigural, se realizan procesos empíricos como la superposición de los triángulos (en donde no es necesaria la descomposición de la figura en sus partes) o la comparación de medidas de pares de lados o ángulos correspondientes en los triángulos.	En esta fase las relaciones de congruencia se dan entre dos triángulos concretos. El objeto conceptual en esta Fase es una noción interfigural; en esta Fase, todavía no se reflexiona sobre ese objeto. Aunque hay una idea de congruencia, solo cobra sentido cuando se le asocia a triángulos concretos. En esta fase la congruencia tiene un carácter puramente aplicativo y no es objeto de reflexión como tal; i.e, no parece que la reflexión del estudiante se dirija deliberadamente hacia la congruencia como tal. La noción de congruencia gramaticalmente funge como predicado.
Fase 3. Inicio de la congruencia como objeto de reflexión	
Proceso	Objeto
En esta fase los procesos y las acciones que se llevan a cabo responden a una necesidad de considerar a los triángulos de manera general y no solo como casos concretos. En este contexto, los alumnos realizan procesos cognitivos en los que reflexionan directamente sobre la congruencia relacionada con esos objetos genéricos. En esta fase, ellos cambian el foco de atención: de los triángulos concretos dirigen su interés hacia la congruencia como un objeto de reflexión; en estos procesos buscan caracterizar a la congruencia de triángulos apelando a sus componentes (lados, ángulos, base, área…). Aunque el interés o necesidad de los alumnos en esta fase es desprenderse de los casos concretos, la falta de herramientas conceptuales los lleva a regresar al uso de métodos empíricos de representación y verificación de la congruencia; sin embargo, a diferencia de la fase previa, los triángulos concretos que utilizan son considerados por el alumno como representaciones generales de los triángulos.	En esta fase el alumno empieza a concebir a la congruencia como un objeto sobre el cual el alumno reflexiona y al cual le asocia propiedades. En esta Fase, por ejemplo, se encuentran aquellas respuestas en donde el alumno hace referencia explícita a alguna caracterización de la congruencia. En esta fase se distinguen dos sub fases: Si las propiedades con las que busca caracterizar a la congruencia no son matemáticamente relevantes para definirla, su respuesta se ubica en la Fase 3.1. En este caso, las caracterizaciones que realizan los alumnos de la congruencia de triángulos son asistemáticas, incoherentes y usualmente realizadas con componentes atípicos (Base, altura, perímetro, área). Si las caracterizaciones sobre la congruencia son relevantes, su respuesta se ubicaría en la fase 3.2. En este caso, esas caracterizaciones suelen ser coherentes y sistemáticas, y usualmente se acude a componentes típicos (Lados y ángulos). Gramaticalmente, en esta Fase la congruencia juega ya el papel de sustantivo.
Fase 4. Reflexión en torno a propiedades de la congruencia como objeto de reflexión	
Proceso	Objeto
En esta fase se dan procesos de reflexión que ya no solo se centran en la congruencia sino en las propiedades que se asocian a la congruencia (que	En esta fase se asocian a la congruencia condiciones suficientes, las que se basan en una definición de la congruencia que se dio en la fase previa. Se trata de

surgieron en la fase anterior). Es usual encontrar procesos en donde se discriminan (ya sea correcta o incorrectamente, desde el punto de vista matemático) condiciones suficientes (o condiciones mínimas) para garantizar la congruencia. Esto lo hace el alumno con la comprensión de que es posible acotar, atendiendo a ciertas condiciones o razones, la cantidad de componentes a considerar para establecer la congruencia de dos triángulos. En el caso en el que se eligen condiciones suficientes correctas, coinciden con lo que en la matemática escolar se conoce como los criterios de congruencia (LLL, LAL y ALA).	nuevas propiedades relacionadas con este objeto conceptual, que lo hacen mucho más general y más sólido, aunque en esta Fase todavía esté atado a consideraciones empíricas. En esta Fase se identifican también dos subfases: Si las caracterizaciones que realizan los alumnos son erráticas o incoherentes (e.g. cuando se dan casos de criterios de congruencia como AA, LLLA, LLLAA) se asocia a la Sub fase 4.1. Por otro lado, si las condiciones mínimas que proponen los alumnos para garantizar la congruencia son matemáticamente correctas (e.g. los criterios de congruencia) se ubica en la Sub fase 2
Fase 5. Procesos de sustentación deductiva.	
Proceso	Objeto
Los alumnos recurren a procesos deductivos, basados en definiciones y propiedades generales, para dar respuesta al por qué de ciertas propiedades de la congruencia (e.g., condiciones suficientes para la congruencia de polígonos) y a otras propiedades de la congruencia que ellos pueden conjeturar o anticipar.	Se consolida el concepto matemático de congruencia, como un concepto general y abstracto, al sustentar algunas de sus propiedades en argumentos de tipo deductivo.

Para ejemplificar las fases del MICP, en lo que sigue se presentan algunas producciones de los estudiantes. Aunque se ofrecen ejemplos particulares de cada fase, la categorización de las respuestas de los alumnos no se realizó considerando esas respuestas de manera aislada. En la interpretación de cada respuesta se tomó en cuenta, como criterio de análisis, los patrones de respuesta identificados en el transcurso de la producción de cada alumno.

Fase 1. Idea empírica intrafigural de congruencia:

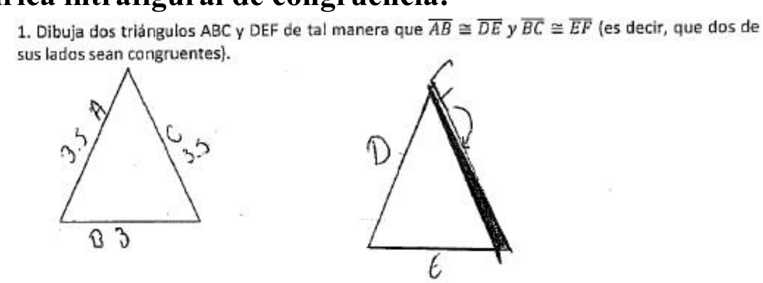

Figura 1. Respuesta del alumno 2 a la pregunta 1 del cuestionario 3

La respuesta de la figura 1 se ubica en esta fase ya que el alumno muestra ser consciente de que el triángulo se puede separar en componentes (lados); y es que él nombra los lados y les da una medida. En este caso, las relaciones de congruencia que se observan solo son intrafigurales, lo cual se puede constatar en el hecho de que él solo dirige su mirada hacia la congruencia de lados que forman parte del primer triángulo (el lado A y el lado C).

Fase 2. Idea empírica interfigural de congruencia.

1.2 ¿Los dos triángulos que dibujaste en el punto 1 son congruentes? Si tu respuesta es SI, ¿qué te permite asegurar la congruencia?, si tu respuesta es NO, ¿Es posible dibujar dos triángulos ABC y DEF congruentes sabiendo que $\overline{AB} \cong \overline{DE}$ y $\overline{BC} \cong \overline{EF}$ (que dos de sus lados son congruentes) y sin saber nada entre la relación de $\overline{CA}$ y $\overline{DF}$?

Puedes dcir que si tal vez a simple vista, ya uno tomando medidas puede darse cuenta que los triangulos no tienen mismas medidas

Figura 2. Respuesta del alumno 1 a la pregunta 1.2 del cuestionario 3

La respuesta de la figura 2 se encuentra en la fase 2 ya que el alumno muestra explícitamente estar pensando en dos triángulos particulares; esto se ve cuando el alumno dice "tomando medidas puede darse cuenta que los triángulos tienen mismas medidas". Además, evalúa la congruencia a través de un método de comparación empírico, que él llama "a simple vista".

Fase 3. Reflexión en torno a la congruencia.

Porque tal vez con tan solo la base no es posible saber la congruencia, pero con una superposicion podriamos ver que son de igual manera congruentes, aunque tambien podriamos tomar en cuenta la area del triangulo tambien

Figura 3. Respuesta del alumno 1 a la pregunta 1.4b del cuestionario 3

En la figura 3 se presenta la respuesta de un alumno a la siguiente pregunta ¿qué otros datos mínimos debemos tener para asegurar la congruencia de dos triángulos si ya se tiene un par de lados correspondientes congruentes? Como resultado el estudiante no parece proponer criterios de suficiencia (como se esperaba); por el contrario, él propone una manera de caracterizar a la congruencia en términos de necesidad, esto último es una constante en muchas de sus otras respuestas. Por otro lado, parece que el alumno carece de herramientas conceptuales para soportar su hipótesis, por lo que debe recurrir a un campo conocido, la superposición, aun cuando intenta caracterizar a la congruencia lejos de los métodos empíricos de verificación. En este caso particular el alumno se ubicó en la subfase 3.1, pues sus caracterizaciones resultan ser atípicas (ya que hace uso de la base de los triángulos).

Fase 4. Reflexión en torno a propiedades de la congruencia.

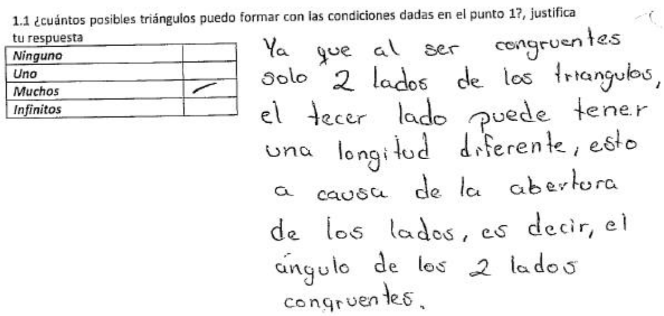
1.2 ¿Los dos triángulos que dibujaste en el punto 1 son congruentes? Si tu respuesta es SI, ¿qué te permite asegurar la congruencia?, si tu respuesta es NO, ¿Es posible dibujar dos triángulos ABC y DEF congruentes sabiendo que $\overline{AB} \cong \overline{DE}$ y $\overline{BC} \cong \overline{EF}$ (que dos de sus lados son congruentes) y sin saber nada entre la relación de $\overline{CA}$ y $\overline{DF}$?

Si, Que todos los triangulos son conguruentes. Como ya dije todas las posibles combinaciones entre $\overline{CA} \cong \overline{DF}$ y si me dice que $\overline{AB} \cong \overline{DE}$ y $\overline{BC} \cong \overline{EF}$ $\therefore$ $\overline{CA}$ y $\overline{DF}$ son congruentes

Figura 4. Respuesta del alumno 6 a la pregunta 1.2 del cuestionario 3

La respuesta de la figura 4 corresponde a este nivel ya que el alumno muestra haber caracterizado ciertos criterios de suficiencia de congruencia de polígonos, aunque para este caso particular dichos criterios sean erróneos. El alumno muestra creer que es posible, teniendo $\overline{AB} \cong \overline{DF}$ y $\overline{BC} \cong \overline{EF}$ asegurar que $\overline{CA} \cong \overline{DF}$, esto muestra que comprende, al menos en un nivel básico, las condiciones de suficiencia, i.e es consciente de que es posible prescindir de componentes en la congruencia de triángulos y aun así seguir asegurando la congruencia.

Fase 5. Procesos de sustentación deductiva.



1.1 ¿cuántos posibles triángulos puedo formar con las condiciones dadas en el punto 1?, justifica tu respuesta

Ninguno	
Uno	
Muchos	✓
Infinitos	

Ya que al ser congruentes solo 2 lados de los triangulos, el tecer lado puede tener una longitud diferente, esto a causa de la abertura de los lados, es decir, el ángulo de los 2 lados congruentes.

Figura 5. Respuesta del alumno 7 a la pregunta 1.1 del cuestionario 3

Se ubica la respuesta en la figura 5 en la fase 5 ya que el alumno presenta un argumento deductivo que sustenta al criterio de congruencia para triángulos LAL.

Comentarios y conclusiones

El MICP es un modelo preliminar. Se espera, en trabajos futuros, poder seguir afinando el modelo agregando propiedades a las fases. Particularmente, en trabajos próximos, los autores de este documento buscarán identificar los tipos de argumentos que se presentan en cada fase. Se considera que el MICP es un modelo que puede ser útil para profesores, investigadores y personas involucradas con la educación en matemática, pues permite analizar las producciones de los estudiantes, sus posibles perfiles con relación al desempeño en tareas de congruencia (Peña, 2019), además de que sugiere hipótesis sobre trayectorias posibles de la construcción del concepto de "congruencia" en el aula.

Los autores del documento han considerado importante detallar en este escrito el proceso de construcción de las categorías del MICP, porque ese proceso constructivo -cuyos detalles se suelen omitir en la literatura en investigación en educación matemática- le permite a los investigadores mirar de manera crítica y a profundidad en los temas de su estudio y les permite generalmente ir más allá de lo que está escrito. Los autores del escrito están conscientes que el trabajo que supone la construcción de las categorías es a veces enorme, que en muchas ocasiones los datos abruman y que habrá muchos momentos en donde el investigador (en formación y ya formado) debe reformular y descartar ideas que ya había desarrollado. Sin embargo, aun con todos los problemas que conlleva la construcción de modelos teóricos o categorías conceptuales, el proceso que esto supone lleva, desde nuestro punto de vista, a comprender básicamente lo que implica hacer un cierto tipo de investigación.

CHILDREN'S DURATIONAL ORGANIZATION OF EVEREYDAY EXPERIENCES: A MATHEMATICAL PERSPECTIVE OF A LINGUISTIC STUDY

Amy Smith
University of Colorado Denver
amy.L2.smith@ucdenver.edu

How do children reason about the durations of daily experiences? Following Tillman and Barner's (2015) linguistic study, three children (age five, six, and seven) were asked to organize four everyday activities from the shortest duration to longest duration: watching a movie, brushing their teeth, sleeping at night, and eating lunch. After creating their "timeline", each child was asked why they ordered the events as they did. By allowing the children the opportunity to reflect on common experiences and explain how they reasoned about durations, we can begin to recognize how children understand time as a quantity. Their responses showed that reflections on lived durational experiences were heavily influenced by physical acts, such as speed of actions or movement of the sun. These findings were consistent with past research on children's conception of physical time (Long & Kamii, 2001; Piaget, 1969).

Keywords: Measurement, Elementary School Education, Cognition

Tillman and Barner (2015) presented a series of linguistic experiments to explore young children's development of durational language. Through these experiments, Tillman and Barner theorized that children hear and use durational words, such as minute and second, but are unable to define these words with precise meanings, such as a minute being made of 60 seconds. The authors' asserted, "a lag [exists] between production and comprehension of duration words" (Tillman & Barner, 2015, p. 58), a point that would be supported by mathematics researchers and educators (Earnest, 2015; Harris, 2008; Kamii & Russell, 2012; Piaget, 1969). Thus, Tillman and Barner's research does not seem to lie solely within the field of linguistics, but also mathematics education research.

Durational words are commonly used in everyday English, for example, a parent telling their child "just a second" or "hang on a minute". During casual conversation these durations are not used as quantified elapsed time intervals, but rather are used as informal estimates of general wait times (Tillman & Barner, 2015). How such informal intervals are understood and used by children is an underrepresented area in mathematics education research. The value of such research would be to establish what temporal conceptions elementary students might bring with them to the mathematics classroom prior to formal time instruction.

Theoretical Framework

Currently, the Common Core State Standards Initiative (CCSSI) places time instruction within the Measurement and Data strand beginning in first grade. According to Common Core, first graders are taught to, "Tell and write time in hours and half-hours using analog and digital clocks" (CCSSI, 2020). There are no precursory standards that establish children's understanding of what hours and minutes are, so it could be inferred that the creators of Common Core believe these durational conceptions are either unimportant or unnecessary for clock reading and time telling, or already known prior to first grade (age six).

This lack of prerequisites seems counter to how Common Core has structured other forms of measurement. According to Common Core, kindergarteners should be able to, "Describe measurable attributes of objects, such as length or weight" (CCSSI, 2020) and, "Directly compare two objects with a measurable attribute in common" (CCSSI, 2020). These standards are addressed prior to learning the tools for such measurement. In other words, kindergarteners are explicitly taught about

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

length-based attributes before being taught how to use the tools to measure them. For example, a kindergartener is taught to compare two lengths of string in order to tell which is longer. This comparison is intended to later bring about strategies for measuring, such as aligning starting points or considering left-overs—both of which are important to consider when measuring time (D. Earnest, personal conversation, May 27, 2019).

Unlike measuring lengths, where quantities can be physically compared against one another as described by the Common Core standards, measuring duration requires the creation of a hypothetical, iterable unit (Piaget, 1969)."The only method of [creating a "mobilized" durational unit] is to reproduce the physical phenomenon whose course (motion) was [the] duration" (Piaget, 1969, p. 67). So, when making judgements about the duration of common experiences, an individual must mentally reconstruct their experience, then dissociate time from perceptive influences, such as effort, emotion, or velocity.

The mental process of distinguishing time from spatial influences is referred to as the operationalization of time (Piaget, 1969). To construct *operational time*, one needs to coordinate succession (the consecutive sequence of events) and duration (the intervals of and between events). This, unlike *intuitive time*—which is based on spatial perceptions—means the individual understands time is continuous, homogeneous for all individuals, and uniform in its measurement (Russell, 2008). For example, a child who conceived of time intuitively would believe that as they walked faster, time moved faster. When reasoning operationally about time, this child would know that their actions have no impact on the duration of their experience.

Piaget (1969) contended that children were able to reason operationally about time by the age of nine (around fourth grade). Long and Kamii (2001), however, found it was not until sixth grade (around the age of 11) and Russell (2008) argued that it was not until eighth grade (around the age of 13). Irrespective of which of these studies might demonstrate an accurate age for the operationalization of time, none place the necessary reasoning for time measurement at first grade (age six), as described by Common Core (CCSSI, 2020) and Tillman and Barner's (2015) study. I hope this study may begin illustrating how children in the early elementary years think about duration based on their lived experiences.

Methodology

This multiple case study (Yin, 2003) followed a modified investigation from Tillman and Barner's (2015) *Experiment 3*, which explored how children placed familiar events on a figurative "timeline". During *Experiment 3*, Tillman and Barner asked children, age five to seven, and adults, to place whole numbers, everyday experiences (e.g., watching a movie, washing hands), units of time (e.g., seconds, hours), and timed durations (e.g., four minutes, two hours) on an open number line. Participants were not asked about their reasoning for their placements, instead a quantitative analysis was completed on each age group.

To understand how children might reason about different durations from reflections on their daily experiences, I asked three children (age five, six, and seven) to organize four activities from shortest to longest amount of time, following the last study of *Experiment 3*. Each child was asked to reflect on why they arranged the events as they did, so that I could complete a qualitative analysis.

Participants and Procedure

To represent the same youth population used by Tillman and Barner (2015), three children: Kris (age five), Sam (age six), and Casey (age seven) were interviewed. All three participants were from the same elementary school in a large suburban city in the western United States. Each child, and their parents, consented to participate in this interview, as part of a larger study on how children reason about durational experiences.

Kris, Sam, and Casey were video, and audio recorded during one-on-one interviews. The interview protocol was modified from Tillman and Barner's (2015) *Experiment 3*. Each child was given four cards with pictures and words of common activities: watching a movie, brushing their teeth, sleeping at night, and eating lunch. These activities slightly differed from those used in *Experiment* 3 in order to better relate to the sample population. Each child was asked to arrange the cards along a continuum from what took the shortest amount of time to the longest amount of time. After completing their "timeline", each child was asked to explain why they organized the cards as they did.

Following each interview, field notes were taken, and each interview was transcribed. Transcripts captured words, hesitations, and actions of each child. All transcripts were member checked by the child and their parents prior to analysis.

Data Analysis

Given the exploratory nature of this research, and the open-endedness of the responses, I used a constant comparison analysis (Glaser & Strauss, 1967). Reasonings were coded inductively, then codes were compared to note any similarities, differences, or apparent progression between and across participants.

The focus of this analysis was not on the accuracy of the child's organization, but rather the durational reasoning presented during their explanation. For example, Casey, age seven, ordered the events: brushing teeth as the shortest duration, then sleeping at night, then eating lunch, then finally watching a movie as the longest duration. This order was not the same as either of the other two participants, nor was it accurate by the actual average length of each activity. However, Casey's explanation displayed a different interpretation of what sleeping at night meant, which explained how her durational order made sense.

After initial coding, themes were created, hypothesizing possible attributes being attended to during the three children's durational reasoning, such as effort exerted, standard units of time, and physical indicators of passing time. These themes were compared against previous studies of children's conceptions of time.

Findings

Tillman and Barner's (2015) quantitative results showed that children in all three age groups (five, six, and seven years old) performed fairly poorly when organizing the durations of common events. The authors' asserted that given these results, "it seems highly unlikely that children's learning of the rank ordering of duration is mediated by knowledge of the approximate durations of events (e.g., that children learn 'an hour' by mapping it to events described as 'an hour', and noting the duration of those events)" (Tillman & Barner, 2015, p. 68). In other words, when children organize familiar experiences, it does not seem that they are using an understanding of the actual duration of each activity.

Through the interviews, I found that at some point, each of the three children explained their sequence of events using standard durational units (e.g., minutes, hours). However, when asked how they knew these units, none of them were able to justify the actual durations. Rather, other explanations for the durations were given, such as how enjoyable the experience was or what their effort to complete the activity.

Kris: Age Five

Kris began by sorting the activities into two columns, what he called the "short amount of time side" (brushing teeth and watching movie) and the "long amount of time side" (sleeping at night and eating lunch). When asked if he felt that it took the same amount of time to watch a movie as brush your teeth, he said that one was shorter, and pointed to the brushing teeth card. Similarly, when questioned about sleeping at night and eating lunch, he said sleeping at night was longer. This progression can be seen in Table 1.

Table 1. Kris’s Organization Process and Reasoning

Initial Order	“Short amount of time” Brushing teeth Watching a movie		“Long amount of time” Sleeping at night Eating lunch	
Final Order	Brushing teeth	Watching a movie	Eating lunch	Sleeping at night
Reasoning	“Like five minutes.”	“You can watch much.” “Like 15 minutes.”	“About 10 minutes.”	“About 30 minutes.”

Kris’s initial ordering of the events was more of a classification than a seriation, where he “put everything that [was] alike together” (Piaget, 1985, p. 100) under the umbrellas, “short” or “long” amounts of time. One question that I overlooked during the interview was why he chose to group these events in such a way. Instead, I focused on his sequencing of events from the original *Experiment 3* (Tillman & Barner, 2015). Though I do feel this was a missed opportunity to better understand his overall durational reasoning.

After creating his final “timeline”, Kris began by explaining his reasoning from the middle of the events, with watching a movie. He stated that it was placed in the middle because “you can watch much”. Here, Kris seemed to be equating the amount of activity (“much”) with duration, a common conception in early time reasoning (Piaget, 1969).

As Kris continued his explanation, he switched his reasoning from activity of an event, to standard units of time—explaining that brushing teeth was five minutes, eating lunch 10 minutes, and sleeping at night 30 minutes. I asked Kris about his use of these specific durational words, which prompted him to add that watching a movie took “like 15 minutes”. From this, it seems that Kris knows that the word “minutes” can be used to explain lengths of time, an understanding highlighted by Tillman and Barner (2015). However, looking at how he now ordered the minutes of each event (5, 15, 10, 30), the value does not align with the chronological duration.

I asked Kris specifically about the chronology of the durations, comparing the order of the numbers given versus the order the events were placed. This comparison seemed to confuse Kris, as highlighted in the following excerpt.

A (Author): You said this was five minutes [taps brushing teeth card], 15 [watching movie card], 10 [eating lunch card], 30 [sleeping at night car], is that the right order?
K (Kris): I don’t know.
A: Do numbers go 5, 15, 10?
K: No/
A: Do they go [flipped watching movie and eating lunch cards] 5, 10, 15?
K: No. [furrows his brow and shakes his head]
A: [Puts cards back] Okay, so you think it takes you longer to eat than watch a movie?
K: Yup!

Kris seemed confused by the rearranging of the cards, and focused more on his perceived duration of each event rather than the numbers he had assigned to the minutes of each event. This aligns with Tillman and Barner’s (2015) findings that overall, the five-year-old participants performed better on organizing the duration of familiar events than on organizing timed durations (such as nine seconds or two minutes). There may also be a connection to Kris's concept of number, although more study would be needed to make such a claim.

Sam: Age Six

Sam quickly organized the four events: first, brushing teeth on the far left (shortest duration), then eating lunch, watching a movie, and finally sleeping at night on the far right (longest duration), as shown in Table 2. She was very deliberate about pulling the cards in increasing durational order, moving from shortest to longest activity, and did not verbalize her reasoning during this process, as the other two participants did.

Table 2. Sam's Organization Process and Reasoning

Final Order	Brushing teeth	Eating lunch	Watching a movie	Sleeping at night
Reasoning	"That's two minutes." "I sometimes count it of a second and then made it up to two minutes." "30 seconds in a minute, 60 seconds in two minutes."	"Pretty easy and you can sometimes shove it in your mouth."	"It's not longer than, if you would start like in the middle of the night it wouldn't even be in the middle of the night, it would be, like, before the middle of the night."	"Would be like all the night, it'd be like all the day."

When asked to explain why she chose to order the events as she did, Sam started her explanation with watching a movie, similar to Kris. However, where Kris explained the duration of a movie through action, as "watching much", Sam explained the duration compared to the time of day one might watch a movie (night) and the progression of time chunked as "the night". Sam went on to compare watching a movie being the middle of the night to sleeping at night being all night and all day. This reasoning seemed to align with the use of start and end points in measurement reasoning (D. Earnest, personal conversation, May 27, 2019; Kamii & Russell, 2012; Piaget, 1969), where darkness and light serve as figural endpoints. Because in Sam's reasoning she could watch a movie that both starts and ends in the dark, but sleeping at night starts in the dark and ends in the day (light), the duration of sleep is longer than watching a movie.

From using physical indicators of time (sun-up versus sun-down), Sam changed her durational measure to explain eating lunch through effort and activity. This use of action to explain time is a common characteristic of reasoning intuitively about time (Piaget, 1969). When asked how "shoving food in her mouth" changes the amount of time the activity takes, Sam responded by saying:

S (Sam): You would just get a handful and shove it in your mouth. [pretends to quickly shove handfuls of food in her mouth]
A (Author): How would that change how long it took you to eat your lunch?
S: Um, uh [looks up, hesitates for six seconds] I don't know.

Sam seemed to correlate her actions to the amount of time that something can take to complete, but she could not reason how or why. Piaget (1969) explained that young children are unable to conserve velocity, believing that quicker actions equate to more time. Sam seemed to have moved past this reasoning. When she modeled eating quickly to explain how eating your lunch is a shorter activity than watching a movie, she seemed to demonstrate the inverse relationship between action and duration (i.e., moving faster results in a shorter duration).

Finally, when asked why she put brushing teeth at the far-left side of the timeline, Sam quickly responded, "cause that's two minutes". This was the first time Sam used standard units. This was also the first time during Sam's explanation that she did not hesitate in her response. I asked how she knew it took two minutes to brush her teeth, which cause her to pause repeatedly and stumble through an explanation of counting two minutes, which consisted of counting 30 seconds (which she explained was a minute) twice.

From other interviews I have conducted with children of Sam's age, "two minutes" has been repeatedly given as the duration of brushing teeth. Through many of these other interviews, children have explained that it is two minutes because: "That's what my mom told me", "That's what the dentist said to do", and "That's how long my toothbrush counts to". I cannot say if any of these accounts explain Sam's reasoning, however, with her inaccurate calculation of 30 seconds to a minute and the immediacy of her initial response, I would conjecture that she has been told by an outside source that brushing teeth takes two minutes.

Casey: Age Seven

Casey's process of organizing the events was much slower than the other two participants. She began by moving watching a movie, eating lunch, and sleeping at night to the right side (longer durations) and brushing teeth to the far left (shorter duration). She then arranged the three "longer duration" activities along the "timeline", as seen in Table 3.

Table 3. Casey's Organization Process and Reasoning

Initial Order	Brushing teeth		Watching a movie Eating lunch Sleeping at night	
Final Order	Brushing teeth	Sleeping at night	Eating lunch	Watching a movie
Reasoning	"It's just easy so you can go really quick."	"Takes a long time because I'm not that tired."	"I'm a really slow eater."	"Like an hour, that's why it's really long."
		"Not as long much time as eating."		

From the beginning, Casey seemed to focus on the effort she took to complete each activity as an explanation for the amount of time it took to complete. Casey began by stating that brushing her teeth was "easy, so you can go really quick". This reasoning seemed different than Sam's description of eating being "easy and you can sometimes shove it in your mouth", in that Casey explained that *because* it is easy you can go fast. This causal relationship seems to demonstrate a more advanced conception about the inverse relationship between velocity and duration, and was reaffirmed by Casey later in the interview, as shown below.

A (Author): If you brush your teeth fast, what does that do to the amount of time it takes you to brush your teeth?
C (Casey): Less, fast, it takes less amount of time because you go fast.
A: So faster makes less amount of time?
C: Yes.
A: If you were eating your lunch and you wanted it to take longer, what could you do?
C: Like eat really slow.

Prior to this exchange, Casey had explained that she was a slow eater when she compared sleeping at night as taking a long time but not as much time as eating. This comparison may seem illogical, since for most people sleeping at night takes longer than eating, however, I believe that Casey interpreted sleeping at night as the act of falling asleep not as the entire duration of being asleep. Thus, Casey described falling asleep as taking a "long time" because she's "not that tired".

When Casey then compared the duration of falling asleep against eating lunch, Casey seemed to, "Directly compare two objects with a measurable attribute in common" (CCSSI, 2020). In other words, Casey took the attribute time and compared the two events. And while I would argue that to Casey, time is the effort she exerts to complete an activity—not necessarily the operationalized time Piaget (1969) discussed—she still seemed to be correlating two events with this common attribute to order their lengths.

Similar to Sam, when I asked Casey about the duration of the final event, watching a movie, she flipped her reasoning from effort (easy, really slow) to standard units (an hour). Once again, Casey compared the events by stating, "[watching a movie is] like an hour and none of these stuff (points to other three cards) takes like an hour, so that's why it's really long". This is interesting, though, because unlike her previous comparison of two efforts, this is comparing effort against a standard duration. Unfortunately, I did not ask how she knew that a movie took an hour, however, this mixing of temporal conceptions may indicate some transition in reasoning, from action being a proxy for duration to time being a standardized quantity.

Discussion

From a linguistic framework, Tillman and Barner (2015) concluded that "the lexical category that children form for duration words is not a simple grouping of these words, but rather a structured, ordered scale that reflects some knowledge of the relative temporal magnitudes of the words" (p. 73). This scale, Piaget (1969) might have argued, results from the operationalization of time—from intuitive perceptions of time to the coordination of temporal and spatial relations.

Across the three interviews, Kris, Sam, and Casey demonstrated varied conceptions about time measurement as they organized the four events (watching a movie, brushing their teeth, sleeping at night, and eating lunch) along their figural timelines. But, by providing the opportunity for these children to share their reasoning, several common themes arose that echoed past mathematical research, most notably the use of action as a proxy for duration.

Piaget (1969) noted "that to primitive intuition, time is simply the 'prolongation of activity'" (p. 60) and was representative of pre-operational thinking. Kris, Sam, and Casey all explained time through activity, where "watching much" or "eating slowing" justified the placement of their duration. This attention to activity may indicate an intuitive perception of time, which, for this age range, would align with past research (Long & Kamii, 2001; Piaget, 1969; Russell, 2008).

Additionally, both Sam and Casey went further to explain how ease of activity created shorter durations (i.e., it's easy so it doesn't take much time). Perceptively, though, I believe that Sam and Casey were using the term "easy" as a substitute for "routine". Some activities such as waiting for paint to dry or being a passenger on a long road trip, might be considered "easy" as they involve little effort, however, the actual duration of these activities could be quite long. For Sam and Casey, the act of eating lunch or brushing teeth, may be so routine that it has created an instance of "temporal compression" (Flaherty, as cited by Evans, 2004, p. 736), where low levels of stimuli cause low levels of information processing, resulting it time feeling like it passes quickly. Conversely, when Casey described falling asleep at night as "[taking] a long time because I'm not that tired", it seems she was describing a "protracted duration" (Flaherty, as cited by Evans, 2004, p. 737), where the event felt long, despite the fact that she situated it on the shorter duration side of her timeline. Both temporal compression and protracted durations are based on perception, thus, indicative of intuitive reasoning of time.

Beyond the focus on activity, all three children used standard units of time to explain their sequence of events. This was not unexpected for two reasons. First, Common Core places time instruction in first grade (CCSSI, 2020), which both Sam and Casey had experienced (as a first and second grader, respectively). And second, much of what young children understand about time is the result of what their parents and other adults have told them (Earnest, 2018; Lareau, 2011; Piaget, 1969). This was most evident by Sam's description of brushing her teeth taking two minutes with no real explanation of why. However, for all three children, the actual durations they understand for these standard units cannot be fully analyzed given the current data. Kris seemed to understand that minute was a word to describe time, but he sorted the durations as 5, 15, 10, 30 minutes and was not able to reason about the ordering of the numbers. Casey conceptualized an hour as being a long amount of time, but never explained what an hour meant beyond this. There is clearly more to learn about how children reason about these durational units as measurements of time and their everyday activities.

Tillman and Barner (2015) presented a broad quantitative analysis of how children order durational words and experiences. Many of their findings aligned with previous mathematical research on children's conceptions of time (Earnest, 2015, 2018; Harris, 2008; Kamii & Russell, 2012; Piaget, 1969). It is encouraging to see common findings across fields of research, linguistics and mathematics.

GEOMETRY AND MEASUREMENT:

BRIEF RESEARCH REPORTS

ACKNOWLEDGING NON-CIRCULAR QUANTIFICATIONS OF ANGULARITY

Hamilton L. Hardison
Texas State University
HHardison@txstate.edu

In recent years, researchers have advocated for measuring angles by measuring circular arcs (i.e., circular quantifications of angularity). Leveraging results from a teaching experiment with ninth-grade students, I demonstrate the existence of non-circular quantifications of angularity, which have not previously been acknowledged in existing empirical research or standards.

Keywords: Cognition, Geometry and Geometrical and Spatial Thinking, Measurement

Angularity is an important geometric attribute throughout K–12+ curricula. It arises in many contexts including classifying shapes, congruence, similarity, transformations, construction, proof, coordinate systems, and trigonometry. Despite this prevalence, few studies have investigated how students reason about angularity (Smith & Barrett, 2017). At the undergraduate level, researchers have argued that robust quantifications of angularity are critical for trigonometry (Akkoc, 2008; Moore, 2013). However, research on angularity with high school students is especially scarce. This presents a problem. In fact, Moore (2013) noted, "future studies that investigate secondary students' quantification of angle measure are needed…" (p. 243). To this end, I conducted a teaching experiment with ninth-grade students to understand how they quantified angularity. In this report, I elaborate the quantifications of angularity indicated by two students and consider implications of these results.

Theoretical Components and a Hypothesis

This study was informed by principles of quantitative reasoning (Thompson, 1994; 2011). A quantity is an individual's conception of a measurable attribute of an object or situation; quantities are mental constructions consisting of three interrelated components: (a) an object, (b) an attribute, and (c) a quantification. A quantification involves a collection of mental operations that an individual could carry out to measure an attribute or interpret a measurement value in a given context. For example, upon assimilating an angle model an individual might establish a goal of determining how open the angle model is in degrees; alternatively, an individual might be asked to consider how to make a one-degree angle. In these instances, the collection of mental operations activated would be components of the individual's quantification of angularity.

Following Thompson's (2008) first-order conceptual analysis, Moore (2013) elaborated that quantifying angularity involves (a) considering a circle centered at an angle's vertex, (b) making a multiplicative comparison of two lengths (e.g., arc length and circumference), and (c) recognizing this ratio is invariant across all possible circles centered at the angle's vertex; for example, a one-degree angle "subtends 1/360 of the circumference of any circle centered at the vertex of the angle" (p. 227). This approach is compatible with the CCSSM standards, where angle measure is explicitly introduced in Grade 4. I refer to these quantifications of angularity as *circular quantifications of angularity* because they leverage multiplicative comparisons of arcs and other circular lengths (e.g., circumference, radius, etc.). Circular quantifications of angularity yield coherent interpretations for angle measure across standard units of angular measure; thus, such quantifications of angularity are productive, particularly for the study of precalculus mathematics and beyond. However, circular quantifications of angularity are sophisticated, and angle measure is introduced relatively early in curricula. Therefore, it is reasonable to question: Is it possible for students to quantify angularity in

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

other ways? Might these other quantifications support students in later constructing circular quantifications of angularity?

When one discusses the measure of an angle, one is describing the size of the interior of the angle (Hardison, 2019). The major hypothesis investigated in the present study was that students might establish productive non-circular quantifications of angularity by enacting extensive quantitative operations on angular interiors. Extensive quantitative operations are operations that introduce units (Steffe, 1991). In length and area contexts, Steffe & Olive (2010) provide numerous examples of such operations including iteration (imagining making and uniting copies of an established unit to produce a composite whole) and partitioning (imagining the simultaneous production of equal-sized parts within an established whole).

Methods

The data and analyses presented in subsequent sections are drawn from a teaching experiment (Steffe & Thompson, 2000; Steffe & Ulrich, 2013) conducted over an academic year in the southeastern U.S. with four ninth-grade students. At the time of the study, all students were enrolled in a first-year algebra course. The overarching goal of the teaching experiment was to investigate how the students quantified angularity and how these quantifications changed throughout the study (see Hardison, 2018); the author served as teacher-researcher for all teaching sessions. Throughout the study, students engaged in mathematical tasks involving rotational angle models (e.g., rotating laser) and non-rotational angle models (e.g., hinged wooden chopsticks). Each student participated in 13–15 video-recorded sessions, which were conducted individually or in pairs approximately once per week outside of their regular classroom instruction; each session was approximately 30 minutes in length. The records of students' observable behaviors (e.g., talk, gestures, written responses, etc.) were analyzed in detail via conceptual analysis (Thompson, 2008; von Glasersfeld, 1995). In this report, the activities of two students, Bertin and Kacie, are foregrounded to illustrate the existence of non-circular quantifications of angularity and to evidence that the construction of circular quantifications of angularity can be supported by non-circular quantifications.

Data and Findings

The results in the following sections are structured around the analysis of four purposefully selected examples of mathematical interactions with Bertin or Kacie.

Angular Repetition and Iteration

To establish models for students' ways of reasoning at the onset of the teaching experiment, students were asked to solve a variety of tasks. One such task involved two pairs of hinged wooden chopsticks: one short pair that could be freely adjusted and one long pair which was fixed. Each student was asked to set the short pair of chopsticks to be four times as open as the long pair of chopsticks. When presented with this task, Bertin proceeded by immediately tracing four adjacent copies of the long chopsticks on a piece of paper and setting the short pair of chopsticks to contain these four adjacent copies.

I refer to Bertin's physical actions as angular repetition. Through angular repetition, Bertin produced an angle model four times as open as the given angle model. Because Bertin engaged in angular repetition without hesitation, I infer he imagined uniting adjacent copies in visualized imagination prior to his physical actions. In other words, the immediacy of Bertin's activities suggests an anticipation indicative of the mental operation of angular iteration. Nothing in Bertin's observable activities indicated that Bertin was considering circular arcs as he solved this task; instead, the figurative material subjected to angular iteration was the interior of the given angle model. Because this task was from his initial interview, Bertin's way of reasoning was previously established and not engendered by the teacher-researcher. Thus, Bertin's activities indicated he may have constructed a non-circular quantification of angularity prior to the study.

One-Degree Angles

Three months later, Bertin was asked how to make an angle with a measure of one degree. Bertin replied, "If you get a ninety-degree angle [*gestures a right angle*], you can divide that into nine so it would be like ten degrees each, and then you can divide each one of those into ten, but it would need something like really really small to write with." The gesture Bertin enacted indicated he first brought forth a familiar angular template in visualized imagination, specifically a right angle. His response also indicated he had assigned this right-angle template a measure of 90°, thereby positing it as a composite unit. Bertin then imagined partitioning the right angle into nine 10° parts, each of which he subsequently partitioned into ten 1° subparts. Thus, Bertin indicated producing 90 one-degree angles within a right angle in visualized imagination. As in the previous example, Bertin's way of reasoning did not leverage circles or arcs; instead, Bertin demonstrated he had established a normative conception of a one-degree angle via extensive quantitative operations enacted on the interior of a familiar angular template.

Contraindication of a Circular Quantification of Angularity

Five months into the study, Bertin was presented with tasks involving central angles to determine whether he had constructed a circular quantification of angularity. In one task, he was asked to determine the measure of a central angle in degrees, given that the length of the green subtended arc was one inch and the green circle's circumference was six inches (Figure 1 left).

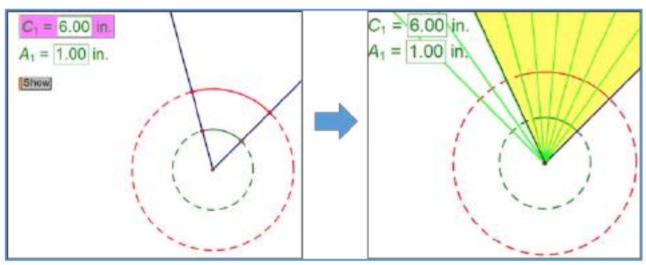

Figure 1: A Central Angle Task (left) and a Model of Bertin's Solution (right)

After an approximately 10-second pause, Bertin tentatively responded, "like seventy," and explained that he "kind of based off of ninety degrees" as he dragged the cursor to form a right angle containing the given central angle. When pressed for how he might precisely determine the measure, Bertin indicated with the cursor that he imagined partitioning the right angle into ten-degree parts; he then counted how many of these parts were contained in the central angle's interior. The green lines in Figure 1 (right) approximate how Bertin dragged the cursor to indicate ten-degree parts. Afterwards, Bertin reiterated, "it's like around seventy somewhere."

Bertin's activities indicated his reliance upon a non-circular quantification of angularity and were remarkably similar to his production of one-degree angles: he started with a familiar template (a right angle); posited this right-angle template as a 90° composite unit; and he partitioned it into nine 10° parts, which he leveraged to solve the task at hand. Bertin's solution is commendable; however, notably absent are any reference to the given measures for the arc or circumference. Thus, Bertin's activities contraindicate a circular quantification of angularity.

Evidence That Non-Circular Quantifications Can Support the Circular Counterpart

To illustrate that non-circular quantifications of angularity might support the construction of the circular counterpart, I present and analyze Kacie's activities on a final interview task involving a central angle. At this point, Kacie had developed a non-circular quantification of angularity similar to

Bertin's. In particular, Kacie had established the following way of reasoning: if *n* adjacent copies of an angular section exhaust a full angle, then the angle has a measure of $360°\div n$. The central angle task from Kacie's final interview involved determining the measure of a blue central angle subtending a green arc 3.47 cm long in a circle of circumference 22.83 cm. Kacie's reasoning is described in the transcript, which has been edited for brevity.

T: How would you determine the measure of the blue angle?
K: Um, [*11s pause*]. You could subtract, um, the three point four seven and the twenty two point eighty three. And that might give you your measurement. Because that's what that angle is like that – well, no. Just kidding. [*16s pause*]. Yeah. I guess you could subtract.
T: And what would that subtraction tell you?
K: Um [*4s pause*]. No! Wait. You could do twenty two point eight three divided by – wait, no. Yeah. Divided by three point four seven and that would give you the number of times the angle would go around the circle. And then you could do … three hundred sixty divided by that number and then that would give you the measurement of the angle.
T: Can explain why that works?
K: … well twenty two point eighty three divided by three point forty seven … would give you a number of how many times the green arc could go around the circle. And then that would give you how many times the blue angle would need to go to the circle to reach back to its starting point. And then if you did three hundred and sixty divided by the number of times the blue angle needed to go around it would give you the measurement

Kacie used the known arc length as a unit for measuring the known circumference. She considered the quotient of these lengths (i.e., $22.83\div3.47$) without enacting the numerical division and interpreted this quotient as how many times the green arc "could go around the circle." Kacie also interpreted this quotient in terms of the central angle, which indicated she mentally united the arc and the central angle and was subjecting these united objects to the same mental operations. Having established the number of adjacent copies of the central angle needed to exhaust a full angle, Kacie relied on a previously established way of reasoning to solve the task. In short, Kacie was able to solve this task involving arc length by leveraging the non-circular quantification of angularity she had previously established.

Discussion, Conclusions, and Implications

Bertin and Kacie developed powerful non-circular quantifications of angularity reliant upon (a) establishing mental templates for familiar angles, (b) positing these familiar templates as composite angular units, and (c) making and measuring other angles via the application of extensive quantitative operations to angular interiors. These non-circular quantifications of angularity have not previously been identified and celebrated in empirical literature. Such quantifications are productive and should be recognized in classrooms and curricular standards along with circular quantifications. I hypothesize non-circular quantifications of angularity naturally precede, and are necessary for constructing, circular quantifications of angularity. Future studies are needed to investigate this hypothesis; however, Bertin's spontaneous angular repetition during the initial interview and his description of one-degree angles evidence that non-circular quantifications can precede circular quantifications, and Kacie's activities evidence that non-circular quantifications of angularity can support the circular counterpart. Additional research is needed to determine the prevalence of circular and non-circular quantifications of angularity at various grade levels.

PROSPECTIVE HIGH SCHOOL MATHEMATICS TEACHERS' USES OF DIAGRAMS AND GEOMETRIC TRANSFORMATIONS WHILE REASONING ABOUT GEOMETRIC PROOF TASKS

Karen Hollebrands
North Carolina State University
kfholleb@ncsu.edu

Deniz Ozen Unal
Aydin Adnan Menderes University
deniz.ozen@adu.edu.tr

The purpose of the study was to examine prospective teachers' uses of diagrams and approaches to congruence while solving proof tasks. Eight prospective high school mathematics teachers were given two proof tasks to solve at the beginning and end of a mathematics education course. Analysis revealed that at the beginning of the course preservice teachers' approached congruence proofs using a perceptual or correspondence approach and interacted and used a descriptive mode of interaction with diagrams. At the end, their approaches to congruence included more instances of transformations and measures and their interactions with diagrams included fewer uses of the descriptive mode and more instances of representational and functional modes.

Keywords: Geometry and Geometrical and Spatial Thinking; Reasoning and Proof; Representations and Visualization

Introduction and Related Literature

The study of geometry in high school is often students' first experiences with conjecturing, justification, and formal proof. Most mathematics standards recommend that students be familiar with different approaches to proof that include synthetic, analytic, and transformational methods (Coxford, 1991; National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010). Yet many teachers have not had experiences using geometric transformations to write formal proofs. There is also research that suggests students' and teachers' interactions with diagrams can support their conjecturing and proving activities (Herbst, 2004; Gonzalez & Herbst, 2009; Chen & Herbst, 2013).

There is significant research related to students' and teachers' abilities to write formal proofs. In a recent research synthesis, Stylianides, Stylianides, and Weber (2017) identified three perspectives on proof abstracted from the literature: "proving as problem solving, proving as convincing, and proving as a socially embedded activity" (p. 239). We adapted a proving as problem solving perspective in which participants were presented four proof tasks to solve in a task-based interview setting. Within this perspective, Selden and Selden (2013) make distinctions between the formal-rhetorical part of a proof and the problem-centered part of the proof. The former focuses on the logical sequencing of steps when writing a formal proof while the latter refers to the creative problem solving that is involved in considering how one might go about proving a conjecture. The problem-centered part of proving is similar to the identification of a proof plan (Melis & Leron, 1999) or proof idea (Reiss, Heinze, Renkl, Grob, 2008) that occurs prior to the writing of a formal proof. It is within this area that we focus our analysis on describing how preservice teachers interact with diagrams while constructing proofs involving congruence.

Gonzalez and Herbst (2009) investigated high school students' conceptions of congruence and then identified perceptual (PERC), correspondence (CORR), transformational (TRANS), and measure preserving (MeaP) conceptions of congruence. The perceptual conception is one that relies on visual information provided in a diagram to determine if two objects appear congruent. The correspondence conception is one in which two objects are congruent if corresponding sides and angles are congruent. The transformational conception uses properties of geometric transformations to map one geometric object to another. The measuring conception relies on measures of objects to determine if

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

they are congruent. The tasks selected for the current study could be approached by students holding any of these four different conceptions of congruence.

Conceptual Framework

Building on the work of Duval (1995), Herbst (2004) proposed four modes of students' interaction with diagrams as empirical (EMP), representational (REPR), descriptive (DESC), and generative. With empirical interactions, the actor has proximal, physical experiences with diagrams. The actor's operations on diagrams (measuring, looking, drawing) is limited to actual properties of the physical drawing. This identifies the diagram as an object; that is, a diagram is taken as a figure without semiotic mediation (Chen & Herbst, 2013). In the representational mode, the actor uses distal physical experiences to make depictions about the diagram and the diagram is seen as a sign of the object. Herbst (2004) also suggests two other modes of interactions, descriptive and generative, to characterize the role of diagrams in the process of proving. In the descriptive mode the actor sets up a distal relationship with a diagram while making statements that could be read off the diagram. Also students use visual perception when they are doing proofs and verify this perception by additional symbols like hash marks or arcs. This mode is a hybrid mode that students use both visual perception to make conjectures like the empirical mode and also see diagrams as symbols to justifying their statements like the representational mode when proving (Chen & Herbst, 2013). Conversely, within the generative mode, students make sensible changes that are not originally given and make "reasoned conjectures" in predicting and making hypotheses about the figure. Students interact in proximal relationship and work generatively with diagrams by using definitions and properties of the geometric objects as well as making changes. Gonzalez and Herbst (2009) proposed the functional mode (FUNC) of interaction to define students' interactions with dynamic geometry diagrams. They describe how students relate outputs and inputs when they use the dragging feature of the dynamic geometry software. Within this mode the combination of dragging and measuring provides students opportunities to explore relationships. Students may also check invariants when making changes to the diagram by dragging and set up the same relation between several diagrams. The purpose of this study was to examine preservice teachers' (PT) interactions with diagrams as they solved proof tasks that were amenable to synthetic or transformational approaches.

Context and Methods

The current study took place at a large public university. Eight preservice (PT) high school mathematics teachers (four males and four females, identified as S1-S8) enrolled in a senior level mathematics education course agreed to participate. Approximately three weeks of the course were devoted to the study of transformations, congruence, and similarity. An emphasis on proof and justification was included throughout the course which addressed number (real, complex), rates of change, functions (linear, exponential, logarithmic), and statistics. The participants were required to solve three tasks at the beginning and four tasks (three were the same) at the end of the semester. At the beginning, PTs were provided iPads with the ShowMe app (interactive whiteboard app) and asked to record themselves solving the tasks. At the end, PTs were invited to participate in task-based interviews; they were provided with the same materials and technology they had used in class. For this paper, analysis of the first two tasks is provided. These tasks were selected and adapted from high school mathematics curriculum and prior research that emphasized transformational and synthetic approaches to proof. Task 1 was adapted from the Mathematics Vision Project Secondary II Curriculum (Module 5, page 16, https://www.mathematicsvisionproject.org/secondary-mathematics-ii.html). Task 2 was modified from professional development materials created by Jim King that were used to prepare teachers to teach congruence using a transformation approach (Figure 1).

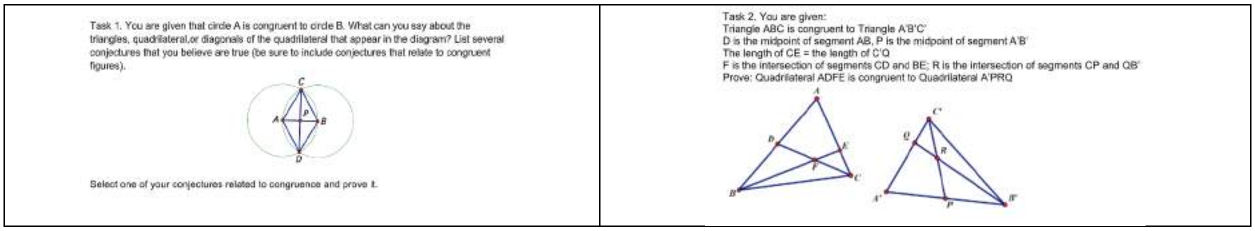

Figure 1. The first two geometry tasks used in the study

For each of the eight PTs, video recordings of their work on the first two tasks from the beginning and end were reviewed and coded to characterize their approach to proving congruence and coded to identify how they interacted with diagrams. The data were analysed by the researchers independently in line with the theoretical framework. Afterwards researchers discussed and agreed on the codes for trustworthiness and consistency.

Results

The most common conception of congruence involved a combination of the CORR with PERC based reasoning. At the beginning, only one PT (S4) used a TRANS approach on the first task. This PT and one other (S6), changed the placement of the second triangle in the second task for ease of determining which sides and angles corresponded to one another. Although this repositioning involved a rotation, this strategy was not used to justify why the quadrilaterals were congruent and thus not coded as a TRANS approach. At the end three PTs (S3, S4, S8) used a TRANS approach. Also only two PTs chose to use dynamic geometry in solving the first task (S1, S8). When examining PTs' interactions with diagrams, we note that there were 11 instances of the DESC, two instances of the REPR, and three instances of the GENE at the beginning. At the end, there was a greater variety in the types of interactions with diagrams. There were seven instances of the DESC, three instances of the REPR, three instances of GENE, and two instances of FUNC mode.

On the first task, all teachers at the beginning made conjectures about the two equilateral triangles and the four congruent right triangles created by the circles. Three of the teachers (S1, S4, S8) made conjectures about the quadrilateral and among these only S4 used reflections in his proof. Most of the PTs noticed that the sides of the quadrilateral are radii of the two circles and used that information to prove triangles congruent. The PTs who made conjectures about the quadrilateral proved it was a parallelogram (S1) or a rhombus (S4, S8). Almost all PTs (except S4) built their conjectures based on the PERC. Even if teachers approached the first task by PERC, they also used a CORR (coded as PERC-CORR). Only S4 utilized the TRANS during the reasoning process at the beginning. None of the teachers used dynamic geometry at the beginning. At the beginning teachers generally interacted with figures DESC, but there are GENE (S2, S4) and a REPR instances (S8). At the end S1 and S8 tried to prove their conjectures for Task 1 using dynamic geometry. Especially, S1 measured all the line segments and used the drag test to justify his/her conjectures (congruent triangles) and S8 used reflections as well as dragging. Also there was one MeaP, three instances of PERC, two instances of CORR, and two instances of TRANS conceptions. From the point of interaction with diagrams, PTs' interactions have varied at the end as three instances involve a DESC, two instances of REPR, one instance of GENE, and two instances of FUNC mode of interaction with diagrams.

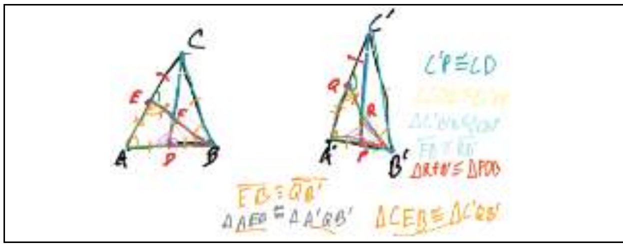

Figure 2: Example of correspondence approach

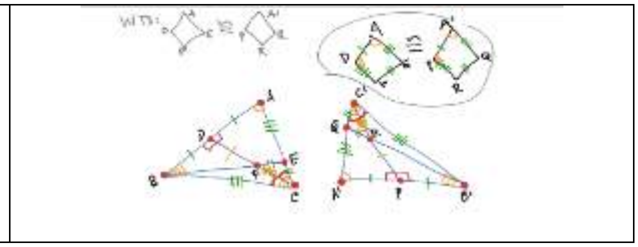

Figure 3: Example of generative mode

On the second task, at the beginning most teachers (S1, S2, S5, S6, S8) used a CORR approach combined with the PERC. They often started the task by marking the given information and using the fact that the two triangles are congruent to identify corresponding parts. In the process of constructing their proof they often made inferences about congruent objects from the diagram using visual perception. At the end, there were no instances of a completely PERC and three instances of the use of TRANS (S3, S4, S8), one of which was combined with a CORR. PTs' descriptions of each of the TRANS described the transformation (e.g., rotation, translation) and stated where points would be mapped, but did not specify a center and angle of rotation or a translation vector (Figure 4). Four PTs used a combination of perceptual and correspondence approaches and one PT decided to skip this question.

Discussion

When looking across the eight participants and two tasks implemented before and after the course we observed that there were no instances of EMP interactions. This is not surprising since most observations of empirical interactions with diagrams occur before high school (Herbst, 2004). Although there was no change in the number of GENE, only one participant was the same and two new participants used this mode. The number of REPR modes increased by one and the number of DESC decreased from 11 to 7. The appearance of the FUNC mode was identified in participants who used dynamic geometry. Analysis of the conceptions of congruence across participants shows more variation in the ways PTs reason. While at the beginning participants wrote proofs that primarily used PERC and CORR approaches, at the end participants used MeaP when using dynamic geometry and used transformations more often.

The identification of the interaction between PERC and CORR approaches to congruence was useful to the researchers in describing how PTs engaged in proof problems using an approach with which they were familiar (correspondence), but when unsure about how to continue made inferences from the diagram based on visual information to proceed with the proof. Their proof idea, proving two figures congruent using a CORR approach, was correct, but it was in the details of formalizing that idea that they encountered challenges. While Selden and Selden (2013) make distinctions between the formal-rhetorical part of a proof and the problem-centered part of the proof the challenge experienced by many of our participants seemed to lie somewhere between these two activities. While in many cases they understood how to go about solving the proof problem, it was in the details of logically moving from one step to the next where they encountered challenges. This aspect of proof writing might be worth examining in future research.

Geometric figures can play a mediating role in students' reasoning, solving a problem, or justifying the truth of a proposition. These objects have been studied in various investigations, where the interactions that students have with figures that are constructed by the teacher or presented in a textbook have been analyzed. In this report, we describe an example of the interaction that undergraduate students had with figures constructed by us, prior to solving a task; and constructed by them during said resolution. The results show a tendency towards the empirical operations of the students on the figures with which they interacted; and the need to incorporate auxiliary elements in the figures, such as labels or segments, in order to solve the proposed tasks.

Keywords: Geometry and Geometrical and Spatial Thinking; Representations and Visualization; Reasoning and Proof; Student-figure interaction; Empirical operations

In this work we show part of an investigation with undergraduate students, in which the role of a geometric figure during the resolution of different tasks was characterized. Taking into account the work of Herbst and Arbor (2004), we describe the modes of interaction that the students had with the figures, according to the way in which they were presented: accompanied by a proposition before carrying out a task; or constructed by the student during the resolution of the task.

Literature review

Various studies have analyzed the characteristics and functions of geometric figures during the process of solving a task. Below we show a description of some investigations that have been relevant in the study of the geometric figure, and the main ideas that have emerged around this topic.

Spatial and conceptual properties of a geometric figure

A geometric figure is considered by Fischbein (1993) as a mental representation where spatial and conceptual properties of a geometric object interact. Spatial properties are those that have to do with the shape, size and position of the figure; while the conceptual properties are related to the abstract idea of a geometric object, with characteristics such as ideality and perfection.

The heuristic role of the geometric figure

Duval (1995) suggests that the geometric figure can play a heuristic role in the reasoning of an individual to solving a task. From the point of view of the author, the representation of a geometric figure can help find the main idea of a proof or support the solution of a problem.

To describe the heuristic role of the geometric figure, Duval (1995) defines four forms of apprehension: perceptual, sequential, descriptive, and operational. Particularly, the heuristic role of a figure can be presented with the operative apprehension, since this refers to the modification of a figure in such a way that ideas for the solution of a task are produced.

Difference between drawing and geometric figure

Laborde (1996) points out that a drawing is a material identity on a support (paper, for example), which acts as a signifier of a theoretical referent. In this sense, the author defines the geometric figure as a set of pairs, whose components are a geometric reference and one of the possible drawings that represent it. Relations between the drawing and its referent are constructed and interpreted by those who produce or reads the drawing, so the meaning of a geometric figure is determined by who interacts with it.

In this investigation we use the term geometric figure when we refer to the graphic representations of objects or geometric situations, which are described in a proposition.

Research Problem

Many of the studies regarding the geometric figure analyze the interactions that an individual has with figures that are constructed and presented by a teacher or in a textbook, leaving aside the interactions with figures that are constructed by students during the resolution of a task. The purpose of this research is to investigate and describe the different interactions that undergraduate students had with geometric figures presented in two different ways: presented by us and constructed by them.

Theoretical framework

The analysis of the obtained results was made considering what was established by Herbst and Arbor (2004) regarding the modes of interaction between a subject, a diagram and a geometric object. The authors use the term diagram equivalently to what we refer to as a geometric figure; while by geometric object they refer to the referent represented in the diagram. The modes of interaction that had an impact on the results obtained are described below:

Empirical: is that interaction where a subject performs physical operations on a diagram (for example, measuring, observing or incorporating new elements). The arguments presented about these actions are restricted by the characteristics of the diagram and the properties of the instruments used (ruler, compass, etc.). In this sense, the subject considers the diagram as an equivalent of the geometric object it represents, allowing it to communicate its results based on the operations it performs.

Representational: in this mode of interaction, the subject interprets the geometric object through the graphic representation of the diagram, limiting himself to considering only the characteristics of said object established in a proposition. With this interaction the diagram does not provide additional knowledge about the geometric object, but only acts as a sign of it. Unlike the empirical interaction, the characteristics of the diagram are not restricted by physical operations, but by the geometric knowledge of the subject to interpret and represent what is established in a proposition.

The remaining modes of interaction are descriptive and generative. The first has to do with the simultaneous interpretation of the signs shown in a diagram with the properties established in a proposition, while the second suggests the joint construction of a diagram and a deductive proof. However, these modes of interaction are not reflected in the results presented here.

Method

This section describes the characteristics of the research participants, as well as the way the tasks implemented in the research were presented.

Participants

The research participants were students between 20 and 22 years old, who were chosen considering the experience suggested by their respective careers (BUAP, 2011), particularly in geometry courses.

Implemented Tasks

The tasks were applied in two different ways: a group was presented with tasks whose content was a proposition and a figure that represented it; while another group was presented with the same tasks, but showing only the proposition and suggesting that the respective figures were constructed. In each task, it was requested to justify a property of the figure based on the characteristics described in the proposition.

Results

The following results reflect significant aspects of students behavior, when interacting with pre-constructed figures and with figures constructed by them.

Results about the task with figure

The task that was implemented was the following: in the figure (Illustration 1) the parallelogram ABCD is presented, from which it is known that the points M and N are midpoints of the sides DC and AB respectively. How do you justify that the AM and CN segments are parallel?

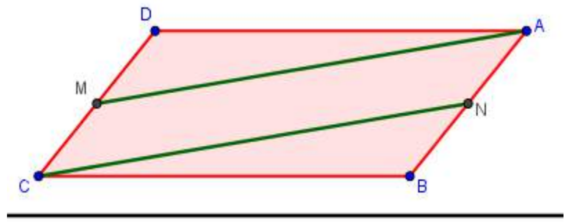

Illustration 1. Figure that accompanied the proposal of the task.

A student traced over the figure the segment MN and considered that it was the perpendicular bisector of the segments DC and AB (Illustration 2). This action was the starting point for the justification of the student's response.

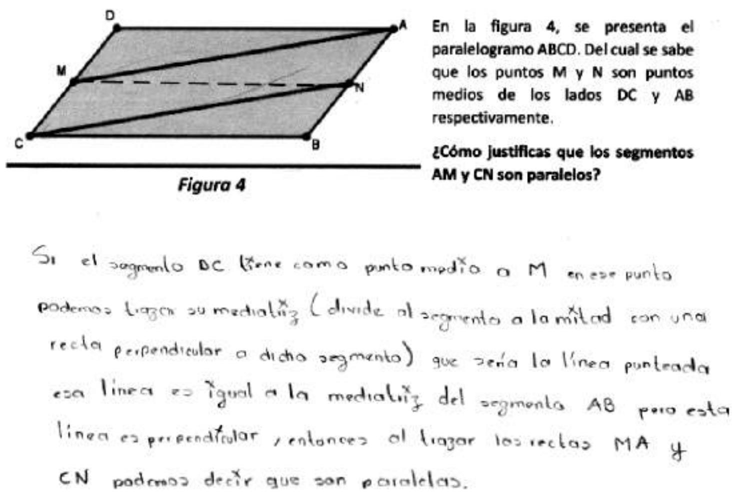

Illustration 2. Trace made on the figure presented.

The student explicitly manifests knowledge about the properties of a perpendicular bisector, in particular, the perpendicularity of this line with the segment it divides. However, the student assumes this property without any justification and without relating it to the properties of the figure shown. The perception of the figure leads the student to affirm the parallelism of the AM and CN segments, without this affirmation having a logical support.

The form of interaction between the student and the figure is totally empirical, since the arguments are restricted by the line that he drew in the figure and his observation to argue the justification.

Results about the task without figure

The wording of the task that was only composed of one proposition was as follows: A parallelogram of vertices A, B, C and D, has as midpoints of two opposite sides the points M and N respectively (M is the midpoint of CD and N is the midpoint of AB). How do you justify that the MA and NC segments are parallel?

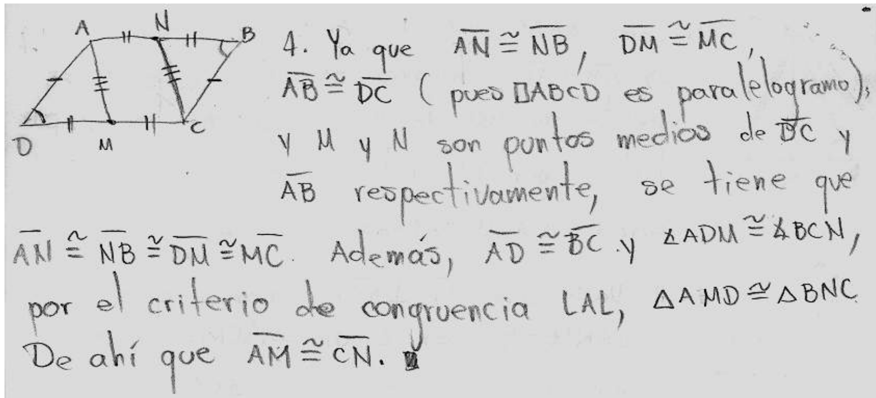

Illustration 3. Figure and student response.

Illustration 3 shows the response of a student who identifies a pair of triangles within the parallelogram that he constructed. The student argues the congruence of these triangles to justify his answer. However, the answer was inconclusive since the student did not mention that the congruence of the triangles results in the parallelism of the AM and CN segments.

The interaction of the student with the figure is representational type, since only considered the properties of the geometric object described in the proposal, to construct his figure. In addition, the characteristics of the figure constructed are restricted by the geometric knowledge of the student and not by empirical actions.

Conclusions

The figure as an object for support in solving geometric tasks involves various aspects that must be considered, one of them is the way a student interacts with a figure during the resolution of a task.

The results that we present indicate a tendency towards the empirical interaction of the students with the figures that accompany a proposition, mainly, it reflects a need to incorporate new elements on the figures. In the tasks that contained only one proposition, a need to externalize the mental image of the geometric object that was described was reflected. The representation of this object can help to keep a check on the arguments that are established to justify a property.

Las figuras geométricas pueden jugar un papel mediador en el razonamiento de los estudiantes, al resolver un problema o justificar la veracidad de una proposición. Estos objetos han sido estudiados en diversas investigaciones, donde se han analizado las interacciones que los estudiantes tienen con figuras que son construidas por el profesor o presentadas en un libro de texto. En este reporte, describimos un ejemplo de la interacción que tuvieron estudiantes de licenciatura con figuras construidas por nosotros, previo a la resolución de una tarea; y construidas por ellos durante dicha resolución. Los resultados muestran una tendencia hacia las operaciones empíricas de los estudiantes sobre las figuras con las que interactuaron; y la necesidad de incorporar elementos auxiliares en las figuras, como etiquetas o segmentos, para poder resolver las tareas propuestas.

Palabras clave: figura geométrica, interacción estudiante-figura, operaciones empíricas

En este trabajo mostramos parte de una investigación con estudiantes de licenciatura, en la que se caracterizó el papel que juega una figura geométrica durante la resolución de diferentes tareas. Tomando en cuenta el trabajo de Herbst y Arbor (2004), describimos los modos de interacción que tuvieron los estudiantes con las figuras, según la forma en que estas fueron presentadas: acompañada de una proposición antes de realizar una tarea; o construida por el estudiante durante la resolución de la tarea.

Revisión de Literatura

En diversos estudios se han analizado las características y las funciones de las figuras geométricas durante el proceso de resolución de una tarea. Enseguida mostramos una descripción de algunas investigaciones que han sido relevantes en el estudio de la figura geométrica, y las principales ideas que han surgido en torno a este tema.

Propiedades espaciales y conceptuales de una figura geométrica

Fischbein (1993) considera que una figura geométrica es una representación mental donde interactúan propiedades espaciales y conceptuales de un objeto geométrico. Las propiedades espaciales son aquellas que tienen que ver con la forma, tamaño y posición de la figura; mientras que las propiedades conceptuales están relacionadas con la idea abstracta de un objeto geométrico, con características como idealidad y perfección.

El papel heurístico de la figura geométrica

Duval (1995) sugiere que la figura geométrica puede jugar un papel heurístico durante el razonamiento de un individuo al resolver una tarea. Desde el punto de vista del autor, la representación de una figura geométrica puede ayudar a encontrar la idea principal de una prueba o apoyar la solución de un problema.

Para describir el papel heurístico de la figura geométrica, Duval (1995) define cuatro formas de aprehensión: perceptiva, secuencial, descriptiva y operativa. Particularmente, el papel heurístico de una figura se puede presentar con la aprehensión operativa, ya que esta se refiere a la modificación de una figura de tal forma que se produzcan ideas para la solución de una tarea.

Diferencia entre dibujo y figura geométrica

Laborde (1996) señala que un dibujo es una identidad material sobre un soporte (papel, por ejemplo), la cual actúa como un significante de un referente teórico. En este sentido, la autora define a la figura geométrica como un conjunto de pares, cuyos componentes son un referente geométrico y uno de los posibles dibujos que lo representan. Las relaciones entre el dibujo y su referente son construidas e interpretadas por quien produce o lee el dibujo, así, el significado de una figura geométrica es determinado por quien interactúa con ella.

En esta investigación utilizamos el término figura geométrica cuando nos referimos a las representaciones graficas de objetos o situaciones geométricas, las cuales se describen en una proposición.

Problema de investigación

Muchos de los estudios referentes a la figura geométrica analizan las interacciones que un individuo tiene con figuras que son construidas y presentadas por un profesor o en un libro de texto, dejando de lado las interacciones con figuras que son construidas por los estudiantes durante la resolución de una tarea. El propósito de esta investigación es indagar y describir las diferentes interacciones que estudiantes de licenciatura tuvieron con figuras geométricas presentadas de dos diferentes formas: presentadas por nosotros y construidas por ellos

Marco teórico

El análisis de los resultados obtenidos se hizo considerando lo establecido por Herbst y Arbor (2004) respecto a los modos de interacción entre un sujeto, un diagrama y un objeto geométrico. Los autores utilizan el término diagrama de forma equivalente a lo que nosotros nos referimos como figura geométrica; mientras que por objeto geométrico se refieren al referente representado en el diagrama. Los modos de interacción que tuvieron incidencia en los resultados obtenidos se describen a continuación:

Empírico: es aquella interacción donde un sujeto realiza operaciones físicas sobre un diagrama (por ejemplo, medir, observar o incorporar nuevos elementos). Los argumentos que se presentan sobre estas acciones son restringidos por las características del diagrama y las propiedades de los instrumentos que se utilizan (regla, compás, etcétera). En este sentido, el sujeto considera al diagrama como un equivalente del objeto geométrico que representa, lo que le permite comunicar sus resultados con base en las operaciones que realiza.

Representacional: en este modo de interacción el sujeto interpreta al objeto geométrico a través de la representación gráfica del diagrama, limitándose a considerar únicamente las características de dicho objeto establecidas en una proposición. Con esta interacción el diagrama no aporta un conocimiento adicional sobre el objeto geométrico, sino que actúa únicamente como un signo de este. A diferencia de la interacción empírica, las características del diagrama no están restringidas por operaciones físicas, sino por el conocimiento geométrico del sujeto para interpretar y representar lo establecido en una proposición.

Los modos de interacción restantes son el descriptivo y generativo. El primero tiene que ver con la interpretación simultanea de los signos mostrados en un diagrama con las propiedades establecidas en una proposición, mientras que el segundo sugiere la construcción conjunta de un diagrama y una prueba deductiva. Sin embargo, estos modos de interacción no están reflejados en los resultados que aquí presentamos.

Método

En esta sección se describen las características de los participantes de la investigación, así como la forma en que fueron presentadas las tareas implementadas en la investigación.

Participantes

Los participantes de la investigación fueron estudiantes de entre 20 y 22 años, quienes fueron elegidos considerando la experiencia que sugerían sus respectivas carreras (BUAP, 2011), particularmente, en los cursos de geometría.

Tareas Implementadas

Las tareas se aplicaron de dos formas distintas: a un grupo se le presentaron tareas cuyo contenido era una proposición y una figura que la representaba; mientras que a otro grupo se le presentaron las mismas tareas, pero mostrando únicamente la proposición y sugiriendo que se construyeran las respectivas figuras. En cada tarea se solicitó justificar una propiedad de la figura con base en las características descritas en la proposición.

Resultados

Los siguientes resultados reflejan aspectos significativos del comportamiento de los estudiantes, al interactuar con figuras preconstruidas y con figuras construidas por ellos.

Resultados sobre la tarea con figura

La tarea que se implementó fue la siguiente: en la figura (Ilustración 1) se presenta el paralelogramo ABCD, del cual se sabe que los puntos M y N son puntos medios de los lados DC y AB respectivamente. ¿Cómo justificas que los segmentos AM y CN son paralelos?

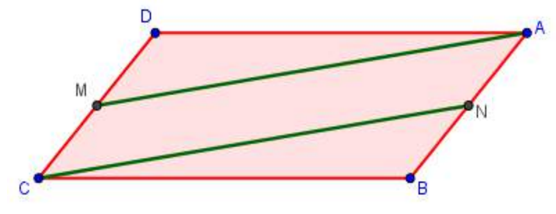

Ilustración 1. Figura que acompañó a la proposición de la tarea.

Un estudiante trazó sobre la figura el segmento MN y consideró que era la mediatriz de los segmentos DC y AB (Ilustración 2). Esta acción fue el punto de partida para la justificación de la respuesta del estudiante.

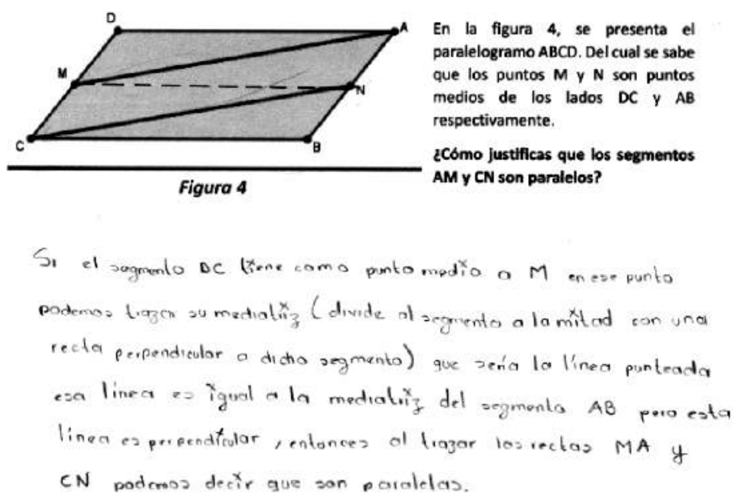

Ilustración 2. Trazo realizado sobre la figura presentada.

El estudiante manifiesta explícitamente el conocimiento sobre las propiedades de una mediatriz, en particular, la perpendicularidad de esta recta con el segmento que divide. Sin embargo, asume esta propiedad sin ninguna justificación y sin relacionarla con las propiedades de la figura mostrada. La percepción de la figura conduce al estudiante a afirmar el paralelismo de los segmentos AM y CN, sin que esta afirmación tenga un sustento lógico.

El modo de interacción entre el alumno y la figura es totalmente empírico, ya que los argumentos están restringidos por la línea que trazó en la figura y su observación para argumentar la justificación.

Resultados sobre la tarea sin figura

La redacción de la tarea que solo estaba compuesta por una proposición fue la siguiente: Un paralelogramo de vértices A, B, C y D, tiene como puntos medios de dos de sus lados opuestos a M y N respectivamente (M es punto medio de CD y N es punto medio de AB). ¿Cómo justificas que los segmentos MA y NC son paralelos?

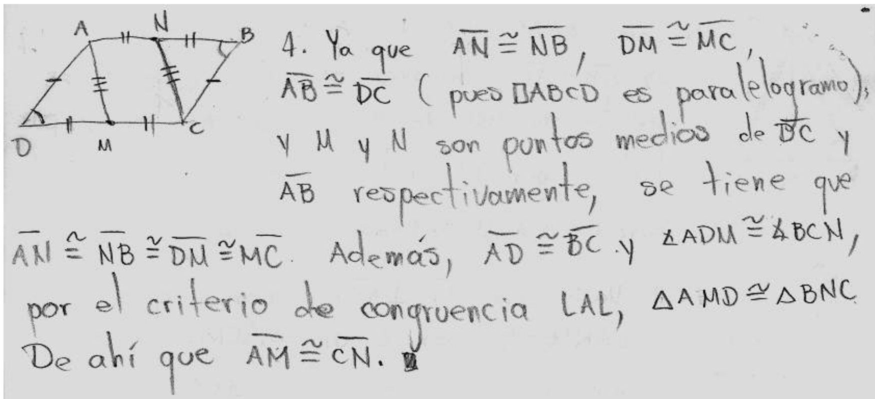

Ilustración 3. Figura y respuesta del estudiante.

En la Ilustración 3 se observa la respuesta de un estudiante quien identifica un par de triángulos dentro del paralelogramo que construyó. El estudiante argumenta la congruencia de estos triángulos para justificar su respuesta. Sin embargo, la respuesta quedó inconclusa ya que no mencionó que la congruencia de los triángulos trae como consecuencia el paralelismo de los segmentos AM y CN.

La interacción del estudiante con la figura es de tipo representacional, ya que solo consideró las propiedades del objeto geométrico, descritas en la proposición, para construir su figura. Además, las características de la figura construida están restringidas por el conocimiento geométrico del estudiante y no por acciones empíricas.

Conclusiones

La figura como objeto para el apoyo en la resolución de tareas geométricas involucra diversos aspectos que deben ser considerados, uno de ellos, es la forma en que interactúa un estudiante con una figura durante la resolución de una tarea.

Los resultados que presentamos señalan una tendencia hacia la interacción empírica de los estudiantes con las figuras que acompañan a una proposición, principalmente, se refleja una necesidad de incorporar nuevos elementos sobre las figuras. En las tareas que contenían solo una proposición se reflejó una necesidad de exteriorizar la imagen mental del objeto geométrico que se describía. La representación de dicho objeto puede ayudar a llevar un control sobre los argumentos que se establezcan para justificar una propiedad.

USING DESIGN-BASED TASKS TO TEACH AREA MEASUREMENT

Edward S. Mooney
Illinois State University
mooney@ilstu.edu

Jeffrey E. Barrett
Illinois State University
jbarrett@ilstu.edu

Geometric measurement is a critical domain that is difficult for many students. The focus of this study was to determine if the incorporation of design processes into instructional activities for area measurement may enhance engagement and learning of students from low-resource, historically marginalized communities. We adapted activities from a learning trajectory for area measurement, prompting Grade 3 students to integrate knowledge of arrays, multiplication, and area measurement. Results suggest the design focus prompted students' integration of knowledge of space and number by engaging in novel representations of designed objects and by prompting multiplicative thinking.

Keywords: Design Experiment, Elementary School Education, Geometry and Geometrical and Spatial Thinking, Learning Trajectories

We employed design and measurement tasks to teach mathematics across complex cultural contexts. Bishop (1988) considered mathematics a poly-cultural activity. He said people in many cultures engage in six fundamental mathematical activities to develop mathematical knowledge: counting, locating, measuring, designing, playing and explaining. Similarly, "…science learning can be understood as a cultural accomplishment" (National Research Council [NRC], 2012, p. 283). The Common Core Standards for Mathematics recommend students use geometry to solve design problems (National Governors Association Center for Best Practices and Council of Chief State School Officers, 2010). The Next Generation of Science Standards (NGSS Lead States, 2013) suggest constructing explanations and designing solutions to prepare students for STEM fields. At Grades 3 – 5, students should, "Generate and compare multiple possible solutions to a problem based on how well each is likely to meet the criteria and constraints of the problem" (NGSS Lead States, 2013, p.46). We explored design work as a means to engage mathematical learning across cultural groups among students.

We selected area measurement and design problems as tools to support mathematics instruction across cultural contexts. We used a learning trajectory (LT) for area measurement (Barrett, Clements, & Sarama, 2017) to develop plausible assessment and instructional tasks (Barrett, Cullen, Behnke & Klanderman, 2017; Barrett & Battista, 2014; Battista, 2006, 2012; Sarama & Clements, 2009). The Cognitively-Guided Instruction group (Carpenter & Fennema, 1992; Fennema, Carpenter, & Franke, 1997) benefited from productive adaptations of tasks (Brown & Campione, 1996). Likewise, we drew on students' community funds of knowledge to adapt our tasks (Celedòn-Pattichis et al., 2018; Wager & Carpenter, 2012).

We had two goals: (a) determine if using design work to adapt instructional activities from an LT for area measurement would enhance learning and engagement, and (b) find whether design processes support mathematical learning. We expected the tasks to help students establish area units as cognitive tools for measuring space, through multiplication or addition. By anticipating spatial collections of units, students might extend skip counting and transition toward multiplicative reasoning in an array structure. We sought to promote students' use of arrays as models to measure area. We expect to suggest a model for improving the development of asset-based LTs that bridge cultural, community-based practices among elementary students. This was our rationale for adapting existing LT instructional tasks to (1) feature design processes, and, (2) integrate multiplication operations, arrays and area measurement.

(2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

Method

Participants were a convenience sample of twenty-two Grade 3 students in an urban Midwest classroom and their teacher. Their school district consists of approximately 13,000 students (20.1% White, 57.7% Black, 11.3% Hispanic). Approximately 68% of the students at the school receive free or reduced lunch and 8% are English learners. We used a written assessment adapted from the LT (Barrett, Clements, & Sarama, 2017, pp. 105-115), with classroom observation to identify four levels of thinking among 22 students: Physical Coverer and Counter (3 students), Complete Coverer and Counter (5), Area Unit Relater and Repeater (9) and Initial Composite Structurer (3). We targeted these levels of thinking in design work within area measurement tasks.

Instruction Design Cycle

What we report here is the feasibility study phase of a design experiment (Middleton, Gorard, Taylor & Bannan-Ritland, 2008). This phase is meant to evaluate an intervention through qualitative methods such as observations, interviews, and case studies to determine what aspects of the intervention work and those that need improvement.

Prior to instruction, the researchers observed and helped students in the classroom to build familiarity and rapport. Later, we interviewed students in focus groups. We asked them how they may already use mathematics outside of the classroom to count, locate, measure, design, play or explain (Bishop, 1988). We conducted three lessons during one week of school in the Fall of 2019. Each lesson was led by one of the authors, with assistance from the classroom teacher. Each lesson began with whole-class discussion of a complex measurement question on area. The first lesson was an adaptation of patio tasks targeting LT levels often found among Grade 3 students (Barrett et al., 2017, p. 133-137). We set a designing task using a novel problem, to find the number of buses that could fit in a parking lot. Day 2, we asked them to design and draw a parking lot to fit a given number of cars or buses. Finally, on Day 3, we asked students to design and draw a park for pets, to provide room for a given number of dogs to move around freely for exercise. The teacher and researchers surveyed students' progress by assisting students who asked questions and posing questions to students while they worked. Students worked independently at first, and later in teams of two or four. The researchers kept field notes. Student work was collected for analysis. At the end of each lesson, the researchers reflected on what occurred in the class to develop the goal and a focal task for the subsequent lesson.

We analyzed the students' work in two ways. First, we examined all three tasks to determine strategies used to solve each. We asked ourselves how students made use of arrays or units in developing solutions. For the second and third tasks, we examined whether the students met the constraints of the task in the process of designing a solution.

Results

For the sake of the paper, we only discuss the results of the third day of instruction. We presented students with an image of a dog kennel. In the image it showed that a 6 x 6 foot square was an adequate area for a dog to run around in. We mapped out the square area on the floor of the classroom so students could see the space, walking around inside the mapped-out region to show the space needed per dog. We gave students a 1.5 x1.5 inch square cutout piece of cardboard. We told the students it represented the space that one dog needed to move around. The task we posed for them was to design a rectangular dog park (Constraint 1) that had enough room for 24 dogs (Constraint 2). At the end of the lesson, we had students present their designs. Table 1 shows the strategies students used in creating their dog parks.

Table 1: Strategies Used in Designing Dog Park

Strategies	Number of Students
Consistent Units with Some Use of Arrays	3
Consistent Units with Grouping	7
Consistent Units with no Grouping	7
Inconsistent Units No Clear Spatial Arrangement	1
No Use of Units Shown	4

Ten students made use of grouping and arrays to create their dog parks. Most students (n = 17) made use of consistent units in their designs. In dealing with the constraints students sometimes met both constraints (see Table 2), but still they were not successful in the total design project. For example, some students created a rectangular area that had room for more than 24 dogs. Other students accounted for the space for 24 dogs but appointed another rectangle to be the actual dog park.

Table 2: Met Dog Park Constraints

Constraints	Number of Students
Area of Park Design for 24 Dogs	6
Dog Park Rectangle	4
Both Constraints Met	6
Neither Constraint Met	6

Conclusion

Given the brief span of the intervention we conducted, we were not expecting students to move on to a new level of the learning trajectory (LT) for area measurement strategies. Rather, we used the LT levels as a rubric to find a suitable instructional level given students' exhibited knowledge of area measurement. Our findings with these design-focused tasks suggest students were creating designs and engaging with area measurement tasks that involved multiplication schemes in productive ways which is in keeping with AURR levels. This finding suggests design-centered tasks of this type offer ways of supporting student thinking and of observing their reasoning at these particular levels of a LT for area. This may provide a way of improving the instructional task descriptions as the LT is modified to broaden its impact on a wider range of students in various contexts and communities.

Furthermore, the design process of instruction appears helpful in focusing students' attention on the meaningful association among arrays, multiplication operations with number, and the measure of rectangular shapes. By engaging contexts that fit with our observations about the students' own experiences, we apparently gained access to familiar stories from their daily routines and community-based language for spatial quantity. The teacher was pleased to note that several students who typically did not engage in mathematics stayed engaged with the tasks for as long as they did. More work is needed to find what motivated this level of investment in the tasks.

Dealing with design constraints had mixed results from our vantage point; some students did not address any of the constraints, although other students successfully addressed one or more constraints. Nevertheless, students in Grade 3 demonstrated the capability to address design constraints related to measurement and space. The design emphasis, with the integration of measurement, multiplication schemes, and arrays as tools appears to be a viable way to adapt learning trajectory-based activities for area measurement. The lesson outcomes indicate promise that students in Grade 3 can engage in design activities with constraints related to multiplicative reasoning using skip-counting and grouping schemes. The interaction among these schemes may have prompted students to engage in the quantitative reasoning by access to their knowledge of such contexts as scanning to find whether a parking lot is empty, partly filled, or full. We believe the prominence and meaningfulness of the context provided a way for the mathematics of area measurement to be addressed as an integrated part of instruction on multiplication and arrays. This is consistent with work in statistics education showing the importance of linking context knowledge to the statistical schemes for organizing and reporting on data in such a context (Langrall, Nisbet, & Mooney, 2006).

We believe further design cycles may need to draw out a more comprehensive analysis of the multiplication processes and the arrays as tools for measuring the capacity of a parking lot to hold cars. We plan further work with the same students to have them redesign a dog park to meet constraints related to the area measurement and to the shape of the region (by requiring a rectangle). We also expect to include further ways to prompt students to check their own design by using a grouping scheme for collections of units. This could focus them more on iterating squares to fill space, and link to arrays and measuring area. The process of testing, designing, retesting and redesigning are vital STEM skills for students to develop (https://stem.getintoenergy.com/stem-skills-list/). The redesign process is important as we learn to extend the instructional tasks found in learning trajectories (e.g., the area LT) to different communities.

Ideally, teachers will use similar design-based tasks to adapt and work with their students in different community contexts. The principles of designing, measuring and describing, taken from analyses across a wide range of culture and communities by Bishop (1988) may productively inform both teachers and researchers who want to adapt learning trajectories for other content areas. Our findings suggest that designing, describing and measuring may be productive ways of engaging students as young as grade 3 in substantive mathematical projects. This may support them as they learn the structural advantages of noticing or setting up arrays to support area measurements and multiplication operations.

SELF-INSTRUCTIONS FOR APPLYING WRITING IN GEOMETRY PROBLEM RESOLUTION

Luz Graciela Orozco Vaca
Secretaría de Educación Jalisco
luzgracielaorozco@gmail.com

This work reports a teaching experiment, which explores the use of writing as a metacognitive tool in high school Geometry problem solving. We develop a qualitative research study, to explore how explicit writing directives can help students to understand, organize and monitor the steps involved in the different phases of a cycle of activities for Geometry problem solving in ninth grade.

Keywords: Problem Solving; Metacognition; High School Education; Geometry and Geometrical and Spatial Thinking

Introduction

In my professional experience as a teacher I have observed lack of comprehension in Mathematics concepts and procedures in students as well as disorganized strategies when solving problems. Such disorganization is observed when students start solving the problem without clearly identifying the data, nor the procedure and the developed rationale to get an answer. Also, the notes they make in the process are disorganized and lack a systematic feature.

From 2006 to 2013, the Mexican Ministry of Education set a nationwide multiple choice evaluation focused to language, mathematics and other subjects from the national syllabus for each school cycle in basic education (ENLACE). From 2015 up to now, such evaluation changed only to language and mathematics (PLANEA). Such evaluations, known by their acronyms in Spanish, serve as a diagnostic for basic education in Mexico, however, a noticeable side effect was that many teachers and students, looking for the improvement in their school rank, developed strategies for success in multiple choice answers, demeaning their skills to face open ended questions in mathematics.

Theoretical framework

This experiment is focused in Veenman (2012) identified learning process, as areas where metacognitive skills are mainly developed: reading, problem solving, learning by discovery and writing, also, we considered Hyde's (2002) research with primary school students where reading and math problems solving are mixed.

Veenman (2012) describes metacognitive skills as the regulation of cognitive process, this means, the acquired capacity for supervision, orientation, direction and control of one`s learning behavior and problem solving. Actually, metacognitive skills are the learning activities and the main determiners to learning results.

Hyde (2006) follows the guidelines of cognitive psychology and uses the braiding term to state that language, thinking and mathematics can be braided into one entity, achieving though connections among those three important processes, a stronger, more lasting and powerful result than if worked individually. With the braiding term it is suggested that the three components are inseparable, with mutual and necessary support. He assures that the stronger the connections among the related ideas are, the deeper and richer the understanding of the concept will be.

Hyde (2006), states that the braiding context benefits kids to imagine, visualize and connect mathematics into context. He assures that this model has been used efficiently in the instruction of small classes involving the teacher's support. The questions are useful to discuss the problem orally, so students interiorize such questions to use them by themselves for later tasks.

After reviewing Veenman's (2012) work, which distinguishes between the metacognitive knowledge and the metacognitive skills to focus their development in science teaching, as well as Hyde's (2006) research, who applies the Braiding Model in primary education to solve problems in mathematics, we consider some useful elements in their work to design our teaching experiment that uses writing from self-instructions as a metacognitive tool when solving geometry problems.

Methodology

In our teaching experiment, students were given self-instructions shown as simple questions, to help them develop the activities at the starting, during and after solving the problem (Table 1). This was intended to gradually introduce the students so, through writing, they started analyzing the given information in the problem, continued with the necessary rationale and representations to interpret the problem situation, and finally they followed the adequate procedures, verifying through justification that they had the right answer realizing how they go to it.

In the teaching experiment, 12 problems selected by the Ministry of Education in the State of Jalisco were selected to practice for the State's Olympics in Mathematics in Primary and Secondary schools (OEMEPS), since these problems require reasoning and creativity in students, they must work with descriptions, explanations and justifications when solving them, and different paths could be followed for the answers.

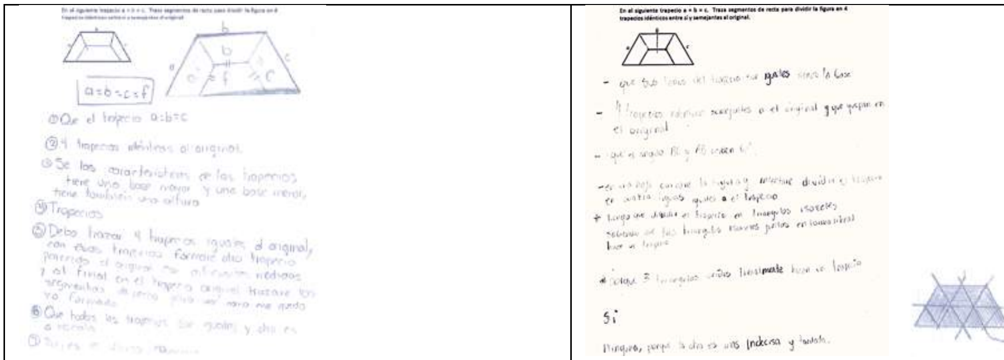
These problems were solved in 20 sessions, 45 minutes each, by 10 students from 9th grade in Mexico City, and they were highly motivated working for their admission exams for High School. The first four sessions, self-instructions were explained to them from examples in collective problem solving. In the rest of the sessions, students answered individual worksheets for 12 problems with self-instructions written on the blackboard as a reminder. The last four sessions, different solving processes for each problem were exteriorized and each student defended his/her answers. The written productions for data analysis are the sources as well as the notes from the teacher-researcher.

Table 1: Veenman's connections between self-instructions and metacognitive skills.

Self-instructions designed to use writing when solving problems.		Veenman's Learning Activities representing metacognitive skills.
Start	What information am I given in the problem?	Reading.
	What do I need to find?	Task analysis,
	What knowledge do I have about the topic?	Activation of previous knowledge.
During	How am I going to do it?	Planning.
	Which steps should I follow?	Follow or change the plan.
	Which drawings can help me get to the solution?	Note taking.
After	How do I justify my answer?	Performance evaluation.
	Is this the only way to get to the answer?	Summing up.
	Which other ways could be used?	Process Reflection.

Results

Results are presented according to the self-instructions order for the teaching experiment. Such self-instructions guided the research and oriented students to work in the activities at the staring of the problem, then the activities during its solving and finally, activities after the problem solving. Students followed self-instructions with their own presentation style, for instance, one student organized through a subsequent number, another uses a hyphen to each (Fig 1b).



a b

Figure 1. Complete answers by two students.

Activation of previous knowledge was given through students answers to the first three questions at the starting of the problem solution, which is the process of remembering the information kept in their minds, relate it to the identified information and deciding which process they will use to obtain the answer, as we see during the problem solving.

"that trapezoid a = b = c" "4 trapezoids identical to the original" *"I know the trapezoids features, they have a major base and a minor base, and they also have height".*	*"The trapezoid sides are the same, except the base"* *"4 identical trapezoids similar to the original and that fit in the original" That angles BC and AB are 60º".*
a	b

Figure 2. Two students' answers at the starting of the task.

During the problem solving students come up with the same answer for the questions "How am I going to do it?" and "Which steps should I follow?" When describing their procedures organization and clearly relate the ideas for the process (Figure 3a and 3b).They also rely on their notes and the trapezoids they draw out form the step description (note taking) or in the marks in the given drawings in the task along with the drawings they sketch as well as written signals (a, b, c, f).Together, descriptions and drawings guided them to follow the process step by step and get the right answer. (Fig. 1a, 1b).

Once the problem solution is obtained, the last questions lead them to think about the process they had applied when describing their justification as well as to look for other ways to solve the problem, however, in this problem none of them identified another procedure to obtain the answer.

"I must draw 4 trapezoids equal to the original; with them I will form another trapezoid similar to the original with different measures and at the end of the original trapezoid I will draw the line segment to see how it looks once I finish". "All trapezoids are the same and the other is escalated". a	*"On a piece of paper I will trace the figure and I will try to divide the trapezoid into four equals to the trapezoid". "I must divide the trapezoid into isosceles triangles knowing that the isosceles triangles together aligned make a trapezoid"* b

Figure 3. Two students' answers when developing the task.

Conclusions

With the use of this learning experiment we noticed, first of all, self-instructions are indeed an action plan, they guide students step by step during all the problem solving process, and secondly, when students wrote down the justification to their answers they carefully reviewed the steps they followed. This means, not only did they analyze if they got the correct answer but also recognized the successful steps to solve the problem, this means that writing helped them understand the solving process, guided by the self-instructions given at the beginning of the experiment.

AUTOINSTRUCCIONES PARA APLICAR LA ESCRITURA EN LA RESOLUCIÓN DE PROBLEMAS DE GEOMETRÍA

SELF-INSTRUCTIONS FOR APPLYING WRITING IN GEOMETRY PROBLEM RESOLUTION

Luz Graciela Orozco Vaca
Secretaría de Educación Jalisco
luzgracielaorozco@gmail.com

Este trabajo reporta un experimento de enseñanza, que explora si el escribir de forma sistematizada puede ser una herramienta que les facilite la resolución de problemas a los estudiantes de educación básica. Desarrollamos un estudio de investigación cualitativa, para indagar como las directivas de escritura de manera explícita pueden ayudar a los estudiantes a entender, organizar y controlar los pasos implicados en las distintas fases de un ciclo para la resolución de problemas de geometría en el noveno grado de educación.

Palabras clave: Autoinstrucciones, Escritura. Resolución de Problemas.

Introducción

A lo largo de mi experiencia profesional como docente he observado una deficiente comprensión de conceptos y procedimientos matemáticos por parte de los estudiantes, así como estrategias desorganizadas en la resolución de problemas. Esta desorganización se observa cuando ellos comienzan a resolver el problema pero no distinguen claramente los datos, ni los procedimientos y el razonamiento que desarrollan para llegar a la respuesta. De la misma manera las anotaciones que realizan en el proceso son desordenadas y carecen de un carácter sistemático.

De 2006 a 2013, el Ministerio de Educación Pública aplicó en todo el país una evaluación de opción múltiple guiada en lenguaje, matemáticas y otras asignaturas del plan de estudios nacional en cada ciclo escolar de la educación básica (ENLACE). A partir del 2015 a la fecha cambio la evaluación enfocada unicamente a lenguaje y matemáticas (PLANEA). Estas pruebas conocidas por sus siglas en español, ayudan a diagnosticar la educación básica en México, pero un efecto secundario no deseado de este tipo de valoración, fue que muchos profesores y estudiantes, en sus esfuerzos por mejorar las marcas de sus escuelas, desarrollan estrategias para lograr el éxito en pruebas de opción múltiple, en detrimento de las habilidades para hacer frente a preguntas abiertas en matemáticas.

Marco teórico

Este experimento está centrado en los procesos de aprendizaje que han sido identificados por Veenman (2012) como las áreas donde mayormente se desarrollan las habilidades metacognitivas: lectura, resolución de problemas, aprendizaje por descubrimiento y escritura, además consideramos las indagaciones con estudiantes de primaria efectuadas por Hyde (2006), donde se combina la lectura y la resolución de problemas de matemáticas.

Las habilidades metacognitivas las describe Veenman (2012) como la regulación de los procesos cognitivos, es decir la capacidad adquirida de la supervisión, orientación, dirección y control de la propia conducta en el aprendizaje y la resolución de problemas. En sí las habilidades metacognitivas son las propias actividades de aprendizaje y son el principal determinante de los resultados en el mismo.

Hyde (2006) se guía por los principios de la psicología cognitiva y utiliza el término de trenzado para indicar que el lenguaje, el pensamiento y las matemáticas pueden ser entrelazados en una sola entidad, logrando que al hacer conexiones entre estos tres procesos importantes, el resultado sea más fuerte, durable y poderoso que si se trabajará cada uno de forma individual. Con el término trenzado sugiere que las tres componentes son inseparables de apoyo mutuo y necesario. Afirma que cuanto más fuerte son las conexiones entre las ideas relacionadas más profunda y más rica es la comprensión del concepto.

Hyde (2006) hace hincapié que el contexto del trenzado beneficia a los niños para imaginar, visualizar y conectar las matemáticas con el contexto. Afirma que este Modelo se ha utilizado con eficacia en la instrucción de una clase con grupos pequeños y con el apoyo del maestro. Las preguntas son eficaces para discutir el problema en grupos pequeños así como las estrategias de representación en el lenguaje oral, de esta manera los estudiantes comienzan a internalizar estas preguntas para utilizarlas por si mismos durante las tareas posteriores.

Una vez revisado el trabajo de Veenman (2012), que hace una distinción entre el conocimiento metacognitivo y las habilidades metacognitivas para orientar el desarrollo de éstas en la enseñanza de las ciencias; así como las investigaciones de Hyde (2006) quien aplica el Modelo del Trenzado en educación primaria, para la resolución de problemas en matemáticas; consideramos algunos elementos útiles de dichos trabajos para hacer el diseño de nuestro experimento de enseñanza que consiste en utilizar la escritura a partir de autoinstrucciones como herramienta metacognitiva en la resolución de problemas de geometría.

Metodología

En nuestro experimento de enseñanza se dieron autoinstrucciones a los estudiantes, presentadas como preguntas sencillas, para auxiliarlos en el desarrollo de las actividades del inicio, durante y después de la resolución del problema (Tabla 1). Lo anterior con la intención de inducirlos gradualmente para que a través de la escritura comenzaran un análisis de la información proporcionada en el problema, continuarán con la exploración y representaciones necesarias para interpretar la situación del problema y finalmente siguieran los procedimientos adecuados, verificando por medio de la justificación que llegaron a la respuesta correcta y se dieran cuenta cómo lo hicieron.

En el experimento de enseñanza, se seleccionaron 12 problemas propuestos por la Secretaría de Educación de Jalisco para el entrenamiento de las Olimpiadas Estatales de Matemáticas en Educación Primaria y Secundaria (OEMEPS) debido a que estos problemas requieren razonamiento y creatividad del estudiante, en los cuales se deben trabajar descripciones, explicaciones y justificaciones en su resolución y se pueden seguir diferentes caminos para obtenerla.

Estos problemas fueron resueltos en 20 sesiones de 45 minutos cada uno, con un grupo de 10 estudiantes de noveno grado de una escuela en la Ciudad de México, quienes estaban altamente motivados trabajando para preparar sus exámenes de admisión para bachillerato. En las primeras cuatro sesiones se explicaron las autoinstrucciones a los estudiantes a partir de ejemplos en la resolución de problemas trabajando colectivamente su aplicación. El resto de las sesiones los estudiantes contestaron las hojas de trabajo individual para los 12 problemas, con las autoinstrucciones expuestas en el pizarrón como recordatorio. Las últimas 4 sesiones se exteriorizaron los diferentes procesos de solución en cada problema y cada estudiante defendío sus respuestas. Las fuentes de datos para el análisis son las producciones escritas de los estudiantes, y las notas de campo del profesor-investigador.

Tabla 1: Conexión entre las autoinstrucciones y las habilidades metacognitivas de Veenman

Autoinstrucciones diseñadas para utilizar la escritura en la resolución de problemas		Actividades de Aprendizaje representativas de las Habilidades Metacognitivas (Veenman)
Inicio	¿Cuáles son los datos que me da el problema?	Lectura
	¿Qué necesito encontrar ?	Análisis de la tarea
	¿Qué conocimientos tengo acerca del tema?	Activación de los conocimientos previos
Durante	¿Cómo le voy hacer?	Planificación
	¿Qué pasos voy a seguir?	Seguir el plan o cambiar el plan
	¿Qué dibujos me pueden ayudar para llegar a la solución?	Toma de notas
Después	¿Cómo justifico la respuesta que encontré?	Evaluación del desempeño
	¿Es el único camino que se puede seguir para llegar a la respuesta?	Recapitular
	¿Qué otras formas puedes aplicar?	Reflexión sobre el proceso

Resultados

La presentación de los resultados va de acuerdo con el orden de las autoinstrucciones diseñadas para el experimento de enseñanza, las cuales fueron la guía de la investigación y orientaban a los estudiantes a trabajar las actividades al inicio de la resolución del problema, enseguida las actividades durante la resolución y por último las actividades después de la resolución del problema. Los estudiantes siguieron las autoinstrucciones dando cada uno su estilo de presentación, por ejemplo mientras que un estudiante les da un orden por medio de un número subsecuente (Figura 1a), otro simplemente utiliza un guión para cada una (Figura 1b).

 a	 b

Figura 1. Respuestas completas de dos estudiantes

A través de las respuestas de los estudiantes a las tres primeras preguntas del inicio de la resolución del problema (Figura 2a y 2b) se dio la activación de los conocimientos previos, que es en sí el proceso de recordar la información registrada en su memoria, relacionarla con la información que identificaron y tomar la decisión de que proceso aplicarán para obtener la respuesta como lo vemos durante la resolución del problema.

"que el trapecio a = b = c" "4 trapecios idénticos al original" "Se las características de los trapecios, tienen una base mayor y una base menor, tienen también una altura". a	"Que sus lados del trapecio son iguales, menos la base" " 4 trapecios idénticos semejantes a el original y que quepan en el original " "Que el ángulo BC Y AB miden 60º". b

Figura 2. Respuestas del inicio de la resolución de dos estudiantes

Durante el proceso de solución del problema los estudiantes brindan una misma respuesta, para las preguntas ¿cómo le voy hacer? y ¿qué pasos voy a seguir?, al describir la organización de sus procedimientos y relatar con claridad las ideas para el proceso (Figura 3a y 3b). Se apoyan también en las anotaciones y representaciones de los trapecios plasmadas por ellos fuera de la narración de los pasos (la toma de notas) o las marcas en los dibujos dados en el problema en conjunto con los dibujos que ellos elaboraron así como las señales escritas (a, b, c, f). En conjunto las descripciones y los dibujos les orientaron para seguir sus procedimientos paso a paso y tener la solución de manera correcta (Figura 1a y 1b).

"Debo trazar 4 trapecios iguales al original, con esos trapecios formare otro trapecio parecido al original con diferentes mediadas y al final en el trapecio original trazaré los segmentos de recta para ver como me quedo ya formado". *"Que todos los trapecios son iguales y otro es a escala".* a	*"En una hoja calcaré la figura y intentare dividir el trapecio en cuatro iguales iguales a el trapecio". "Tengo que dividir el trapecio en triángulos isosceles sabiendo que los triángulos isósceles juntos en forma lineal hacen un trapecio" "Porque 3 triángulos juntos linealmente hacen un trapecio".* b

Figura 3. Respuestas del desarrollo de la resolución de dos estudiantes

Después de obtener la solución del problema, las últimas preguntas los guiaron a reflexionar sobre el proceso que habían aplicado anteriormente al narrar su justificación y a buscar otros caminos que los llevaran a la solución del problema, aunque en este problema ninguno de ellos identificó otro procedimiento para llegar a la respuesta.

Conclusiones

Con la aplicación del experimento de enseñanza nos percatamos, en primer lugar, que las autoinstrucciones son en sí un plan de acción, las cuales guían al estudiante paso a paso durante todo el proceso de la resolución del problema y en segundo lugar, que cuando ellos escribieron la justificación de sus respuestas revisaron detenidamente los pasos que siguieron. Esto es, no solo analizaron si llegaron a la respuesta correcta, sino que reconocieron qué pasos les resultaron exitosos en la resolución, es decir, la escritura les ayudó a entender el proceso de solución, orientados por las autoinstrucciones dadas al inicio del experimento.

DIFFICULTIES TO JUSTIFY GEOMETRIC PROPOSITIONS WHEN SOLVING LOCI PROBLEMS WITH GEOGEBRA

DIFICULTADES PARA JUSTIFICAR PROPOSICIONES GEOMÉTRICAS AL RESOLVER PROBLEMAS DE LUGARES GEOMÉTRICOS CON GEOGEBRA

José Luis Soto Munguía

cesar.romero@unison.mx

A study developed with engineering students from the University of Sonora, Mexico, about their difficulties to justify geometric propositions is presented here. The work is framed within an Analytical Geometry course designed with GeoGebra as support, and refers the topic of loci. The theory of geometric paradigms is used to explain these difficulties and the study reveals that the geometry education of students entering University is mainly limited to natural geometry, showing a precarious familiarity with the methods of natural axiomatic geometry.

Keywords: Geometry and Geometrical and Spatial Thinking, Instructional activities and practices, Technology

Introduction

To explore the extent to which engineering students can justify geometric propositions, five teaching sequences on the subject of geometric loci have been designed. The sequences have been designed to be implemented with GeoGebra, taking as reference the methods used by Descartes (1954, pp. 50-55) in the presentation of his hyperbolograph, to identify the geometric relationships of the construction and find the equation of the hyperbola. The activities were proposed in an Analytical Geometry course taught to 35 Civil Engineering students during the first semester of 2018.

Theoretical elements

Students' responses were analyzed within the framework of the geometric paradigm theory proposed by Houdement and Kuzniak (2003); According to these authors, under the term elemental geometry, three distinct types of paradigms coexist that lead to the distinction of three types of geometry: *natural geometry*, *natural axiomatic geometry* and *formalist axiomatic geometry*. The first two geometries are described below, as they are those used in the present work, as written by Kuzniak (2006):

Natural geometry can be seen as an empirical science in which objects are closely linked to reality, which can be measured and physically compared. The propositions in this geometry are validated experimentally as they depend on the sensory perception of them.

In *natural axiomatic geometry,* geometric objects are only approximations to reality and are defined by the axioms of classical Euclidean Geometry. The propositions here are validated by demonstrations constructed from euclidian axioms and previously proven geometric results.

In the design of the teaching sequences, we attempt to recover the ideas developed by Descartes on geometric loci, particularly those in the construction of the hyperbolograph (Descartes, 1954, pp. 50-55). From Descartes's method we retake two main principles:

1. Identification of the quantities that change and those that remain constant during the plotting of the curve and the relationships between them, as shown in Arcavi (2000).
2. Deduction requires the use of the methods of natural axiomatic geometry, since it is based on the properties of similar triangles, established as theorems in this geometry.

Both characteristics seem desirable to us in the mathematical formation of an engineer, the first because of the importance it has in algebraic modeling of geometric situations and the second because it facilitates the explanation and argumentation of geometric results.

Design and implementation of didactic sequences

Based on the ideas of Descartes, Arcavi and Kuzniak, and the use of GeoGebra, we have developed a series of didactic sequences on the notion of loci. The main goal is for engineering students to justify some elementary geometric results with arguments typical of natural axiomatic geometry.

There is a total of five sequences on which the students worked over a two-week period, where each student had a computer with GeoGebra installed and worked independently. In all the sequences, the students are first offered a construction in GeoGebra, in which the Cartesian axes are omitted so that students can concentrate on the elements of the construction and the relationships that manifest by varying the elements of the figures. As an example, the following table summarizes the objectives and characteristics of sequence 2.

Table 1 Characteristics of Sequence 2

Objectives: a) Identify the relationships between quantities, which are preserved by varying k and presenting geometric arguments about their veracity. b) Verify that the curve plotted by P is a circumference and geometrically justify this result. c) Algebraically represent the relationships identified in (a). d) Find the equation in terms of s and t of the circumference of Figure 1b, and in terms of x and y in Figure 1c.		
Characteristics of the constructions		
AB is a fixed line, *CBD* is an angle of value *k*, *BE* is the bisector of *CBD*, *AP* is parallel to the bisector traced from *A*, and *P* is the intersection between *AP* and *BP*.	The construction is the same as in Figure 1a, but it adds a perpendicular to *AB* from *P* that intersects *AB* in *Q*, also labels segment *BQ* as *s* and *QP* as *t*.	The construction is the same as shown in Figure 1b but has been translated and rotated so that the AB line matches the *X-axis* and to and *B* match the origin.
		Figure 1a	Figure 1b	Figure 1c

This sequence begins with the GeoGebra construction from Figure 1a, in which the student is asked to explore the construction by varying the slider *k*, which controls the CBD angle, and to note that the point P describes a circumference when moving the construction. The tasks here are intended to systematize exploration: that those quantities (measures of angles and segments) that change are first distinguished from those that remain constant, and then that the students establish the possible relationships between these quantities, mainly equality relationships. The work with this construction concludes by requesting the students to geometrically justify the detected relationships. The sequence concludes with the introduction of Cartesian coordinates to be used as a reference (Figure 1c) and algebraically express the curve drawn by point *P* when the parameter *k* is changed.

Analysis

Throughout the development of these activities, we have focused our attention on the questions in which students are asked to justify some geometric proposition, since our main interest is to observe the nature of the arguments they built. We will focus our analysis on the answers to these questions in sequence 2.

In this activity, having explored the construction shown in Figure 1a, and once they have established which angles remain the same when dragging *k*, students seamlessly conclude that the triangle *ABP* is isosceles. As can be seen in the following responses, their difficulties begin when they try to justify some of the results obtained. Item (d) of the worksheet asks them to justify why does the triangle remains isosceles and item (e) asks them to justify why does the segment *BP* works as the radius of the circle, i.e. why does its magnitude not change. The construction provides data on the angles and on the segment *AB*, it was expected that they would conclude that the triangle *ABP* is isosceles on the basis that two of their angles always remain the same and that they could argue that *as a consequence* their opposite sides AB and BP should always be the same.

Four types of responses were detected, illustrated below:

In the first type we place the students who have offered answers whose forms of argumentation are inconsistent, in which arguments that appear to be located in Paradigm 2 are mixed with others based on facts observed with little or no relation to what is asked to justify. In this case we locate the following answers:

Table 2 Example of type 1 answers

d)	It is isosceles since two angles remain the same, since they are co-corresponding angles with others and thus we can determine if they are equal or not.
e)	Because it acts as the radius of a circle that which always has the same magnitude and is linked to a center as in the current case.

In a second case, another student uses the isosceles triangle definition to justify that the triangle is isosceles. And when he tries to justify why the segment *BP* maintains its constant magnitude, he uses its visual perception as a source of argumentation.

Table 3 Example of type 2 answers

d)	Because it has two equal angles and two equal sides, which are characteristics that made it an isosceles triangle
e)	Because the construction makes the segment AP to always be of fixed length.

It is clear that the students located in this case do not recognize the hypotheses of the problem and confuse the causes with the effects on the construction, indicating that they do not base their response on a deductive reasoning and are therefore located in Paradigm 1.

In the third type of responses the students mix Paradigm 1 ways of arguing with arguments specific to Paradigm 2, this is the case of the following response, which provides an answer to item (d) that was independent from the observation, but does not make it clear that equality of the angles implies equality of the sides, instead the student responds to item (e) very clearly that in the case of an isosceles triangle with a fixed side, the other side must have a fixed length. We consider that the answer to the first item does not correspond to Paradigm 2, but its response to the second item fits in the ways of arguing specific to this paradigm.

Table 4 Example of type 3 answers

d)	Despite of its movement there is still two equal sides and two equal angles.
e)	Segment *AB*'s length is 8 and as it is an isosceles triangle it's the same as *BP*, then, despite the movement, they will measure the same and stay constant.

Finally, the fourth type of response includes those that can be located in Paradigm 2, where it is observed that the student recognizes the data provided as hypotheses from which he can build his arguments. The following two responses illustrate this case.

Table 5 Example of type 4 answers

d)	Because it has two equal internal angles and therefore the opposite sides to the angles are equal.
e)	Since the triangle is isosceles, it forces the segment *BP* to remain the same length as *AB*, and as *AB* never changes, neither does *BP*.

Conclusions

Of the 35 students who were part of the group, 8 of them were able to present arguments to justify propositions, which can be located in Paradigm 2, those represented in the Type 4 responses. The rest, to some extent, showed arguments of Paradigm 1. This proportion illustrates a serious problem, showing that most students are unable to use deductive arguments to justify geometric propositions. We emphasize that their responses indicate that they can identify geometric facts, but they cannot present deductive arguments to explain them.

These results motivate us to, in the future, study the characteristics of the teaching of Geometry at the pre-university level, where the source of some of the difficulties observed could be found. Finally, we want to add that the use of GeoGebra has been attractive to students, but this has not been reflected in improving the nature of the arguments put forward by students.

Se presenta aquí un estudio desarrollado con estudiantes de Ingeniería de la Universidad de Sonora, México, sobre sus dificultades para justificar proposiciones geométricas. El trabajo está enmarcado en un curso de Geometría Analítica diseñado con apoyo de GeoGebra y se refiere al tema de lugares geométricos. Se utiliza la teoría de los paradigmas geométricos para explicar estas dificultades y el estudio revela que la formación en geometría de los estudiantes que ingresan a la Universidad, está limitada principalmente a la geometría natural, mostrando una precaria familiaridad con los métodos de la geometría axiomática natural.

Palabras clave: Geometría y Pensamiento Geométrico y Espacial, Actividades y Prácticas de Enseñanza, Tecnología

Introducción

Con el propósito de explorar hasta qué punto los estudiantes de ingeniería pueden justificar proposiciones geométricas, se han diseñado cinco secuencias didácticas sobre el tema de lugares geométricos. Las secuencias han sido diseñadas para desarrollarse con GeoGebra y tomando como referencia los métodos usados por Descartes (1954, pp. 50-55) en la presentación de su hiperbológrafo, para identificar las relaciones geométricas de la construcción y encontrar la ecuación de la hipérbola. Las actividades fueron propuestas en un curso de Geometría Analítica impartido a 35 estudiantes de Ingeniería Civil durante el primer semestre de 2018.

Referencias teóricas

Las respuestas de los estudiantes se analizaron en el marco de la teoría de paradigmas geométricos propuesta por Hedemount y Kuzniak (2003); según estos autores bajo el término geometría elemental, coexisten tres tipos distintos de paradigmas que conducen a distinguir tres tipos de geometría: la geometría natural, la geometría axiomática natural y la geometría axiomática formalista, se describen a continuación las dos primeras geometrías, que son las que se utilizan en el presente trabajo, según la versión de Kuzniak (2006):

La *geometría natural* puede verse como una ciencia empírica en la que se trabaja con objetos muy ligados a la realidad, que pueden ser medidos y comparados físicamente. Las proposiciones aquí pueden validarse experimentalmente porque dependen de la percepción sensorial que se tiene de ellas.

En la *geometría axiomática natural* los objetos geométricos son solamente aproximaciones a la realidad y son definidos por los axiomas de la Geometría Euclidiana clásica. Las proposiciones aquí son validadas mediante demostraciones construidas a partir de los axiomas euclidianos y de resultados geométricos previamente demostrados.

En el diseño de las secuencias didácticas, se han intentado recuperar las ideas desarrolladas por Descartes sobre lugares geométricos, en particular aquellas que están presentes en la construcción del hiperbológrafo (Descartes, 1954, pp. 50-55). Del método utilizado por Descartes, rescatamos dos características que serán tomadas en cuenta para el diseño de las secuencias:

1. La identificación de las cantidades que cambian y las que permanecen fijas durante el trazado de la curva y de las relaciones entre ellas, tal como se muestra en Arcavi (2000).
2. La deducción exige el uso de los métodos propios de la geometría axiomática natural, puesto que está basada en las propiedades de los triángulos semejantes, establecidas como teoremas en esta geometría.

Ambas características nos parecen deseables en la formación matemática de un ingeniero, la primera por la importancia que tiene en la modelación algebraica de situaciones geométricas y la segunda porque facilita la explicación y la argumentación de resultados geométricos.

Secuencias y aplicación

Retomando las ideas de Descartes, Arcavi y Kuzniak y apoyándonos en el software GeoGebra, hemos elaborado una serie de secuencias didácticas sobre la noción de lugar geométrico. La idea es que los estudiantes de ingeniería justifiquen algunos resultados geométricos elementales con argumentos propios de la *geometría axiomática natural*.

Las secuencias fueron cinco en total y los estudiantes las desarrollaron a lo largo de dos semanas, en un centro de cómputo en el que cada quien contó con una computadora con el software GeoGebra instalado. En todas las secuencias se ofrece primeramente al estudiante una construcción en GeoGebra, en la que se omiten los ejes cartesianos para que los estudiantes se puedan concentrar en los elementos de la construcción y las relaciones que se manifiestan al variar elementos de las figuras. Como ejemplo, la siguiente tabla resume los propósitos y características de la secuencia 2.

Tabla 1 Características de la secuencia 2

<table>
<tr><td colspan="3">Propósitos: a) Identificar las relaciones entre las cantidades, que se conservan al variar k y presentar argumentos geométricos sobre su veracidad. b) Verificar que la curva trazada por P es una circunferencia y justificar geométricamente este resultado. c) Expresar algebraicamente las relaciones identificadas en a). d) Encontrar la ecuación en s y t de la circunferencia de la Figura 1b) y en términos de x y y en la Figura 1c).</td></tr>
<tr><td colspan="3">Características de las construcciones</td></tr>
<tr><td>AB es una recta fija, CBD es un ángulo de medida k, BE es la bisectriz del ángulo CBD, AP es la paralela a la bisectriz trazada por A y P es el punto de intersección de AP y BP.</td><td>La construcción es la misma que en la Figura 1a), pero se ha trazado desde P , una perpendicular a AB que interseca a AB en Q y se ha etiquetado como s al segmento BQ y como t al segmento QP.</td><td>La construcción es mostrada en la Figura 1b), pero se ha trasladado y rotado para que la recta AB coincida con el eje X y B coincida con el origen.</td></tr>
<tr><td></td><td></td><td></td></tr>
<tr><td>Figura 1a</td><td>Figura 1b</td><td>Figura 1c</td></tr>
</table>

En esta secuencia, se inicia con la construcción de la Figura 1a, en la que se han trazado las rectas AB y BD (de tal forma que BD forme un ángulo de k grados con la recta fija AB), la bisectriz del ángulo CBD y una recta paralela a la bisectriz EB, que pasa por A. Luego se pide al estudiante que explore la construcción haciendo variar el deslizador k, el cual controla el ángulo CBD, y que al mover la construcción observe que el punto P describe una circunferencia. Las tareas aquí pretenden sistematizar la exploración: que se distingan primero aquellas cantidades (medidas de ángulos y segmentos) que cambian de las que permanecen constantes, durante el movimiento y luego que establezca las relaciones posibles entre estas cantidades, principalmente las relaciones de igualdad. El trabajo con esta construcción concluye con la solicitud al estudiante de que justifique geométricamente las relaciones detectadas. La secuencia concluye con la introducción de coordenadas cartesianas para tomarlas como referencia (Figura 1c) y expresar algebraicamente la curva trazada por el punto P, cuando se hace variar el parámetro k.

Análisis de resultados

A lo largo del desarrollo de estas actividades, hemos concentrado la atención en aquellas preguntas en las que se solicita a los estudiantes justificar alguna proposición geométrica, porque nuestro interés principal es el de observar la naturaleza de las argumentaciones construidas por los estudiantes. Concentraremos nuestro análisis en las respuestas a estas preguntas en la secuencia 2.

En esta actividad, después de haber explorado la construcción mostrada en la Figura 1a y una vez que han establecido cuáles son los ángulos que permanecen iguales al arrastrar k, los estudiantes concluyen sin dificultades que el triángulo ABP es isósceles. Como podrá verse en las respuestas siguientes, sus dificultades empiezan cuando intentan justificar algunos de los resultados obtenidos. En el inciso d) se les pide que justifiquen por qué el triángulo se mantiene isósceles y en el inciso e) se solicita que justifiquen por qué el segmento BP funciona como radio del círculo, es decir por qué su magnitud no cambia. La construcción ofrece datos sobre los ángulos y sobre el segmento AB, se esperaba entonces que llegaran a la conclusión de que el triángulo ABP es isósceles partiendo de que dos de sus ángulos permanecen siempre iguales y pudieran argumentar que por lo tanto sus lados opuestos AB y BP debieran ser siempre iguales.

Se detectaron cuatro tipos de respuestas, que ilustraremos a continuación:

En un primer caso ubicamos a los estudiantes que han ofrecido respuestas cuyas formas de argumentación han resultado poco coherentes, en los cuales se mezclan argumentos que parecieran ubicarse en el Paradigma 2, con otros basados en hechos observados con poca o nula relación con lo que se pide justificar. Ubicamos en este caso las respuestas siguientes:

Tabla 2 Un ejemplo de respuestas de tipo 1

d)	Es isósceles ya que 2 ángulos permanecen iguales ya que son ángulos correspondientes con otros y así podemos determinar si son iguales o no.
e)	Porque actúa como el radio de un circulo el cual siempre tiene la misma magnitud y está anclado a un centro, así como ocurre en el presente círculo.

En un segundo caso, el estudiante recurre a la definición de triángulo isósceles para justificar que el triángulo es isósceles. Y cuando intenta justificar por qué el segmento BP mantiene su magnitud constante, recurre a su percepción visual como fuente de argumentación.

Tabla 3 Un ejemplo de respuestas de tipo 2

d)	Porque tienen dos ángulos iguales y dos lados iguales por lo tanto son características por la cual se conforma un triángulo isósceles.
e)	Porque la construcción obliga a que el segmento AP siempre se mantenga fijo.

Es claro que los estudiantes ubicados en este caso no reconocen las hipótesis del problema y confunden las causas con los efectos en la construcción, lo cual indica que no basan su respuesta en un razonamiento deductivo y por lo tanto se ubican en el Paradigma 1.

En un tercer tipo de respuestas se observa que el estudiante mezcla formas de argumentar del Paradigma 1 con argumentos propios del Paradigma 2, éste es el caso de la respuesta siguiente, en la se ofrece una respuesta al inciso d) que se ha desprendido de la observación, pero no deja en claro que la igualdad de ángulos implica la igualdad de lados, en cambio responde al inciso e) con mucha claridad al respecto de que tratándose de un triángulo isósceles con un lado fijo, el otro lado deberá tener una magnitud fija. Consideramos que la respuesta al primer inciso no corresponde al Paradigma 2, pero su respuesta al segundo inciso cae en las formas de argumentar propias del este paradigma.

Tabla 4 Un ejemplo de respuestas de tipo 3

d)	A pesar de su movimiento siguen siendo con dos lados iguales y tiene ángulos iguales.
e)	El segmento AB mide 8 y al ser triángulo isósceles mide igual que BP, entonces a pesar del movimiento medirán lo mismo y se mantiene constante.

Y el cuarto tipo de respuesta son las que propiamente pueden ubicarse en el Paradigma 2, en donde se observa que el estudiante reconoce los datos proporcionados, como hipótesis a partir de las cuales puede construir sus argumentaciones, las siguientes dos respuestas ilustran este caso.

Tabla 5 Un ejemplo de respuestas de tipo 4

d)	Porque tiene dos ángulos iguales y por lo tanto dos lados iguales que son los opuestos a los ángulos iguales.
e)	Porque al ser triángulo isósceles obliga a que el segmento BP permanezca de la misma magnitud del AB, y como AB nunca cambia, este tampoco.

Conclusiones

De los 35 estudiantes que integraban el grupo, 8 de ellos pudieron presentar argumentos para justificar proposiciones, que pueden ubicarse en el Paradigma 2 y que aquí hemos catalogado como respuestas de Tipo 4. El resto, en mayor o menor medida, mostraron utilizar las formas de argumentación propias del Paradigma 1. Esta proporción ilustra un problema serio, al mostrar que la mayor parte de los estudiantes se encuentran imposibilitados para usar argumentos deductivos al justificar proposiciones geométricas; destacamos que sus respuestas indican que pueden identificar hechos geométricos, pero no pueden presentar argumentos deductivos para explicarlos.

Los resultados nos motivan a estudiar en el futuro las características de la enseñanza de la Geometría en el nivel pre-universitario, en donde pudiera encontrarse la fuente de algunas de las dificultades observadas. Queremos agregar por último que el uso de GeoGebra ha resultado atractivo para los estudiantes, pero esto no se ha reflejado en mejorar la naturaleza de las argumentaciones presentadas por los estudiantes.

SPATIAL IMAGINATION TO WORK ON 3D SPACE USING A FIGURAL DEVICE

IMAGINACIÓN ESPACIAL PARA TRABAJAR OBJETOS EN EL ESPACIO 3D USANDO UN DISPOSITIVO FIGURAL

Currently, the spatial imagination is not explicitly developed in schools, it will be necessary to interpret 3D objects that are represented in 2D. To develop the ability of 3D spatial imagination, it is necessary to consider the spatial location and relative position between objects. Relating sets of points with appropriate variations of triads of type (x, y, z) promotes this ability. In this ongoing research, the numerical variation of the entries associated with the graphic objects provides indicators of location and relative position of points, lines or planes to high school students. We find selective numerical variation, supports the development of spatial imagination, whose repeated use will train a habit in orientation, which must be worked to become transparent.

Keywords: Geometry and Geometrical and Spatial Thinking

According to research related to the analysis of syllabus and textbooks of middle and higher education, for the study of topics such as vector spaces, an explicit introduction to the development of spatial imagination is not considered necessary, which then is a disadvantage in graphic interpretations. However, in these syllabus there is a graphic approach that tries to be solved through the graphic point-ordered pair relationship, which does not seem to be sufficient for the type of tasks proposed. At the same time, 3D representations are scarce and the problems associated with interpretation are not addressed because they are used as an illustration and not as a mathematical object; due to that situation, students do not have the opportunity to go beyond a formal education that emphasizes algebraic treatment, because they do not have graphical representations (Van Dormolen, 1986).

On the other hand, students show a natural propensity to identify more easily some directions over others in tasks of graphic interpretation in the case of graphs in representations of 3D spaces, which contributes to disorienting the student in tasks of spatial imagination (Cohen , 2001). Other sources of conflict arise in the interpretation of perspective, due, among other things, to the fact that we must reorganize the information to understand that this interpretation is present and that the graphic representation is subordinate to it, that is, "seeing and knowing" are two different things, according to Parzysz (1988). Preference to identify lines or sets of lines in a general way can also be an obstacle if there is not a direct instruction to determine their orientation (Bakó, 2003).

Because the interpretation of the perspective or 3D depth in a plane is a work in which the visual information must be decoded, from our point of view it is necessary to have indicators that guide the spatial imagination to carry out an adequate treatment of 3D graphic objects.

Some learning proposals to work with 3D space, link the figural properties of drawing with its mathematical characteristics through the use of orthogonal projections, which have a constructive and prescriptive foundation, that is organized through parallelism and perpendicularity (Parzysz , 1988), and goes in the direction of establishing spatial indicators for students to improve their spatial imagination. Therefore, we consider it of great importance to provide such indicators that guide students for the interpretation of 3D space in terms of locating the position of points as well as sets of points in their relative positions.

Theoretical framework

In learning mathematics, the use of signs as semiotic instruments (Vigotsky, 1981a) that allow knowledge to be mediated, provides adequate conditions for students to develop reflective practice (Radford, 2006, 2012); therefore, it is important to associate mathematical ideas such as graphics, in terms of a practice that uses semiotic instruments, particularly when we establish relationships between algebraic objects and graphics, to integrate the interpretation of 3D graphics into a single body of knowledge, as in this case.

On the other hand, mathematical objects such as graphs, have a visual and abstract character, so it can be considered as a figural concept (Fischbein, 1993), mathematical objects that can be thought of in a double status, as objects and as concepts. In particular, geometric objects are figural concepts, since they reflect spatial properties (shape, position, magnitude) and at the same time, they possess conceptual qualities such as ideality, abstraction, generality, perfection, among others (Fischbein, 1993), and apparently this is also the case for graphs.

Because the figural properties are ostensive, that is "they are in front of the eyes", they allow us to differentiate their location and their relative position, in addition to the fact that their position is the only property of graphic objects, because they are represented in homogeneous spaces of representation where the only quality is their position (Nemirovsky, 2001). We are able to lean on these properties to develop spatial imagination, which in our case includes both, the ability to locate points, as well as the ability to establish the relative position between graphic objects that include points, lines and planes.

In order to establish spatial indicators for the spatial imagination, we will be using a treatment on the position of points of the type (x, y, z) which by means of the numerical variation of their coordinates, describes points and sets of associated points as points, lines and planes, which depending on the situation take on the role of spatial indicators. Used in this way, the triads become signs that associate properties of algebraic description and spatial position, which makes them what we have named, a figural device, when used for this dual purpose. Besides that, due to its perceptual nature, its repeated use would allow students to develop habits of thought (Cuoco, Goldenberg and Mark, 1996) until they acquire a form of transparency (Roth, 2003) in their location and relative position.

Next, we propose what are our research hypotheses:

1. The spatial imagination can be developed by positional approximations by means of the numerical variation of the triad (x, y, z) associated with the points that can describe lines and planes, as well as the hability to establish their relative position.
2. The acquisition of habits of thought plays a central role in the acquisition of the ability of spatial imagination, if the variation of the triads is associated with the position of the objects described.

Methodology

In particular, in the case of visual interpretation of three-dimensional space, it is possible to make use of certain types of figural devices when we use the triad (x, y, z) that has its origin in the representation of points in three-dimensional spaces. Based on their position properties, we explore the relationship between each coordinate of the triad (x, y, z) and those of the points in space.

The activity carried out establishes that each of the coordinates refers to a specific orientation in space, which makes it possible to make constant some of the values of the coordinates to vary one or two of them or to vary all three. This allows the coordinate to be associated with the relative position of the points and point sets, using the axes as an orientation reference.

We proceeded with two different environments for locating points and sets of points. On the one hand, in a physical environment we made use of a manipulable (Godino, 1998) for the realistic representation of the 3D space, where we used a model consisting of three slightly transparent plastic sheets, of different colors, assembled in such a way that they represented the eight octants, and the joints of each sheet formed the axes of space. For the second environment, graphical representations were used in GeoGebra.

The developed procedure was based on establishing a location relationship supported by the numerical variation in the triad coordinates (x, y, z), asking for the point or set of points that were described from the variations made and the coordinates with constant values in the two environments.

Implementation

The implementation of this research was carried out in two groups of the sixth semester of high school: group A, consisted of 20 students and group B, consisted of 36, all of them 17 and 18 years old and none of them with a notion of 3D space. They were given a class where they were introduced to three-dimensional space, explaining concepts and placing triads in different octants. After this, we did a case study with the student Elías from group B, and we did a follow-up interview that we describe below.

First phase: physical model and location of areas associated with the signs. It was a reminder of the positional meaning that the triad can acquire, as in cases where the points have the following signs: a) (±, -, ±) b) (+, +, +) c) (+, - , ±) d) (-, +, ±) e) (+, ±, ±) f) (-, -, -). The work was accompanied by the comparison of the location of the triad that Elías made first in his worksheets, varying the possibilities of orientation depending on the signs. He was also asked for suggestions on points with specific properties.

Second approach: Variations. The researchers proceeded to make variations, first, we set a coordinate allowing the variation in the two remaining positions, so that the sets of points described formed planes to reflect on the properties of the lines formed by the intersections of parallel and perpendicular planes at this stage, particularly with the canonical planes. Then we set a pair of coordinates allowing the variation of the missing position, so that the sets of points described now formed lines, parallel to one of the axes, as in the cases of (-1, 2, z), (1, y, 3) or (x, 2, -1), among others; the sets were located in the space provided by GeoGebra.

We present an extract from the interview with Elías, that allowed the researchers to see the use of the triad as a figural concept in the case of the variation of two coordinates with the other one fixed; we asked him to mention 5 triads in which the first coordinate had the same value and the second and third varied, those points were graphed in the software (Figure 1) and he was asked:

INV: What do you observe about these points? (Figure 1)
Elías: Now they are all facing each other.
INV: Would they be on some plane? Would all the points be inside this? (indicates the region of the points)
Elías: From the plane? Yes.
INV: What plane would it be?
Elías: It would be (5, y, z)
After Elías said (5, y, z), the plane was graphed as in Figure 2 to verify:

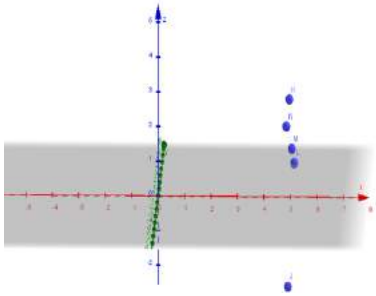

Figure 1: Graphed points

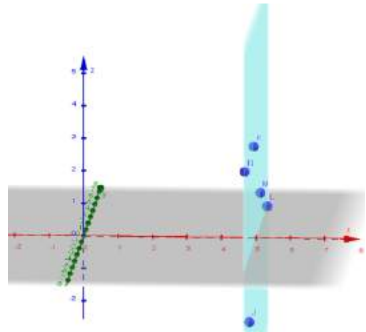

Figure 2: Plane (5, y, z)

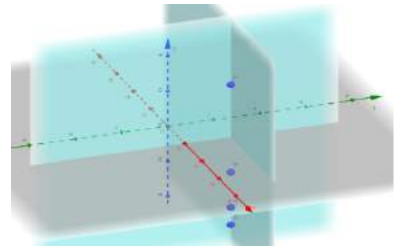

Figure 3: Planes (2, y, z) y (x, 2, z)

Subsequently, the student was asked to mention four triads in which the first and second coordinates were fixed and the third varied, those points were graphed in GeoGebra and Elías was able to visualize that they were "on top of each other", that is "there is only one line left" and there could be two planes - (2, y, z) and (x, 2, z) - that could go through that line (Figure 3).

Results.

In the group stage of the experiment, students were able to have a first adequate approach to three-dimensional space, this was observed qualitatively from the variational management they gave to triads with different signs, placing them correctly in one of the eight octants of space, and by making sense of the "new" axis, the Z axis. In addition, although the manipulative was only used at the beginning to determine the orientation and the octants, in the interview the student Elías used it and expressed that this model made it easier for him to locate the triads, that is, it allowed him to better organize his thoughts. We saw this reflected at different times: when he identified each graphed plane and related them to their corresponding triads; when he was asked to mention five triads where only the first one was fixed and the other two varied, managing to visualize the plane in which they were located; and finally, when he chose different triads, with the first two coordinates fixed and varying the third, to visualize the intersection of two planes that form in them, and these, in their role as a figural device led him to also identify the line generated with those triads. Achieving an approximation to the transparency of the particularly chosen triads.

IMAGINACIÓN ESPACIAL PARA TRABAJAR OBJETOS EN EL ESPACIO 3D USANDO UN DISPOSITIVO FIGURAL

SPATIAL IMAGINATION TO WORK ON 3D SPACE USING A FIGURAL DEVICE

Actualmente en las escuelas no se desarrolla explícitamente la imaginación espacial, esta será necesaria para interpretar objetos 3D que se representan en 2D. Para desarrollar la habilidad de la imaginación espacial en 3D es necesario considerar la ubicación espacial y la posición relativa entre objetos. Relacionar conjuntos de puntos con variaciones adecuadas de triadas del tipo (x, y, z) promueve esta habilidad. En esta investigación en curso, la variación numérica de las entradas asociadas a los objetos gráficos proporciona indicadores de ubicación y posición relativa de puntos, rectas o planos a los estudiantes de bachillerato. Encontramos que la variación numérica selectiva apoya el desarrollo de la imaginación espacial, cuyo uso reiterado tiende a formar un hábito en la orientación, el que debe ser trabajado para convertirse en transparente.

Palabras clave: Geometría y Pensamiento Geométrico y Espacial

De acuerdo con investigaciones relacionadas con el análisis de programas de estudio y libros de texto de nivel medio superior y superior, para el estudio de temas como el relativo a los espacios vectoriales no se considera necesaria una introducción explícita al desarrollo de la imaginación espacial, lo que luego es una desventaja en la interpretación gráfica. Sin embargo, en dichos programas hay un enfoque gráfico que pretende ser resuelto a través de la relación punto gráfico-pareja ordenada, que no parece ser suficiente para el tipo de tareas que se proponen. Al mismo tiempo las representaciones 3D son escasas y no se atienden las problemáticas asociadas a la interpretación porque son usadas como una ilustración y no como un objeto matemático, por lo que los estudiantes no tienen oportunidad de ir más allá de una educación formalista que enfatiza el tratamiento algebraico, debido a que no cuentan con representaciones gráficas (Van Dormolen, 1986).

Por otro lado, los estudiantes manifiestan una propensión natural a identificar con más facilidad unas direcciones sobre otras en tareas de la interpretación gráfica en el caso de gráficas en representaciones de espacios 3D, lo que contribuye a desorientar al estudiante en tareas de imaginación espacial (Cohen, 2001). Otras fuentes de conflicto se presentan en la interpretación de la perspectiva debido, entre otras cosas, a que debemos reorganizar la información para entender que esta interpretación está presente y que la representación gráfica se supedita a ella, es decir "ver y saber" son dos cosas distintas al decir de Parzysz (1988). También puede ser un obstáculo la preferencia para identificar unas rectas o conjuntos de ellas de manera general si no hay una instrucción ex profeso para determinar su orientación (Bakó, 2003).

De manera que la interpretación de la perspectiva o profundidad 3D en un plano es un trabajo en el que se debe decodificar la información visual, desde nuestro punto de vista es necesario contar con indicadores que orienten la imaginación espacial para llevar a cabo un tratamiento adecuado de los objetos gráficos en 3D.

Algunas propuestas de aprendizaje para trabajar con el espacio 3D ligan las propiedades figurales del dibujo con sus características matemáticas a través del uso de proyecciones ortogonales, las cuales tienen un fundamento constructivo y prescriptivo, el que es organizado a través del paralelismo y la perpendicularidad (Parzysz, 1988), lo que avanza en la dirección de establecer indicadores espaciales a los estudiantes para mejorar su imaginación espacial. Por ello, consideramos de gran importancia proporcionar dichos indicadores que orienten a los estudiantes para la interpretación del espacio 3D en términos de ubicar la posición de puntos así como de conjuntos de ellos en sus posiciones relativas.

Marco Teórico

En el aprendizaje de la matemática, el uso de los signos como instrumentos semióticos (Vigotsky, 1981a) que permitan mediar el conocimiento proporciona condiciones adecuadas para que los estudiantes desarrollen una práctica reflexiva (Radford, 2006, 2012); por ello, es importante asociar las ideas matemáticas como la gráfica en términos de una práctica que hace uso de instrumentos semióticos, en particular cuando establecemos relaciones entre los objetos algebraicos y los gráficos para integrar en un solo cuerpo de conocimiento la interpretación de la gráfica 3D, como en el caso que nos ocupa.

Por otro lado, los objetos matemáticos como la gráfica tienen un carácter visual y abstracto, por lo que puede ser considerada como un concepto figural (Fischbein, 1993), objetos matemáticos que pueden ser pensados en un doble estatus, como objetos y como conceptos. En particular, los objetos geométricos son conceptos figurales, ya que reflejan propiedades espaciales (forma, posición, magnitud) y al mismo tiempo, poseen cualidades conceptuales como idealidad, abstracción, generalidad, perfección, entre otras (Fischbein, 1993), y al parecer este también es el caso de las gráficas.

En tanto que las propiedades figurales son ostensivas, esto es "están frente a los ojos", nos permiten diferenciar su ubicación y su posición relativa, además de que su posición es la única propiedad de los objetos gráficos, debido a que son representados en espacios de representación homogéneos donde la única cualidad es su posición (Nemirovsky, 2001). Estamos en condiciones de apoyarnos en estas propiedades para desarrollar la imaginación espacial, que en nuestro caso incluye tanto la habilidad para localizar los puntos, así como la de establecer la posición relativa entre objetos gráficos que incluyen puntos, rectas y planos.

Con el objeto de establecer indicadores espaciales para la imaginación espacial, estaremos haciendo uso de un tratamiento sobre la posición de puntos del tipo (x, y, z) que mediante la variación numérica de sus coordenadas nos describen puntos y conjuntos de puntos asociados como puntos, rectas y planos, los cuales según sea la situación toman dicho papel de indicadores espaciales. Usadas así las triadas se transforman en signos que asocian propiedades de descripción algebraica y de posición espacial, lo que las convierte en lo que hemos dado en llamar un dispositivo figural cuando es usado con este doble propósito. Además de que, por su naturaleza perceptual, su uso reiterado permitiría a los estudiantes desarrollar hábitos de pensamiento (Cuoco, Goldenberg y Mark, 1996) hasta adquirir una forma de transparencia (Roth, 2003) en la localización y la posición relativa de ellos.

A continuación, proponemos las que son nuestras hipótesis de investigación:

1. La imaginación espacial puede ser desarrollada por aproximaciones posicionales mediante la variación numérica de la triada (x, y, z) asociada a los puntos que pueden describir rectas y planos, así como pueden establecer su posición relativa.

2. La adquisición de hábitos de pensamiento juega un papel central en la adquisición de la habilidad de imaginación espacial si se asocia la variación de las triadas con la posición de los objetos descritos.

Metodología

En particular, en el caso de la interpretación visual del espacio tridimensional, es posible hacer uso de cierto tipo de dispositivos figurales cuando usamos la triada (x, y, z) que tiene su origen en la representación de los puntos en el espacio tridimensional. Con base en sus propiedades de posición exploramos la relación entre cada coordenada de la triada (x, y, z) y las de los puntos sobre el espacio.

La actividad desarrollada establece que cada una de las coordenadas se refiere a una orientación específica en el espacio, lo que permite hacer constantes algunos de los valores de las coordenadas para variar uno o dos de ellos o variar los tres. Esto permite asociar la coordenada con la posición relativa de los puntos y conjuntos de puntos, usando a los ejes como referencia de orientación.

Procedimos con dos entornos distintos para la localización de puntos y conjuntos de puntos. Por un lado, en un entorno físico hicimos uso de un manipulable (Godino, 1998) para la representación realista del espacio 3D, donde usamos un modelo formado por tres láminas de plástico ligeramente transparente, de diferentes colores, ensambladas de tal forma que representaban los ocho octantes, las uniones de cada lámina formaban los ejes del espacio. Para el segundo entorno se usaron representaciones gráficas en GeoGebra.

El procedimiento desarrollado se basó en establecer una relación de localización apoyada en la variación numérica en las coordenadas de la triada (x, y, z), preguntando por el punto o conjunto de puntos que eran descritos a partir de las variaciones hechas y de las coordenadas con valores constantes en los dos entornos.

Puesta En Marcha.

La puesta en marcha de esta investigación se llevó a cabo en dos grupos de sexto semestre de bachillerato: el grupo A, conformado por 20 estudiantes y el grupo B, conformado por 36, todos ellos de 17 y 18 años y ninguno con noción del espacio 3D. Se les dio una clase donde se les introdujo al espacio tridimensional, explicando conceptos y ubicando triadas en diferentes octantes. Después de esto, hicimos un estudio de caso con el estudiante Elías del grupo B, le hicimos una entrevista de seguimiento que describimos a continuación.

Primera fase: modelo físico y localización de zonas asociadas a los signos. Se trató de un recordatorio del significado posicional que puede adquirir la triada como en los casos en que los puntos tienen los siguientes signos: a) (±, -, ±) b) (+, +, +) c) (+, -, ±) d) (-, +, ±) e) (+, ±, ±) f) (-, -, -). El trabajo se acompañó de la comparación de la ubicación de la triada que Elías hizo primero en sus hojas de trabajo variando las posibilidades de orientación dependiendo de los signos. También se le pidieron sugerencias sobre puntos con propiedades específicas.

Segunda aproximación: Variaciones. Las investigadoras procedimos a hacer variaciones, en primer lugar, fijamos una coordenada permitiendo la variación en las dos posiciones restantes, de manera que los conjuntos de puntos descritos formaron planos para reflexionar en las propiedades de las rectas formadas por los cruces de planos paralelos y perpendiculares en esta etapa, en particular con los planos canónicos. Luego fijamos un par de coordenadas permitiendo la variación de la posición faltante, de manera que los conjuntos de puntos descritos ahora formaron rectas paralelas a alguno de los ejes como en los casos de (-1, 2, z), (1, y, 3) o (x, 2, -1), entre otros; los conjuntos fueron ubicados en el espacio proporcionado por GeoGebra.

Presentamos un extracto de la entrevista con Elías que a las investigadoras nos permitió ver el uso de la triada como concepto figural en el caso de la variación de dos coordenadas con la otra fija; le pedimos que mencionara 5 triadas en las que la primera coordenada tuvieran el mismo valor y la segunda y la tercera variaran, se graficaron esos puntos en el software (Figura 1) y se le preguntó:

INV: ¿Qué observas de estos puntos? (Figura 1)
Elías: Ahora todos están uno frente a otro.
INV: ¿Estarían sobre algún plano? ¿Todos los puntos estarían adentro de esto? (señala la región de los puntos)
Elías: ¿Del plano? Sí.
INV: ¿Qué plano sería?
Elías: Sería (5, y, z)

Luego de que Elías dijo (5, y, z), se graficó el plano como en la Figura 2 para comprobar:

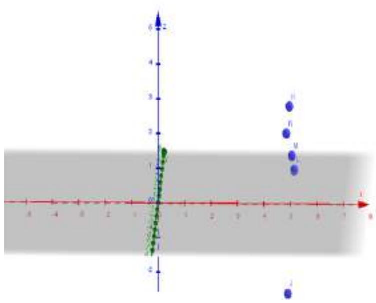

Figura 1: Puntos graficados

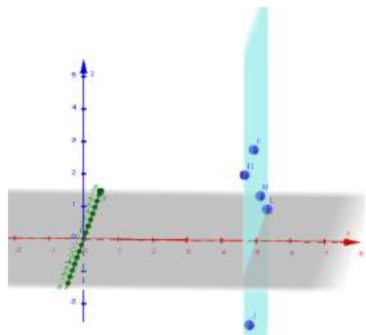

Figura 2: Plano (5, y ,z)

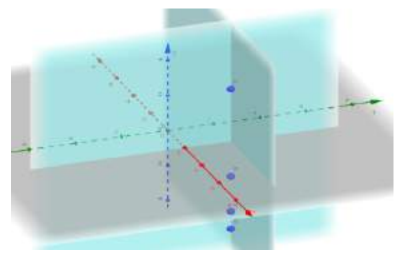

Figura 3: Planos (2, y, z) y (x, 2, z)

Posteriormente, se le pidió al estudiante que mencionara cuatro triadas en las que la primera y la segunda coordenadas fueran fijas y la tercera variara, se graficaron esos puntos en GeoGebra y Elías pudo visualizar que estaban "uno encima del otro", es decir que "queda una línea nada más" y que podrían ser dos planos - (2, y, z) y (x, 2, z) - los que podían pasar por esa línea (Figura 3).

Resultados.

En la etapa grupal del experimento se logró que los estudiantes tuvieran un primer acercamiento adecuado al espacio tridimensional, esto se observó de forma cualitativa a partir del manejo variacional que le daban a las triadas con diferentes signos ubicándolas correctamente en alguno de los ocho octantes del espacio y al darle sentido al "nuevo" eje, el eje Z. Además, aunque el manipulable sólo se usó al inicio para determinar la orientación y los octantes, en la entrevista el estudiante Elías hizo uso de él y expresó que este modelo le facilitaba ubicar las triadas, es decir, le permitía una mejor organización de sus pensamientos. Lo cual vimos reflejado en diferentes momentos: cuando identificó cada plano graficado y los relacionó con sus triadas correspondientes; cuando se le pidió que mencionara cinco triadas donde solo la primera quedara fija y variaran las otras dos, logrando visualizar el plano en el que se encontraban; y finalmente, cuando escogió diferentes triadas con las dos primeras coordenadas fijas y variando la tercera, para visualizar la intersección de dos planos que se forman en ellas, y estos en su papel de dispositivo figural propiciaron que también identificara la recta generada con esas triadas. Logrando una aproximación a la transparencia de las triadas elegidas particularmente.

ENHANCING SPATIAL ABILITIES THROUGH EXPOSER TO COMPUTER-AID DESIGN PROGRAMS

Ashley M. Williams
Texas A&M University
amcraft91@tamu.edu

Robert M. Capraro
Texas A&M University
rcapraro@tamu.edu

Spatial ability is important in the learning and understanding of mathematics and has been recognized as an indicator of mathematics achievement and STEM success. The present study aims to investigate how experiences with computer-aid design programs can enhance student's spatial ability measured by mental rotation skills. Quantitative data were collected before and after intervention using the redrawn Vandenburg and Kuse Mental Rotation Test by Peters et al. (1995). A paired sample t-test and 95% confidence intervals indicated a statistically significant difference between observed pre and post test scores. The calculated Cohen's d effect size of 0.63 indicated the CAD intervention had a positive impact on students' mental rotation skills. It can be concluded that utilizing these technologies can aid in developing and improving spatial abilities which can lead to improved mathematics achievement and STEM success.

Keywords: Spatial Thinking, STEM, Teaching Tools, Technology

Introduction and Literature Review

Improving mathematics science, technology, engineering and mathematics (STEM) success is a very relevant issues in research and education. Spatial ability has been recognized as a predictor of adult success in STEM areas across several longitudinal studies that followed a large population of both normative and intellectually gifted individuals from adolescence to adulthood (Shea, Lubinski, & Benbow, 2001; Wai, Lubinski, & Benbow, 2009). In addition, researchers have found that spatial ability provides validity to mathematical and verbal reasoning abilities yet in education there is little emphasis on the development of spatial abilities (Basham & Kotrlik, 2008). Psychologists and education researchers have been interested in the connection between spatial ability and mathematics achievement since the mid-1900's (Bishop, 1980) and prior research has supported this link (e.g. Carr et al., 2019; Casey, Nuttal, & Perzris, 1997; Ganley & Vasilyeva, 2011; Gilligan, Flouri, & Farran, 2017; Hawes, Moss, Caswell, Seo, & Ansari, 2019; Rabab'h & Veloo, 2015; Rutherford, Karamarkovick, & Lee, 2018; Verdine et al., 2014). Despite the acknowledgement and confirmation of the connections between spatial ability and STEM success, specifically mathematics achievement, there is little research on the development of spatial abilities. In the current study, researchers investigated how the implementation of computer-aided design software and 3D printing class with adolescents is associated to growth in spatial ability measured via mental rotation skills.

Mental Rotation. Spatial ability is often organized into three categories: (1) spatial perception, (2) spatial visualization, and (3) mental rotation (Linn & Peterson, 2004). All three categories are important for learning and understanding of mathematics and can improve students' problem solving and reasoning skills. In the current study mental rotation is measured as an indicator of spatial ability.

Mental rotation of objects is a fundamental spatial ability that affects several aspects of life. Mental rotation is primarily associated with the skill to mentally rotate images or objects into particular orientations. The ability to mentally rotate objects includes the visual inspection and mental simulation of the object's rotation in space (Hegarty & Waller, 2005). Mental rotation ability is important for success in several academic and career fields, especially the science, technology, engineering, and mathematics (STEM) domains (Károlyi, 2013). Mental rotation skills are utilized in performing many everyday tasks such as rearranging furniture, packing the car trunk, navigating a map, and parking a car, among many other examples academic and job tasks in non-STEM careers.

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

Mental rotation is especially useful in several career areas (e.g. architecture, industrial design, engineering, sculpting, surgery, kinesiology, dentistry, and aviation). Interventions and activities that develop and improve mental rotation skills could lead to increased success in STEM and related domains. Computer-aided design (CAD) programs and 3D printing activities is an excellent way to utilize advanced technologies to develop and improve students' spatial abilities.

CAD Programs. Computer-aided design programs are utilized to create detailed three-dimensional models and two-dimensional drawings. Computer-aided design programs are most commonly used by engineers for drafting, designing, and developing diverse and complex machinery components (Sharma & Dumpala, 2015). They are also widely used by designers due to its ability to offer the creation of intricate designs (Martin & Velay, 2012) in a way that is more accessible to others. Computer-aided design programs and manufacturing tools, such as 3D printers, are ever-present in current product commercialization environment and students entering this environment need to be practiced in using such tools (Johnson & So, 2015). The utilization of CAD programs in 3D printing and design classes showed positive influences on student's mathematics skills, real-life skills, interests and motivation (Kwon, 2017). There are several types of CAD programs on the market such as *TinkerCAD*, *SketchUp*, *SolidWorks*, and *AutoCAD*, all of which are used create 2-dementional renderings of 3-dementional designs.

CAD and Mental Rotation. Spatial ability and mental rotation in children are often neglected in early education but can be promoted through experiences with three-dimensional modeling programs (Matthews & Geist, 2002). Students' mental rotation has been identified as a predictor of success in STEM domains and computer-aided design (CAD) programs have overcome barriers to spatial expression (Chang, 2014) that has been an essential tool in engineering education (Chester, 2007). Mental rotation skills could be developed and improved through the use of certain technologies (e.g. CAD software and 3D printing) which can lead to improved mathematics achievement and STEM success.

Methodology

In the present study a quasi-experimental study was conducted to explore the relationship between the utilization of CAD programs and students' mental rotation skills. To determine how the implication and use of CAD programs in a classroom influenced student's mental rotation skills, data were collected during a week-long CAD intervention. The current study was guided by the following research question: How will student's mental rotation skills be influenced after experiences and utilizing computer-aid design programs in a 3D printing class?

Participants. The sample was comprised of 1 middle school student and 24 high school students who attended a one-week STEM summer camp at a research-intensive university. The ethnic backgrounds of the sample included 15 Caucasians (60%), 7 Hispanics (28%), 1 African Americans (4%), and 2 whom did not disclose ethnicity (8%). The sample is comparable to the United States population with a noted difference that African Americans were slightly underrepresented in the sample. The sample included 5 females (20%) and 20 males (80%), females were underrepresented in the sample regardless of the level of comparison.

Instrument. The *Mental Rotations Test* was used to assess participants mental rotation skills (Peters et al., 1995) and adaptation of the original paper and pencil *Mental Rotations Test* by Vandenberg and Kuse (1978). The test contained 24 items with five 3D drawings of cubical figures per item. Each item contained one target figure on the left and four answer choices on the right. The participants were to identify which two of the answer choices were identical to the target but rotated along the y axis. The two other answers were mirror-images of the target and thus could not become identical to the target by rotation. The test was given in two parts, the participants were given three minutes to complete the first 12 questions, a two-minute break, and three minutes to complete the remaining 12 questions. Two undergraduate students recorded participants answers into an excel spreadsheet which was then checked by a senior doctoral student. Recorded answers were then scored by the instructor. One point was given for each correct answer, and one point is subtracted for each incorrect answer yielding a maximum of 48 points. The internal consistency for this sample was measured using Cronbach's (1951) alpha coefficient; score reliability was high with a 0.84 for the pre-test and 0.89 for post-test. All participants were tested both before and after the intervention at the same time by the same test administrator and instructions.

CAD Programs Used for Instruction. In the present study two different 3D CAD programs (TinkerCAD and SketchUp) were introduced and utilized. These two CAD programs were chosen because they both are available free TinkerCAD, owned by Autodesk, is a free, online 3D modeling program that runs in a web browser and is known for its simple interface and ease of use. TinkerCAD allows users to start their designs with 3D geometric primitives (Avila & Bailey, 2016) that can be combined and manipulated. Geometric primitives are basic geometric shapes (e.g. sphere, cube, cylinder, pyramid) that can be assembled with others to construct more complex shapes (Boubekeur, Kaiser, & Ybanez Zepeda, 2019). Starting with these basic 3D shapes provides a much simpler mode to create complex shapes and objects. TinkerCAD provides an easy, early training ground to introduce solid modeling and 3D printing to a younger or less experienced students.

SketchUp, owned by Trimble Inc., is a 3D modeling computer program used for a variety of applications including but not limited to architectural, interior design, mechanical engineering, and video game design. SketchUp starts with 2D geometric primitives (e.g. point, line, plane, circle) and allows users to push or pull them into 3D objects (Avila & Bailey, 2016). SketchUp provides a platform for users to sketch and create 3D designs with much more creativity, precision, detail, and complexity than TinkerCAD. SketchUp could be considered an intermediate to advanced CAD program but is still user friendly and accessible. Several SketchUp packages are offered at different price points but a free web-based version is now available. The free version was used in the present study.

Intervention

During a one-week STEM summer camp participants were randomly assigned and placed in a 3D printing class. The class met for one and a half hours each day for one-week: Monday through Friday. The class was instructed and facilitated by a third year female Mathematics Education PhD student who had previous training in 3D printing and Sketch-Up. She also had two years of experience (two projects per school year) utilizing a 3D printer, TinkerCAD, and Sketch-Up in high school Geometry classes (on level and pre-AP). On the first day participants took the pre-test and listened to an introduction to 3D printing, the engineer design process, and were given guidelines for the first project *Make your own Trophy* (see Table 10. They created TinkerCAD accounts, explored the software, and created their trophy. Day two the instructor introduced SketchUp and guided participants through how to use the available tools. They then received three open-ended final projects to choose from.

Table 1: Project descriptions

Project Title	Description
Make your own trophy	Create an award for yourself to receive at the end of the camp that is less than 5"x5"x5", has your name, and consist of at least 10 shapes.
Fusion of Art and Function	Design and create something that is both fun/interesting to look at and is functional.

Project Title	Description
Historical Structure	Choose and replicate any historical structure of your choice.
Product Prototype	Invent the next big thing; design and create a prototype of a brand-new product.

For the final project participants were given the option to work in TinkerCAD or SketchUp; which required participants to self-assess their skill level and choose a platform for which they were comfortable using. It was unknown to the instructor what prior knowledge, skills, and/or experiences participants would have entering the class, therefore a beginner program and an intermediate/advanced program were offered so participants of various skill levels would remain actively engaged by attempting to avoid disengagement caused by frustration, boredom of a steep learning curve of the CAD program. Only two participants chose to work in SketchUp. Day three and four were project workdays where the participants worked independently on their final projects. During this independent work time their trophies were being printed and participants were taken in small groups to the 3D printer room to see them in action. The instructor provided them with additional information about the printer and printing procedures then answered any questions they had. On the fifth day participants finished their final project and shared their design.

Data Analyses

Quantitative data were collected pre and post intervention to assess participants mental rotation skills using the Mental Rotations Test - Form A (Peters et al., 1995). First, data were analyzed using a paired sample *t*-test to investigate the statistical differences between mental rotation skills before and after the intervention. Prior to conducting the paired sample *t*-test, Q-Q plots and box plots of the pre-test and post-test scores were analyzed to assess score distribution and check for outliers. Second, to provide a visual representation of the results, 95% confidence intervals (CIs) for the pre and post test scores were examined. The 95% CI indicates that if the study was conducted an infinite number of times, the calculated point estimate would be captured 95% of the time. Using 95% CIs provides a visual depiction of the preciseness of the estimate and a direct comparison model for other similar studies (Thompson, 2002). Finally, Cohen's *d* effect size estimates were computed to quantify the magnitude of the difference between pre and post test scores. Due to the small sample size of the present study *t*-test results may be skewed therefore effect size is more suitable for the given data. Effect size indices are valuable in quantifying the effectiveness of an intervention because they are unitless, making them comparable across studies, and do not depend on sample size (Sullivan & Feinn, 2012). Reporting effect size is an important practice in order to report and interpret results in a trustworthy way that is usable for scholars and practitioners (Thompson, 1999a). In addition, reporting effect sizes, even for results that are not statistically significant, aids in compelling researcher to think meta-analytically and provides grist to possible future meta-analyses (Cumming & Finch, 2001; Thompson, 1999b; Thompson, 2001). Statistical package SPSS 25 was used in the aforementioned data analyses.

Overall, the results indicated that mental rotation skills, as measured by the instrument, were improved by the CAD intervention. No class time was spent on reviewing mental rotations or practicing with similar diagrams. Therefore, direct instruction in the concept is not a potential threat to validity.

GEOMETRY AND MEASUREMENT:

POSTER PRESENTATIONS

"A SQUARE IS NOT LONG ENOUGH TO BE A RECTANGLE": EXPLORING PROSPECTIVE ELEMENTARY TEACHERS' CONCEPTIONS OF QUADRILATERALS

Pavneet Kaur Bharaj
Indiana University
pkbharaj@iu.edu

Dionne Cross Francis
Indiana University
dicross@indiana.edu

Keywords: Geometry and Geometrical Thinking; Teacher Education – Preservice; Teacher Knowledge; Instructional activities and practices

Developing knowledge of the characteristics and properties of two- and three- dimensional geometric shapes are considered key content for elementary-aged students to learn. Quadrilaterals, one of the conceptually complex topics in geometry, have a range of attributes such as side length, angle measure, relationships between opposite/adjacent angles/sides, length and bisection of diagonals, etc. Previous research corroborated that transitioning from the introductory information about attributes of these shapes to mentally manipulating and proving the properties is challenging. Many teachers across elementary through senior grades, struggle with geometry content, and consequently, so do their students (Bhagat & Chang, 2015). Research reports that prospective teachers have difficulty in identifying specific shape types based on properties, rather than visual recognition (Burger & Shaughnessy, 1986) and struggle to determine other properties or define the relationships between various quadrilaterals. Drawing on Tall and Vinner's (1981) description of concept-image and concept definition, this study aims to add to the existing literature by answering the research question: *What conceptions do prospective elementary mathematics teachers have of the attributes of the family of quadrilaterals?*

The participants in this study were 19 prospective elementary teachers (2 male and 17 female) between 17-24 years of age enrolled in a content course designed to support knowledge of geometry and measurement in the elementary curriculum using a problem-solving approach. Data sources include the PSTs responses on a 26-item (15 closed and 11 open-ended) geometry tests. Findings showed that PSTs reasonings seemed to be fixed towards certain images rather than mental manipulation of the attributes and concept definitions (Vinner, 1991). For instance, PSTs considered rectangle as a figure with two long parallel sides and two shorter parallel sides and four 90° angles, while defined parallelogram as a slanted shape. PSTs tended to over-generalize the attributes of certain common quadrilaterals showing a continuous exposure to a geometrical shape in specific orientation (e.g., square having a horizontal base). While responding to the question, 'do the diagonals of kite bisect each other?', most of the PSTs responded incorrectly having generalized the properties of the diagonals of a square, rectangle, and rhombus.

The results of this study highlight the importance of emphasizing the two-way interaction between concept image and concept definition by explicitly showing interactions between theoretical and practical application of the learned ideas. Creating the definitions of quadrilaterals based on understanding of attributes (Fujita & Jones, 2007; Usiskin & Griffin, 2008), and exploring the inclusive relationship between various quadrilaterals (Fujita, 2012) may support PSTs in developing conceptions using non-prototypical examples. In this regard, time, high-quality tasks, and appropriate scaffolding are essential to strengthening understanding of quadrilaterals specifically, and geometric concepts more broadly.

Brent Davis
University of Calgary
kfrancis@ucalgary.ca

This poster describes how programming robots might support both the development of spatial reasoning and growth in mathematical understanding using interpretive video analysis of two Grade 4 students' attempts to program their robot to follow a pentagon.

Theoretical Perspective. We argue that programming robots to move could lead to growth in mathematical understanding and contribute to developing spatial reasoning. We draw on Pirie and Kieren's (PK) (1994) model of growth in mathematical understanding which describes modes of engagement with mathematical concepts as seven distinct levels with increasing abstraction. We suspect that spatial reasoning is essential to all modes, but that it is especially relevant to the first three elements (*primitive knowing*, *image making*, and *image having*).

"[S]patial reasoning … refers to the ability to recognize and (mentally) manipulate the spatial properties of objects and the spatial relations among objects" (Bruce et al., 2017, p. 147). Davis et al. (2015, p. 141) attempted to collect the many competencies and habits associated with spatial reasoning into a model that represents the emergent complexity of spatial reasoning skills as co-evolved and complementary nature of the mental and physical actions.

Research Question. We questioned how programming robots might provide children with opportunities to gain mathematical understanding and develop spatial reasoning.

Data Collection Techniques and Analyses. Consistent with Knoblauch et al.'s (2013) notions of interpretive video analysis, we reviewed and selected one video based on instances of observable spatial engagement from 9 months of weekly videos collected of 32 Grade 4 students in 2 classrooms. In this video, a pair of students is attempting to program an EV3 LEGO Mindstorm robot to trace the third vertex of a pentagon having previous success following the first two straight-turn segments. We identified spatial elements in the two students' interactions according to Davis et al.'s (2015) framework while they engaged in determining how to steer their robot to travel around the 108^{o} vertex. We then analysed levels of mathematical understanding according to the PK model.

Summary of Findings. In this video one can observe the children working with many aspects of spatial reasoning and mathematical understanding. Drawing upon Davis et al.'s (2015) elements of spatial reasoning, the students were simultaneously INTERPRETING, [DE]CONSTRUCTING, MOVING, SITUATING, ALTERING and SENSATING. In the video, we observed the pair engage in how the distance the robot turns relates to the number of wheel rotations. The mathematical concepts included additive thinking, angles, properties of shape, measurement (distances, robot turns), multiplicative thinking (number of wheel rotations), pattern recognition, and direct proportion. Students' growth in understanding dynamically progressed between *primitive knowing*, *image making*, and *image having*. Our findings highlight how programming robots could support both the inner modes of PK's growth in mathematical understanding and contribute to developing spatial ability.

FUNKY PROTRACTORS CREATED BY PROSPECTIVE TEACHERS

Hamilton L. Hardison
Texas State University
HHardison@txstate.edu

Hwa Young Lee
Texas State University
hylee@txstate.edu

Keywords: Geometry and Geometrical and Spatial Thinking, Instructional Activities and Practices, Measurement, Teacher Knowledge

Angles and angle measure are important and frequently leveraged concepts throughout school mathematics curricula. Yet, relative to other quantities like length, area, and volume, very little scholarly literature addresses how students and teachers understand angle measure (Smith & Barrett, 2017). From the scant extant literature, it is clear that developing productive conceptions of angle measure is non-trivial for students and teachers alike (Akkoc, 2008; Lehrer, Jenkins, & Osana, 1998; Smith & Barrett, 2017). In the U.S., individuals' challenges in quantifying angularity may be partially attributed to instructional approaches that (a) overemphasize the use of conventional protractors to measure angles and (b) fail to address how the design of these conventional tools renders them appropriate for measuring angles (Moore, 2012). This is especially problematic given that well-prepared beginning teachers must be skilled in explaining how to select appropriate tools for particular mathematical goals (Association of Mathematics Teacher Educators, 2017).

To occasion conversation and reflection about angular measurement and protractors in our geometry courses for prospective teachers, we designed tasks involving a collection of non-standard tools that might be used to measure angles. We refer to these tools as *funky protractors* (Hardison & Lee, 2020a). For each funky protractor we designed, we altered one or more features to differentiate it from a conventional protractor (e.g., uncommon shape, equally spaced linear or angular intervals, non-standard angular unit of measure, etc.). We intentionally designed some funky protractors to be valid tools for measuring angles and others to be invalid; in previous implementations, we have asked prospective teachers to determine which funky protractors are valid tools for measuring angles and to justify their decisions. Thus, funky protractor tasks are the angular analogue of the "strange ruler" tasks others have used to promote critical thinking about linear measure (Dietiker, Gonulates, & Smith, 2011). Elsewhere, we have discussed prospective teachers' decisions regarding the validity of funky protractors, as well as the strategies they leveraged to support their decisions (Hardison & Lee, 2020b, this volume).

In this poster presentation, we report on an extension of the funky protractor tasks, which we implemented with prospective middle and secondary teachers enrolled in one section of a geometry content course at a large public university. After evaluating the validity of four funky protractors and engaging in a whole-class discussion, prospective teachers were asked to create two of their own funky protractors: one that would be a valid tool for measuring angles and one that would not be a valid tool for measuring angles. We present examples of the funky protractors that prospective teachers created and analyses of these items. In particular, we (a) summarize how successful prospective teachers were in creating valid and invalid tools for angular measurement, (b) describe the features prospective teachers manipulated when designing their own funky protractors, and (c) discuss prospective teachers' perspectives on the pedagogical utility of funky protractors.

GESTURES IN GEOMETRY: HOW DO GESTURES CONTRIBUTE TO ENGAGEMENT AND VOCABULARY ACQUISITION THROUGH GAME PLAY?

Keywords: Embodiment and Gesture; Geometry and Geometrical and Spatial Thinking; Instructional activities and practices

Gestures have been shown to improve students' abilities to process new mathematics concepts (Goldin-Meadow et al., 2009) and reduce cognitive load (Ping & Goldin-Meadow, 2010). Producing gestures related to mathematical concepts have been shown to support reasoning as learners ground their understanding of math concepts in body-based movement (Walkington et al., 2014). Such findings show the affordances of gesturing to create meaningful representations in mathematics. However, less is known about how giving students the option to gesture in activities impacts engagement and vocabulary acquisition for geometry concepts.

We adapted a modified version of the game Taboo, designed for high-school geometry students (Carter, 2015), where players take turns being the hint-giver with 60 seconds to verbally describe geometry terms on cards (e.g., *intercept*, *parallelogram, function*). The hint-giver creatively describes each term, avoiding the taboo words (e.g., intercept: *cross, axis, graph*).

A pilot study was conducted to examine whether the option to gesture while playing Geometry Taboo may contribute to engagement, performance, and vocabulary acquisition for high school geometry students. The study took place in two tenth grade geometry classes. The first day, 25 participants completed a paper-and-pencil timed pretest that required matching the 25 terms from the Geometry Taboo cards with pictures. The second day, students played the game in small groups for two rounds consisting of each player in the group having one turn to describe as many geometry terms as possible to their group. One group was able to use *speech and gestures* to describe terms on the cards; the other group was restricted to *speech only* hints. The next day, students completed a mirroring posttest and online survey about their experience.

An ANCOVA, controlling for pretest performance revealed no significant differences in posttest scores by condition but overall students improved slightly from pretest (M = .34, SD = .19) to posttest (M = .48, SD =.23). Next, an ANCOVA predicting total points earned by each student during the game, controlling for pretest found no significant differences but there was a trend that students in the *speech-and-gesture* condition (M = 8.2 points, SD = 4.2) scored more points than students in the *speech-only* condition (M = 6.0 points, SD = 2.9), p = .08. This suggests that the option to gesture may make describing terms easier rather than relying on speech alone. Surveys suggested largely positive perceptions of the game; 21 students responded that they would like to play again in class.

We draw limited conclusions from this pilot study. The exposure to the intervention may have been insufficient; more time playing could have led to increased learning. However, differences in game performance and student input suggest that the option to gesture makes the game easier and accessible for students, which in turn, could impact engagement and learning.

NAVIGATING COMPLEXITIES IN DEFINITIONS OF LENGTH AND AREA

Eryn M. Stehr
Georgia Southern University
estehr@georgiasouthern.edu

Jia He
Augusta University
jhe@augusta.edu

Deficiencies in elementary students' conceptual understanding of spatial measurement have persisted, emerging through educational research (e.g., Kamii & Kysh, 2006) and national assessments (e.g., National Assessment of Educational Progress [NAEP]). Investigating several decades of results from the NAEP, Kloosterman, Rutledge, and Kenney (2009) described persistent measurement deficiencies. Research suggests that elementary students struggle with conceptual understanding of spatial measurement (i.e., length, area, volume) and graduating preservice teachers (PSTs) often share their struggles. For example, elementary students struggle in understanding distinctions between area and perimeter and relationships between their measures (e.g., Bamberger & Oberdorf, 2010; Barrett & Clements, 2003; Woodward & Byrd, 1983). The intuitive expectation that measures of perimeter and area always increase or decrease together is an enduring, commonly held misconception (e.g., Lappan, Fey, Fitzgerald, Friel, & Phillips, 1998; Tan Sisman & Aksu, 2016). PSTs, soon to be teaching such concepts, have shown similar misconceptions (e.g., Ma, 1999; Livy, Muir, & Maher, 2012; Wanner, 2019).

We examined definitions related to length and area measurement in 11 textbooks specifically developed for use with preservice elementary teachers in mathematics content courses. Our selection of the textbooks was guided by Raven (2006) and represents a wide range of textbooks that vary in organization, coverage of topics, and attention to pedagogy. The books are written by mathematicians, mathematics educators, or both.

Two researchers adapted and clarified an existing framework to code definitions of spatial measurement in elementary curricula with respect to selected aspects (Gilbertson, He, Satyam, Smith, & Stehr, 2016). We identify the coding unit, a definition, as a focused description of meaning, set apart from other text. We captured definitions of length and area using the textbook index and scanning relevant sections. Two researchers independently coded each definition and met to compare coding and resolve discrepancies.

Based on Stehr and He (2019), we used a four-step measurement process: (1) select an object and measurable attribute, (2) select a unit of measure, (3) compare the attribute of the object with the unit, and (4) express the measure. We provide our analytical frameworks and findings in the poster. In the first step of the measurement process, select an object and an attribute of that object to be measured. A measurable spatial attribute is a characteristic of an object that can be quantified, has dimensionality, takes up space, and often has clear boundaries. To select a unit of measure in the second step, note that the unit could be standard or nonstandard, a reproducible unit that tessellates space, using parts of a unit as needed, and may be be continuous or discrete. In the third and fourth steps, the measure of an attribute is expressed by comparing the attribute to the unit to determine the number of units and parts of units that cover or fill the space without leaving gaps or overlaps. The comparison may include procedural tool use. The final measure of an attribute is expressed as a multiple of the standard or nonstandard unit.

The goal in analyzing textbook definitions and finding variation is not necessarily to point out gaps or failings, because textbooks may add to definitions through tasks or other text. We focus attention on the ways definitions could be written at multiple levels of sophistication and with careful choice of aspects, hoping to open a larger discussion.

A RESEARCH APPROACH ON THE ROLE OF SPACE IN THE CONSTRUCTION OF CONIC SECTIONS

Luis Carlos Vargas-Zambrano
Cinvestav
luis.vargas@cinvestav.mx

Gisela Montiel-Espinosa
Cinvestav
gmontiele@cinvestav.mx

The results of a literature review of an ongoing research about the construction of the solid conic section and its transition to plane conic section are presented. The review was done in Mathematics Education and History of Geometry Teaching with a main emphasis on the construction of the solid conic as a cutting of the cone, these treatments of conics absent in the curriculum can give meaning to the current treatments of school mathematics. The review concludes with five essential elements that will define the type of study, the study object, and the position of our research in the field.

Keywords: Geometry and Geometrical and Spatial Thinking, High School Education.

The initial research object for the development of the literature review was *construction of the conic as a cone's cutting and its transition to the plane*. As a first point, one of the problems reported by Mathematics Education research is the absence of conic section's geometric treatments in High School Education, because the conic section's algebraic treatments is in Analytical Geometry class (Pérez-Moguel, 2018; Salinas & Pulido, 2017; Contreras, Contreras & García, 2003); nevertheless, the meanings of these notions are linked to the Plane and Space Geometry.

In this way, History of Geometry Teaching recognizes: school mathematics are based on the mathematics of the 17th century (Barbin, 2008; 2012; Dennis, 2009); in particular, the solid conic section's construction isn't since 1905 in the curriculum (Barbin, 2012; 2008), and it's replaced by a narrative about the cuttings of a cone made by Apollonius of Perga (Fried, 2007; 2001), and then to define them on the plane from the foci and directrix (as the case may be), without any link to the Apollonius' cuttings (Salinas & Pulido, 2017). Indeed a second point, we identify conics as "a perennial notion with many properties, many theories and contexts, geometric and algebraic approaches, relations between plane geometry and space" (Barbin, 2008, p. 157); therefore, we synthesize the chronology of the study and development of this notion: *Solid Conic Section; Plane Conic Section; Analytical Conic Section* (Coolidge, 1968; Bartolini Bussi, 2005; Bongiovanni, 2007).

As a third and more important point, the research of Pérez-Moguel (2018) will be a fundamental antecedent because her historical-epistemological study of parabola's geometrical construction as a cone's section, she identifies a series of *actions* and *activities* that encourage us to ask ourselves about the practices associated to construction of the solid conic section and its passage to plane conic section. Among these actions, Pérez-Moguel (2018) highlights the transition between 3D and 2D dimensions in solid parabola's construction, coinciding with Salinas and Pulido (2017) who consider that spatial ability is fundamental in the construction of solid conic sections. Therefore the new object of investigation, modified after the review will be: *spatial processes, and practices associated to solid conic section's geometrical construction relative to the cone's cutting, and its transition to the plane conic section,* in the original text *Apollonius of Perga: Conics*.

We investigated how 53 elementary teachers interpreted the impact of the contexts in which they work on their mathematics instruction, and what those interpretations reveal about the agency individual teachers were able to achieve. Latent class analysis revealed two distinct classes, with teachers in one class perceiving that their contexts had a greater and more supportive impact than teachers in the other class. Interviews of four elementary mathematics specialists then revealed that the extent to which agency was achieved depended on not only their evaluations of the constraints and affordances of their contexts, but also their past experiences and future goals.

Keywords: teacher agency; policy; elementary mathematics specialists; latent class analysis

Although decades of policy have sought to limit teacher agency through, for example, highly prescriptive curriculum and accountability regimes (e.g., Biesta, 2010), discourses in mathematics education have emphasized how teachers exert agency in their specific enactments of broader policy (National Research Council, 1997; OECD, 2005). Theories of agency suggest that mathematics teachers have always interpreted and responded to policies, even those designed to limit agency, based on their experiences and frames of references (e.g., O'Day, 2002; Osborne et al., 1997; Zancanella, 1992). Discourses focused on agency, however, raise questions about what it might mean for teachers to be agents and the extent to which teachers can achieve agency. In this paper, we share a mixed methods study that investigates how elementary mathematics teachers achieve agency in their unique contexts. In particular, we focus on how elementary teachers interpret the impact of the contexts in which they work on their mathematics instruction and what those interpretations reveal about the agency they are able to achieve.

Theoretical Framings & Related Literature

We view agency as a temporal process informed by the past (iterational dimension), oriented towards the future (projective dimension), and achieved in the present (practical-evaluative dimension) (Emirbayer & Mische, 1998). In other words, teachers build upon past experiences and understandings to refashion and appropriate patterns of behaviors. Motivated to create a future that is different from the past and present, teachers generate possible trajectories of action. Although agency is tied to the past and future, it can only be achieved in the present as teachers make judgements based on evaluations of the constraints and affordances of their contexts. An implication is that, in response to present problems, teachers who are able to draw upon a greater repertoire of past experiences or form a wider range of alternative futures might achieve greater levels of agency (Priestley et al., 2015).

However, agency is not simply a quality of teachers; it is a dynamic interplay between both individual efforts and ecological conditions (Biesta & Tedder, 2007). Carried out in concrete situations, agency is achieved as teachers engage with their ecological contexts. Teachers may

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

achieve agency in one situation but not another, and that may depend on the availability of social, cultural and economic resources.

Prior studies on teacher agency have highlighted the importance of both teacher capacity and ecological capacity. Regarding the former, research suggests that teachers' experiences and beliefs play an important role in the achievement of agency (Sloan, 2006; Vähäsantanen, 2015). A wide range of past experiences may enhance agency by allowing teachers to see alternatives to the present, while strong beliefs about student learning enable teachers to develop a broader set of aspirations (Priestley, 2011; Priestley et al., 2012). In contrast, when teachers' discourses and goals are framed in terms of policy (e.g., meeting accountability expectations), projective elements of agency are reduced because teachers' potential to envision alternative futures is narrowly defined by the constraints of policy (Biesta et al., 2015).

Regarding the latter, research suggests that the ecological contexts in which teachers work influence the extent to which teachers are able to achieve agency. Teachers' evaluation of the professional obligations of their contexts may limit the actions they take towards projected goals (Priestley et al., 2012). For example, teachers working in contexts where standardized outcomes are highly valued may feel pressured to forgo ambitious instructional practices for those that are better suited for meeting accountability expectations (e.g., those focused on developing procedural fluency). However, access to ecological resources, such as professional relationships with administration and other teachers, may foster agency by supporting teachers to develop their practice, take risks, and see alternative futures (Coburn & Russell, 2008; Priestley et al., 2013).

Our study builds upon existing research by examining how elementary mathematics teachers - a group not yet investigated in the research on teacher agency - are able to achieve agency in their unique ecological contexts. We expand beyond the individual case study methodology commonly used in studies on teacher agency to also include quantitative analyses of surveys reporting the extent to which teachers evaluated their contexts as impacting their mathematics instruction. Specifically, we investigated the following questions: 1) how do elementary mathematics teachers interpret the impact of their ecological contexts on their mathematics instruction? and 2) what do different interpretations reveal about the agency individual teachers are able to achieve? Though the practical-evaluative (present) dimension is foregrounded, the judgments mathematics teachers make about the affordances and constraints of their contexts are influenced by the projective (the instructional goals teachers have for the future) and iterational dimensions (the past experiences they draw upon to achieve those goals).

Methods

Study Context

This study originates from a larger multi-year project focused on the beliefs, knowledge, practices, and student achievement for certified elementary mathematics specialists (EMSs) (McGatha et al., 2017). Among 55 participating teachers, there were 24 EMS and 31 comparison teachers that were recruited from the same schools (or districts) and same grade levels as the EMS teachers. A variety of data were collected for the larger project, including teacher surveys, measures of teacher knowledge, and observations of teachers' instructional practices. In addition, eight EMS teachers were selected as case study participants and each participated in five semi-structured interviews that were audio-recorded and transcribed.

Data & Participants

For the present study, we focused on a set of items from the teacher survey that asked participants about the impact of 14 items on their mathematics instruction. The 14 items were: 1) current state standards; 2) district curriculum frameworks; 3) district and/or school pacing guides; 4) state testing/accountability policies; 5) district testing/accountability policies; 6) textbook/program selection policies; 7) teacher evaluation policies; 8) students' motivation, interests, and effort in mathematics; 9) students' reading abilities; 10) community views on mathematics instruction; 11) parent expectations and involvement; 12) principal support; 13) time for you to plan; 14) time available for your professional development (see Figure 1 for survey directions). These items were completed by 53 teachers (23 EMS and 30 non-EMS). In addition, we analyzed the interviews of four case study EMS teachers: Amy, Denise, Emma, and Mary. Selection of the cases is further discussed in the Data Analysis section.

What is the extent of the impact of each of the following on your mathematics instruction?					Indicate the nature of the impact			
No impact (1)	Some impact (2)	Great impact (3)	Not applicable (4)	Don't know (5)	Mostly inhibits effective instruction (1)	Mostly supports effective instruction (2)	Both inhibits and supports effective instruction (3)	Not applicable (4)

Figure 1: Survey Directions

Amy and Denise taught at the same school in a district with five K-4 elementary schools. Part of the instructional day at this school included a math intervention time where students engaged in Rocket Math, a fluency program, with the stated goal of improving state standardized test scores. The district's curricular program was Math in Focus and teachers were provided a pacing guide that suggested how much time to spend on each topic.

Emma and Mary taught at different schools within a district that served 13 elementary schools. The district's curricular program was Go Math and, as in Amy and Denise's school, teachers were provided a suggested pacing guide. The district administration also encouraged teachers to engage students in weekly problem solving, though this was taken up by teachers in various ways, which will be further discussed in the cases of Emma and Mary.

Data Analysis

Using the 14 survey items described above, we employed latent class analysis (LCA) with the poLCA package in R (Linzer & Lewis, 2011) to identify groups of teachers who perceived different impacts of their ecological contexts (i.e., the 14 items) on their mathematics instruction. To create binary variables for LCA, we first created a holistic score for each item combining 'extent' and 'nature' of impact (e.g., great impact and mostly inhibits =1; great impact and mostly supports =5). Based on exploratory factor analysis, we consolidated the 14 items into 6 factors. These were named by their 'type': standards (items 1, 2), textbook/pacing guide (items 3, 6), accountability policies (items 4, 5, 7), students/community (items 8, 9, 10, 11), principal (item 12), and time (items 13, 14). To dichotomize each factor, we calculated the average score of the items and coded "supportive" (average > 3) as 2 and "inhibitive or mixed" as 1. Then we conducted the LCA analysis using the factor scores for each participant. After 100 iterations of 2-class and 3-class models, we selected the 2-class model because both the Bayesian information criterion (BIC) and the Akaike information criterion (AIC) were minimized (2-class: BIC = 422.575, AIC = 396.961; 3-class: BIC = 443.926, AIC = 404.520).

We selected two teachers from each latent class: Amy and Emma from the first class and Denise and Mary from the second class. As described earlier, Amy and Denise taught at the same school and Emma and Mary taught in the same district. These teachers were selected because they worked in similar ecological contexts and, comparing across the two classes, we were able to explore how they interpreted the impact of their contexts on their instruction differently and how those interpretations influenced their achievement of agency. These four teachers participated in five semi-structured interviews that elicited their vision and goals for teaching mathematics, supports available for and challenges anticipated in enacting that vision, the resources available for teaching (e.g, curriculum materials), the influence of state-mandated standardized assessments, and their understanding and implementation of mathematics teaching standards. Our analysis attended explicitly to how the iterational (e.g., prior experiences; understanding of math standards), projective (e.g., vision and goals for teaching) and practical-evaluative (e.g., resources, supports, and challenges for enacting vision; influence of standardized assessments) dimensions informed how each teacher was able to achieve agency.

Results

Classes of Impact on Mathematics Instruction

The LCA analysis revealed two distinct latent classes: SUPPORTED (Ecological Factors Supported Instruction) and MIXED (Ecological Factors Inhibited and Supported Instruction). Teachers in SUPPORTED (45% of teachers), on average, perceived that their ecological contexts had a greater and more supportive impact on their mathematics instruction than those in MIXED (55% of teachers). For example, teachers in MIXED had a 0% probability of reporting that accountability policies (state testing, district testing, and teacher evaluation) supported their mathematics instruction, compared to an 87% probability among teachers in SUPPORTED. The three factors that had the greatest difference in perceived support between the two classes are accountability policies, standards, and principal support. Figure 2 shows, for each class, the probability of a teacher reporting that a particular factor supported their mathematics instruction.

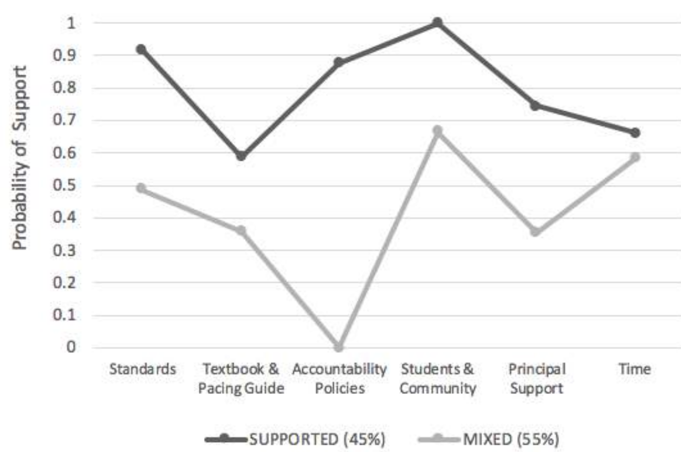

Figure 2: Conditional item probability plot for two classes

Cases of Amy and Denise (Same School)

Amy was an instructional coach for several years, and after completing an EMS program, returned to the classroom as a third-grade teacher. Illustrative of the SUPPORTED class, Amy conveyed little concern with regard to the district's accountability policies and pacing guide. For example, Amy perceived that the only stress regarding state testing was that "the computers didn't work the way they were supposed to." Amy's evaluation may explain why she did not use the test preparation materials like her partner teacher did:

> When my kids started doing that packet and I watched them, I'm like, "This is crap. I am not doing this. Stop…" The conversations were so much better than making them do 25 problems on their own. And my partner did it the traditional way…My principal is cool with

> it. He was like, "I don't want you to spend the whole month prep on it. They don't need it. They can think and that's the main thing."

This agentic activity - deciding not to engage students in test preparation materials - was supported by Amy's principal, who accepted her justification that her students were able to think and reason mathematically. Amy's decision to engage in mathematical conversations rather than practice problems also reflected her vision of mathematics instruction and her goals for student learning. Making specific references to the Standards for Mathematical Practice, Amy explained, "…it's so important for kids to be able to interchange numbers and to problem solve. And I think, honestly, the math practice standards are probably something that gets skipped over so much, and those are so important…Like taking a problem, making sense of it."

Drawing upon her goals and vision for mathematics learning, Amy was also able to achieve agency when she decided to devote extra time for Calendar Math in place of Rocket Math: "I kinda talked to my principal about it. I would like next year, instead of doing the Rocket Math, it's so very, it's a basic, it's a procedure, is what it is.…instead of doing Rocket Math with the group, I would like to teach Calendar [Math] to my second group. Because I add so much." Perceiving support from her principal, Amy saw Calendar Math as an alternative future to Rocket Math that better reflected her vision for instruction by developing a deeper understanding of mathematics concepts and providing students opportunities for reasoning and sense-making.

Amy's achievement of agency drew to a large degree upon her capacity to enact her goals for student learning and develop a wide repertoire for maneuvering her school context. In other words, she was able to draw upon her past experiences and imagine alternative futures to test preparation and Rocket Math. Supported by resources (e.g., the principal), and unconstrained by accountability policies, Amy was able to achieve a relatively great deal of agency.

At the same school as Amy, Denise taught fourth grade. The interviews took place during her fifth year of teaching. Illustrative of the MIXED class, Denise associated a great deal of stress and risk with the district pacing guide, which she described as constraining what and how she teaches: "I think it'd be more free on your pacing of how you teach and then you can do fun projects but it's like, 'oh, we can't do that cause it's gonna take a week to do that. And it's gonna put us behind,' and so to me I always feel like it goes back to that pacing guide." In this excerpt, Denise attended to how the pacing guide constrained her agency to engage her students in fun projects and hands-on activities. Such learning opportunities figured prominently in Denise's broader description of her vision for mathematics teaching and learning:

> I want them to have, to know the vocabulary, to be able to use it and just, and that just comes with understanding. I'd see like presenting the lesson but then we have our hands-on activity, like we're doing things together like as we're working though the lesson and understanding concepts, they're doing it with me or they have their boards and they're writing it out.

Unlike Amy, whose vision emphasized sense-making and engaging in mathematical practices, Denise viewed mathematics learning as participating in interactive activities to practice vocabulary and procedures after teacher demonstration.

Denise also felt pressured by state tests, stating "I think that's the pressure that's put on you to do well because that's what's reflected in the school on the state test." She saw students' standardized performance as reflecting on her performance as a teacher, which is a stark contrast to Amy who only described stress related to the computer testing system. Influenced by her evaluation of the pressures of her ecological context, Denise engaged in substantial test preparation, stating "I'll go back and like go lower so that way we can walk our way up but going back in that re-teach piece like a month - like with review, of course we review before the [state standardized] test but it's like being better about, okay, you did fractions last month, let's do like a bell ringer right now." In this, Denise describes that she prepares for the state test by reteaching previously taught content, sometimes starting at a "lower" level. She even wishes that she had more time throughout the year to spiral back on prior knowledge.

Denise acted similarly in response to students' lack of advancement in their Rocket Math fluency program. She said that:

> I pulled back from that [fluency] because it wasn't working. It's like for some of them - don't get me wrong. Like my lower kids though it wasn't working for them because it's like part of it they don't put in the work… it's like you get to the sixth time they're not passing it and then it's like okay, so let's go back re-teach.

Denise's solution to the perceived problem of low math fluency was to reteach and review. By blaming students for their lack of effort, she also engaged in deficit discourses about students ("my lower kids…don't put in the work") that relieved her of responsibility for student learning. These cases illustrate that her agency was constrained by a lack of past experiences and beliefs that would allow her to imagine alternatives to reteaching and reviewing.

Constrained by the pacing guide and accountability policies of her ecological context, Denise seemed to enact a self-limiting form of agency framed by short-term goals and discourses focused around achievement and fluency. And without a range of past experiences or ambitious instructional goals to draw upon, Denise's repertoire for maneuvering her context was limited.

Cases of Emma and Mary (Same District)

Emma and Mary both taught fourth grade, but at different elementary schools within their district. A representative of the SUPPORTED class, Emma perceived that her context's accountability policies positively impacted her mathematics instruction. Though she acknowledged stress and pressure associated with standardized testing, she perceived that her context supported her in meeting such accountability expectations. For example, she explained that the curriculum was aligned with state standards, that instructional coaches taught students test-taking strategies, and that the district's weekly problem solving provided test preparation throughout the school year. For Emma, such policies supported her instructional goals, which were focused on achievement and proficiency: "My goal, always talk to them about improvement. That no matter where you start--for example, I had a student last year that started at common assessment for the first quarter at 19%, and then she got to 45%."

Emma's beliefs and goals for student learning are reflected in her understanding of problem solving. She explained that problem solving included highlighting and underlining key words to figure out which operation to use. Emma described that in her class,

> We would give a problem at the beginning of the week, and then the same type of skill problem at the end of the week…During the problem-solving time we would meet with that group that was struggling. Then, the last day of the week we would do it again and see how they improved.

For Emma, "problem solving" did not primarily involve making sense of problems and reasoning about numbers and concepts, but rather practicing and acquiring answer-getting skills.

Though Emma perceived that her ecological context supported her mathematics instruction, she seemed to enact a form of agency limited by her goals and conceptions of proficiency and achievement. Specifically, Emma did not achieve agency in ways that afforded students opportunities to meaningfully engage in conceptual understanding of mathematics, as her repertoire of iterational beliefs and projective futures was constrained.

Unlike Emma, Mary perceived that her context negatively impacted her mathematics instruction. Representative of the MIXED class, Mary perceived that accountability policies and the pacing guide constrained her instruction, stating that

> Because you know you're behind in your timeline and you know that students are going to be assessed on all these skills and you worry...Do I really want them to be able to just know how to get the right answer from rounding, or do I want them to really understand the number sense behind it?

Mary's achievement of agency was constrained by the pressures of standardized testing, limiting her ability to maneuver between district policies and her own goals for student sense-making.

Though Mary's agency was constrained by her ecological context in some instances, she was able to achieve agency in others. For example, Mary was able to take up an informal leadership role in her building to present to peers about problem solving. In describing the goals of her presentation, she stated that:

> Just because you're getting the kids a word problem does not mean that they are participating in problem solving because I remember student teaching within the district six years ago and there was Word Problem Wednesday and the teacher did the word problem up on the board for the kids and then the kids did the word problem that was exactly the same but with different numbers.

In this excerpt, Mary achieves agency in challenging, in front of her peers, the view that word problems imply problem solving: in particular, if students are mimicking the teachers' solution, they are not truly engaged in problem solving. Ironically, Mary's counterexample of problem-solving describes Emma's approach. Drawing upon her experiences and goals for student learning, Mary was able to achieve agency in promoting a problem solving that emphasized student reasoning and sense-making.

Though Mary was able to build upon iterational and projective dimensions to achieve agency in some instances (e.g., promoting problem solving opportunities), her repertoire for maneuvering her ecological context was constrained by practical-evaluative dimensions in other instances (e.g., rushing to cover the assessed material). In other words, though she was able to imagine a sort of problem solving that aligned with her goals for student learning, her achievement of agency was constrained by accountability policies.

Discussion & Conclusion

Our study contributes to the research base on teacher agency by revealing how elementary mathematics teachers perceive and achieve agency differently, even though they may share some ecological conditions. Using LCA, we found two unique classes: teachers in SUPPORTED perceived that their contexts had a greater and more supportive impact on their mathematics instruction than those in MIXED. Interviews then allowed us to investigate cases where agency was achieved differently within and between these classes. Drawing upon the theoretical literature (Biesta & Tedder, 2007; Emirbayer & Mische, 1998), these cases revealed the temporal nature of agency; in particular, how teachers' evaluations of their ecological contexts' constraints and supports dynamically interacted with their iterational experiences and projected goals (see Table 1).

Table 1: Summary of temporal dimensions of four case study teachers

	SUPPORTED Class	MIXED Class
Same School	Amy (achieved great deal of agency) • Iterational: beliefs about student learning focused on sense-making and mathematical practices • Practical-evaluative: felt supported by principal & unconstrained by context • Projective: able to imagine alternatives to test preparation and Rocket Math	Denise (constrained and self-limiting form of agency) • Iterational: beliefs about student learning focused on fluency and achievement • Practical-evaluative: felt constrained by pacing guide and accountability • Projective: unable to imagine alternatives to reteaching for test preparation and fluency
Same District	Emma (self-limiting form of agency) • Iterational: beliefs about student learning focused on proficiency and achievement • Practical-evaluative: perceived context as supporting goals • Projective: unable to imagine problem solving that focuses on reasoning and sense-making	Mary (constrained agency) • Iterational: beliefs about student learning focused on sense-making and problem-solving • Practical-evaluative: felt constrained by pacing guide and accountability • Projective: able to imagine problem solving that aligns with goals and vision

Emma's case suggests that feeling supported by one's ecological context is not sufficient for achieving agency, especially when teachers – even certified EMSs - lack ambitious goals and visions for mathematics instruction. Foregrounding the iterational and projective dimensions of the cases of Emma and Denise raises an important implication for teacher education: the need for teachers to have strong professional discourses about mathematics teaching and learning beyond those framed by policy (Biesta et al., 2015). Attention to the practical-evaluative dimension reveals that Mary's agency was constrained by her context's accountability policies as they conflicted with her goals for student learning. Such factors were not as constraining for Amy as she had more personnel resources (e.g., principal) to draw upon. This suggests a second implication for policy: the need to build ecological capacity. Mary's case illustrates how a teacher - one with experiences and visions aligned with ambitious mathematics teaching - can achieve agency in some situations and not others, depending on the availability of social, cultural and economic resources (Priestley et al., 2013).

If policies are to promote teacher agency, our findings suggest a need for building both teacher capacity and ecological capacity. This includes not only attending to the repertoire of past experiences and future trajectories mathematics teachers are able to draw upon, but also the ways their ecological contexts constrain and support their mathematics instruction. And, in our view, mathematics educators are especially well positioned to advocate for such policies.

In this study, we tested the extent to which researchers with classroom experience can predict students' happiness and engagement in elementary math classes. The research group analyzed lesson transcripts and hypothesized which classrooms students rated as high-engagement/high-happiness. We sorted the teachers into high or low groups with 50% accuracy. We suggest four possible explanations for the group's inability to accurately guess: (1) students and adults have different views of which classroom practices will generate student happiness, (2) failure to consult literature on the conceptualization of happiness in elementary aged children, (3) existence of a halo effect and (4) contextualized relationships in classroom environments matter. To conclude, we suggest methodological improvements to increase the probability of identifying high engagement practices in elementary math classrooms via transcript analysis.

Keywords: affect, emotion, beliefs, and attitudes; elementary school education; policy matters

Introduction

Students' experiences in the classroom matter. We see two components of the student experience as especially important: levels of academic achievement and happiness. Drawing on the conceptual framework of Talebzadeh & Samkan (2011), student happiness is associated with several factors related to school performance of both students and teachers. Psychologists note that student happiness affects the school environment and can increase students' performance on measures of academic achievement as well as socio-emotional growth; outcomes often touted as key goals of education (Suldo, 2016) Additionally, there is a relationship between student happiness, teacher happiness, and learning (Blazar & Kraft, 2017). These three factors interact in different ways depending on the student's level of happiness. In general, happy students perform better academically and socially (Parrish & Parrish, 2005; Quinn & Duckworth, 2007). Although Parrish and Parrish (2005) did not look at measures of student achievement specifically, they did find that as students' happiness increases, students also increase in collaborative learning, respect, and enjoyment of school. Quinn & Duckworth (2007) found that students ages 10-12 who had higher levels of subjective well-being "went on to earn significantly higher final grades after controlling for IQ" (p. 3). Additionally, Quinn & Duckworth (2007) noted that students with higher levels of subjective well-being were more successful than their peers at raising their level of academic achievement. More broadly, researchers of happiness note that happiness is often linked with personal well-being (e.g., Graham, Powell, Thomas & Anderson, 2017; Price, Allen, Ukoumunne, Hayes & Ford, 2017). Because elementary school students spend upwards of a fourth of their day at school, understanding how students conceptualize happiness in the classroom is important for their overall well-being (Graham, Powell, Thomas & Anderson, 2017). If researchers have the ability to identify high happiness classrooms using transcripts, there may be opportunities for school-level actors to provide specific pedagogical support to increase students' self-reported measures of happiness in their

elementary math class. Furthermore, understanding which instructional components predict student happiness will support future efforts to validly measure and improve student happiness at the classroom level. Given the importance of student happiness in the classroom, this paper investigates the ability of a research team to identify elementary math classrooms where students rated their experience as high engagement/high happiness versus classrooms where students rated their experience as low engagement/low happiness. Using survey data at the student level, transcript review, and video observations, this is the first study of U.S. public schools that provides guidance regarding the methods researchers should use to gauge students' happiness and engagement in elementary math classrooms. In the subsequent sections, we explain our original investigation to predict students' level of engagement/happiness using three lesson transcripts, why our findings aligned with previous research regarding the use of transcripts to predict a student's class perception, and we provide suggestions to improve the use of transcripts to predict students' conceptualizations of happiness in the elementary math classroom.

Investigation & Methods

We began with a group of twelve elementary math teachers, all of whom participated in a larger study that randomly assigned fourth and fifth-grade teachers to student rosters in four East Coast school districts in the United States (Blazar, 2015). This subset of teachers was selected based on high value-added scores, which allowed the investigation to focus on students' engagement/happiness while holding increases in students' academic achievement levels on standardized tests constant. Before beginning the project, researchers learned that six of the teachers received high ratings for engagement/happiness and six teachers received low ratings for engagement/happiness. Engagement/happiness ratings came from a student survey.

For each teacher, the research group reviewed three lesson transcripts and three video recordings of the class over one academic year. Due to IRB restrictions, two senior research group members had access to video recordings and transcripts of each class. The other four members of the research group only had access to the transcripts of each class. Each week researchers were randomly assigned two of a particular teacher's three videos or transcripts to review. Researchers met in person each week to discuss features of lessons that would align with their perceptions of high engagement/happiness or low engagement happiness. Given the thin literature base regarding the identification of student engagement/happiness via transcript and video review, the group used an open coding system. Prior to the weekly meeting, researchers worked independently to identify the most salient features of a teacher's practice that would align with students' conceptualization of their elementary math classroom as either a high engagement/happiness space or a low engagement/happiness space. At the end of each meeting, one researcher wrote a memo regarding the prominent features of the teacher's practice that the researchers hypothesized would increase or decrease students' engagement/happiness in math class. The research team also offered a guess about the engagement/happiness level of students in the class. The research group discussed their guesses until arriving at a consensus. The guesses were recorded in a spreadsheet.

At the conclusion of the coding and guessing process for all twelve teachers, the faculty advisor shared with researchers the survey results from each teacher's students. The research group was not successful at guessing whether students would rate a particular teacher as either high engagement/high happiness or low engagement/low happiness. In the end, only 50% of the predictions aligned with student perceptions of engagement and happiness in the math classroom (Table 1).

Table 1: Research Team Guess Spreadsheet

Teacher Identification Number	Happiness/Engagement Score via Student Survey	Researcher Guesses
12002	High	Low
12006	Low	Low
12008	Low	Low
12020	Low	High
13102	High	Low
14019	Low	Low
14030	High	High
14040	High	Low
14060	Low	High
14117	High	High
14127	Low	High
11070	High	High

The transcripts and the video did not provide the research team with the level of context required to accurately assess the dynamics in the classroom that would align with a student's perception of happiness/engagement in their elementary math class (Miles & Huberman, 1994; McCormack, 2000). As predicted by other studies that relied on transcript review, with limited context the research team was unable to accurately guess students' level of engagement/happiness.

Identification of Methodological Issues

After reviewing the original investigation, we propose four methodological issues that decreased the probability that the research group could correctly identify whether students rated the classroom as high or low engagement/happiness: (1) students and adults have different views of which classroom practices will generate student happiness, (2) failure to consult literature on the conceptualization of happiness in elementary aged children, (3) existence of a halo effect and (4) contextualized relationships in classroom environments matter.

Differing Conceptualizations of Happiness Related Classroom Practice

The literature on student happiness indicates that students and teachers may approach features of a happiness and engagement from different perspectives, which may indicate why a group of researchers were unable to view the transcripts from the student perspective. In a mixed-methods study, Tenny (2011) found that while the themes that emerged in her literature review also emerged in her findings, additional themes emerged that were not present in the literature. Based on the review of the literature, Tenny (2011) expected the following to impact student happiness: appropriate level of challenge, level of academic support, engagement and enjoyment through hands on meaningful, and collaborative activities, and positive relationships. Students also stated that physical and mental breaks, frequency of testing and homework were also important factors in their happiness. While researchers are capturing salient features of what contributes to classroom happiness for students, their adult objectivity can serve as a hindrance to them being able to identify components of classroom instruction that are important to young children. Holder and Coleman (2008) state that happiness in children may be different than that of adults because children lack the cognitive maturity and life experiences that influence the happiness of adults. In their study of how well-being is conceptualized and practiced in schools, Graham et al. (2017) found that teachers and students differed in their responses. In addition, the student-reported teacher actions that contributed to well-being were divergent among elementary- and secondary-aged students (Graham et al., 2017).

Failure to Consult Literature on Elementary Student's Conceptualization of Happiness

The research team did not consult the literature on student engagement/happiness in elementary school classes. Instead, the team reviewed the literature for studies that specifically focused on elementary school math classrooms and student engagement and happiness; finding none, the team decided to conduct the qualitative analysis using an open coding system. In retrospect, the literature on the elementary student engagement/happiness broadly could have provided the initial investigation with a stronger approach. Without a framework, the group brought their personal experiences and conceptualizations of student happiness to the transcript review process. Examining the classroom memos, the researchers lacked a clear definition regarding what features of a classroom would be indicators of a student's perception of a specific classroom as high engagement/happiness versus low engagement/happiness (Merriam, 1998).

Possibility of Halo Effect

The halo effect could have significantly biased our results. Students who score higher on standardized tests might be more likely to rate their teachers and classrooms higher in engagement/happiness (Egalite & Kisida, 2018). While we knew all the teachers in the study had substantial improvements in how their students performed on standardized testing, we were not privy to students' academic success. Without knowing the students' baseline math scores, it was unclear if students made substantial gains in the year of the study or if students had experienced greater gains in the years previous to joining the classroom of study. As a result, it may be that teachers rated as high engagement were rated so because of students' experiences and growth in math classes the year before and had limited relationship with the current teacher's actual day-to-day practices.

Relationships Matter (students-to-student & teacher-to-student)

The literature on student happiness indicates that relationships in the school are important to the way students conceptualize happiness. During our initial investigation, the research group used data that did not capture the relationships in the classroom. As a result, the group could not determine the peer-to-peer effects in a specific classroom nor could the group accurately gauge the level of connectivity between teachers and students. Our use of transcripts and videos without interacting with teachers and students provided insufficient data regarding the level of relationships in the classroom; thus the relationship between student connectivity to their peers or teacher was missing (Miles & Huberman, 1994; McCormack, 2000). To be clear, we are not saying that teachers are unimportant; rather, the relationship among teachers and students underscores the academic and social processes in the classroom, and more emphasis should be placed on these relationships when understanding how teachers impact student outcomes--whether academic or those relating to student well-being (Blazar & Kraft, 2017).

Recommendations

Our findings indicate that using transcripts to capture a student's conceptualization of happiness/engagement is complicated. If researchers, administrators, and teachers are interested in measuring student's happiness and engagement in elementary classrooms they should consider adhering to the following strategies:

1. Stimulated recall interviews with students (Davis, 1989). This method allows children to impart insights on the thought process and behavior of other children and "provide us with a point of view to which we apparently have lost direct access." (Davis, 1989, p. 39).
2. Measure a student's level of happiness and engagement over more than one time period.

3. Researchers should attempt to collect contextual information such that researchers can utilize classroom, teacher, and student information to identify practices that support student engagement/happiness (McCormack, 2000).

This self-study is a collaboration of Mathematics Teacher Educators (MTEs) with the goal of raising issues of identity and equity within their elementary mathematics methods courses. A common problem of practice surfaced among the MTEs of how to support prospective teachers (PTs) in their development of seeing students' mathematical strengths. The research question was: How can MTEs collaboratively work towards addressing issues of identity and equity across varied institutional contexts?

Self-study involves the systematic studying of the self as a teacher within a context, aimed at improvement (LaBoskey, 2007) and is still emerging as a means for MTEs to study their own practice (Suazo-Flores et al., 2018). We sought to explore pedagogical practices in our methods courses to support PTs in seeing the mathematical strengths of PK-6 students. We selected an article by Skinner, Louie and Baldinger (2019) as a common course reading and developed a protocol that included pre/post PT reflective prompts around the article's strategies for seeing students' mathematical strengths. In order to examine our pedagogical practices we gathered and analyzed the following: (a) positionality statements, (b) lesson plans, including the selection of discussion facilitation questions, (c) post-implementation reflections from the MTEs and PTs, and (d) recordings and notes from our monthly meetings. Reflecting on these data offered insight into pedagogical changes for future course iterations.

Engaging in iterative cycles of practice, reflection, and change allowed us to continually learn from each other and modify our instruction. Based on insights from our colleagues and our own self-reflections, issues of practice to be taken up in future iterations were identified. These included the need to (a) directly address power and privilege with our PTs, (b) model and discuss trusting elementary students with challenging mathematics tasks, and (c) interrogate systemic issues in mathematics teacher preparation, such as purposeful field placements, and PT and elementary student assessment tools. Holistically, the self-study process helped us to develop collective terminology and refine our understanding and use of equity-based practices encompassing various mathematics education organizations' definitions and position statements. Through self-study we supportively and collaboratively pushed each other to reflect on our own teaching with and through equity-based pedagogies, recognizing that our enactment is vital for PTs who teach mathematics for equity and access (Chao et al., 2014).

A MODEL FOR MATHEMATICS INSTRUCTIONAL IMPROVEMENT AT SCALE

Alison Castro Superfine
University of Illinois at Chicago
Amcastro@uic.edu

Benjamin Michael Superfine
University of Illinois at Chicago
bsuperfi@uic.edu

Keywords: Design-based implementation research; Instructional improvement

In this poster, we propose a model for school math instructional improvement that is adaptable to local settings and the organizations and practitioners in them. Different school districts have different problems of practice, and thus adaptive integration of interventions is important as they go to scale—as Penuel et al. (2011) find, successful "scaling up" depends on local actors who make continual, coherent adjustments to interventions as they make their way through various levels of an organization. Indeed, school- and district-level infrastructures that are not optimally designed to support instructional improvement can constrain professional development (PD) efforts to improve the effectiveness of the existing teaching force (Spillane & Hopkins, 2013). Similarly, school districts have been shown to influence the ways in which schools and school leaders implement a wide range of improvement efforts at the school level, thus helping or hindering such implementation (Honig & Rainey, 2014).

The model we propose is particularly designed to improve teachers', teacher leaders', and administrators' understanding of effective math teaching and learning, and to enhance the organizational capacities of schools and districts to support such improvements in math. The model is grounded in a Design-Based Implementation Research process involving collaboration between researchers, and district and school personnel to co-develop math PD from district through teacher levels. The components are: (1) gathering information about problems of practice collaboratively identified by districts, schools, and the research team, and developing related goals; (2) designing and implementing coherent PD that is aligned with identified problems of practice; and (3) engaging in iterative cycles of development, implementation, and revision to productively adapt the model to changing conditions. The iterative redesign process enhances the productive adaptation of the model, allowing it to be effective at scale.

In this poster, we will present our preliminary findings from the first cycle of iterative co-design of the model with stakeholders in four different school districts, including design considerations and challenges that emerged from the co-design process. In doing so, our aim is to make a significant contribution to the knowledge base regarding the process of organizational change in educational settings, effective teacher and administrator PD in math, and researcher-local stakeholder collaboration.

EVOLUTION OF ELEMENTARY MATH LEADERS' COLLABORATIVE PLANS FOR SCHOOL-LEVEL CHANGE

Brendan Dames
University of Missouri
btdppf@mail.missouri.edu

Corey Webel
University of Missouri
WebelCM@missouri.edu

Keywords: Teacher Education – Inservice, Professional Development, Instructional Leadership, Elementary School Education

Research is needed to better understand how elementary teachers develop and make progress toward enacting and supporting new visions of mathematics instruction while transitioning to an informal leadership role (Chval et al., 2010). This study follows 13 elementary mathematics teachers within a Midwestern United States school district who are pursuing Elementary Mathematics Specialists (EMS) certification through fellowships provided via a project funded by the National Science Foundation. The fellows, working in six school-based teams, were asked as a part of their program to create and maintain action plans: revisable documents outlining their evolving visions and plans for improving mathematics teaching in their schools. In analyzing these plans, we investigated the question: What initiatives do the groups plan to implement in their buildings, and how do these plans evolve over the course of the school year?

Initial data included focus group interviews with each team and all four iterations of the action plans. Each school team submitted a revised version of their action plan monthly as a part of their EMS course. In order to name the ways in which each team evolved throughout the course of the project, we defined the following components of the fellows' plans: the scope of the initiative (within-own-classroom, grade-level teams, schoolwide, district-wide), focus (challenging perceptions of student competency, building a positive mathematical culture, supporting student identity formation through instructional practices), and medium (collaboration between mathematics leaders, grade-level collaboration, professional development, teacher observation, class restructuring).

A cross-case comparison revealed multiple trajectories for the groups of fellows. While five of six school-based teams named goals for their own classroom instruction in the first iteration of their plan, not one team applied a schoolwide lens. However, on the fourth iteration, all six teams were seen to employ a schoolwide lens. Interestingly, we found that only one school had maintained the same focus on "eliciting student thinking/providing student feedback" from the first to fourth version of their action plan, and that particular team additionally named that focus at a schoolwide level on the fourth iteration.

We also examined various factors of support (district, administrative, colleagues) and identity (leadership and confidence in mathematical content knowledge) as potential impacts on the trajectories followed by each school team. For example, one school team began to apply a schoolwide scope due to an empowering administrator who asked the fellows to develop professional development for staff, while another team adopted a schoolwide scope because the team perceived their peers' conceptions of student competency as deficit-based. Future analysis will continue to monitor the evolution of fellows' action plans for the duration of the larger project.

Keywords: Teacher Educators, Curriculum Analysis, Teacher Knowledge

The purpose of this research study was to consider how a group of early career mathematics teacher educators (MTEs), from across the U.S., who participated in a continuous improvement lesson study (Berk & Hiebert, 2009), learned to better support their elementary preservice teachers' (PSTs) learning. In this poster, we share the continuous improvement lesson study process we used and discuss changes made to our researched lesson throughout the process. We also share the final version of the lesson and call on other MTEs to utilize continuous improvement lesson studies.

Methodology

This study took place across institutions and adopted the continuous improvement framework (a type of lesson study) which presents a model of curriculum development through studying one researched lesson with cycles of planning, enactment, analysis and revision (Berk & Hiebert, 2009). Four MTEs participated in this study over a period of five semesters in which either all or some of the MTEs taught the lesson. Once the lesson was finalized, we sought to answer the following research questions: What was the nature of the changes made to the researched lesson throughout the continuous improvement lesson study process? How did these refinements better support our PSTs? To answer these questions, all lesson changes were mapped for each iteration of the lesson and rationales for the changes were gathered from transcribed group meetings and individual MTE reflections. In addition, we gathered evidence of our PSTs' thinking, both written and oral, to document how PSTs' thinking changed and contributed to the changes made. Breaking the lesson down by components and lesson iteration, we were able to investigate each component's effectiveness. We used open coding and coded MTE written reflections and transcripts for places we discussed changes and the rationales for those changes.

Results and Implications

Eight structural changes (those changes made on how the lesson was structured) from the initial lesson to the final version were identified. We will share the changes ranging from which elements of a case-study to present to the PSTs at different points in the lesson to the types of questions we asked to better elicit PSTs' noticing of children's single digit multiplication thinking (Jacobs, Lamb & Philipp, 2010). As early career MTEs, we found that our commitment to developing a researched lesson following the continuous improvement framework deepened our sense of belonging to the MTE community, acted as an important means of professional development, and because of our collaborations, we were able to orchestrate better discussions. We were able to push our PSTs' learning to higher levels, more so than we could have done on our own.

MATHEMATICAL KNOWLEDGE FOR TEACHING

RESEARCH REPORTS

SURVEY OF PRESERVICE TEACHERS' PEDAGOGICAL CONTENT KNOWLEDGE FOR STUDENTS' MULTIPLICATIVE REASONING

Christine K. Austin
Kent State University
causti17@kent.edu

Karl W. Kosko
Kent State University
kkosko1@kent.edu

Multiplication and division are vital topics in upper level elementary school. A teacher's pedagogical content knowledge (PCK) influences both instruction and students' learning. However, there is currently little research examining teachers' PCK within this domain, particularly regarding professional education of future teachers. To help address this need, the present paper presents an initial validity argument for a survey of preservice teacher's PCK for multiplication and division.

Keywords: Teacher Knowledge; Number Concepts and Operations

Overview & Purpose

Multiplicative reasoning is a critical concept in upper elementary school (grades 3-5) that facilitates student reasoning of later mathematics concepts (Hackenberg, 2010). Whole number multiplication and division is formally introduced in grades 3-5 (CCSSI, 2010), leading to their inclusion in initial licensure mathematics methods courses for early childhood, elementary, and middle grades preservice teachers (PSTs). However, there is limited research on PSTs' professional knowledge in this area (Thanheiser et al., 2014). Such literature tends to focus on PSTs' understanding of the content (Harkness & Thomas, 2008; Menon, 2003), and often conveys a large portion of novice teachers lack sufficient understanding of declarative knowledge related to multiplication and division. Yet, the professional knowledge needed to teach mathematics, or Mathematical Knowledge for Teaching (MKT), involves more than a deep understanding of the content (Hill et al., 2008b). Pedagogical Content Knowledge (PCK) "goes beyond knowledge of subject matter," in that it is a "particular form of content knowledge that embodies the aspects of content most germane to its teachability" (Shulman, 1986, p. 9). Indeed, there is evidence to suggest that PCK for mathematics is more sophisticated than content knowledge (Copur-Gencturk et al., 2019), but there is relatively little study of PSTs' PCK for multiplication and division of whole numbers (Thanheiser et al., 2014). One reason for this is the relative difficulty in defining and creating measures of PCK (Copur-Gencturk et al., 2019; Hill et al., 2008a). In our own work, we sought such a measure to gauge the effect of a teacher education initiative. The lack of a measure of PSTs' PCK for multiplication and division, therefore, fueled our need to create such a measure. Thus, the purpose of this study is to construct an initial validity argument for a survey of preservice teachers' pedagogical content knowledge for elementary children's multiplicative reasoning.

Background Literature & Theoretical Perspectives

Pedagogical Content Knowledge

This study reports on the design and initial validation of an MKT assessment of whole number multiplication and division. Current assessments of MKT have focused on either specific courses, such as Geometry or Algebra I (Herbst & Kosko, 2014; McCrory et al., 2012) or a wide range of content within a single mathematical domain, such as numbers and operations (Hill et al., 2008a). For example, McCroy et al. (2012) developed an instrument to test teachers' mathematics-teaching-knowledge of Algebra, constructing items specific to student reasoning of algebra problems. McCrory et al.'s (2012) definition of mathematics-teaching-knowledge is similar to PCK, as it includes knowing a student's mathematical reasoning and understanding possible misconceptions. Similar to McCrory et al. (2012), Herbst and Kosko (2014) developed items to investigate MKT in Geometry teachers by constructing items based on students reasoning and approach to geometry problems. Hill et al. (2008a) also created items focusing on PCK, but the majority of their assessment is focused on both common and specialized content knowledge for teaching. While the aforementioned efforts for designing PCK items have met some success, when scholars have designed MKT assessments for specific concepts, such as fractions, the focus tends to be on content knowledge, and not PCK (Izsák et al., 2019).

Although prior research provides useful contributions to the field, the lack of specified focus on aspects of PCK in measurement development has led to underspecification of the domain both within and beyond our focus on multiplication and division. Analyzing items from two different MKT measures, Copur-Cencturk et al. (2019) note that "what constitutes PCK and how PCK differs from [specialized content knowledge] SCK are not well articulated… We need a more in-depth understanding of teachers' instructional strategies that help their students learn and how teachers' knowledge of students' thinking is revealed in mathematics instruction and informs their teaching" (p. 494). Hill et al. (2008a) suggest the problem is two-fold in that there is a lack of research on teachers' PCK and that "the field has not developed, validated, and published measures to assess" (p. 373) such knowledge. Since Hill et al.'s (2008a) writing this statement, items assessing PCK have been successfully written and validated. However, these are typically couched in an overarching assessment of MKT (Depaepe et al., 2015; Herbst & Kosko, 2014). By contrast, this paper focuses explicitly on PCK. Shulman (1986) defines aspects of PCK as:

> An understanding of what makes the learning of specific topics easy or difficult: the conception and preconceptions that students of different ages and backgrounds bring with them to the learning of … frequently taught topics and lessons. If those preconceptions are misconceptions … teachers need knowledge of the strategies ... in recognizing the understanding of learners (p. 9).

There are two primary subdomains of PCK: Knowledge of content and students (KCS) and knowledge of content and teaching (KCT). KCS is defined by Ball et al. (2008) as the knowledge of knowing students as well as knowing the mathematical framework. Within this domain of PCK it is required that teachers know how a student is going to think through a problem and anticipate what problems students will find daunting and confusing (Ball et al., 2008). In contrast, Ball et al. (2008) defined KCT as having the knowledge of how to effectively teach combined with the knowledge of the mathematical subject matter. Teachers with a high level of KCT can use various models to illustrate a concept to students at varying stages of learning (Ball et al, 2008).

Both subdomains have been successfully assessed within the literature. Hill et al. (2008a) developed an assessment to identify KCS and was, to an extent, successful. The findings suggest that in order to answer an item pertaining to a common student error, student understanding, common student developmental sequences, and common student computations a teacher must possess content knowledge (CK) and KCS (Hill et al., 2008a). McCroy et al. (2012) suggested a framework to develop an assessment to measure KCT outside of Algebra by establishing the difference of math knowledge and teaching knowledge. In addition, Herbst and Kosko (2014) constructed an instrument to measure KCS and KCT as well as common content knowledge (CCK) and specialized content knowledge (SCK). The items developed to assess KCS in teachers "probe[d] for their knowledge of students' conceptions and errors in tasks" pertaining to geometry (Herbst & Kosko, 2014, p. 41). Their assessment was able to detect that experienced teachers were more successful at identifying student conceptions/misconceptions than less experienced teachers. The KCT items Herbst and Kosko (2014) constructed followed the same trend; experienced teachers were better able to determine appropriate tasks and examples to effectively illustrate a concept in comparison to less experienced teachers (Herbst & Kosko, 2014). These prior efforts at constructing PCK items, in the context of MKT as a larger construct, informed our own efforts at item design.

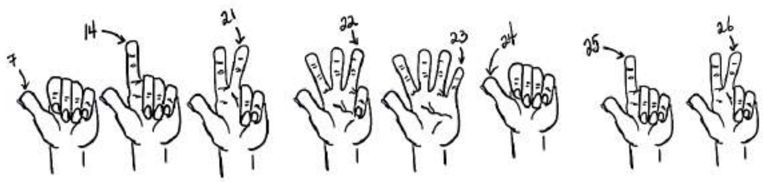
The present paper focuses on KCS of Multiplication and Division and follows item design recommendations of Ball et al. (2008) and Herbst and Kosko (2014). Specifically, items were written to assess teachers’ knowledge of students’ conceptions and errors in whole number multiplication and division for grades 3 to 5. In the next section, we describe this process in detail.

Development of the PCK-MaD Assessment

In this section, we describe the development of items for an assessment of Pedagogical Content Knowledge for Multiplication and Division (PCK-MaD). Items for the initial version of PCK-MaD were designed specifically to assess the KCS dimension of Ball et al.’s (2008) MKT framework. We anticipate including KCT items in a later version of the assessment but sought to focus on KCS as an initial step. Following recommendations from prior work in this area (Ball et al., 2008; Herbst & Kosko, 2014), we designed items focusing specifically on variations in upper elementary school children’s conceptions of multiplication and division. To do this, we focused on grades 3-5 Common Core Standards for Mathematics on multiplication and division standards (CCSSI, 2010) as a means of identifying key concepts to write items. Next, we conducted a literature review of mathematics education research on these and related concepts that described the nature of children’s reasoning. We paired this review of research with a review of practitioner resources (Battista, 2012; Van de Walle et al., 2019).

Figure 1 provides an example item to help illustrate this process of item design, writing, and revision. The item, designated M01, was designed to assess teachers’ knowledge of children’s developmental skip-counting, and aligns with CCSS standard 3.0A.A.1 specifying that children need to interpret products of whole numbers. Variations of skip-counting have been observed by researchers, including a phenomenon where students begin to miss certain skip-counts (Mulligan & Mitchelmore, 1997; Sherin & Fuson, 2005). Steffe (1994) describes this as a point where children are beginning to compose iterable units, counting with whole numbers other than 1, but that this action is still very dynamic for the child. Rather, the composite whole number has not been fully abstracted for the child, and as they attempt to skip-count, they may lose track between coordinating the unit to be skip-counted and coordinating the number of skip-counts. In Figure 1, we illustrate this form of reasoning with a context of multiplying 7 and 8, and an illustration of skip-counting with one’s fingers. Distractors were included to represent other points in learning progressions described for practitioners (Battista, 2012; Van de Walle et al., 2019). For example, Battista (2019) describes repeated addition as distinct from uncoordinated skip-counting. It is also a distinction that may be difficult for some PSTs to observe, making option #4 a useful distractor. Although Figure 1 provides a final version of item M01, multiple revisions occurred as language and figures were reviewed and critiqued by the project team.

Ashley was asked to multiply 7 and 8. She counted on her hands to solve the task (illustrated below):



Based on Ashley's actions, which statement is the best assessment of her reasoning?

①	Ashley skip counted by sevens to solve 7 times 8, but mixed up her skip-counts with the number of skip-counts she was using.
②	Ashley skip counted by sevens to solve 7 times 8, but began skip-counting with a different number part-way through.
③	Ashley, with the aid of her fingers, decomposed 7 times 8 into two smaller problems.
④	Ashley, with the aid of her fingers, used repeated addition to multiply 7 and 8.

Figure 1. Example PCK-MaD item assessing for understanding of children's developmental skip-counting.

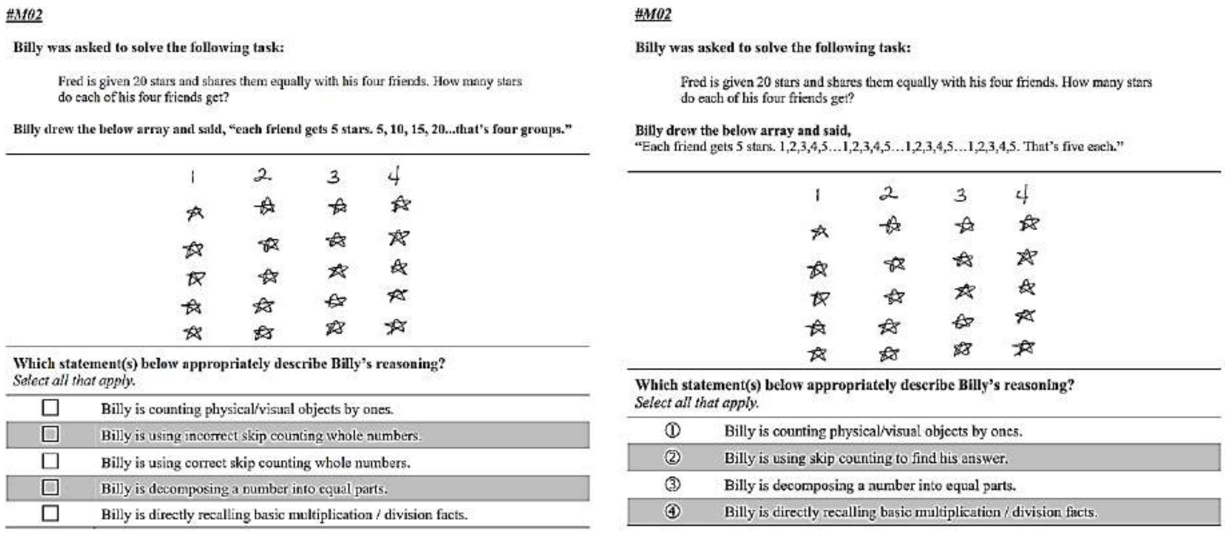
After all items had been successfully vetted by project team members, we conducted cognitive interviews with two elementary math coaches who were widely recognized by the field for their expertise. Cognitive interviewing is a process in which a participant engages in a one-on-one interview to complete an assessment. After completing each item, the participant is asked what they thought the item was asking them to do, what they answered, and why they answered the way they did (Karabenick et al., 2007). For the PCK-MaD, cognitive interview data was used to examine whether items were interpreted as intended, and whether rationales for responses focused on aspects of students' mathematical thinking (i.e., KCS). Each interview was roughly 2 hours in length, but within this time through feedback on items was given.

Item M15, Figure 3, illustrates an example of a question that was *not* altered based on the feedback from the two math coaches. By contrast, Figure 2 depicts an example that was drastically modified due to the constructive criticism. This item was originally designed to be multiple response but was modified to become a multiple-choice item. In addition, the language of the item pertaining to the sample students reasoning was revised to be clearer of the intended thought process due to the discrepancy of responses from the two expert teachers:

Expert Teacher #1: "Billy is decomposing items into equal parts."

Expert Teacher #2: "It looks like he is counting visual items by one"
In response to why she answered that way:
Expert Teacher #2: "Because of the fact that all twenty were represented by stars so it looks like he counted 1, 2, 3, 4, 5."

The different responses illustrated to us that the item stem was unclear, and some of the options may have been interpreted in ways we did not intend. The reasoning for "Billy" was modified to be clearer of his mathematical reasoning of counting the stars and changed to a multiple-choice item to not distract the users further. Unfortunately, the cognitive interviews also resulted in one item being removed completely from the assessment due to the overall confusion of the participants. Some items were revised with very minor adjustments (missing punctuation, a typo in an image, etc.). Following cognitive interviews, 9 items received some revision (minor to moderate), 4 items remained as-is, and 1 item was fully removed.



Original Question Revised Question

***Figure 2*: PCK-MaD questions M02 example of revision after cognitive interviews.**

Another outcome of our cognitive interviews was a realization of the cognitive demand of several items. Evidence from the literature suggests that KCS items may be more difficult than other MKT domains (Copur-Cencturk et al., 2019; Herbst & Kosko, 2014), and we found that many of our KCS items were indeed more difficult. Therefore, we created three additional items, following cognitive interviews, in an effort to have KCS items with an easier difficulty level.

Following the framework of Herbst and Kosko (2014) items were developed to measure KCS in pre-service teachers. Revision of the items based on the feedback from the expert teachers resulted in the pilot PCK-MaD assessment. The adjustments made to the items added to clarity and refined the level of difficulty of the language. However, to properly vet the items and gather further validity of the assessment, we collected pilot data from preservice teachers (PSTs) enrolled in a teacher education program. This process served to collect validity evidence for an initial validity argument for the PCK-MaD.

Method

Sample and Procedure

Participants included 58 PSTs, with 47 preparing to become elementary teachers (grades K-3 with an endorsement option for grades 4-5) and 11 preparing to become middle grades teachers (grades 4-9). Participants were in the latter half of their teacher education (31 juniors; 27 seniors). The majority of junior participants were elementary PSTs (n=27) preparing to take the first of two mathematics methods courses. Although these participants had some pedagogical coursework and field experience, they hadn't received formal education on PCK for multiplication/division. Four juniors were middle grades PSTs who had completed the first of two mathematics methods courses. Senior elementary PSTs (n=20) had completed two mathematics methods courses, with several field-based assignments relating to multiplicative reasoning across grades K-3. All participating elementary PSTs expressed their intent to complete an additional mathematics methods course focusing on grades 4-5, but none had completed this course at time of data collection. The majority of middle grades PSTs (7 of 11) were seniors and were enrolled in the second of two mathematics methods courses in their program.

Analysis and Results

Given the early stage of developing our PCK survey, the present paper examines validity evidence from test content and response processes. Validity evidence for *response processes* refers to "whether test takers are, in fact, reasoning about the material given instead of following a standard algorithm applicable only to the specific items on the test" (AERA et al., 2004, p. 15). Wolf and Smith (2007) suggest that psychometric measures can be used to assess the degree that the theoretical rationales for item content align with response processes. Therefore, to examine evidence for response processes in the present paper, we conducted a classical item analysis to examine the internal reliability of items and the resulting measure, and to examine the relative difficulty of those items in comparison with one another.

The PCK survey included 15 questions, with six questions conveyed in a multiple-response (i.e., select all that apply) format. For example, question M15 presents six different student algorithms and asks the survey respondent to select those that used all partial products (see Figure 3). This effectively conveys six different items for M15. Thus, for the 15 questions we examined, there were 41 items, due to the six multiple response questions. Our initial item analysis model, including all 41 items, resulted in a Cronbach's alpha coefficient of .47. For surveys and piloted assessments such as the one in this paper, the typically accepted threshold is at or near *.70* (Nunnally & Bernstein, 1992). Therefore, we examined the point-biserial correlations for each item to identify candidates for removal. Point-biserial coefficients below .30 are considered to not meaningfully contribute to the total score, possibly due to variance in response (Crocker & Algina, 2006). Rather than remove all such items, it is customary to remove one item at a time, so that the remaining items' point-biserial coefficients can be recalculated for a new model. In addition to identifying particularly low coefficients, items are examined in the context of their theoretical contributions to the model, as well as evidence from cognitive interviews and/or written work on the surveys. For example, the sixth item on question M15 had an initial point-biserial coefficient of .021 (see Figure 3). The low coefficient essentially flagged the item for review. We then considered evidence from our cognitive interviews in which unfamiliarity with the lattice method and how it functioned mathematically resulted in incorrect responses. Thus, this option for question M15 was removed. A similar process took place for all iterations of item analysis. Our final model included 21 items, from nine questions, with a Cronbach's alpha coefficient of .68. This suggests at least 68% of the variance in responses is due to the measured construct (PCK for multiplication and division). Point-biserial coefficients for most items were above or near the .30 threshold. Item difficulty for the remaining items ranged from .20 (20% of the sample answered correctly) to .90 (90% of the sample answered correctly), with a mean score of 14.88 (SD = 3.14, Range = 5 to 16).

Validity evidence for *test content* considers how well assessment content represents PCK for children's multiplicative reasoning, and how well this content aligns with interpreting PSTs' scores (AERA et al., 2004). To analyze this, we will examine the intended purpose of the assessment (i.e., to measure the effect of teacher education) using an independent samples t-test for PCK scores of juniors and seniors. Results were statistically significant (t = 2.686188, df = 56, p = .00933), indicated that senior PSTs had higher PCK scores (15.8674) than junior PSTs (13.6690). To ensure the comparison between junior and senior PSTs was not influenced by major, we examined the difference between elementary and middle grades PSTs' scores and found no statistically significant difference (t = 0.673, df = 56, p = .503). We also examined whether PSTs who had a field placement in grades 3-5 would have higher PCK scores and found no statistically significant difference between those with and without such field experience (t = 0.396, df = 56, p = .743). Considered collectively, these results suggest that, for participants in the current study, the PCK survey distinguishes between PSTs who are earlier or later in their teacher education program. Such a difference does not appear to be due to intended licensure (elementary or middle grades) or having grades 3-5 field experience.

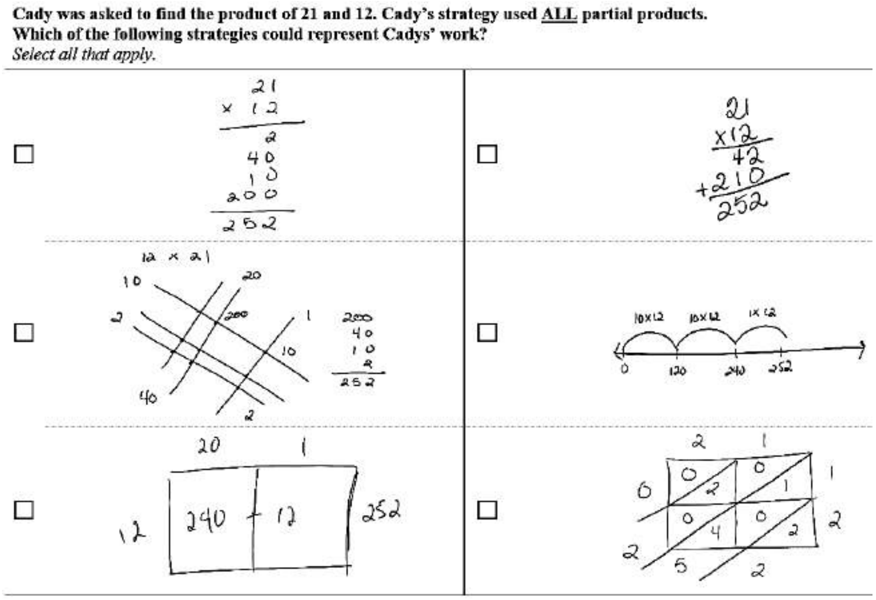


Figure 3: **PCK-MaD that assesses children's strategy-use with partial products.**

Discussion

To our knowledge, there is no prior assessment for PCK of multiplication and division for whole numbers. This study reported on the initial piloting of our assessment of PST's knowledge of content and students (KCS) with a focus on multiplicative reasoning. Given the need for additional research on PSTs' PCK for multiplication and division (Thanheiser et al., 2014), development of a measure for this domain has the potential for informing the field in this regard. The findings of this study suggest that our survey can distinguish between PCK scores of PSTs at different levels of teacher education (i.e., senior vs. junior). On one hand, this provides useful validity evidence for the PCK-MaD's ability to distinguish between PSTs at different points in their teacher education. However, this finding also lends support for the effectiveness of teacher education programs at developing PSTs' PCK. Both implications of this particular finding, while useful, should be interpreted with caution as the current study represents an initial pilot of an assessment and involves a sample from a particular teacher education program.

Psychometric data from the PCK-MaD item analysis and data from the two cognitive interviews suggest that the piloted assessment does measure the intended construct. However, future research is needed to improve the assessment. Results suggest initial support for an assessment of KCS, but additional items focusing on KCT should be developed. Further, results here focus predominately on responses from PSTs, suggesting a need to examine responses from inservice teachers to establish a better understanding of normative KCS in the field. Despite the early stage of this work, results suggest that the PCK-MaD may be used as-is for assessing the effect of teacher education initiatives.

TEACHERS' ATTENTION TO AND FLEXIBILITY WITH REFERENT UNITS

Yasemin Copur-Gencturk
University of Southern California
copurgen@usc.edu

Ibrahim Burak Olmez
University of Southern California
olmez@usc.edu

In this study, we explored teachers' attention to and flexibility with referent units as well as how teachers' understanding of referent units is related to their performance on other fraction concepts and their professional background. By using data collected from 246 U.S. mathematics teachers in Grades 3–7 where fractions are taught, we found that teachers' attention to and flexibility with referent units were moderately related. Whereas some teachers' professional background variables could explain their flexibility with referent units, none of the variables was linked to their attention to referent units. Furthermore, both teachers' attention to and flexibility with referent units seemed to be associated with their performance on other fraction concepts.

Keywords: Rational Numbers, Teacher Knowledge

Fractions are critical content in the upper elementary and middle grades curriculum (e.g., Common Core State Standard Initiatives [CCSSI], 2010). Despite teachers' computing well on fraction arithmetic, they usually struggle with understanding fractions conceptually (e.g., Izsák, 2008). For instance, teachers can confuse problem situations asking for division by a fraction with those asking for multiplication by a fraction (e.g., Ma, 1999) or overgeneralize rules for whole numbers to fractions such as division makes numbers smaller (Jansen & Hohensee, 2016).

Several scholars have argued that such difficulties with understanding fractions might be related to the whole number bias (e.g., Vamvakoussi, Christou, & Vosniadou, 2018), whereas others have argued that not understanding number magnitude may be the underlying reason (e.g., Siegler, 2016). Scholars in mathematics education have also brought up referent units (RU), which are critical, yet overlooked, for having a conceptual understanding of fractions (e.g., Izsák, Orrill, Cohen, & Brown, 2010). Empirical work has provided support for the importance of RU (e.g., Izsák, Jacobson, and Bradshaw, 2019). For example, Izsák et al. (2010) analyzed 201 U.S. middle grades teachers' responses to a set of items and found two classes that distinguish the teachers based on their understanding of RU. In a recent study that analyzed 990 U.S. middle grades teachers' responses to a multiple-choice assessment, Izsák et al. (2019) found that teachers who were proficient in RU tended to perform better on the remaining components of reasoning about fractions.

Although past research has provided insights into teachers' understanding of RU, it has focused heavily on such understanding in fraction multiplication and division situations, given that RU change during the process (e.g., Izsák et al., 2019). Thus, these studies capture teachers' *flexibility with* RU, which can be defined as "a teacher's ability to keep track of the unit to which a fraction refers . . . and to shift their relative understanding . . . as the referent unit changes" (Lee, Brown, & Orrill, 2011, p. 204). Although fraction multiplication and division situations provide an invaluable opportunity to examine whether teachers can identify referent units correctly and think accordingly as the referent unit changes, we argue that RU are important in any fraction concept. Our argument is grounded in the view that understanding RU also includes *attention to* RU, even in less explicit situations. To illustrate what we mean by *attention to* RU, when comparing fractions, creating equivalent fractions, and performing fraction operations such as fraction addition and subtraction, the same referent unit is used for the fractions involved. For instance, when two fractions are added, both fractions refer to the same whole. Thus, *attention to* RU could capture another characteristic of teachers' understanding of RU.

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

In sum, although prior work has provided evidence for the importance of RU in understanding fractions, we still know little about the relationship between different characteristics of RU. In particular, we hypothesized that in addition to flexibility with RU, attention to RU is an important characteristic of teachers' understanding of RU and, in general, of their overall performance on fractions. To test our hypothesis, we created two constructed-response problems, one capturing teachers' *attention to* RU in a fraction comparison situation and the other capturing teachers' *flexibility with* RU in a fraction multiplication situation involving a visual representation. By using data collected from 246 U.S. in-service teachers who were teaching mathematics in Grades 3–7, we examined the relationship between teachers' performance on these two problems and the extent to which teachers' professional background was related to their responses to these two problems. Finally, we explored how teachers' responses to these two problems were related to their overall performance on a fractions measure. We aimed to answer the following research questions:

1. To what extent do teachers pay attention to RU?
2. To what extent do teachers demonstrate flexibility with RU?
3. What is the relationship between teachers' attention to and flexibility with RU?
4. What aspects of teachers' professional background are related to their attention to and flexibility with RU?
5. To what extent are teachers' attention to and flexibility with RU, along with their professional background, associated with their overall performance on fractions?

Our study contributes to the current literature in three significant ways. First, prior work has not focused on the relationship between teachers' understanding of different characteristics of RU. Thus, by examining the relationship between teachers' attention to and flexibility with RU, we aimed to contribute teachers' understanding of RU and fraction operations. Second, limited research (Izsák et al., 2019) has investigated the relationship between teachers' professional background and their understanding of RU. Thus, knowing the extent to which teachers' professional background is associated with their attention to and flexibility with RU will have implications for mathematics teacher education. Finally, by investigating the relationship between teachers' understanding of RU and their performance on a fractions measure, we aimed to provide further evidence for how teachers' understanding of RU might be linked to their overall performance on fractions.

Theoretical Framework

Referent units can be defined as units number refer to in mathematical situations. Although it is possible for teachers and students to perform algorithms correctly without relying on RU, a conceptual understanding of fractions requires one to explicitly attend to the units and to be aware of the units in these situations (Philipp & Hawthorne, 2015). Let us illustrate the RU in two different problem situations:

1. Which fraction is larger: 1/3 or 1/2?
2. One serving of yogurt is 1/3 of a cup. For one meal, Amanda ate 1/2 of a serving. How many cups of yogurt did Amanda eat?

In the first problem, the answer can be found by finding a common denominator for both fractions and noticing that 2/6 is smaller than 3/6. However, the comparison makes only sense if both fractions refer to the same unit. Thus, attention to RU is necessary to develop a conceptual understanding in situations where the referent unit stays the same. In this way, teachers can overcome several misconceptions such as the larger the denominator, the larger the fraction or adding across numerators and denominators (Newton, 2008). In the second problem, however, the numbers refer to different units. Whereas 1/3 and the product, 1/6, refer to 1 cup, 1/2 refers to one serving, which is 1/3 of a cup. When performing the standard algorithm, the answer, 1/6, can be found by multiplying across numerators and denominators. On the other hand, a conceptual understanding of fractions requires showing flexibility with RU by understanding that the RU for 1/2 and 1/3 are different and thinking accordingly as the referent unit changes. Therefore, partitioning the serving size into two parts and shading one part is needed to show 1/2 of 1/3 (Figure 1b). Because the problem asks for the number of cups, the referent unit of 1/6 then becomes 1 cup, the whole rectangle (Figure 1c).

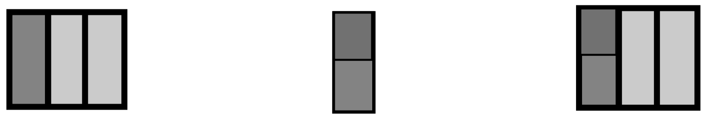

Figure 1: (a) 1/3 of the rectangle; (b) 1/2 of the 1/3; (c) 1/6 of the rectangle

Most prior work on RU has focused on teachers' understanding of fraction multiplication and division, and reported both future and in-service teachers' struggle with RU (e.g., Baek et al., 2017; Izsák, 2008; Izsák et al., 2019; Lee, 2017; Webel et al., 2016). Much of this research used fraction multiplication and reported teachers' reliance on the overlapping method, which uses the same referent unit for the multiplier, multiplicand, and product. These studies have acknowledged that using the overlapping method either results in incorrect answers or causes mostly step-by-step algorithms instead of conceptual understanding about what it means to multiply two fractions.

Methods

The data were collected from 246 in-service mathematics teachers in Grades 3–7 across 21 states in the United States. Teachers in our sample were mostly female (84%) and White (68.1%). In addition, 25.2% of the teachers had a master's degree, 77% of them were teaching mathematics in Grades 3–5, and 23% were teaching mathematics in Grades 6–7. While 70.3% had traditional certification, 19.3% had a credential in mathematics, and 52.5% were fully certified.

As seen in Table 1, the fractions measure used in this study consisted of a set of six items adapted from prior research (e.g., Siegler, 2015), the DTMR survey (Izsák et al., 2019) and the Teacher Education and Development Study in Mathematics (TEDS-M) survey (Tatto et al., 2012), and teacher education resources (Van de Walle, Karp, & Bay-Williams, 2019). We also administered the background survey (Izsák et al., 2019) and collected information regarding the professional background of our sample.

Table 1: Fractions measure items

Key concept	Item
Attention to RU	Is it possible for 1/3 to be greater than 1/2? Explain your thinking.
Equivalent fractions	In the figure, how many **MORE** small squares need to be shaded so that 4/5 of the total number of small squares are shaded? Explain your answer. Comparing fractions	For each set of fractions, put < , >, or = to make the statement true. $\frac{9}{21}\ \frac{15}{21}$ $\frac{31}{57}\ \frac{23}{57}$ $\frac{61}{44}\ \frac{33}{44}$ $\frac{20}{17}\ \frac{20}{33}$ $\frac{49}{48}\ \frac{49}{47}$ $\frac{71}{60}\ \frac{71}{52}$

Estimating the sum of fractions	The fractions $\frac{19}{35}$ and $\frac{41}{66}$ have been placed on a number line. **Without computing**, please estimate the sum of $\frac{19}{35}+\frac{41}{66}$ by placing a dot on the number line where you think the sum would be found. Explain your answer. Flexibility with RU	This item cannot be displayed because it is currently part of the DTMR survey (Izsák et al., 2019). We provided a drawn rectangle and asked teachers to model fraction multiplication and explain their answer.
Estimating the quotient of fractions	The fractions $\frac{19}{35}$ and $\frac{41}{66}$ have been placed on a number line. **Without computing**, please estimate the quotient of $\frac{41}{66}\div\frac{19}{35}$ by placing a dot on the number line where you think the quotient would be found. Explain your answer. 
We independently coded the items on attention to and flexibility with RU. The agreement was over 90% for each item. We classified teachers' responses to the item on attention to RU into three categories: no attention to RU, partial attention to RU, and full attention to RU. Specifically, teachers assigned to the first category did not refer to any RU implicitly or explicitly in their explanations. The second category included teachers who were using the same referent unit. The third category captured teachers who responded that the answer depended on the referent unit. We also classified teachers' responses to the item on flexibility with RU into three categories: no flexibility with RU, partial flexibility with RU, and flexibility with RU. The first category included teachers who did not demonstrate flexibility with RU at all in their responses such as "I am unsure how to model that the product of 1/3 × 1/4 is 1/12." The second category included teachers who used the overlapping method such as "She should draw two vertical lines to divide the rectangle into 3 equal-sized parts across, then shade in one of the vertical rectangles. The shaded piece that is overlapped demonstrates the 1/12." The third category included teachers who demonstrated flexibility with RU by keeping track of the units with explanations such as: "She should divide the picture into 3 equal-sized pieces vertically and show that 1/3 of the 1/4 is 1/12 of the whole." We also scored the remaining four fraction items and the agreement was greater than 90%.

To report teachers' attention to and flexibility with RU, we computed the percentages of responses in each category. To investigate the relationship between teachers' attention to and flexibility with RU, we used a Pearson chi-square test. We also computed the correlation between these categories by using gamma statistics, given that the categories for each problem were ordinal. To investigate the relationship between teachers' responses to the referent unit problems and their professional background variables, we ran a separate ordinal logistic regression for each problem. Finally, to examine the relationships among teachers' overall performance on other items of the fractions measure, their attention to and flexibility with RU, and the professional background variables, we ran a linear regression in which the total score was predicted by teachers' attention to and flexibility with RU and the aforementioned background variables.

Results

Teachers' Attention to Referent Units

As shown in Figure 2, 54.5% of the teachers demonstrated attention to RU by responding that 1/3 could be greater than 1/2, depending on the referent unit. For instance, one teacher explained that "If I am comparing two different-sized objects, then 1/3 may be greater than 1/2." On the other hand, 19.9% of the teachers demonstrated partial attention to RU by reporting that 1/3 could not be greater than 1/2 and by explicitly using the same referent unit to justify their responses. Furthermore, 25.6% of the teachers did not demonstrate attention to RU (Figure 2). Specifically, 57% of these teachers did not provide any explanation that showed why 1/3 could not be greater than 1/2, whereas 25.4% of the teachers constructed equivalent fractions in their explanations. For example, one teacher wrote "To easily compare these fractions, you can find common denominators, 2/6 and 3/6. The one half will always be greater than the one third." Lastly, 17.6% of the teachers either made factual statements in their explanations without mentioning any referent unit or they converted fractions into percentages by reporting that 1/3 and 1/2 means 33% and 50%, respectively.

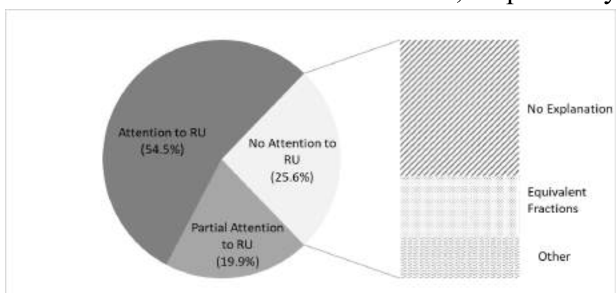

Figure 2: Teachers' performance on the item that measured their attention to RU

Teachers' Flexibility with Referent Units

Teachers' responses to the flexibility with RU item suggested that only 11.8% of the teachers demonstrated flexibility with RU (Figure 3). Those teachers reported that the referent unit for 1/4 was the entire rectangle and that the referent unit for 1/3 was 1/4 of the rectangle (i.e., the shaded part), not the entire rectangle. They also pointed out that 1/12 was 1/3 of the 1/4 rectangle. For example, one teacher explained "divide the picture [1/4 of the given rectangle] into 3 equal-sized pieces vertically and show that 1/3 of the 1/4 is 1/12 of the whole." On the other hand, the remaining teachers (88.2%) appeared to struggle demonstrating flexibility with RU. In particular, 44.3% of the teachers demonstrated partial flexibility with RU by relying on the overlapping method. They did not specify different RU for 1/3 and 1/4, and their explanations implied that for both 1/3 and 1/4, they considered the entire rectangle as their referent unit. For instance, one teacher explained that "Divide the rectangle vertically into 3 equal-sized parts and shade in one part. The overlapping part between the horizontally shaded part and vertically shaded part (one square) is 1/12." Unlike the aforementioned two categories, 43.9% of the teachers did not demonstrate any flexibility with RU. Those teachers did not appear to consider any referent unit, and they did not provide explanations for each fraction.

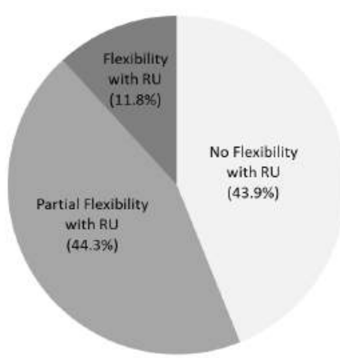

Figure 3: Teachers' performance on the item measuring their flexibility with RU

Relationship between Attention to and Flexibility with Referent Units

We found a significant, but moderate relationship between relationship between teachers' attention to and flexibility with RU ($\chi^2(4) = 13.3$, $p = .01$; $G = .35$). As shown in Figure 4, 60.3% of the teachers who did not pay attention to RU failed to demonstrate flexibility with RU, whereas 35.1% of the teachers who paid attention to RU failed to demonstrate flexibility with RU.

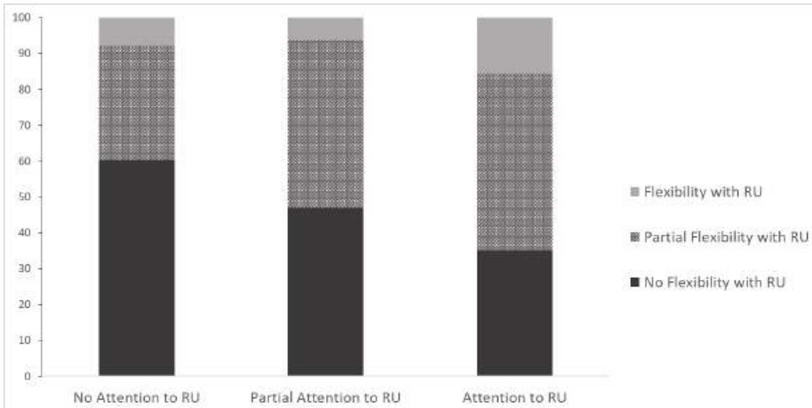

Figure 4: Teachers' performance on for different levels of attention to RU

Relationship Between Understanding of Referent Units and Professional Background

We also examined the relationships between teachers' understanding of RU and their various professional background variables. As shown in Table 2, none of the variables for teachers' background was associated with their attention to RU, whereas middle grades teachers and traditionally certified teachers showed more flexibility with RU compared with upper elementary and non-traditionally certified teachers. For example, the odds of middle grades teachers showing flexibility with RU was 2.67 times higher than that of elementary grades teachers ($p = .001$). This means that middle grades teachers were 2.67 times more likely to demonstrate flexibility with RU than elementary grades teachers.

Table 2: Logistic Regression of Probability of Attention to and Flexibility with RU

Teachers' professional background	Attention to RU	Flexibility with RU
Number of mathematics content courses (3 or more)	0.880 (.23)	0.667 (.18)
Number of mathematics methods courses (3 or more)	1.084 (0.32)	1.088 (0.32)
Fully certified teachers	0.875 (0.24)	0.923 (0.25)
Middle school mathematics teachers (Grades 6 & 7)	0.983 (.30)	2.666** (.81)
Traditionally certified teachers	1.265 (0.38)	2.098* (.64)

Note. Odds rations shown. Standard errors are in parentheses. *$p < 0.05$, **$p < 0.01$.

Relationship Between Knowledge of Referent Units and Fractions

As shown in Table 3, teachers' attention to and flexibility with RU significantly predicted their overall performance on the fractions measure. Specifically, when teachers' attention to and flexibility with RU were entered into the model separately, teachers who paid attention to RU significantly outperformed those who did not pay attention (effect sizes of .41 and .58 for the partial attention to and attention to referent unit categories, $p = .035$ and $p < .0001$). Similarly, those who demonstrated partial flexibility or flexibility with RU also performed significantly better on the fractions measure compared with those who did not show flexibility with RU (effect sizes of .52 and .60 for teachers who were in the groups showing partial flexibility and flexibility with RU, $p < .0001$ and $p = .007$).

Table 3: Teachers' performance on fractions predicted by their Attention to and Flexibility with Referent Units and Professional Background

	Attention to RU	Flexibility with RU	Attention to and flexibility with RU, and professional background
Attention to and flexibility with RU			
Partial attention to RU	0.140* (.067)		0.142* (.064)
Attention to RU	0.198*** (.053)		0.175*** (.052)
Partial flexibility with RU		0.171*** (.047)	0.105* (.048)
Flexibility with RU		0.198** (.073)	0.115 (.072)
Professional background			
Number of mathematics content courses			−0.042 (.046)
Number of mathematics methods courses			0.059 (.50)
Fully certified teachers			−0.024 (.046)
Middle school mathematics teachers			0.206*** (.053)
Traditionally certified teachers			0.039 (.052)

Note. $N = 238$ for all models. The numbers in parentheses are standards errors. $*p < 0.05$, $**p < 0.01$, $***p < 0.001$.

Finally, when teachers' attention to and flexibility with RU were included in the model along with their professional background variables, teachers who demonstrated partial attention to RU or those who demonstrated full attention to RU still performed better than those who did not demonstrate attention to RU (effect size of .43 and $p = .028$ for the partial attention to RU category; and effect size of .53 and $p = .001$ for the full attention to RU category). However, teachers' flexibility with RU did not seem to be significantly correlated with their overall performance on the fractions measure. This is possibly because of the correlation we reported earlier between teachers' professional background variables and their flexibility with RU. Of these variables, the only significant predictor of teachers' overall performance was being a middle grades teacher. Indeed, the difference between elementary and middle grades teachers' performance was an effect size of .63, $p < .001$. Other variables, such as the number of courses or being fully certified, did not link to their overall performance on fractions.

Discussion

In the present study, we examined U.S. in-service teachers' attention to and flexibility with RU and the relationship between these two characteristics, along with how teachers' understanding of RU was linked to their professional background and performance on the fraction items. We found that although about half of the teachers paid attention to RU, only 12% of the teachers showed flexibility with RU, which suggests that showing flexibility with RU is a more difficult concept to grasp. Our findings regarding teachers' flexibility with RU are similar to those from prior work (e.g., Lee et al., 2011; Webel et al., 2016). Furthermore, in alignment with past research (e.g., Izsák, 2008; Lee et al., 2011; Webel et al., 2016), teachers in our study commonly used the overlapping method to model fraction multiplication, indicating these teachers' difficulty with making sense of fraction multiplication.

Furthermore, our findings suggest a significant, but moderate relationship between teachers' attention to and flexibility with RU. These results may provide initial evidence that these items capture different characteristics of teachers' understanding of RU. It is interesting that teachers' performance on the item measuring flexibility with RU was associated with the teachers' preparation route, whereas the item measures attention to RU was not associated with any teacher background indicators. This may be because teacher education programs focus more on modeling fraction multiplication and division, given that many studies on future teachers have focused on fraction multiplication (e.g., Baek et al., 2017).

In a similar vein, it is important to point out that the number of mathematics content and methods courses was not associated with teachers' attention to and flexibility with RU. In an extensive review, Olanoff et al. (2014) reported an urgent need for research that finds ways to improve future teachers' understanding of fractions. The present study suggests that emphasizing attention to RU in teacher preparation programs, even when the referent unit stays the same, could help future teachers improve their understanding of fractions.

Our findings also underscore the importance of teachers' attention to and flexibility with RU in relation to their performance on other fraction concepts. In particular, teachers who paid attention to RU performed better than those who did not. Similarly, teachers who demonstrated flexibility with RU performed better on other fraction concepts than those who did not demonstrate such flexibility. Furthermore, when both attention to and flexibility with RU were included together, in addition to teachers' professional background variables, teachers who paid attention to RU or those who used the overlapping method for fraction multiplication performed better on the remaining items of the fractions measure than did those who did not pay attention to RU or those who showed no flexibility with RU. However, teachers who showed full flexibility with RU did not perform well compared with those who did not show any flexibility after adjusting for attention to RU. In sum, these findings also confirm the importance of teachers' understanding of RU in their mastery of other fraction concepts.

TEACHERS' REVIEW OF TASKS AS A TOOL FOR EXAMINING SECONDARY TEACHERS' MATHEMATICAL KNOWLEDGE FOR TEACHING

One important aspect of teaching is reviewing tasks in preparation for instruction. The goal of the multicase study of four secondary teachers was to examine the interplay between their mathematical knowledge for teaching [MKT] and what they attend to when reviewing a mathematics task. We engaged secondary mathematics teachers in a semi-structured, clinical interview focused on a non-routine mathematical task involving exponential growth. The results suggest experienced teachers may not explicitly attend to learning opportunities in their review of a task, and their own mathematical work contributes to their anticipation of student work and thinking. This work highlights how researchers focused on MKT can use clinical interviews as a tool for extracting and describing a teacher's MKT.

Keywords: Mathematical Knowledge for Teaching; Instructional Activities and Practices; Curriculum Enactment

Mathematical knowledge for teaching [MKT] is the "knowledge needed to carry out the work of teaching mathematics" (Ball, Thames, & Phelps, 2008, p. 395). Ball et al. (2008) clarify that *teaching* mathematics includes "everything that teachers must do to support the learning of their students" (p. 395). As such, this work includes planning, instruction, and assessment. Others in the literature suggest, in agreement, that pedagogy, the curriculum, and teachers' mathematical understanding are interconnected (e.g., Davis & Simmt, 2006; Sullivan, Knott, & Yang, 2015). For example, Sullivan et al. (2015) argue that "tasks do not exist separately from the pedagogies associated with their use nor are the pedagogies independent of the task" (p. 84).

One aspect of the mathematical work of teaching is reviewing mathematical tasks for potential use during instruction (Ball, 2017). From selection to implementation, teachers' use of mathematical tasks impacts the types of learning opportunities their students experience (e.g., Stein, Grover, & Henningsen, 1996). Sullivan et al. (2015) note that tasks allow students the opportunity to experience mathematical concepts and ideas. They claim that "the role of the teacher is to select, modify, design, redesign, sequence, implement, and evaluate tasks" (p. 83). Furthermore, "in planning and teaching, the role of the teacher is to identify potential and perceived blockages, prompts, supports, challenges, and pathways" (Sullivan et al., 2015, p. 86).

The purpose of this research study was to explore the aspects of a teacher's MKT elicited when reviewing a mathematics task. Specifically, we claim that aspects of a teacher's MKT including specialized content knowledge [SCK], knowledge of content and teaching [KCT], and knowledge of content and students [KCS] (Ball et al., 2008) become evident during task analysis. To investigate our claim, we pursued the following research question: What aspects of a secondary mathematics teachers' MKT can we describe from their review of a nonstandard exponential functions task? Our focus on exponential functions answers a call for increased research considering topics at the secondary level (Speer, King, and Howell, 2015).

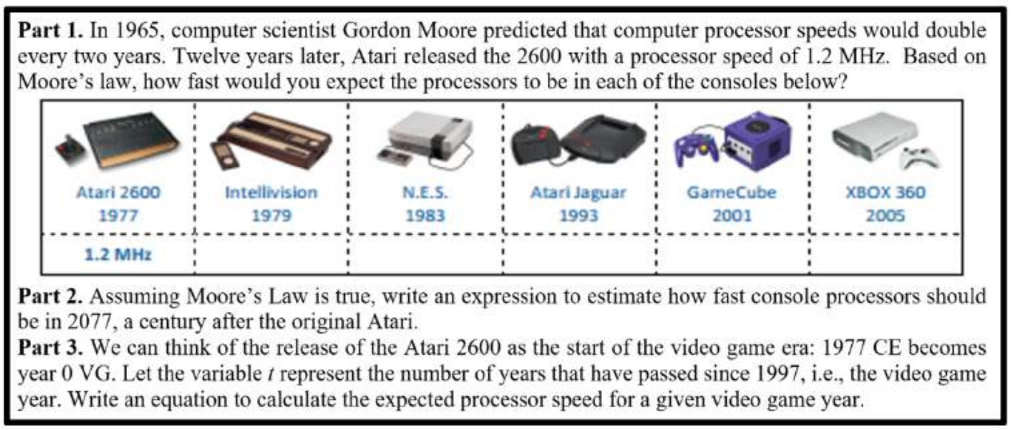
Methods

The study was part of a larger research study focused on the work of 16 high school teachers from the Great Plains region of the United States while they were teaching exponential functions in courses ranging from Algebra I to Precalculus. The research team identified the teachers as "highly effective" based on recommendations from the teachers' administrators or peers. The teachers had 5 to 25 years of teaching experience.

Data collection for the larger study consisted of multiple stages. First, a member of the research team conducted classroom observations of five lessons pertaining to exponential functions. In addition to observations, the teachers engaged in pre- and post-lesson interviews focused on the entire set of lessons as well as pre- and post-lesson interviews for each lesson. Second, a member of the research team administered a pre- and post-lesson assessment measuring the teachers' students' understanding on exponential functions topics. Finally, each teacher engaged in a semi-structured, clinical interview, called the *MKT Interview*, which focused on the teachers reviewing two non-standard exponential functions tasks. In this paper we focus on the first task of the MKT Interview, the *Xbox Xponential* task (see Figure 1).



Part 1. In 1965, computer scientist Gordon Moore predicted that computer processor speeds would double every two years. Twelve years later, Atari released the 2600 with a processor speed of 1.2 MHz. Based on Moore's law, how fast would you expect the processors to be in each of the consoles below?

Atari 2600 1977	Intellivision 1979	N.E.S. 1983	Atari Jaguar 1993	GameCube 2001	XBOX 360 2005
1.2 MHz					

Part 2. Assuming Moore's Law is true, write an expression to estimate how fast console processors should be in 2077, a century after the original Atari.

Part 3. We can think of the release of the Atari 2600 as the start of the video game era: 1977 CE becomes year 0 VG. Let the variable *t* represent the number of years that have passed since 1997, i.e., the video game year. Write an equation to calculate the expected processor speed for a given video game year.

Figure 1: The Xbox Xponential task (modified from Mathelicious, 2015).

During a semi-structured, clinical interview, a member of the research team asked the teacher to review the *Xbox Xponential* task. The teachers were prompted to articulate the mathematical opportunities to learn the task had the potential to support if used during classroom instruction. During the interview, the researchers collected video data of the teacher engaging with the task. Data analysis focused on how teachers approached the task mathematically and the descriptions they used to express the ways they thought students would interact with the task. We chose the Xbox task because it supported students to think about key mathematical ideas related to exponential functions and contained nonstandard elements. Specifically, the task provided opportunities for students to think about how a change in the independent variable other than one unit impacts the change in the dependent variable and how to capture that change in a table, an expression, and an equation. We anticipated that learners would work through calculating specific values using a multiplicative relationship between dependent and independent variables using recursive reasoning (part one), generalizing their work into an expression for a specific year (part two), and creating a general equation for the relationship (part three). This work provided the opportunity for students to learn about: the connections between multiplicative growth and exponential functions, the connections between repeated multiplication and exponents, and the importance of defining independent and dependent variables.

The Cases

Guided by an interpretive theoretical perspective (Creswell, 2013), we selected four teachers who engaged with the Xbox Xponential task during the clinical MKT interview in this multicase study (Stake, 2006). As part of our theoretical perspective, our participants developed "subjective meanings of their experiences," and our role as researchers was to interpret our participants' responses by relying "as much as possible on the participants' views" (Creswell, 2013, pp. 24-25). However, our analysis included interpretations and observations to investigate the teachers' MKT. The individual cases of Helen, Abby, Frankie, and Molly provided contrasting views of the Xbox Task and their cross-case analysis provided evidence of their collective MKT.

Helen

For part one of the task, Helen immediately identified the gaps in time and indicated them with arrows and increments from cell to cell in the table. For example, from 1983 to 1993, she drew an arrow and wrote "+10" to indicate the 10-year gap in time. She noted that all of the gaps in time are even which made "them all nice and easy" because "you [do] not have to deal with what happens if it is not an even number." After determining the gaps in time, Helen used a recursive strategy to find the values for the processing speeds by multiplying the previous value by a power of two based on the number of two-year intervals. For part two of the task, Helen initially wrote $y = 1.2 \cdot 2^{100}$. After moving on to part three of the task, she returned to part two to modify her answer to $f(100) = 1.2 \cdot 2^{100/2}$ which she simplified to $f(100) = 1.2 \cdot 2^{50}$. Finally, for part three of the task, she wrote her answer as $f(t) = 1.2 \cdot 2^{t/2}$. Helen completed all parts of the task as designed before addressing what learning opportunities were possible. With the exception of Helen's comment about the gaps in time in the table for part one being "nice and easy," Helen did not comment on her thinking while completing the task. It is interesting to note that Helen was able to attend to the two-year gaps and intervals in part one of the task, but she did not initially attend to them in part two of the task. It was only after moving on to part three that she returned to correct her answer.

With respect to the sequence of tasks, Helen claimed that "it's always easier for students to handle the numeric at first, especially if it's their first introduction to exponential functions." Starting with the table supports this view. She believed that her students would be able to "reason their way through" the table by attending to the two-year intervals and gaps in time. While some students might use a "brute force" strategy of repeatedly multiplying by two, Helen hoped that the table would motivate her students "to start thinking of another way." By doing that, she claimed that this "would allow them to make that jump into actually formalizing [the context] and writing it algebraically in general." Helen sees exponents as a tool students could use to complete the task. Helen noted that the sequence of tasks supports students at all levels to be able to complete the task since "not all students would be able to start [with part three]." The sequence gives all students "a path towards getting the ultimate goal of the [task] which would be coming up with [the function in part three]." Throughout these comments Helen is primarily focusing on students' completion of the task and the prior knowledge they need for successful completion of the task.

Helen highlighted that repeated multiplication is "a huge aspect of why we use exponential functions." She viewed the table as potentially supporting her in teaching students "about the behavior of exponential functions." Specifically, "the idea that you are doubling every certain number of years." In contrast to her previous comments, Helen, is now focused on student thinking about a key mathematical idea. Her comments stemmed from her view that the doubling is occurring every two years is "an interesting twist from the [tasks] that [her students] may be used to seeing." She hypothesized that her students would not recognize that they would need to divide the value in the exponent by two which is the same mistake she initially made when completing the task herself.

Abby

For part one of the task, Abby filled in the table by repeatedly multiplying the value in the previous table cell by two, ignoring the gaps in time. After completing the table in this way, she moved on to part two. She first wrote the equation, $f(x) = 1.2(2)^{x-1}$. Then, when she attempted to define her variable, x, she realized her error in part one. She then returned to part one of the task by identifying the size of the gaps in the years: +2, +4, +10, +8, and +4 respectively. Then, for each of the table cells, she identified the number of two-year intervals and multiplied the previous values by two raised to the exponent related to that number of intervals. For example, from 1983 to 1993 she multiplied 4.8 by 2^5 in order to calculate the value associated with 1993, or ten years after 1983. Later in the interview, Abby admitted that she did not attend to the years and assumed that they were "nice equal" intervals.

After completing the table for the second time, Abby returned to her earlier work where $f(x) = 1.2(2)^{x-1}$ was already written on the paper. Abby then defined x as "every two years." After asking herself, "does that work?" and checking values, Abby erased the original exponent $x - 1$ as well as her definition for the variable x. Looking back at the table, Abby changed the definition of the variable x to "# of yrs since 1997" and changed the exponent to $x/2$. Again, Abby checked her work by evaluating using her equation and comparing the values with the table in part one of the task. After reading the prompt for part three of the task, Abby noted that she "should read the question" for part two of the task. For her answer, Abby wrote and calculated $f(100) = (1.2)(2^{50}) = 1.251\times 10^{15}$ for part two of the task. She then moved on to part three of the task where she wrote $f(t) = 1.2(2)^{t/2}$ and defined the variable t as "# of yrs since 1997." Abby appeared to skim the task initially and completed what she assumed the parts of the task were asking. It was only after moving on to subsequent parts did Abby identify that she may have made an error. This suggests that Abby assumed that the task followed the format of (1) fill in the table for consecutive values, then (2) write an equation to model the context.

Abby noted that the overall sequence of tasks allowed students to access the mathematics at different levels. First, she liked "that we can model it numerically with the table." This is something that the students "could get just with a little calculator work and it is something that [the students] could actually conceptualize." Second, she noted that the task is an easy context to understand which would motivate students to complete it. Finally, the sequence of tasks "stair steps" students through the parts towards an answer and "gives them a method to check their work as they go." Specifically, the table allows students to see that they should divide by two in part two of the task as well as provides them with a way to check their function in part three of the task. Overall, Abby viewed the goal of the task as formulating a model which she claimed is done in part three of the task. She did not articulate any mathematical ideas that students would have the opportunity to think about through engagement with the task.

Abby noted that she could use the task to highlight the connections between the context and the actual real-world data. She noted that the task "would definitely teach [the students] to pay attention to their data." This mirrors the mistake Abby made while completing the task. Using this task, she might ask students to determine whether Moore's Law is true. Abby emphasized the use of graphing and using the table to check answers as strategies she would use to teach the task as well as a strategy for students to complete the task; again, highlighting Abby's focus on what students will do.

Frankie

Frankie only completed portions of the task for herself, and only after being prompted to do so by the interviewer. Frankie never filled in values for the table in part one of the task. However, she noted that, in order to complete the table, a rule like 1.2×2^x would be helpful and "is almost demanded" by the task design. In part two of the task, Frankie used her previously identified rule as a guide to find the answer $S_{2077} = 1.2 \times 2^{100/2}$. Frankie viewed part three of the task as a more formal version of the rule she constructed earlier. Specifically, the answer to part three of the task was $S(t) = 1.2 \times 2^{t}$ with the caveat that the *t* needed to be "adjusted." That is, "if *t* is the number of years, then you also have to have the idea that it's going to be divided by two." As a result, she rewrote her answer as $S(t) = 1.2 \times 2^{t/2}$.

Frankie highlighted the gaps in time for the various gaming systems. She noted that her students would likely need experience with problems that contain varying gaps in time to be successful in completing the task. In particular, she believed that her students' "tendency would be to just double and not pay attention to the years and how far apart they [are]." For those students who did attend to the gaps in years, Frankie expressed concern that they would get "hung up" on the 10-year jump. She believed that the table "is not necessarily going to get [the students] to an expression." To complete the table, the students might need "some intermediate values" in the table in addition to "really think[ing] about how the doubling is happening and how many doublings would take place." Frankie highlighted that students do not encounter tasks with interval gaps in other areas of the curriculum with the exception of linear functions. As a result, it would not be something that the students would immediately notice.

Frankie did not see a connection between part one of the task and part two of the task which might stem from the fact that she never completed the task as designed. As noted before, Frankie used a rule to support writing the answer to part two of the task. She claimed that her students would need to have "recogniz[ed] that doubling piece" in order to find the answer to part two of the task. While Frankie acknowledged that her students would need to have identified that the doubling was occurring over a two-year span, she did not connect part one of the task as supporting this realization in her students. If students successfully identified the doubling was occurring every two years, she believed some of her students would simplify their answers to part two of the task to "be two to the 50th power." Other students, she believed would simply raise to the 100th power without dividing by two. In her experience, her students, "when given something like 1.2×2^{x}, [the students] know to put a number in there and to get something." She noted that her students do not consider how "the power is changing." Throughout her comments Frankie is focused on the aspects of the task students are familiar or unfamiliar with and how they will respond.

Frankie viewed the purpose of the task as writing an example of a known formula type which matches the given data. She argued that "adjust[ing]" the power in part three of the task was the trickiest part of the overall task. She believed that her students would be able to work through parts one and two of the task "pretty well" and would not necessarily need to recognize "that any number of years is going to have to have [an] adjustment." While Frankie thought that students at "several levels" could be successful, she was concerned about students getting "caught up in the information" which would "keep them from moving forward."

Molly

Prior to starting the task Molly said that she had seen the task before when looking for material. When Molly began working on part one, she noted the varying gaps in years given in the table and said "this would give students an opportunity to start thinking about doubling periods." Molly suggested that she might have structured the table to start at year 0 and use the number of years since 1977 instead of using the actual years. As she continued to discuss student thinking around the table Molly created a table with "# of doubling periods" as the independent variable which she completed for three doubling periods. She transferred her work from the created table to the table provided in the task. Even though Molly said that she would present the information differently, she liked the way the task designers chose to present the information. Molly thought that the structure of the table would cause students to think about doubling periods as opposed to years. She said, "I think they're just thinking about doubling periods and they're working with exponents without realizing that's what they're working with." Molly did not complete the remainder of part one and it did not appear that Molly completed any of part the task for herself; rather, she the work she did was in service of illustrating the thinking she expected students to engage in.

When she began part two, Molly underlined "write an expression" and "a century." While discussing why the task designers included "a century," Molly initially seemed to misinterpret the task, she said "a century, ok and then they've given them another little hint here, so they're telling them that even though 2077 isn't, oh no, I'm sorry I was going back to 1965, so maybe that's what a student would do too." It seemed as if Molly had not thoroughly read the task and assumed that the initial processor speed was given for the year 1965. After clarifying the instructions Molly wrote the expressions $1.2(2)^{100/2}$ and $1.2(2)^{50}$. As with part one, Molly's work appeared to be in service of illustrating potential student thinking. She said the thinking in part two was similar to the thinking required for part one because students needed to focus on the number of doubling periods. She expected students to write $1.2(2)^{50}$ instead of $1.2(2)^{100/2}$ because "they're not going to want to see a fraction there so they would think about, it's doubled, I had to multiply it by two, fifty times." Molly said students might struggle with seeing how to come up with a pattern based on the starting point because they have to move from doing the problem recursively in part one to needing to base their expression off of a starting point in part two.

For part three, Molly underlined "write an equation for the expected processor speed for a given year" and then wrote $y = 1.2(2)^{(t-1977)/2}$ while explaining that part two can be generalized by starting with an original value and "multiplying by two a whole bunch of times." Molly explained the exponents as subtracting 1977 from the year you are looking for and then dividing by two. The equation mimics Molly's process in calculating the processor speeds. Only after the interviewer asked Molly a question which prompted her to reread the task did she write $y = 1.2(2)^{t/2}$ as her final answer for part three. Again, indicating that Molly did not thoroughly read the task but worked off of assumptions about the nature of the task. Molly summarized the overall structure of the task as, "from scaffolding from something that's very simple, just coming up with number answers … I need fifty years in the future, so I'm not going to be able to just keep extending my chart to get that … and so now I needed to take this and extend it to something where I can generalize." Molly said that this sort of task structure was common.

Cross Cases Analysis and Discussion

With this research study, we sought to describe aspects of a teacher's MKT based on what they attend to when reviewing a mathematics task for potential use during instruction. We claim that the previous case summaries provide rich opportunities to explore and describe aspects of the teachers' MKT including specialized content knowledge [SCK], knowledge of content and teaching [KCT], and knowledge of content and students [KCS] (Ball et al., 2008).

Ball et al. (2008) identified SCK as the "mathematical knowledge not typically needed for purposes other than teaching" (p. 400). This knowledge includes the ability to identify and interpret student mathematical work as well as the ability to make "features of particular content visible to and learnable by students" (Ball et al., 2008, p. 400). We chose this task partially because the relationship "doubling every two years" has the potential to make important mathematics visible to students. Specifically, doubling indicates that the relationship is exponential while the "every two-year period" adds a unique difficulty when compared to tasks the teachers would typically use. In the previous summaries, we saw that all of the teachers noted that "doubling every two years" was a significant part of the task. The ways in which the teachers spoke about the significance of "doubling every two years" revealed interesting aspects of their SCK

Helen saw the gaps in the years as something students needed to attend to in order to complete the table. She anticipated that students may not realize the number of years passed needed to be divided by two. She hoped the gaps would encourage students to use exponents as a push towards writing a function. Here she seemed to be implying something about student thinking but this was not explicit. When Helen talked about doubling, she explicitly discussed student thinking saying that students will understand something about the nature of exponential functions. Here we see that Helen's SCK allowed her to see the usefulness of the two-year gaps as supporting her students towards using exponents and writing an equation.

In contrast, Molly discussed the two-year gaps as doubling periods. Unlike the other teachers Molly did not anticipate the two-year gaps to be an issue for students. Rather she described students as finding the number of doubling periods for the two- and four-year gaps without necessarily realizing that they are dividing the number of years by two. Molly believed that students would realize that two years is one doubling period and that four years is two doubling periods. Molly thought that students might have more difficulty in thinking about the number of doubling periods for the ten-year gap. From Molly's interview, it is clear she saw the structure of the table as a key aspect of the task because it supports students in thinking about doubling periods. Molly's identification of aspects of the task which makes visible the key mathematical idea of doubling periods of exponential functions is an important component of SCK.

KCT "combines knowing about teaching and knowing about mathematics" (Ball et al., 2008, p. 401). For example, Ball et al. (2008) noted that teachers must "choose which examples to start with and which examples to use to take students deeper into the content" (Ball et al., 2008, p. 401). With respect to the task design, Abby, Molly, and Helen commented that they liked how the sequencing of the task provided scaffolding towards the equation and that starting with numerical calculations was easier for students. They all saw the goal of the task as doing something (writing a function) rather than thinking about some key mathematical ideas. This suggests that the three teachers KCT includes the idea that students can develop models of exponential growth from exploring values in a table, then calculating a larger value, and finally writing a formalized equation.

In contrast to Abby, Helen, and Molly, Frankie did not see the first part of the task as supporting students in completing the later parts of the task. For example, she identified the ten-year gap as especially significant as an obstacle that could prevent successful completion of the task. Frankie claimed that having a rule is almost required to complete the table and frequently discussed prior experience students would need to be successful in completing the task. Frankie's view of the purpose of the task was slightly different from Abby, Helen, and Molly. Where Abby, Helen and Molly saw the purpose as writing an equation based on the work done to create the table, Frankie saw the purpose as fitting a known equation type to the situation. This suggests that Frankie's KCT, as elicited by the task and the interview, does not include the same construct that the other teachers' have. Frankie's view of the purpose may be a consequence of her choice to write an equation to solve the first part of the task instead of solving the task as written. Her reliance on her equation to complete the table may have prevented her from seeing the ways that the table supported students to write an expression in part 2 and an equation in part 3.

Ball et al. (2008) defined KCS as the "knowledge that combines knowing about students and knowing about mathematics" (p. 401). This knowledge includes an understanding of the content so that the teacher can identify what has the potential to be confusing, challenging, easy, motivating, and interesting for students (Ball et al., 2018). In the preceding cases we saw that Helen, Abby, and Molly all wrote answers at some point during their work on the task that did not address the prompt as written, but rather what they assumed the prompt was. . For example, some errors stemmed from not realizing that the years in the table do not all have a gap of two or writing an expression with 100 as an exponent. All three teachers corrected their errors as they progressed through the task. Then, the teachers anticipated students encountering difficulty with the aspects of the tasks in which the teachers themselves made mistakes. This suggests that an aspect of the teachers' KCS is based on and includes knowledge of their own errors with respect to the task, indicating they possess the mathematical understanding to complete the task as written.

One of the most striking differences among how teachers reviewed the Xbox task surfaced when considering the coherence between the teachers' doing of the task and the ways students would think about and engage in the task. Molly focused on the way students would need to think about the mathematical concepts inherent in the task and only completed aspects of the tasks as a way to articulate student thinking. Unlike Molly, Abby and Helen completed the tasks for themselves before talking about students. When Abby and Helen discussed students, they tended to focus on describing what students may do and struggle with, but they did not articulate *why* or what thinking would create the struggle. Frankie, in contrast, did not complete the task as designed and discussed things not related to student mathematical thinking. Of the four teachers, Molly showed the greatest integration between the mathematics of the task and the students' thinking related to the task. That is, this task review assessment elicited evidence of Molly's SCK/KCS for exponential functions that we were not able to elicit from Helen or Abby.

Conclusion

The MKT interview was useful for gathering insight into teachers' MKT related to KCS, KCT, and KCC. The insight comes from doing an interview that allowed for teachers to articulate their own thinking in regards to a non-traditional task rather than selecting predetermined answers. We hypothesize that the interactions within an MKT interview provide a more genuine representation of MKT and call for further investigation.

INDUCTIVE REASONING IN MATHEMATICS TEACHERS WHEN RESOLVING GENERALIZATION TASKS

This study reports an analysis of inductive reasoning of Mexican middle school mathematics teachers, when solving tasks of generalization of a quadratic sequence in the context of figural patterns. Data was collected from individual interviews and written answers to generalization tasks. Based on Cañadas and Castro's inductive reasoning model, we found that most of the teachers followed four stages to obtain a general rule: observation of particular cases, search of patterns, conjecture formulation and generalization.

Keywords: Reasoning and Proof, Algebra and Algebraic Thinking, Inductive Reasoning, Figural Pattern, Generalization, Teacher.

Introduction

Inductive reasoning is a thought process that leads to the discovery of general rules by the observation and combination of specific instances (Polya, 1994). It is considered to be an important route to develop critical thinking and student´s ability to solve problem situations, to generalize different mathematical patterns and for mathematics learning (Sosa Moguel, Aparicio Landa, & Cabañas-Sánchez, 2019; Castro, Cañadas, & Molina, 2010; Papageorgiou, 2009; Haverty, Koedinger, Klahr, & Alibali, 2000). In addition, it also contributes on the route to make mathematical proof. However, students face difficulties with the formal validation processes. Some of these difficulties are linked to their reasoning skills and their capabilities to make and understand proofs immediately. For this, an adaptation process is required, as well as a logical progression in the development of their reasoning, from closer everyday reasoning to the concrete, to more abstract mathematical reasoning (Castro, Cañadas & Molina, 2010). Thus, it is recognized that induction fosters the development of these types of abilities, from the formulation of conjectures and their formal proof to guarantees of the veracity of the conjecture (Cañadas & Castro, 2007). In this regard, the National Council of Teachers of Mathematics [NCTM] (2000) stresses the need to develop middle school students' proficiency in using inductive (and deductive) reasoning to examine patterns and structures in order to identify regularities and make and evaluate conjectures about possible generalizations, in linear or quadratic patterns. Based on these demands on students, mathematics teachers are implicitly linked. To do so, they need the ability to help students make, refine, and explore conjectures on the basis of evidence and use a variety of reasoning techniques to confirm or refute those conjectures (NCTM, 2000). According to Brodie (2010), "teachers can, through questions and prompts, try to provoke learners into thinking in particular ways and support them to compare, verify, explain, and justify their conjectures" (p. 45). In addition, Ball and Bass (2003) say that, teachers need abilities in providing resources to the students to allow them to develop these skills and to use environments that make this possible.

On the other hand, most of the inductive reasoning research that studies it as a thought process and as a generator of knowledge in generalization tasks context, mainly refer to linear relationships. Few have been focused on quadratic ones (Kirwan, 2017), both in training and in-service teachers. This article examines the inductive reasoning of Mexican middle school mathematics teachers, when solving tasks of generalization of a quadratic sequence.

Theoretical Framework

Inductive reasoning is the human thought action that produces statements and reaches conclusions, starting with the observations of particular cases until arriving at a generality (Cañadas, 2002). It is a cognitive process that contributes to the advancement of knowledge, where more information is obtained than is provided by the initial data with which that process begins. Inductive reasoning in this study is analyzed from the inductive reasoning model proposed in Cañadas and Castro (2007). This model is based on Polya´s (1966) steps, Cañadas´s empirical work (2002) and Reid´s (2002) stages.

Inductive Reasoning Model

The inductive reasoning model is made up of seven stages. They are presented in an ideal order. They start with the observation of particular cases and end with the generalization. Not all these stages necessarily occur. In the following we describe these stages:

Observation of particular cases. The starting point of inductive reasoning is the experience with particular cases.

Organization of particular cases. The use of different strategies to systematize and facilitate work in particular cases.

Search of patterns. Some regularity or behavior is detected. Patterns are considered as something that is repeated regularly (Stacey, 1989), their recognition allows the development of the ability to generalize. There are different types of patterns: numerical, pictorial, figural, computational procedures or repetitive patterns (Amit & Neria, 2008).

Conjecture formulation. It is a statement about all possible cases, based in particular ones but with an element of doubt. This statement seems reasonable, but the validity needs to be validated. It has not been convincingly validated and it is not yet known that there are many examples that contradict it, nor is it known that it has any false consequence (Mason, Burton, & Stacey, 1988).

Conjecture validation. At this stage, there is an attempt to validate the conjecture for new specific cases, but not in general.

Generalization. Mathematics patterns are related to a general rule, not only to some cases. Based on a conjecture which is true for some particular cases, and having validated such conjecture for new cases (conjecture validation), students might hypothesize that the conjecture is true in general. Generalization is the deliberate extension of reasoning or communication beyond considered cases, recognizing and explaining their similarity (Kaput, 2008).

General conjectures justification. At this point, a formal proof can provide the final justification that guarantees the truth of the conjecture.

Method

This research is a qualitative and interpretative. It was carried out with sixteen middle school mathematics teachers (nine women and seven men) with between 5 and 14 years of teaching experience in public schools in Mexico. They were voluntarily involved in this study through inductive reasoning workshops in the context of mathematics education congresses. The participating teachers had professional qualifications as middle school teachers (Nine a mathematics bachelor's degree, two in Mathematics Education and five in Telesecundaria), so they all studied mathematical concepts such as sequences and linear an quadratic sequences. The selection criterion of the participants was to have experienced as a third grade teacher the teaching quadratic sequences using numerical and figural patterns. Taking into account the above, two task were designed on the generalization of quadratic sequences (see figure 1). The patio tile task adapted from Kirwan's study (2017) and the frog quadratic pattern task from Rivera's study (2013).

These tasks consist of increasing patterns with arithmetic progression of order 2 in the natural numbers. Teachers worked individually for 20 to 30 minutes on the tasks. After the analysis of their answers, six of them were interviewed, to understand in greater depth their inductive reasoning process and also because they had shown different ways of reasoning.

Table 1: Quadratic sequence tasks used in the research.

Task 1: The patio tile task. In the building of a patio, circular stones of equal size are placed. To observe the progress of the construction, you take a photo of the patio by stage.  a. How many circular stones have been placed for the sixth stage if the construction of the patio is carried out in the same way? Justify your answer. b. How many stones are there in stage 50? Justify your answer. c. How can you find the number of circular stones for any number of stages? Explain your answer	Task 2: The frog quadratic pattern task. Observe at the sequence of the following figures. Extensively justify the solution process in each of the questions.  a. How many gray squares are there in figure 5? b. How many gray squares are there in figure 7? c. How many gray squares are there in figure n?

Results

In this study the inductive reasoning stages most of the teachers followed were: Organization of particular cases, search of patterns, conjecture formulation and generalizing. Less frequently, the organization of particular cases and the conjecture validation. None of the teachers showed the involvement of the conjecture justification step.(see Table 2).

Table 2. Stages of inductive reasoning followed by mathematics teachers

Task	Stages						
	Observation of particular cases	Organization of particular cases	Search of patterns	Conjecture formulation	Conjecture validation	Generalization	General conjectures justification.
T1	11	5	12	7	2	11	0
T2	9	4	11	8	6	8	0

Observation and organization of particular cases

In task 1, eleven teachers observed particular cases and in task 2, nine. Most identified the number of objects at each stage of the sequence. In some cases, their work consisted of strategic counts based on the decomposition of the figures. The visualization of the figural pattern was fundamental to help teachers identify some configurations at the given stages. Other teachers relied on counting to establish the k-th terms and identify the type of sequence. Although it is recognized that teachers worked with particular cases, at least 3 of them faced difficulties in advancing to the following stages.

The teachers who used the organizing the particular cases stage (see Table 2) used double-entry tables, in which they established a correspondence between two variables, the number of objects in the figural pattern, with the number of the stage or figure, in the context of the demands of the tasks. The tables were represented in two ways, vertical and horizontal. This last form was used by the teachers who used the differences method in their inductive process to identify the type of sequences.

Search for Patterns

The teachers who identified the pattern resorted to two ways of proceeding (see Table 3):

A) Figure decomposition: The objects of the figural pattern were perceived as basic configurations: squares and / or rectangles. From this, a useful mathematical structure was associated to explain and justify the behavior of these objects.

B) Differences method: They identified the recurrence pattern between the k-th terms of the sequence associated with the figural pattern. Subsequently, they worked with the first difference and recognized that it is not constant, then the second differences were determined and observed that it is constant. Thus, they derived that the sequence is quadratic. Finally, they find the coefficients of the sequence of the form $ax^2 + bx + c$, to establish the general rule of quadratic sequence.

Formulation and justification of the conjecture

The teachers analyzed the behavior of the objects in the figures (figural pattern). At first, they made their conjectures through additive and multiplicative structures, then they transformed them into an algebraic structure, in terms of n (demand for the task) or with another variable. Few justified their conjectures. Of those who did, it was of the algebraic type and they validated it with particular cases.

Generalization

The results show that eleven of the sixteen teachers managed to construct the general rule that explains the behavior of the figural pattern in task 1 and eight teachers in task 2. Those who generalized without making conjectures used the difference method to recognize the type of sequence (quadratic) and based on that, they determined the general rule associated with the figural pattern. The generalization constructed by those who formulated a conjecture, verified its veracity. In some teachers, this process was carried out with the particular cases proposed and in others, through new cases, such as near and far terms. This process consisted of evaluating the conjecture, in correspondence between the quantity of the objects and the number of the stage or figure. Two ways of expressing the general rule were recognized, one algebraically and the other verbally.

Table 3: Ways of proceeding for the teacher when solving generalization tasks

Ways of proceeding	Task	Examples
Figure decomposition	T1	 Based on this way of perceiving the objects of the figural pattern in T1, they constructed a general rule associated with a multiplicative and additive structure: $(n+1)(n+2)+2$

Discussion and conclusion

This article examined the inductive reasoning of Mexican middle school mathematics teachers, when solving quadratic sequences generalization tasks. From a methodological point of view the tasks encouraged teacher´s work in near and far stages in order to build and validate a conjecture which explains the behavior of the involved figural pattern and to establish it as the general rule. Although as was mentioned above, not all of them showed the validation of their conjectures. On the other hand, it was recognized that not all of these stages necessarily occurred in the inductive reasoning processes carried out by teachers.

With regard to solving tasks in figural patterns generalization, teachers showed the inductive process as a strategy. The study has reported that working with well-defined figurative patterns favors that they be interpreted as configurations in a certain way (Rivera, 2010). In this sense, the teacher's task in this study consisted of involving a significant generalization of patterns. This study also recognizes that the objects of some figural patterns are complex to interpret, even when their construction is well defined. As an example, task 2 where the figural pattern involved more than one object, gray and white squares, in relation to the figure number. The task required the teacher to represent algebraically the behavior of the variable, that is, the gray squares which make up a rectangular figure, also made up of white squares. The distribution of gray squares was not related to a specific geometric figure. These variables influenced teachers' difficulties to recognize the behavior of gray squares.

In line with Rivera (2010), in this study the context of generalization of figural patterns engaged teachers in the coordination of perceptual and symbolic inferential abilities, more specifically, the figural pattern that is high in Gestalt goodness, because it tends to have a well-defined structure that has easily discernible parts and a balanced, and harmonious form of the pattern, which allowed most of the teachers to specify an algebraically useful formula. Naturally, the teachers proceeded in a different way when working with the objects of the figural pattern of each task.

RAZONAMIENTO INDUCTIVO EN MAESTROS DE MATEMÁTICAS AL RESOLVER TAREAS DE GENERALIZACIÓN

INDUCTIVE REASONING IN MATHEMATICS TEACHERS WHEN RESOLVING GENERALIZATIONS TASKS

Este estudio reporta un análisis del razonamiento inductivo de maestros mexicanos de matemáticas de secundaria, al resolver tareas de generalización de una sucesión cuadrática en un contexto de patrones figurales. Los datos fueron recolectados de entrevistas individuales y respuestas escritas de tareas sobre generalización. Con base en el modelo de razonamiento inductivo de Cañadas y Castro, encontramos que la mayoría de los maestros siguieron cuatro etapas para obtener una regla general: observación de casos particulares, búsqueda de patrones, formulación de conjeturas y generalización.

Palabras clave: Razonamiento Inductivo, Patrón figural, Generalización, Maestro.

Introducción

El razonamiento inductivo es un proceso del pensamiento que conduce al descubrimiento de reglas generales mediante la observación y la combinación de instancias específicas (Polya, 1994). Se considera una ruta importante para desarrollar el pensamiento crítico y las habilidades de los estudiantes para resolver situaciones problemáticas, para generalizar diferentes patrones matemáticos y para el aprendizaje de las matemáticas (Sosa Moguel, Aparicio Landa y Cabañas-Sánchez, 2019; Castro, Cañadas, & Molina, 2010; Papageorgiou, 2009; Haverty, Koedinger, Klahr y Alibali, 2000). Además, también contribuye en la ruta para hacer pruebas matemáticas. Sin embargo, los estudiantes enfrentan dificultades con los procesos formales de validación. Algunas de estas dificultades están relacionadas con sus habilidades de razonamiento y sus capacidades para hacer y comprender pruebas de inmediato. Para ello, se requiere un proceso de adaptación y seguir una progresión lógica en el desarrollo de su razonamiento, desde un razonamiento cotidiano más cercano al concreto, hasta un razonamiento matemático más abstracto (Castro, Cañadas y Molina, 2010). Así, se reconoce que la inducción fomenta el desarrollo de este tipo de habilidades, a partir de la formulación de conjeturas y su prueba formal para garantizar la veracidad de la conjetura (Cañadas y Castro, 2007). Al respecto, el Consejo Nacional de Maestros de Matemáticas [NCTM] (2000) enfatiza la necesidad de desarrollar la competencia de los estudiantes de secundaria en el uso del razonamiento inductivo (y deductivo) para examinar patrones y estructuras para identificar regularidades; establecer y evaluar conjeturas sobre posibles generalizaciones, en patrones lineales o cuadráticos. Sobre la base de estas demandas en los estudiantes, los maestros de matemáticas están vinculados implícitamente. Para hacerlo, necesitan de la habilidad para ayudar a los estudiantes a hacer, refinar y explorar conjeturas sobre la base de evidencia y usar una variedad de técnicas de razonamiento para confirmar o refutar esas conjeturas (NCTM, 2000). Según Brodie (2010), "el maestro puede, a través de preguntas y sugerencias, tratar de provocar que los estudiantes piensen de manera particular y ayudarlos a comparar, verificar, explicar y justificar sus conjeturas" (p. 45). Además, Ball y Bass (2003) afirman que los maestros necesitan habilidades para proporcionar recursos a los estudiantes que les permitan desarrollar estas destrezas y utilizar entornos que lo hagan posible.

Por otro lado, la mayoría de las investigaciones de razonamiento inductivo, que lo estudian como un proceso de pensamiento y como un generador de conocimiento en el contexto de tareas de generalización, se refieren principalmente a relaciones lineales. Pocos se han centrado en los cuadráticos (Kirwan, 2017), tanto en la formación como en el servicio de los docentes. Este artículo examina el razonamiento inductivo de los maestros mexicanos de matemáticas de la escuela secundaria, al resolver tareas de generalización de una sucesión cuadrática.

Fundamentación Teórica

El razonamiento inductivo es la acción del pensamiento humano que produce afirmaciones y llega a conclusiones, comenzando con las observaciones de casos particulares hasta llegar a una generalidad (Cañadas, 2002). Es un proceso cognitivo que contribuye al avance del conocimiento, donde se obtiene más información de la que proporcionan los datos iniciales con los que comienza ese proceso. El razonamiento inductivo en esta investigación se analiza a partir del modelo de razonamiento inductivo propuesto en Cañadas y Castro (2007). Este modelo se basa en los pasos de Polya (1966), el trabajo empírico de Cañadas (2002) y las etapas de Reid (2002).

Modelo del razonamiento inductivo

El modelo de razonamiento inductivo consta de siete etapas. Se presentan en un orden ideal. Comienzan con la observación de casos particulares hasta la generalización. No todas estas etapas ocurren necesariamente. A continuación describimos estas etapas:

Observación de casos particulares. El punto de partida del razonamiento inductivo son las experiencias con casos particulares.

Organización de casos particulares. Uso de diferentes estrategias para sistematizar y facilitar el trabajo con casos particulares.

Identificación de patrones. Se reconoce alguna regularidad o comportamiento. Los patrones se consideran como algo que se repite con regularidad (Stacey, 1989), su reconocimiento permite el desarrollo de la habilidad para generalizar. Existen diferentes tipos de patrones: numéricos, pictóricos, figural, procedimientos computacionales o patrones repetitivos (Amit & Neria, 2008)

Formulación de conjeturas. Es una afirmación sobre todos los casos posibles, basados en los particulares, pero con un elemento de duda. La conjetura es una afirmación que parece razonable, pero cuya veracidad no ha sido validada. No se ha validado de manera convincente y aún no se sabe que haya ejemplos que lo contradicen, ni se sabe que tenga alguna consecuencia falsa (Mason, Burton , & Stacey, 1988).

Validación de las conjeturas. En esta etapa, se intenta validar las conjeturas para nuevos casos específicos, pero no en general.

Generalización. Los patrones matemáticos se relacionan con una regla general, no solo con algunos casos. Con base en una conjetura que es cierta para algunos casos particulares, y habiendo validado dicha conjetura para casos nuevos (validación de la conjetura), los estudiantes podrían hipotetizar que la conjetura es verdadera en general. La generalización es extender deliberadamente el razonamiento o comunicación más allá de los casos considerados, reconociendo y explicando su similitud (Kaput,2008).

Justificación de las conjeturas. En este punto, una prueba formal puede proporcionar la justificación final que garantiza la veracidad de la conjetura.

Método

Es una investigación cualitativa e interpretativa. Se llevó a cabo con dieciséis maestros de matemáticas de secundaria (nueve mujeres y siete hombres) con 5 y 14 años de experiencia docente en escuelas públicas de México. Participaron voluntariamente en esta investigación a través de talleres de razonamiento inductivo en el contexto de congresos de Educación Matemática.

Los maestros participantes tenían calificaciones profesionales como maestros de escuela intermedia (nueve una licenciatura en matemáticas, dos en educación matemática y cinco en telesecundaria), por lo que todos estudiaron conceptos matemáticos como sucesiones y sucesiones lineales y cuadráticas. El criterio de selección de los participantes era que hubiesen experimentado como maestro de tercer grado la enseñanza de sucesiones cuadráticas utilizando patrones numéricos y figurales. Teniendo en cuenta lo anterior, se diseñaron dos tareas sobre la generalización de sucesiones cuadráticas (ver figura 1). La tarea de mosaico de patio se adaptó del estudio de Kirwan (2017) y la tarea de patrón cuadrático de rana del estudio de Rivera (2013).

Estas tareas consisten en patrones crecientes con progresión aritmética de orden 2 en los números naturales. Los maestros trabajaron individualmente durante 20 a 30 minutos en las tareas. Después del análisis de sus respuestas, se entrevistó a seis de ellos para comprender en mayor profundidad su proceso de razonamiento inductivo y también porque habían mostrado diferentes formas de razonamiento.

Tabla 1: Tareas de sucesiones cuadráticas utilizadas en la investigación

Tarea 1*: Tarea de la piedra del patio*. En la construcción de un patio, se colocan piedras circulares de igual tamaño. Para observar el avance que sigue la construcción, se toma una foto al patio por etapa  a. ¿Cuántas piedras circulares se han colocado para la sexta etapa si en la construcción del patio se avanza de la misma manera? Justifica tu respuesta. b. ¿Cuántas para la etapa 50? Justifica tu respuesta. c. ¿Cómo se puede hallar la cantidad de piedras circulares para cualquier número de etapa? Describe ampliamente tu respuesta.	**Tarea 2: *Tarea del patrón cuadrático de la rana*.** Observa la secuencia de las siguientes figuras. Justifica ampliamente el proceso de solución en cada una de las preguntas.  a. ¿Cuántos cuadrados grises conforman la figura 5? b. ¿Cuántos cuadrados grises conforman la figura 7? c. ¿Cuántos cuadrados grises conforman la figura n?

Resultados

En este estudio, las etapas de razonamiento inductivo que siguió la mayoría de los maestros fueron: Organización de casos particulares, Búsqueda de patrones, formulación de conjeturas y generalización. Con menos frecuencia, la organización de casos particulares y la validación de conjeturas. Con respecto al paso de justificación de conjeturas, ninguno de los maestros mostró haber estado involucrado (ver Tabla 2).

Tabla 2. Etapas del razonamiento inductivo que siguen los maestros de matemáticas

Tarea	Etapas					
	Observación de casos particulares	Organización de casos particulares	Búsqueda de patrones	Formulación de la conjetura	Validación de la conjetura	Generalización	Justificación de la conjetura

T1	11	5	12	7	2	11	0
T2	9	4	11	8	6	8	0

Observación y Organización de Casos Particulares

En la tarea 1, once maestros observaron los casos particulares y en la tarea 2, nueve. La mayoría, identificó la cantidad de objetos en cada etapa de la sucesión. En algunos casos, este trabajo consistió de conteos estratégicos, basado en la descomposición de las figuras. La visualización del patrón figural fue fundamental, ya que contribuyó a que los maestros reconocieran determinadas configuraciones en las etapas dadas. Otros maestros, se apoyaron del conteo para establecer los términos k-ésimo e identificar el tipo de sucesión. Si bien se reconoce que los maestros trabajaron con casos particulares, al menos 3 evidenciaron dificultades para avanzar a las etapas siguientes.

Los maestros que recurrieron a la organizaron los casos particulares (ver tabla 1) se apoyaron de tablas de doble entrada, en las que establecieron una correspondencia entre dos variables, cantidad de objetos del patrón figural, con el número de la etapa o figura, en el marco de las demandas de las tareas. Las tablas fueron representadas de dos formas, vertical y horizontal. Esta última forma, fue utilizada por los maestros que se apoyaron del método de diferencias en su proceso inductivo, para identificar el tipo de sucesión.

Identificación del Patrón

Los maestros que identificaron el patrón, recurrieron a dos formas de proceder (ver tabla 2):

A. **Descomposición de la figura:** Percibieron los objetos del patrón figural como configuraciones básicas: cuadrados y/o rectángulos. A partir de ello, asociaron una estructura matemática útil para explicar y justificar el comportamiento de estos objetos.
B. **Método de diferencias:** Identificaron el patrón de recurrencia entre los términos k-ésimo de la sucesión asociada con el patrón figural. Posteriormente, trabajaron con la primera diferencia y reconocieron que no es constante, luego se determinaron las segundas diferencias y observaron que es constante. Por lo tanto, derivaron que la sucesión es cuadrática. Finalmente, encuentran los coeficientes de la sucesión de la forma $ax^2 + bx + c$, para establecer la regla general de la sucesión cuadrática.

Formulación y Justificación de la Conjetura

Los maestros percibieron el comportamiento de los objetos en las figuras (patrón figural). Al principio, hicieron estas conjeturas a través de estructuras aditivas y multiplicativas, luego las transformaron en una estructura algebraica, en términos de n (demanda de la tarea) o con otra variable. Pocos justificaron sus conjeturas. De los que lo hicieron, fue el tipo algebraico y lo validaron con casos particulares.

Generalización

Los resultados evidencian, que once de los dieciséis maestros, lograron construir la regla general que explica el comportamiento del patrón figural en la tarea 1 y ocho, en la tarea 2, esto es, generalizaron. Los que generalizaron sin formular conjeturas, usaron el método de diferencias para reconocer el tipo de sucesión (cuadrática) y con base en ello, determinaron la regla general asociada al patrón figural. La generalización construida por quienes formularon una conjetura, la verificaron para comprobar su veracidad. En algunos, este proceso fue realizado con los casos particulares propuestos y en otros, mediante nuevos casos, como términos cercanos y lejanos. Este proceso consistió en evaluar la conjetura, en correspondencia entre la cantidad de los objetos con el número de la etapa o figura. Se reconocieron dos formas de expresar la regla general, una de forma algebraica y otra, verbal.

Tabla 3: Formas de proceder de los maestros al resolver tareas de generalización

Formas de proceder	Tarea	Ejemplos
Descomposición de la figura	T1	 Con base en esta forma de percibir los objetos del patrón figural en T1, construyeron una regla general asociada a una estructura multiplicativa y aditiva: $(n+1)(n+2)+2$
	T2	 Con base en esta forma de percibir los objetos del patrón figural en T2, construyeron una regla general asociada a una estructura multiplicativa y aditiva: $4(1+2n)+n(n+1)$
Método de diferencias	T1	Términos k-ésimo 8 14 22 32 Primera diferencia 6 8 10 Segunda diferencia 2 2 Con base en esta forma de percibir los objetos del patrón figural en T1, construyeron una regla general asociada a una expresión algebraica: x^2+3x+4 A partir del algoritmo de $a+b+c=8$; $3a+b=6$; $2a=2$, hallaron los coeficientes de la sucesión.
	T2	Términos k-ésimo 14 26 56 74 Primera diferencia 12 14 16 Segunda diferencia 2 2 Con base en esta forma de percibir los objetos del patrón figural en T2, construyeron una regla general asociada a una expresión algebraica: x^2+9x+4 A partir del algoritmo de $a+b+c=14$; $3a+b=12$; $2a=2$, hallaron los coeficientes de la sucesión.

Discusión y conclusiones

Este artículo examinó el razonamiento inductivo de los maestros mexicanos de matemáticas de secundaria, al resolver tareas de generalización de sucesiones cuadráticas. Desde un punto de vista metodológico, las tareas alentaron el trabajo del maestro en etapas cercanas y lejanas, para construir y validar una conjetura que explica el comportamiento del patrón figural involucrado y establecerlo como la regla general. Aunque como se mencionó anteriormente, no todos evidenciaron la validación de sus conjeturas. Por otro lado, se reconoció que no todas estas etapas ocurrieron necesariamente en los procesos de razonamiento inductivo llevados a cabo por los maestros.

Con respecto a la resolución de tareas en la generalización de patrones figurales, los maestros mostraron el proceso inductivo como una estrategia. La investigación ha documentado que trabajar con patrones figurales bien definidos favorece que sean interpretados como configuraciones de cierta manera (Rivera, 2010). En este sentido, la tarea del maestro en esta investigación consistió en involucrarse en una generalización significativa de los patrones. Este estudio también reconoce que los objetos de algunos patrones figurales son complejos de interpretar, incluso cuando su construcción está bien definida. Como ejemplo, la tarea 2. El patrón figural involucraba más de un objeto, cuadrados grises y blancos, en relación con el número de la figura. La tarea demandó representar algebraicamente el comportamiento de la variable, es decir, los cuadrados grises que conforman una figura rectangular, también compuesta de cuadrados blancos. La distribución de cuadrados grises no está relacionada con una figura geométrica específica. Estas variables influyeron en las dificultades de los maestros para reconocer el comportamiento de los cuadrados grises.

En línea con Rivera (2010), en esta investigación, el contexto de generalización de patrones figurales involucró a los maestros en la coordinación de habilidades inferenciales perceptivas y simbólicas, más específicamente el patrón figural que es alto en la bondad de Gestalt, porque tiende a tener una definición bien definida, estructura que tiene partes fácilmente discernibles, forma equilibrada y armoniosa del patrón, lo que permitió a la mayoría de los maestros especificar una fórmula algebraicamente útil. Naturalmente, los maestros procedieron de manera diferente al trabajar con los objetos del patrón figural de cada tarea.

AN APPROACH TO DENSITY IN DECIMAL NUMBERS: A STUDY WITH PRE-SERVICE TEACHERS

UN ACERCAMIENTO A LA DENSIDAD EN LOS NÚMEROS DECIMALES: UN ESTUDIO CON PROFESORES EN FORMACIÓN

Mayra Suárez-Rodríguez
Center for Research and Advanced Studies (Cinvestav)
mayra.suarez@cinvestav.mx

Olimpia Figueras
Center for Research and Advanced Studies (Cinvestav)
figuerao@cinvestav.mx

Researchers, who have studied the understanding of the density property in the set of decimal numbers, have shown that the student uses the property of the discrete of natural numbers to solve tasks related to density. So, a restructuring of concepts is necessary, that is, a conceptual change from "the discrete" to "the dense". This report presents evidence from ten pre-service teachers from Mexico City that this change can initiate through the implementation of a didactic sequence. The pre-service teachers managed to visualize that a decimal number can be found in an interval. Consequently, they were able to conceive an infinity. However, several of them persisted with the idea of the existence of a successor in the set of decimal numbers.

Keywords: Teacher training, rational numbers, Concepts of numbers and operations, Mathematical knowledge for teaching

The challenges that students face when solving situations related to the density property of rational numbers have not been an easy process. When a student concludes elementary school, he believes that there is no other number between two decimal numbers. For example, in Argentina, fifth graders (10 years old) think that between 4.2 and 4.3 there is no other decimal (Broitman, Itzcovich & Quaranta, 2003). Ávila (2008) reports that only 10% of students in elementary school answer correctly the exercises of density property raised in the national evaluations in Mexico.

After elementary school, students still have the same thinking about the discrete property of natural numbers during middle school. This can be confirmed in the research carried out by Neuman (1998). He exposes that German seventh graders in elementary education (13 years old) associated common properties with natural numbers to solve questions related to the density of fractions. Hart, in 1981 (as cited in Widjaja, Stacey & Steinle, 2008), stated that between 22% and 39% of students from 12 to 15 years old thought that there were eight, nine or ten decimal numbers between 0.41 and 0.42 (for example, the nine decimal numbers in the order of thousandths: 0.411, 0.412, 0.413, 0.414, 0.415, 0.416, 0.417, 0.418, and 0.419).

The students in college and pre-service teachers are in the last stage of schools. In the United States, future teachers think there is a finite number of intermediate numbers in an interval and a rational number has a successor (Tirosh, Fischbein, Graeber & Wilson, 1999). In Indonesia, half of a population of pre-service teachers considered a finite amount of decimal numbers between two given numbers (Widjaja et al., 2008). Most of the 62 pre-service teachers and more than a tenth of 71 students specialized in mathematics at the university level in Finland used properties corresponding to the natural number system on tasks associated with the density property of fractions (Merenlouto & Lehtinen, 2004).

This problem seems to persist from elementary school therefore the attention was focused on pre-service secondary teachers; in this level the properties of decimal numbers including the density property are studied in more depth. It should mention that this document is an extension of a brief research report presented by Suárez-Rodríguez and Figueras in 2019.

Objectives

Considering the need to overcome the difficulty that a pre-service teacher has about the property of density in the decimal numbers' set, a didactic sequence was proposed (see Suárez-Rodríguez, 2017) to generate a *metaconceptual awareness*. In the process of conceptual change, the student begins to assume a metaconceptual awareness when he is aware that their assumptions and beliefs are hypothetical and limit how you interpret the information you learn (Vosniadou, 1994). Therefore for the present research, the following aims were established: 1. Identify and write explanatory framework — different ways of expressing an individual's interpretations (Vamvakoussi, Vosniadou & Van Dooren, 2013) — that pre-service teachers make about the density property of decimal numbers when they have a metaconceptual awareness, and 2. Analyze the actions of the participants in solving the activities if a conceptual change is promoted.

Theoretical Framework

Carey, in 1987, proposes the cognitive-developmental approach to Conceptual Change, in which she explains how childhood cognition works and develops alternatives to initiate a process of conceptual change. The author points out that the knowledge of an individual's concept, initially, is linked to a *naive theory* (it consists of explanations of innate concepts or concepts learned from everyday experience related to science). An example of a naive theory, or naive idea, in mathematics is one in which the student believes that there are only nine numbers between 1.2 and 1.3, namely: 1.21, 1.22, 1.23, 1.24, 1.25, 1.26, 1.27, 1.28, 1.29 (Suárez-Rodríguez, 2017). Once the knowledge is associated with naive theories, this will be linked with others forming a knowledge system in the student (Carey, 1987).

Vosniadou (1994) proposes that naive theories constitute the *mental models* of the human being and that these models are the first step to initiate a process of conceptual change. For Vosniadou, a mental model is a representation that the student forms about ideas that he or she acquires, either through experience or instruction, and that is accompanied by presuppositions. When a student assumes metaconceptual awareness these models change, the *synthetic models* are produced and represent the students' attempts to reconcile the culturally accepted scientific views with the presuppositions of their naive theories (Vosniadou, 1994). Finally, conceptual change requires changes in the presuppositions and beliefs that the student must make in his representations so that he can access the *scientific concepts*, and thus achieve an understanding of the concepts learned (Vosniadou , 1994; Vosniadou, Vamvakoussi, and Skopeliti, 2008).

In the educational field of mathematics, Stafylidou and Vosniadou (2004) and Vosniadou and Verschaffel (2004) often use explanatory frameworks instead of mental models or synthetic models. The first explanatory frameworks that the student carries out are the first reflections that form a coherent and solid structure about what he learns along with his presuppositions and beliefs (Vosniadou and Verschaffel, 2004). Continuing the idea to these researchers, we can say that the initial explanatory frameworks are the first thoughts a student makes about what he perceives, what he sees, what he plays and explains in his own way, in his words. In the context of a learning process likewise, the expression conceptual change is a process of restructuring concepts when the student is learning information that is not compatible with his knowledge built up to now so the student must make a resignification of concepts. This is how the understanding of the density property involves a process of conceptual change, gradually, a restructuring from "the discreet" to "the dense", as argued by Suárez-Rodríguez and Figueras (2019).

A conceptual change: the restructuring of the discrete to the dense

Ni and Zhou (2005) point out in their research three possible causes that make the student has difficulties to answer tasks associated with rational numbers when he uses knowledge about the natural number. A first cause is related to the innate, that is if the property of the discrete of the set of natural numbers is innate in nature. The second cause is related to the teaching of the properties of the set of natural numbers and the set of rational numbers. And finally, the relationship between student´s learning the concepts and learning the symbology of those concepts. Faced with this, Vamvakoussi and Vosniadou (2012) devised a strategy using the analogy between stretching an "elastic band" and the density property. The student, as he stretches the elastic band, observes that there is more space between "the two points drew"; therefore, there are more "imaginary points". Thus, the students (between 13 and 17 years old) achieved to imagine a similar relationship between the stretch of the garter and the property of density. In the research performed by Vamvakoussi and Vosniadou with 15-year-old students, in 2004, different explanatory frameworks were identified and described, related to a thought linked to finite or infinite quantities of rational numbers in an interval (see Table 1).

Table 1: Characterization of thinking about the quantity number of numbers in an interval

Naive thinking about the discrete	It is thought that there is no other number between two *consecutive false* rational numbers. Vamvakoussi and Vosniadou (2004) created this expression to refer that exists a successor of a rational number.
Advanced thinking about the discrete	It is thought there is a finite quantity of numbers between two consecutive false rational numbers.
Mixed thinking between discrete and dense	In some cases, it is thought that between two rational numbers there is an infinity of numbers; and in other cases, it is thought there is a finite number of intermediate numbers.
Naive thinking about the dense	It is understood that there is an infinity of numbers in an interval, but this situation is not justified by using the density property. The symbolic representation of the extremes of an interval influences the way of thinking; it is believed there can only be an infinite number of decimal numbers between decimals and an infinity of fractions between fractions, but not an infinity of fractions between decimals or otherwise.
Advanced thinking about the dense	There is a sophisticated understanding of the density property; that is, it is understood that there is an infinite number of numbers between two rational numbers, regardless of their symbolic representation and this is justified through the use of the density property.

Methodology

Participants

The population studied was 10 pre-service teachers in mathematics at the secondary basic education of an institution in Mexico City, in 2017. One of these participants was 36 years old and the others were between 18 and 23 years old.

Educational experimentation design

The implementation of the didactic sequence with the pre-service teachers focused on one purpose: to generate metaconceptual awareness. Vamvakoussi and colleagues (2013) indicate that conceptual change through instruction is a slow and gradual process because it not only involves the reorganization of conception but also of the entire knowledge system. However, the authors describe that a conceptual change can be achieved gradually with the following criteria: (a) an in-depth exploration of the concepts to learn, (b) to take into account the student's prior knowledge, (c) to facilitate a metaconceptual awareness, (d) to provide meaningful experiences, and (e) to encourage the use of various representations, whether graphic, written, or made with digital resources.

Considering the previous criteria and the backgrounds that shape the problem about around the understanding of the density property by the student, we designed and elaborated of the activities of the didactic sequence. The sequence was structured in two stages. The first stage is to recognize the participants' first explanatory frames through a paper and pencil questionnaire (diagnosis) and individual interviews. The second stage was elaborated with individual and group activities to identify and analyze their actions, in turn, their explanatory frameworks. This stage was carried out in four sessions about 1. The perception of the dense in concrete materials. 2. Addition and subtraction of decimals, 3. Localization of decimals in intervals, and 4. Comparing decimal numbers.

Results

Results of the questionnaire as diagnosis (first stage)

The pre-service teachers answered an 11-question questionnaire which showed the first explanatory frameworks related to the categories proposed by Vamvakoussi and Vosniadou (2004) about the property of the discrete and the property of density. Below are the responses of several participants to some questions, as well as some of their comments expressed in the individual interviews to find out the justification for their answers.

Naive thinking about the discreet. Some pre-service teachers considered that the extremes of an interval are consecutive and therefore they assured there cannot another number in this interval. Figure 1 shows the case of Amanda. She carried out the process of a fractional representation to a finite decimal writing, and she argued that both ends of the interval are consecutive.

5. Can you find decimal numbers and or fractions between 0.49 and 1/2? Write your answer.

No porque $\frac{1}{2}$ es 0.5 el siguente de 0.49

Amanda shows that 1/2 = 0.5 = 0.50 is the successor of 0.49. She mentions in the interview "0.49 and 1/2 are consecutive".

Figure 1: Naive thinking about discrete (example)

Advanced thinking about the discreet. The finite subdivision process in an interval was one of the initial explanatory frameworks the participants operated to confirm the existence of a finite of decimal numbers in a range. The notion that only numbers on the order of tenths — at most hundredths — are decimal numbers may be influenced by responses related to finite sets within an interval. For example, Fabiola evokes a finite process, considering a certain number of decimal places of a number to affirm that there are nine decimal places in the given interval; therefore, the idea of false consecutive numbers underlies (see Figure 2).

2. How many decimal numbers are there between 1.2 and 1.3?

Si nueve

Fabiola wrote that there were 9 numbers in the range. She said there were only 1.21, 1.22, 1.23, 1.24, 1.25, 1.26, 1.27, 1.28, and 1.29 (as she expressed in the interview).

Figure 2: Advanced thinking about discrete (example)

It is worth mentioning that some pre-service teachers have an initial explanatory framework that a successor is a number greater than itself. Perhaps, Isabella thinks the successor of any number is a larger number, as in her example: natural 7, 8 (See Figure 3).

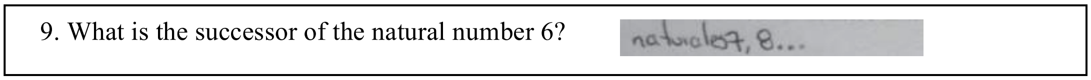

Figure 3: Belief of the successor's existence as a larger number (example)

To finish this first stage of the didactic sequence, it is concluded that half of the pre-service teachers tend to have combined thinking between the discrete and the dense, while three of them apparently have advanced thinking about the discrete and the rest tend to have naive thought related to the discreet.

Results of the activities of the didactic sequence (second stage)

The following paragraphs describe some actions and explanatory frameworks of the teachers in training who interacted with activities in the didactic sequence.

Performances related to the perception of the dense in concrete materials. The purpose of the first activities of the didactic sequence is that the future teacher conceives the notion of an infinity of numbers in an interval through an "infinity of points" in a geometric context. They reported that the more the elastic band was stretched (Vamvakoussi & Vosniadou, 2012), there could be more space; therefore, more imaginable points. The same occurs when blowing up a balloon. The participants pointed out that the more the balloon was blown up, the more space there would, be therefore, more imaginary points.

Performances identified with addition and subtraction with decimal numbers. For this second session, participants answered to two activities that emerged from the activities made by Broitman et al. (2003). The objective of the activities is the recognition of skills in writing different decimal numbers. In one of the activities, the teacher-researcher writes the number *1.5* on the board, then the pre-service teacher writes the greatest number of addends and that the total sum approaches or equals 10. Some participants revealed the use of numbers until two decimal places in this first experience, for example, Karen's explanatory framework. She used numbers with two decimal places, even considering the number 0 for the hundredths, as can be seen in Figure 4. Karen only writes down the numbers between 0 and 1. She first writes the sequence *0.5*, *0.4*, *0.3,* and then registers *0.25*, *0.75, 0.80,* and *0.15*; that is, she decomposes to hundredths. Then she writes *0.20*, *0.70*, *0.40,* and *0.30* and recognizes that zero can have the hundredths position. Perhaps she did not perceive the equivalence between 0.3 and 0.30 as well as 0.4 and 0.40 since the activity required different numbers.

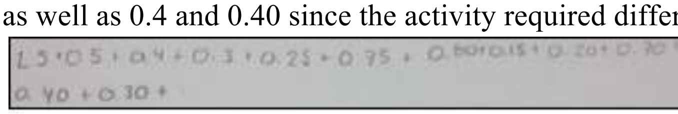

Figure 4: Karen's record on the addition and subtraction activity

Nicolás' explanatory framework was based on registering numbers up to six decimal places, but apparently, he had a strategy (see Figure 5). He wrote down the number *0.000001* and then *0.000009*, and in the following rows the position of the digit 9 changes. Nicolás wrote 9 in the position of the millionths, then in the position of the hundred-thousandths, then in the ten-thousandths, the thousandths, the hundredths, and finally, in the tenths. The process that Nicolás followed was to multiply 9 by $1/10^n$, where n is a natural number, starting with the millionth position (that is, $n = 6$). The sum of the numbers that Nicolás wrote is 1. This participant used numbers up to millionths and in the diagnostic questionnaire showed examples related to advanced thinking associated with the discrete. This fact highlights a process of a gradual conceptual change since he recorded numbers with up to two decimal places in some questionnaire responses.

Figure 5: Nicolás' record on the addition and subtraction activity

Performances linked to locating decimal numbers in intervals. The two activities in this session were developed from one made by Brousseau (1981) that seek to locate numbers in an interval, as well as find intervals for a given number. In one of the activities, future teachers should look for the interval in which the number "thought" by a colleague is found and pose questions to find that interval. The ends of this interval must be decimal numbers whose decimal places are consecutive. Figure 6 shows an example of a participant who wrote the intervals his colleagues mentioned and marked with an "X" those that did not correspond. Olga considered the numerical representation until ten-thousandths in the hidden number, 28.9306. She had shown evidence of naive thinking concerning discrete in the development of the diagnostic questionnaire. It seems, that Olga has been doing a restructuring of concepts because she believed there were only numbers up to two decimal places. Perhaps, she used the numerical representation of the order of the ten-thousandths as a consequence of the socialization of the previous activities (related to additions and subtractions).

Performances associated with comparing decimal numbers. The two comparison activities, in the last session of the didactic sequence, are part of a study carried out by Castillo in 2015, in Mexico. Understanding the density property of decimals from the decimal comparison property is the aim of the activities. In one of the activities, each future teacher must complete a decimal numbers' series. Figure 7 shows the work made by that one of the five participants carried out and completed the sequence correctly. His strategy consisted in detailing the last digits of the numbers that appear to "modify" them and, in other cases, to "add digits" without altering the ordering.

Some teachers in training did not perceive the equivalence between decimals, for instance, Olga, Isabella, Oscar, and Amanda (see Figure 8). Olga added a zero in the ten-thousandth position of the number 30,871. Isabella and Olga added two zeros in the hundred-thousandth and millionth positions of the number 30.8712. While Oscar added a zero in the position of one hundred-thousandths of the number 30.8721, and Amanda added a zero to the end of the expression 30.87125.

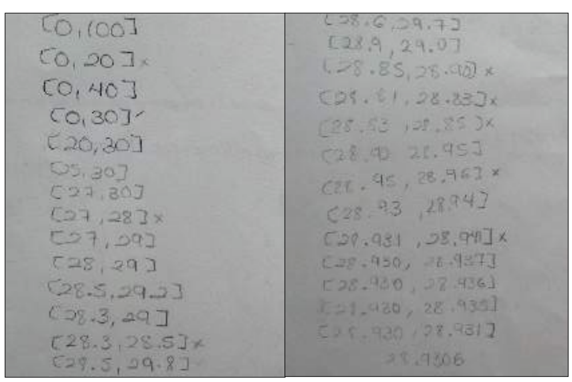

Figure 6: Future teacher's record on the location activity

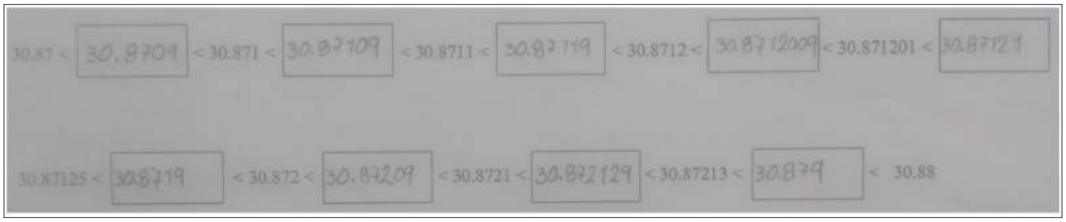

Figure 7: Future teacher's record on the comparison activity

Figure 8: Records of four participants in the comparison activity

After completing the individual test, the future teachers wrote down the numbers written on their worksheets on the board (see Figure 9). In order for the pre-service teacher to achieve a metaconceptual awareness that the property of density helps to visualize the fact that there is no successor in the set of decimal numbers, it was shown that between pairs of false consecutive ones it is found at least a decimal number, therefore an infinity. For example, in Figure 9 (see oval) that observed between the pair of false consecutive *30.8711* and *30.8712* are located the least seven decimal numbers, larger than the first and smaller than the second: *30.87112*, *30.871103*, *30.87119*, *30.871105*, *30.871102*, *30.87115* and *30.871106*

Finally, the teacher-researcher asked the participants if there were other strategies to find intermediate numbers in this activity. Nicolás mentioned "the arithmetic mean". The teacher-researcher accomplished a brief example with a pair of numbers from the activity to show the arithmetic mean helps to find intermediate numbers in an interval.

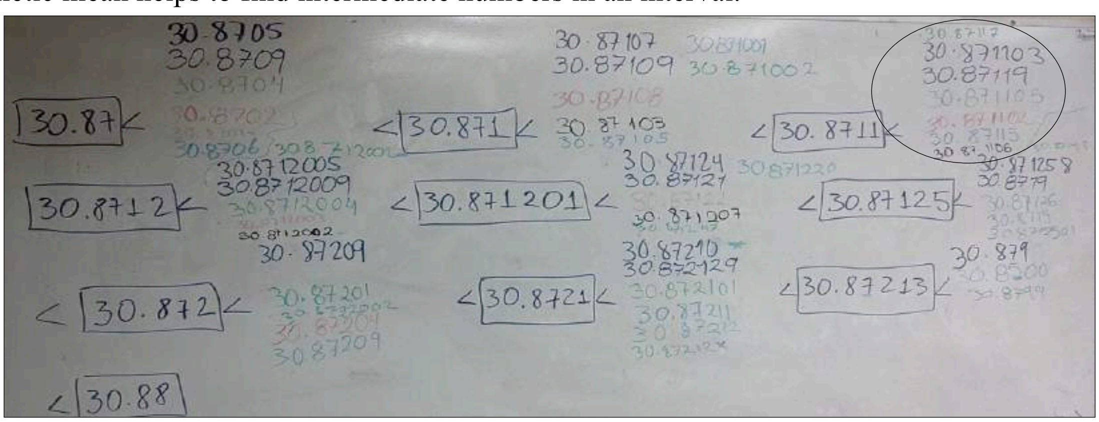

Figure 9: Participants' annotations in the comparison activity

Conclusions and implications

The socialization of the activities of the didactic sequence with the pre-service teachers promotes an approach to the understanding of the density property of the decimal numbers, and, in consequence, a process of conceptual change from the discrete to the dense. In the development of the diagnostic questionnaire, the ten future teachers had evidenced examples of thought associated with the property of the discrete of natural numbers. During the implementation of the activities of the didactic sequence, the ten participants achieved to extend the number of decimal places, a strategy that allowed them to locate numbers in an interval. However, three future teachers questioned the mediation about the existence of a decimal's successor; they even included in their explanatory framework the existence of a successor to a decimal number as a larger number.

Developing the writing of decimal expansion of a number is considered a task that may help the future teacher, or a student in general, in understanding the series' concept. Sums of arithmetic or geometric progressions with infinite terms are series' examples. A number with periodic decimal writing expresses an approximation of a rational number, which is the limit value of rational, for example, the limit value of the decimal expansion 0.0123123123... is 41/3330. Likewise, the development of writing infinite decimal expansions that cannot be expressed as a fraction could help the student to understand the irrational number' concept. Finally, as indicated by Suárez-Rodríguez and Figueras (2019), the didactic sequence is an example of a teaching model that may be of interest to in-service teachers who could start studying the density property in their classroom's lessons.

Acknowledgments

The research project was funded by Conacyt and Cinvestav. Special thanks to the teachers in training who voluntarily participated in the didactic sequence.

UN ACERCAMIENTO A LA DENSIDAD EN LOS NÚMEROS DECIMALES: UN ESTUDIO CON PROFESORES EN FORMACIÓN

AN APPROACH TO DENSITY IN DECIMAL NUMBERS: A STUDY WITH PRE-SERVICE TEACHERS

Mayra Suárez-Rodríguez Olimpia Figueras
Centro de Investigación y de Estudios Avanzados del IPN (Cinvestav)
mayra.suarez@cinvestav.mx figuerao@cinvestav.mx

Investigadores que han estudiado la comprensión de la propiedad de densidad en el conjunto de los números decimales han mostrado que el estudiante usa la propiedad de lo discreto de los números naturales para resolver tareas relacionadas con la densidad. Por lo que es necesaria una reestructuración de conceptos, es decir, un cambio conceptual: de "lo discreto" a "lo denso". En este informe se presentan evidencias de diez profesores en formación, de la Ciudad de México, de que se puede iniciar ese cambio a través de la puesta en marcha de una secuencia didáctica. Los profesores en formación lograron visualizar que en un intervalo se puede encontrar un número decimal, en consecuencia, lograron concebir una infinidad. No obstante, varios de ellos persistieron con la idea de la existencia de un sucesor en el conjunto de los números decimales.

Palabras clave: preparación de maestros en formación, números racionales, conceptos de números y operaciones, conocimiento matemático para la enseñanza

Los desafíos que enfrentan los estudiantes para resolver situaciones relacionadas con la propiedad de densidad de los números racionales no han sido un proceso sencillo. Un estudiante que concluye la educación primaria cree que no hay otro número entre dos decimales. Por ejemplo, en Argentina, los estudiantes de 5to de primaria (10 años de edad) piensan que entre 4.2 y 4.3 no hay otro decimal (Broitman, Itzcovich, y Quaranta, 2003). Por otro lado, Ávila (2008) informa que solo el 10% de los estudiantes de la educación primaria responde correctamente ejercicios vinculados con esta propiedad en los exámenes nacionales en México.

Concluida la educación básica primaria los estudiantes siguen teniendo un pensamiento concerniente con la propiedad de lo discreto del conjunto de los números naturales durante la educación básica secundaria. Como prueba de ello se encuentra la investigación forjada por Neuman (1998) en la que él expone que estudiantes alemanes, de 7° de la educación elemental (13 años de edad), asociaron propiedades afines con los números naturales para resolver preguntas relacionadas con la densidad de fracciones. Hart, en el año 1981 (como se citó en Widjaja, Stacey, y Steinle, 2008), afirmó que entre el 22% y el 39% de los estudiantes de 12 a 15 años de edad pensaban que había ocho, nueve o diez números decimales entre 0,41 y 0,42 (por ejemplo, los nueve números decimales del orden de los milésimos: 0.411, 0.412, 0.413, 0.414, 0.415, 0.416, 0.417, 0.418 y 0.419).

En la última etapa escolar se encuentran los estudiantes universitarios, así como los que se preparan para ser profesores. En Estados Unidos, futuros profesores piensan que hay una cantidad finita de números intermedios en un intervalo y que un número racional tiene un sucesor (Tirosh, Fischbein, Graeber, y Wilson, 1999). En Indonesia, la mitad de una población de profesores en formación considera una cierta cantidad de números decimales entre dos dados (Widjaja et al., 2008). Una mayoría de 62 profesores en formación y más de una décima parte de 71 estudiantes que se especializan en matemáticas a nivel universitario, en Finlandia, utilizaron propiedades correspondientes con el sistema de los números naturales en tareas asociadas con la propiedad de densidad de las fracciones (Merenlouto y Lehtinen, 2004).

Esta problemática pareciera persistir desde la escuela primaria, por ello la atención se enfocó hacia los profesores en formación de secundaria, nivel en el cual se estudia con más profundidad las propiedades de los números decimales, entre ellas la propiedad de densidad. Cabe mencionar que el presente documento es una extensión de un breve informe de investigación presentado por Suárez-Rodríguez y Figueras en el año 2019.

Objetivos

Atendiendo a la necesidad de superar la dificultad que tiene un estudiante para profesor acerca de la propiedad de densidad en el conjunto de los números decimales, se pretendió poner en marcha una secuencia didáctica (ver Suárez-Rodríguez, 2017) con la finalidad de generar una *conciencia metaconceptual*. En el proceso de cambio conceptual, el estudiante empieza a asumir una conciencia metaconceptual cuando es consciente de que sus presuposiciones y creencias son hipotéticas y limitan la forma en que interpreta la información que va aprendiendo (Vosniadou, 1994). Por tanto, para la presente investigación se plantearon los siguientes objetivos: 1. Identificar y describir los marcos explicativos –distintas formas de expresar las interpretaciones de un individuo (Vamvakoussi, Vosniadou, y Van Dooren, 2013)– que hacen los futuros profesores sobre la propiedad de densidad de los números decimales cuando tienen una conciencia metaconceptual , y 2. Analizar las actuaciones de los participantes en la resolución de las actividades en caso de que se promueva un cambio conceptual.

Marco teórico

Carey, en el año 1987, propone el enfoque de desarrollo-cognitivo del Cambio Conceptual, en el que ella explica cómo actúa la cognición infantil y desarrolla alternativas para iniciar un proceso de cambio conceptual. La autora señala que el conocimiento de un concepto de un individuo, inicialmente, está ligado a una *teoría ingenua* (aquella que consiste en explicaciones de concepciones innatas o concepciones aprendidas de la experiencia cotidiana relacionadas con las ciencias). Un ejemplo de una teoría ingenua, o idea ingenua, en matemáticas, es aquella en la que el estudiante cree que solo hay 9 números entre 1.2 y 1.3, a saber: 1.21, 1.22, …, 1.29 (Suárez-Rodríguez, 2017). Luego de que el conocimiento esté asociado con teorías ingenuas, este se va relacionando con otros formando un sistema de conocimientos (Carey, 1987).

Vosniadou (1994) propone que las teorías ingenuas constituyen los *modelos mentales* del ser humano y que estos modelos son el primer paso para iniciar un proceso de cambio conceptual. Para Vosniadou, un modelo mental es una representación que forma el alumno sobre ideas que adquiere, bien sea por experiencia o por instrucción, y que va acompañada de presuposiciones. Cuando un estudiante asume una conciencia metaconceptual estos modelos van cambiando, se producen los *modelos sintéticos*, que representan los intentos que hace el estudiante para reconciliar las opiniones científicas culturalmente aceptadas con las presuposiciones de sus teorías ingenuas

(Vosniadou,1994). Finalmente, el cambio conceptual requiere de cambios en las presuposiciones y creencias que el aprendiz debe realizar en sus representaciones para que pueda acceder a los *conceptos científicos*, y así lograr una comprensión de los conceptos aprendidos (Vosniadou, 1994; Vosniadou, Vamvakoussi, y Skopeliti, 2008).

En el ámbito educativo de las matemáticas, Stafylidou y Vosniadou (2004) y Vosniadou y Verschaffel (2004) suelen usar marcos explicativos en lugar de modelos mentales o modelos sintéticos. Los primeros marcos explicativos que hace el alumno son las primeras reflexiones que forman una estructura coherente y sólida sobre lo que aprende junto con sus presuposiciones y creencias (Vosniadou y Verschaffel, 2004). Siguiendo la idea a estos investigadores, se puede decir que los marcos explicativos iniciales son los primeros pensamientos que hace un estudiante acerca de lo que percibe, de lo que ve, de lo que interpreta, y lo explica a su manera, con sus propias palabras. Así mismo, en el contexto de un proceso de aprendizaje, la expresión cambio conceptual es un proceso de reestructuración de conceptos cuando el estudiante está aprendiendo información que no es compatible con sus conocimientos construidos hasta el momento, por lo que el estudiante debe realizar una resignificación de conceptos. Es así como la comprensión de la propiedad de densidad conlleva un proceso de cambio conceptual, de manera paulatina, una reestructuración de "lo discreto" a "lo denso", como lo sostienen Suárez-Rodríguez y Figueras (2019).

Un cambio conceptual: la reestructuración de lo discreto a lo denso

Los autores Ni y Zhou (2005) en su investigación señalan tres posibles causas que hacen que el alumno tenga conflictos para responder tareas asociadas con los números racionales cuando usan conocimientos acerca del número natural. Una primera causa se relaciona con lo innato, es decir, si la propiedad de lo discreto del conjunto de los números naturales es de naturaleza innata. La segunda se relaciona con la enseñanza de las propiedades del conjunto de los números naturales y la del conjunto de los números racionales. Por último, la relación entre el aprendizaje de los conceptos que el niño adquiere y el aprendizaje de la simbología de dichos conceptos. Ante esto, Vamvakoussi y Vosniadou (2012) diseñaron una estrategia usando la analogía entre el estiramiento de una "liga elástica" y la propiedad de densidad. El alumno a medida que estira la liga observa que hay más espacio entre "dos puntos que están dibujados", por ende, hay más "puntos imaginarios". Efectivamente, los estudiantes (entre 13 y 17 años de edad) lograron concebir una relación de semejanza entre el estiramiento de la liga y la propiedad de densidad.

En la investigación forjada por Vamvakoussi y Vosniadou, en el año 2004, se identificaron y se describieron distintos marcos explicativos concernientes a un pensamiento vinculado con cantidades finitas –o infinitas– entre dos números racionales por estudiantes que tenían entre 15 y 17 años de edad (ver Tabla 1).

Tabla 1: Caracterización del pensamiento sobre la cantidad de números en un intervalo

Pensamiento ingenuo sobre lo discreto	Se piensa que no hay otro número entre dos números racionales *consecutivos falsos*. Esta expresión la acuñaron Vamvakoussi y Vosniadou (2004) para referir que existe un sucesor de un número racional.
Pensamiento avanzado sobre lo discreto	Se cree que hay un número finito de números entre dos números racionales consecutivos falsos.
Pensamiento compuesto entre lo discreto y lo denso	En algunos casos se piensa que entre dos números racionales hay una cantidad infinita de números, y en otros, que hay un número finito de números intermedios.
Pensamiento ingenuo sobre lo denso	Se comprende que hay una infinidad de números en un intervalo, pero no se justifica la situación usando la propiedad de densidad. La representación simbólica de los extremos de un intervalo influye en la forma de pensar; se cree que sólo puede haber una infinidad de números decimales entre decimales y una infinidad de fracciones entre fracciones, pero no una infinidad de fracciones entre decimales, o al contrario.

Pensamiento avanzado sobre lo denso	Hay una comprensión bastante sofisticada de la propiedad de densidad, es decir, se pone de manifiesto que se entiende que entre dos números racionales hay una infinidad de números independientemente de su representación simbólica, y se justifica con la propiedad de la densidad.

Metodología

Participantes

La población estudiada fue de 10 profesores en formación en matemáticas de la educación básica secundaria de una institución en la Ciudad de México, en el año 2017. Uno de estos participantes tenía 36 años de edad y los nueve restantes entre 18 y 23.

Diseño de la experimentación educativa

La puesta en marcha de la secuencia didáctica con los profesores en formación se centró en una finalidad: generar conciencia metaconceptual. Vamvakoussi y colegas (2013) indican que el cambio conceptual a través de una instrucción es un proceso lento y gradual, porque no solo involucra la reorganización de una concepción sino de todo un sistema de conocimientos. No obstante, los autores describen que se puede lograr un cambio conceptual paulatinamente con los siguientes criterios: (a) una exploración profunda de los conceptos a aprender, (b) tener en cuenta el conocimiento previo del estudiante, (c) facilitar una conciencia metaconceptual, (d) proporcionar experiencias significativas, y (e) fomentar el uso de diversas representaciones, ya sean gráficas, escritas, o hechas con recursos digitales.

Teniendo en cuenta los anteriores criterios y los antecedentes que reúnen la problemática en torno a la comprensión de la propiedad de densidad por parte del alumno, se procede al diseño y elaboración de las actividades de la secuencia didáctica. La secuencia se estructuró en dos etapas. La primera para reconocer los primeros marcos explicativos de los participantes a través de un cuestionario (diagnóstico) de papel y lápiz y entrevistas individuales. La segunda etapa se elaboró con actividades individuales y grupales para identificar y analizar sus actuaciones, a su vez, sus marcos explicativos. Esta etapa se llevó a cabo en cuatro sesiones sobre: 1. La percepción de lo denso en materiales concretos, 2. Adición y sustracción de decimales, 3. Localización de decimales en intervalos, y 4. Comparación de números decimales.

Resultados

Resultados del cuestionario como diagnóstico (primera etapa)

Los profesores en formación atendieron a un cuestionario de 11 preguntas el cual arrojó los primeros marcos explicativos relacionados con las categorías propuestas por Vamvakoussi y Vosniadou (2004) sobre la propiedad de lo discreto y la propiedad de densidad. A continuación se muestran las respuestas de varios participantes a algunas preguntas, así mismo se muestran algunas manifestaciones dadas por ellos en las entrevistas individuales con el ánimo de conocer la justificación de sus respuestas.

En Pensamiento ingenuo sobre lo discreto. Hubo estudiantes para profesor quienes consideraron que los extremos de un intervalo son consecutivos y por ello aseguraron que no puede haber otro número en dicho intervalo. En la Figura 1 se muestra el caso presentado por Amanda. Ella realizó el proceso de una representación fraccionaria a escritura decimal finita, y usó el argumento de que ambos extremos del intervalo son consecutivos.

5. ¿Puedes encontrar números decimales y/o fracciones entre 0.49 y 1/2? Justifica tu respuesta.

No porque $\frac{1}{2}$ es 0.5 el siguiente de 0.49

Amanda indica que 1/2 = 0.5 = 0.50 es el sucesor de 0.49. Ella menciona en la entrevista que “0.49 y 1/2 son consecutivos”.

Figura 1: Pensamiento ingenuo sobre lo discreto (ejemplo)

En Pensamiento avanzado sobre lo discreto. El proceso de subdivisiones finitas en un intervalo fue uno de los marcos explicativos iniciales que usaron los participantes para afirmar la existencia de una cantidad finita de números decimales en un intervalo. La concepción de que solamente los números del orden de los décimos –a lo mucho de los centésimos– son los números decimales, puede estar influida en las respuestas relacionadas con conjuntos finitos dentro de un intervalo. Por ejemplo, Fabiola evoca un proceso finito, toma en cuenta una determinada cantidad de cifras decimales de un número para afirmar que hay nueve números decimales en el intervalo dado, por ende, subyace la idea de los números consecutivos falsos (ver Figura 2).

2. ¿Cuántos números decimales hay entre 1.2 y 1.3? Si nueve

Fabiola registró que hay 9 números en el intervalo. Ella dice que solo se encuentran 1.21, 1.22, 1.23, 1.24, 1.25, 1.26, 1.27, 1.28 y 1.29 (manifestaciones en la entrevista).

Figura 2: Pensamiento avanzado sobre lo discreto (ejemplo)

Cabe mencionar que algunos profesores en formación tienen un marco explicativo inicial de que un sucesor es un número mayor que él. Posiblemente, Isabella piensa que el sucesor de cualquier número es un número mayor, como su ejemplo: naturales 7, 8 (Ver Figura 3).

9. ¿Cuál es el sucesor del número natural 6? naturales 7, 8...

Figura 3: Creencia de la existencia de un sucesor como número mayor (ejemplo)

Para finalizar esta primera etapa de la secuencia didáctica se concluye que la mitad de los estudiantes a profesor tienden a tener un pensamiento combinado entre lo discreto y lo denso, mientras que tres, al parecer, tienen un pensamiento avanzado sobre lo discreto y los dos restantes tienden a tener un pensamiento ingenuo afín con lo discreto.

Resultados de las actividades de la secuencia didáctica (segunda etapa)

En los siguientes párrafos se describen algunas actuaciones y marcos explicativos de los profesores en formación quienes interactuaron con actividades de la secuencia didáctica.

Actuaciones vinculadas con la percepción de lo denso en materiales concretos. La finalidad de las primeras actividades de la secuencia didáctica es que el futuro profesor conciba la noción de una infinidad de números en un intervalo a través de una “infinidad de puntos” en un contexto geométrico. Ellos refirieron que entre más se estiraba la liga elástica (propuesta de Vamvakoussi y Vosniadou, 2012) podía haber más espacio, por ende, más puntos imaginables. De la misma manera sucedió con el inflamiento de un globo. Los participantes señalaron que entre más se inflaba el globo habría más espacio, en consecuencia, más puntos imaginarios.

Actuaciones identificadas con la adición y la sustracción con números decimales. Para esta segunda sesión los participantes respondieron a dos actividades que surgieron de las actividades hechas por Broitman y colaboradores (2003). El objetivo de las actividades es el reconocimiento de destrezas en la escritura de números decimales distintos. En una de las actividades la docente-investigadora escribe el número *1.5* en el pizarrón, luego los estudiantes para profesor escriben la mayor cantidad de sumandos y que la suma total se aproxime o se iguale a 10. El uso de números hasta dos cifras decimales se puso de manifiesto en esta primera experiencia por algunos participantes, por ejemplo, el marco explicativo de Karen. Ella utilizó números con dos cifras decimales, incluso tuvo en cuenta el número 0 para las centésimas, como se puede apreciar en la Figura 4. Karen únicamente anota números comprendidos entre 0 y 1. Ella primero escribe la secuencia *0.5*, *0.4*, *0.3*, y luego registra *0.25*, *0.75, 0.80* y *0.15*, es decir, descompone hasta centésimas. Enseguida ella anota *0.20*, *0.70*, *0.40* y *0.30* y reconoce que el cero puede tener la posición de las centésimas. Al parecer, ella no percibió la equivalencia entre 0.3 y 0.30, así mismo, 0.4 y 0.40, puesto que la actividad requería números diferentes.

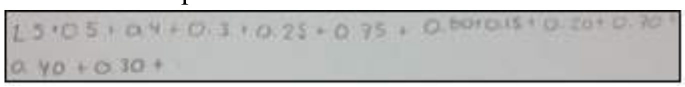

Figura 4: Registro de Karen en la actividad de adición y sustracción

El marco explicativo de Nicolás se basó en el registro de números hasta con seis cifras decimales, pero al parecer tenía una estrategia (ver Figura 5). Él anota el número *0.000001* y después *0.000009*, y en las siguientes filas va cambiando la posición del dígito 9. Nicolás ubica el 9 en la posición de las millonésimas, luego en la posición de las cienmilésimas, las diezmilésimas, las milésimas, las centésimas, y finalmente en las décimas. El proceso que realizó Nicolás fue multiplicar 9 por $1/10^n$, donde *n* es un número natural, comenzando por la posición de las millonésimas (es decir, *n=6*). Se observa que la suma de los números que Nicolás escribió es 1. Este participante, quien en el cuestionario-diagnóstico mostró ejemplos relacionados con el pensamiento avanzado asociado con lo discreto, utilizó números hasta millonésimos. Este hecho pone en evidencia un proceso de inicio de cambio conceptual de manera paulatina, puesto que él registró números hasta con dos cifras decimales en algunas respuestas del cuestionario.

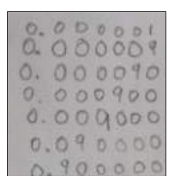

Figura 5: Registro de Nicolás en la actividad de adición y sustracción

Actuaciones identificadas con la localización de números decimales en intervalos. Las dos actividades de esta sesión se elaboraron a partir de una hecha por Brousseau (1981) que tienen la intención de localizar números en un intervalo, así como encontrar intervalos para un número dado. En una de las actividades los futuros profesores deben buscar el intervalo en el que se halla el número "pensado" por un compañero y van elaborando preguntas con el fin de encontrar dicho intervalo. Los extremos de este intervalo deben ser números cuyas cifras decimales sean consecutivas. En la Figura 6 se muestra un ejemplo de un participante quien escribió los intervalos mencionados por sus compañeros e iba marcando con una "equis" cuáles no correspondían. La representación numérica hasta los diezmilésimos en el número escondido, 28.9306, fue tomada en cuenta por Olga. Ella había mostrado evidencias de un pensamiento ingenuo concerniente con lo discreto en el desarrollo del cuestionario-diagnóstico. Olga, al parecer, ha estado haciendo una reestructuración de conceptos, pues ella creía que solo existían números hasta con dos cifras decimales. Es posible que ella haya usado la representación numérica del orden de los diezmilésimos como consecuencia de la socialización de las actividades anteriores (relacionadas con adiciones y sustracciones).

Actuaciones asociadas con la comparación de números decimales. Las dos actividades de comparación, de la última sesión de la secuencia didáctica, se derivaron de una tarea hecha por un estudiante para profesor de una investigación realizada por Castillo en el año 2015, en México. La comprensión de la propiedad de densidad de los decimales a partir de la propiedad de comparación de decimales constituye el propósito de las actividades. En una de ellas, cada profesor en formación debe completar una ordenación de números decimales. En la Figura 7 se evidencia la labor realizada por uno de los cinco participantes que completaron la secuencia de manera correcta. Su estrategia fue detallar los últimos dígitos de los números que aparecen allí para "modificarlos", y en otros casos, para "añadir dígitos o cifras" sin alterar la ordenación.

Algunos estudiantes para profesor no percibieron la equivalencia entre decimales, son los casos de Olga, Isabella, Oscar y Amanda (ver Figura 8). Olga agrega un cero en la posición de las diezmilésimas de la cantidad 30.871. Isabella y Olga agregaron dos ceros en las posiciones cienmilésimas y millonésimas del número 30.8712. Oscar agregó un cero en la posición de las cienmilésimas del número 30.8721. Y Amanda agregó un cero al final de la expresión 30.87125.

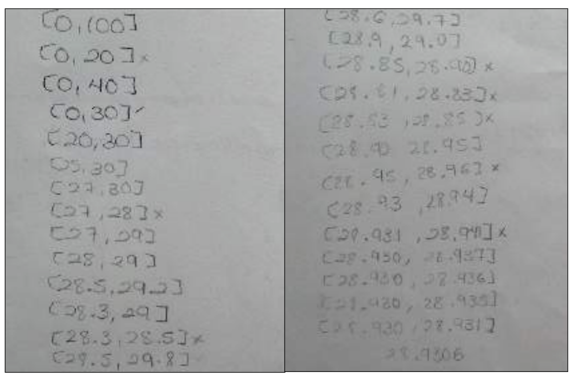

Figura 6: Registro de un profesor en formación en la actividad de localización

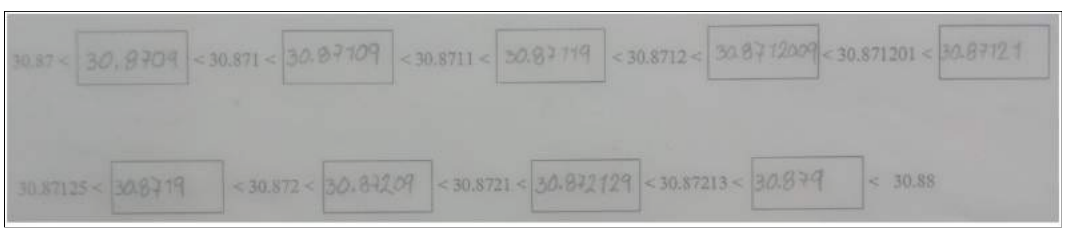

Figura 7: Registro de un futuro profesor en la actividad de comparación

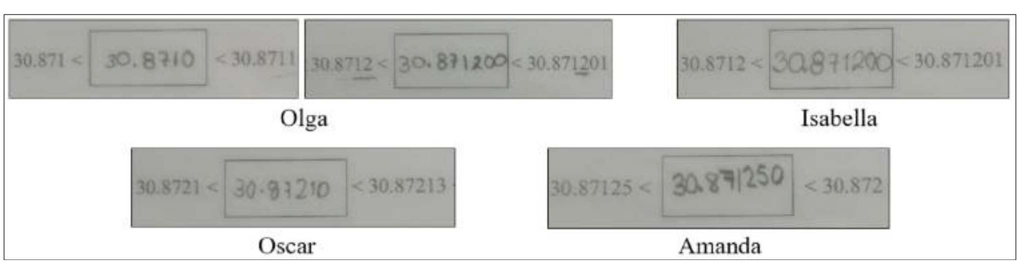

Figura 8: Registros de cuatro participantes en la actividad de comparación

Concluida la prueba individual, los futuros profesores anotaron en el pizarrón los números escritos en sus hojas de trabajo (ver Figura 9). Con el objetivo de que el estudiante para profesor lograra una conciencia metaconceptual de que la propiedad de densidad ayuda a visualizar el hecho de que no existe un sucesor en el conjunto de los números decimales, se mostró que entre pares de consecutivos falsos se halla al menos un número decimal, en consecuencia, una infinidad. Por ejemplo, en la Figura 9 (ver óvalo) se observa que entre el par de consecutivos falsos *30.8711* y *30.8712* se localizan al menos siete números decimales, mayores que el primero y menores que el segundo: *30.87112*, *30.871103*, *30.87119*, *30.871105*, *30.871102*, *30.87115* y *30.871106*. Finalmente, se cuestionó a los participantes si había otras estrategias para hallar números intermedios en esta actividad. Nicolás mencionó “la media aritmética”. Se realizó un breve ejemplo con un par de números de la actividad para mostrar que con ella se puede hallar números intermedios en un intervalo.

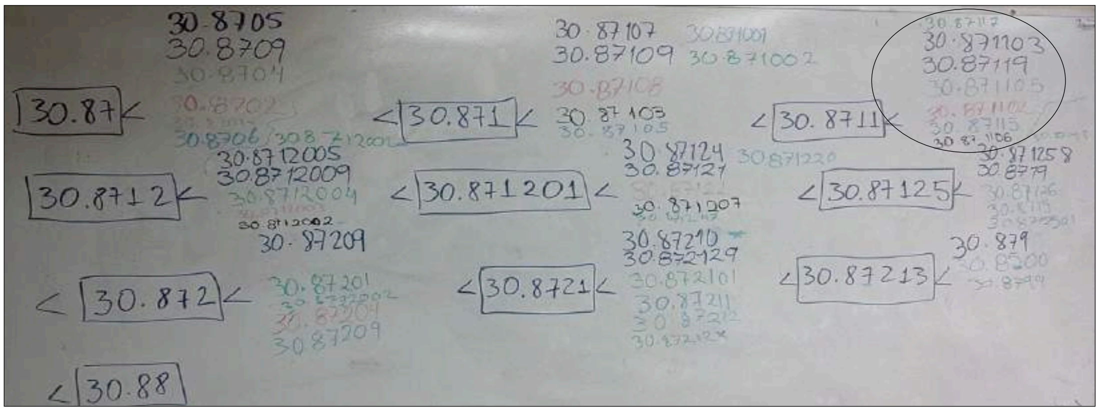

Figura 9: Anotaciones de los participantes en la actividad de comparación

Conclusiones e implicaciones

La socialización de las actividades de la secuencia didáctica con los profesores en formación promueve un acercamiento a la comprensión de la propiedad de densidad de los números decimales, en consecuencia, un proceso de cambio conceptual: de lo discreto a lo denso. En el desarrollo del cuestionario-diagnóstico, los diez profesores en formación habían evidenciado ejemplos de pensamiento asociado con la propiedad de lo discreto de los números naturales. Durante la puesta en marcha de las actividades de la secuencia didáctica, los diez participantes lograron extender la cantidad de cifras decimales, estrategia que les permitió ubicar números en un intervalo. Sin embargo, la mediación sobre la existencia de un sucesor de un decimal fue cuestionada por tres profesores en formación, ellos aun incluían en su marco explicativo la existencia de un sucesor de un número decimal como un número mayor.

Se considera que el desarrollo de la escritura de una expansión decimal de un número es una tarea que posiblemente puede ayudar al profesor en formación, o a un estudiante en general, en la comprensión del concepto de series. Las sumas de progresiones aritméticas o geométricas con infinitos términos son ejemplos de series. Un número con escritura decimal periódica expresa una aproximación de un número racional, que es el valor límite de dicho racional, por ejemplo, el valor límite de la expansión decimal 0.0123123123… es 41/3330. De igual manera, el desarrollo de la escritura de expansiones decimales infinitas que no se pueden expresar como fracción podría ayudar al estudiante en la comprensión del concepto de número irracional. Finalmente, como lo indican Suárez-Rodríguez y Figueras (2019), la secuencia didáctica es un ejemplo de un modelo de enseñanza que puede ser de interés para profesores en servicio quienes podrían iniciar el estudio de la propiedad de densidad en sus aulas de clases.

Agradecimientos

El proyecto de investigación fue financiado por Conacyt y Cinvestav. Un agradecimiento especial a los maestros en formación que participaron voluntariamente en la secuencia didáctica.

We report our findings and perspective to document the knowledge exhibited by three experienced high school teachers in their instructional decisions for lessons on the equation of an exponential function. We describe the nature of the mathematical ideas and connections teachers promoted in discourse and the decisions that supported the emergence and connections of the mathematics. Despite similarities in the structure of the mathematical activities, differences existed in the ideas that emerged in the three teachers' discussions regarding the relationship between the exponent value and the independent variable. We describe links between collections of teacher decisions to their influences on the mathematics discourse.

Keywords: Teacher Knowledge; Classroom Discourse

Introduction and Background Literature

This study aims to contribute to understanding the nature and quality of mathematics teachers' decisions as a means of describing teachers' knowledge for teaching mathematics in practice. The field widely accepts that teachers' knowledge strongly relates to their effectiveness (e.g., Charlambous & Hill, 2008). Expanding on the work to document and assess a cognitive perspective of teachers' mathematical knowledge for teaching, a call exists to integrate conceptualizations of teachers' knowing and their actions in the classroom (Depaepe et al., 2013). Reviewing literature, Stahnke et al. (2016) categorized studies of teacher knowing in action by the situation-specific processes investigated, namely perception, interpretation, and decision-making (Blömeke et al., 2015). Stahnke et al. concluded decision-making is the most challenging for pre-service teachers (PSTs). Meanwhile, decision-making of experienced teachers is tacit, effortless, and based on sophisticated networks of schema (e.g., Shavelson & Stern, 1981). To inform preparation of PSTs, we sought to learn from experienced secondary teachers by inquiring into their decisions in teaching exponential functions topics.

Despite observations of more powerful ways of understanding exponential growth (e.g., Confrey & Smith, 1994), high school curricula often introduce exponential functions through tasks that facilitate making a correspondence between a quantity growing by repeated multiplication and another related quantity (Davis, 2009). Defining exponential growth by repeated multiplication provides a potentially useful entry point (Weber, 2002); however, the metaphor is insufficient for explaining the meaning of expressions such as $2^{2/3}$ (Davis, 2009). In action, learners may reason about changes in the y-value without attending to the y-value's relationship to the x-value (Ellis et al., 2016) and therefore struggle to connect the repeated multiplication to the closed form of an equation (Davis, 2009). The closed form of an equation, when developed, can represent a correspondence view of the function. That is, one builds a rule to represent the relationship between an x-value and its associated y-value in the form of an algebraic equation $y = f(x)$. We sought to describe how teachers work within their available resources and constraints (Schoenfeld, 2011) to facilitate students meeting teachers' learning goals for understanding of equations of exponential functions.

Theoretical Framing

We view knowledge or knowing from an enactivist epistemology (Maturana & Varela, 1992). Enactivism stems from evolutionary biology and conceptualizes an organism interacting and co-evolving with its environment. An organism "knows" within the environmental context if it acts in a way that is fitting and effective for the context (Maturana, 1988). Therefore, knowing or cognition is not a *thing* a person holds but "acting in a world that emerges in the doing itself" (Maheux & Proulx, 2015, p. 212). Knowledge is the body of effective behaviors and the underlying cognition that engender one to perceive the situation and categorize which behaviors are effective (Varela, Thompson, & Rosch, 1991). Learning is "a reciprocal activity — the teacher brings forth a world of significance with the learners" (Towers et al., 2013, p. 425).

In classroom mathematics discourse, there is both "*doing* something (some thing) recognizable as *mathematics*, but also producing *mathematics* as this thing that we are *doing* when we do what we do" (Maheux & Proulx, 2015, p. 215). The mathematics is the "world of significance" that the teacher brings forth with the learners by implementing a plethora of decisions both to set up the environment and to respond to (and with) the students. The mathematical ideas (i.e., concepts, patterns, principles, procedures, relationships) that emerge are not isolated entities. They are connected to and built up from other ideas with forms of coherence and structure fitting for the doers of the mathematics. As Towers et al. (2013) indicate, enactivism prompts observing "the relationship between things in a mathematical environment (ideas, fragments of dialogue, gestures, silences, diagrams, etc.), rather than to what each of those things might mean or represent in their own right and for the individual generating them" (p. 425). We conceptualize the mathematics as the emerging ideas in the discourse of the mathematical activity and the connections made to build up and connect the new ideas from and to other ideas. We define *knowing for teaching mathematics* as the teacher decisions to perturb the learning environment and to participate with students to influence the emergence of mathematics in ways they deem effective for student learning.

Interested in describing experienced teachers' knowing for teaching exponential functions enacted in whole class discourse (WCD), we sought to describe the nature of the mathematical world that emerged as well as the teacher activity that supported its emergence. We describe the nature of the mathematics in terms of the emergent ideas and the connections, consistency, and justifications offered in the discourse. Our research investigated: With respect to the *equation of an exponential function,* what is the nature of the mathematical ideas promoted in WCD and what instructional decisions supported the mathematics to emerge and connections to develop?

Methods

As part of a larger study, we collected data from 16 high school teachers engaged in the teaching of exponential function topics in the courses of Algebra I, Algebra II, College Algebra, and Pre-Calculus. All teachers were identified as highly effective and experienced by their administrators or peers and had obtained master's degrees. The corpus of data included classroom observations and interviews regarding teacher instruction. This study focused on the WCD of three teachers, Gabe, Evelyn, and Abby who had 28, 19, and 24 years of teaching experience respectively. Gabe and Evelyn taught College Algebra while Abby taught IB Math 3 (equivalent to Algebra II). We focused on these three teachers because we perceived surface-level similarities in their lesson structures for introducing the equation of an exponential function or geometric sequence.

We transcribed the classroom observations and partitioned each lesson into smaller segments of episodes and sequences (Wells, 1996) based on transitions of classroom tasks. Transcribed interviews included images of documents the teacher referenced during the interview when appropriate. Using the classroom videos and transcripts we developed concept maps representing the mathematics in WCD, noting connections made between the mathematical ideas (Leinhardt & Steele, 2005). Looking across the concept maps in three teachers' classrooms, we identified three common themes: the role of the independent variable, the relationship between the recursive multiplication and exponential form, and the definition of exponential. We created narratives describing the emerging mathematics and contributing teachers' decisions for each teacher and theme (i.e., nine narratives in total). We used comparative methods to identify contributing decisions and teacher actions in cross case analyses of the three teachers.

Findings

These findings focus on the first theme that emerged during the analysis of the classroom discourse surrounding writing the equation of an exponential function; specifically, the relationship between the value of the independent variable and the exponent of the algebraic expression.

Gabe Narrative

To write each of the three equations, students were told to complete a table of values given at least four consecutive entries and $\Delta x=1$ (see Figure 1). Students only needed to determine the *y*-intercept (i.e., the value when $x=0$) for y_5, the table included the *y*-intercepts for y_6 and y_7. Once students identified multiplying by two to move down the entries in the table (y_5), Gabe reviewed using exponents by leading students through going from 1 to 16 in the table via repeatedly multiplying by two. Gabe asked students how 1(2)(2)(2)(2) could be re-written, thus encouraging them to recall their work with exponents. After writing $1(2)^4$ Gabe asked students for the exponent for y_5. In using an example (y_5) students were told and then reminded (in y_6) that the exponent represents repeated multiplication, so x was the exponent in the general equation. The following excerpt from the WCD highlights Gabe's implicit connection between using exponents in the equation for y_5 due to repeated multiplication and the exponent being x in the equation.

T: So, this <the (2)(2)(2)(2) > would be two to what power? You said something power.
S: Three... fourth.
T: To the fourth power. <writes $1(2)^4$ under the expression 1(2)(2)(2)(2)>
T: So, what we're doing each time is we're multiplying by two, what's our exponent going to be?
S: x
T: Just x. <writes $y_5=1(2)^x$ > So, that's the equation for the first one. [E1:S4:L13-18]

In discussing writing the equation for y_6 Gabe stated, "[n]ow when we write it in this form, it's what we're multiplying by each time because that's what the exponent represents, a series of multiplications" [E1:S7:L3]. When writing the equation for y_7, the exponent was written but not mentioned. During notes, when introducing $y=ab^x$, Gabe defined the exponent saying, "[a]nd then our exponent's the number of times that we're going to be doing it" [E2:S1:L1].

Due to the structuring of the task (i.e., having students write equations from a table of values void of context), defining the independent variable was not needed. Rather, x was implicitly defined as being the exponent because the exponent represents repeated multiplication. Additionally, a need did not exist for making an explicit correspondence between defining the independent variable and stating that x was the exponent. In moving from $1(2)^4$ to asking students what the exponent would be for y_5, Gabe focused exclusively on the y_5 column and did not discuss that the four in the exponent connected to the row corresponding to $x=4$. In fact, the x column of the table was not included on the note sheet that students were given (see Figure 1).

y_5	y_6	y_7
	486	
	162	1000
2	54	1100
4	18	1210
8	6	1331
16		

Write equations for functions 5-7.

Exponential functions:

$y = ab^x$ or $y = ar^t$ or $y = a(1+r)^t$

Compound Interest Formula $A = P\left(1 + \frac{r}{n}\right)^t$

Figure 1: Re-creation of a portion of the note sheet Gabe created and gave to students

Evelyn Narrative

Evelyn introduced writing the equation of an exponential function in two lessons involving the discussion and then summary of three tasks (see Table 1). The prompts for the tasks provided the value of a quantity at a point in time and information that the quantity grew by a multiplicative factor over a set time period (i.e., each day or each year). In small groups, students determined the value of the quantity at other points of time, utilizing recursive multiplication or division. In WCDs, Evelyn oriented students to represent their computations as numerical expressions in a table and then generalize to an equation.

On the One Grain of Rice task, students worked to find how many grains of rice a girl would have on the thirtieth day if she started with one grain of rice and the number of grains doubled each day. As Evelyn predicted prior to the lesson, students reached different answers depending on whether they labeled the starting value Day 1 or Day 0. She considered having students compare the effects of labeling the staring value as Day 1 or Day 0, but in class she chose to have the class come to a consensus in choosing to state the girl received one grain of rice on Day 1, meaning the point (1,1) was in the data set. In WCD, Evelyn noted there could be another choice of creating that point as (0,1). The choice would affect the final answer but not their process. Rather than discussing the effect of the choice, the focus shifted to representing the situation and the students' computations in a table.

The tables created for the One Grain of Rice and Social Media WCDs captured the repeated multiplications used to calculate the values. Evelyn led students to rewrite the expressions as repeated multiplication and then exponential expressions. By recognizing a pattern down the right column of the table, the class generalized that to calculate the value for any point in time multiply the starting value by the growth factor some number of times.

To generalize beyond the table, Evelyn asked students to find expressions for larger values in the table (i.e., the number of users in year 2052). The class discerned a relationship between the exponents in the expressions for the dependent variable and the value of the time variable. For example, students noticed the exponent of the expression for a given year could be found by subtracting five from the years since 2000. The class looked across the two columns to generalize the relationship between the value of the independent variable and the computational exponential expression to find the number of users (or grains of rice) associated with the value of the time variable. Therefore, they developed equations to find the value of the dependent quantity in year x or day d.

Evelyn then presented the contexts for each of the three tasks and the equations they found for each situation reminding students how they defined the independent variable (Table 1) and then replaced each of these with "x." The class made observations that each equation involved a time period and that the exponent was some sort of time period. Evelyn then presented the general form, $y = ab^x$ and the class discussed the role of each parameter. The meaning of x was given as "some time period" and was not defined as the value of the independent variable.

Table 1. Three task summary provided by Evelyn

One Grain of Rice Started with one grain of rice and doubled each day.	Social Media Started with 3.2 million users and tripled each year after 2005.	Fruit Flies Started with 5 flies and they quadruped each day of vacation.
Grains of Rice = 2^{day-1}	#Social Media Users = $3.2(3)^{year-2005}$	#Fruit Flies = $5(4)^{\#days}$

Abby Narrative

Before this observation, students spent time solving and presenting their solutions to the domino skyscraper task (http://threeacts.mrmeyer.com/dominoskyscraper/) which posed the question, "If you wanted to topple over a domino the size of a skyscraper, how many dominoes would you need?" Students were told, "a smaller domino can topple a domino that is up to 1.5 times larger in every dimension" and that the first domino was 5 mm tall. In four small groups, students generated solutions for several skyscrapers by guessing and checking, creating a table, and using an exponential equation. Abby began this class by shifting the conversation from the solution to the task to the equations the students generated.

Abby asked Group 4 to present their equation $y=5(1.5)^x$ and table for the domino task, telling them to define their variables and connect their table to their equation. They explained why their equation was $y=5(1.5)^x$, where x represented the domino number and y represented the height of the domino, and connected it to their table. After the presentation, the class worked in small groups to "make a very clearly defined table. Identifying your variables, alright? And matching it up with your equation, alright? You want to make sure your equation matches up" [E1:S2:L1].

In a small group discussion, Abby asked the students why their equation $u_n=5\cdot1.5^{n-1}$ differed from the one presented. The students offered that the difference of "minus 1" in the exponent was due to their choice to label the initial domino of height 5 the first domino instead of the zeroth domino in their table. The teacher engaged in a similar discussion with another group which had the equation $= \frac{450,000}{1.5^x}$. Although there is not more WCD on this point, Abby engaged with two of the four groups focusing on why their equation was different from the one presented. In these group conversations with Abby, students explained how they constructed their table, how it was different than the table presented and how that impacted their equation, with particular attention to how the independent variable was defined.

In WCD, Abby returned to this theme when developing with students the equation for the general term of a geometric sequence. She began by highlighting the equation $y=5(1.5)^x$ and its associated table. She connected it with their work on geometric sequences by noting that the equation generated a geometric sequence (the y column in the table), that 5 was the initial value, and 1.5 was the common ratio. She pointed out that this table labeled the initial domino as the zeroth term, but that the convention for geometric sequences was to label the initial term (domino) as the first term.

Abby highlighted the work of the group who produced the equation $u_n=5\cdot1.5^{n-1}$, indicating that their first domino was 5 and that it aligned with the initial term of a geometric sequence being called the first term. The class established that the difference in the exponents between the two equations reflected the difference between starting with $x=0$ and $x=1$. Abby connected this to transformations explaining the difference as one equation being the other shifted to the right one. Through an interactive discussion, the students connected the equation $u_n=5\cdot1.5^{n-1}$ to the general term of a geometric sequence of the form $u_n=u_1\cdot r^{n-1}$, where n is the term number, r is the common ratio, and u_1 is the first term. Abby concluded this episode with the comment, "These are equivalent. <Pointing to $y=5(1.5)^x$ and $u_n=5\cdot1.5^{n-1}$.> It's just a matter of defining your variable. Where your starting point is. But they are really equivalent equations" [E4:S6:L10].

Cross-Case Analysis

Differences existed in the ideas that emerged in the three teachers' discussions regarding the relationship between the exponent value and the independent variable in the development of the exponential equations. For Gabe, the idea of the connection between the x-variable and exponent was minimal. In both discussion of a specific function (y_5) and the general forms, Gabe's class indicated the value of the exponent corresponded to the number of multiplications by the constant multiplier and the exponent was x. No connection was made between x as the number of multiplications and the x column of the table. The x column was only referred to when finding the y-intercept as the value of y that corresponded to an x-value of zero and consistently indicated the place where they start doing the repeated multiplications.

For Evelyn, consistency existed in providing intellectual need and opportunity to make a connection between the expression that represents the y-value and the corresponding value of the time variable in each of three contextualized tasks. The class developed tables by thinking about changes in the independent variable by one, implicitly attending to the x-value but focusing on the relationship between values in the y-column. Evelyn asked students to write an expression for a large x-value, skipping values in the table. Thus requiring students to look between columns of the table and generate the relationship between the x-value and the exponent value. They used this observed relationship to write the final equation for the functions in question. These conversations emerged in the particular discussions of generating the equations from tables but did not emerge in the end discussions regarding the general form. In fact, Evelyn noted in her interview that finding the value of the exponent would depend on the specific problem context. Specifically, she said, "[u]m, so to see that form of the starting value, the base and then that the exponent relies on whatever the context of the problem is" [Pre-Int Obs2 08:35]. We did not see a connection made between the exponent value as a transformation of the independent variable and the exponent as counting the number of multiplications.

The student groups in Abby's class created their own equations to model the situation of toppling dominos. Consistently, Abby directed students to check their equations with their table; thus the exponents of the student equations could be modified to account for the values of the corresponding domino number (independent variable). Ideas emerged from the particulars of individual groups making different choices in their work on the same task. The students' equations differed based on how they defined the starting value (i.e., Domino 0 vs. Domino 1). Abby built from the varied approaches of the students to motivate the generalizations providing standard language and definitions as needed. The result was a final general idea that the exponent of the general term of the sequence differed based on the labeling of the term number. Abby connected the idea to a horizontal transformation of functions.

The notion that different equations exist dependent upon defining the independent variable emerged in both Evelyn's and Abby's class due to the opportunity for students to create their own tables modeling the situation. The contexts of the domino and grain of rice tasks did not specify that the starting domino or day corresponded to a specific value of the independent variable; therefore, students made different choices. Abby allowed student groups to develop their own equations and made sure students matched all representations of the situation (sequence, table, context, equation, and later graph). She chose to have multiple groups present their solutions; therefore, the class saw three equations meant to capture the same relationship. The different equations presented a need for Abby to provide some closure to the idea. Students in Evelyn's class did not create equations on their own, but they made different choices in how they labeled the first value. Evelyn chose to lead the WCD of creating the equation and opted to label the independent variable as most of the students did. Not all students saw how the equation might look different based on defining of the independent variable.

All three classes developed and filled in tables, initially, through applying repeated multiplication. To write the equation, Evelyn and Abby's classes attended to the relationship between the x-value and the y-value or exponents of the expression of the corresponding y-value. Evelyn facilitated attention to this relationship by asking students to skip values in the table to find the y-value associated with a large x-value. Abby asked students to check to see if their equation was correct by paying attention to input-output correspondence in the tables.

In Gabe's class, it is unknown if and how students attended to the x-column of the table to determine the equation due to the nature of the tables presented. The values of x in the tables presented were equal to the number of multiplications. Referring to the x-column was not necessary since the rows of the table increased in Δx values of one and the tables provided a row corresponding to $x = 0$. When Gabe asked students what the exponent of the equation should be and a student said, x, it was unclear if x referred to the corresponding input for an output in a single row of a table, if x was a generalization for counting the number of multiplications, or if the exponent was x due to prior knowledge that exponential equations have an x in the exponent.

All three teachers included WCDs toward the end of the lessons providing general forms of the equations of exponential functions (or geometric sequences). Table 2 summarizes the language teachers used for these WCDs. Gabe provided his informal language tied to the process of finding the equations in the table. Evelyn asked students to compare and notice similarities of the structures of the three equations generated. Students described the parameters using their own language which tied to the class's previous mathematical activity. Using the explored domino sequence and equations as examples of the parameters to introduce vocabulary, Abby provided formal definitions of term, term number, and common ratio prior to introducing the general term. Abby's generalizing discussion was the only one which described the exponent of the equation as a transformation of the independent variable.

Table 2. Language and origin of language when defining a general exponential form.

Gabe	Evelyn	Abby
$y = ab^x$ *a:* "a-riginal", y-intercept, value at 0 b: What you're multiplying by *x:* How many times you multiply	$y = ab^x$ *a:* starting value *b:* what you're multiplying by each time period *x:* some sort of time period *y:* total amount of stuff	$U_n = U_1 r^{n-1}$ U_1: First term *r:* Common ratio n: Term number U_n: nth term
Teacher-provided language	Student provided language	Teacher-provided language

Discussion and Conclusions

The enactivist lens prompted us to not only notice single ideas but the relationships and connections among utterances in the discourse which emerged from the nature of the mathematical activity in the room: the activity of creating equations to describe the data of the tables. While the structures of these lessons are similar, attending to connections among ideas as facilitated in the mathematical activity allowed us to notice if and how the thread of the role of the independent variable was integral to the activity. Viewing from an enactivist lens, the teachers' knowing is seen from the mathematical worlds they facilitate to emerge in that context.

Gabe provided tasks incorporating functions and representations of those functions where implicit minimal attention to the x-column or relationship between the x and y values was sufficient. Labeling the exponent as x worked for every equation. He presented the general forms of the equation in a way that aligned with the taught process which included simple procedures and easy-to-remember language. The mathematics of Gabe's classroom was largely characterized by closed-form mathematics, one-word responses, and narrow examples facilitating single ideas to emerge sequentially. We posit Gabe's facilitated instruction prioritizing a mathematics that might be easy for students to replicate without error.

Evelyn asked questions encouraging students to notice and test patterns (e.g., patterns in the relationship between the values of the independent variable and the exponent in the expression for the corresponding y-value). Connections made between ideas existed within the tables which were artifacts of the activity of the mathematical discourse. The inductive reasoning repeated at a higher level when the class compared the structures of the three generated equations and $y=ab^x$. The generalizations about exponential functions were tied to the idea of multiplying a starting value repeatedly to find a total rather than formalizing a relationship between the independent and dependent variable. Evelyn accepted the language and definitions offered by the students rather than providing formal language. Her decision-making prioritized students making and testing generalizations based on the inductive reasoning *inspired by* the collective mathematical activity.

In Abby's class, the attention to the relationship between the independent variable and the equation was grounded in the class practice of reconciling the multiple representations of the growing quantity (context, table, multiple versions of equations, and graphs). Prior to generating the general form of a geometric sequence, Abby provided vocabulary for the relevant parameters of the domino task which corresponded to finding the value of term *n.* Her decisions positioned students as doers of mathematics, enabling students to identify the pertinent mathematical concepts. The decisions positioned her to provide a shared formal language connecting the class' mathematical activities of representing the domino task, making sense of others' representations, and making generalizations about properties of geometric sequences.

We viewed teacher knowing through the decisions teachers make as they engaged in activity (including mathematical activity) with their students to promote the emergence of a mathematical world. Taking this lens freed us from concerning ourselves with the individual actions of the teacher and each student to notice the nature of the activity (pedagogical and mathematical) which seemed to facilitate the emergence and connections among ideas. This work suggests developing teachers as decision makers by engaging PSTs in considering and a deliberate analysis (Brown & Coles, 2011) of the mathematical worlds afforded by collections of teacher moves.

A CLASSROOM EXPERIENCE: VECTOR CONCEPT

Viana García-Salmerón
Universidad Autónoma de Guerrero
viana_nallely@hotmail.com

Flor Rodríguez-Vásquez
Universidad Autónoma de Guerrero
flor.rodriguez@uagro.mx

According to several studies, working with vectors is a problem for students from different educational levels. In this document we propose a Planeacion Didáctica Argumentada (PDA) to address the vector concept at lower secondary school level, emphasizing its features (magnitude, direction and sense) such that, it facilitates the formalization of the mentioned concept in a mathematical context. After implementing the PDA, we evidence that with the right instruction, students can develop skills to work with vectors. After analyzing the results, is possible to establish some aspects that must be considered while teaching vectors, for example: the aspects of the teacher, students, curriculums and the previous physics and math necessary contents.

Keywords: Teaching Activities and Practices, Interdisciplinary Studies.

Introduction

Vector is a mathematical object whose operation goes further than conventional numerical treatment (Zea, 2013); in Physics it can be characterized by displacement, speed, acceleration and force. Working with vectors in Physics at an early stage will allow students to develop skills and have a better understanding of the topic when they are working with a mathematical context later on. (Poynter &Tall, 2005). There are investigations that have focused on identifying difficulties when working with vectors (Knight, 1995; Nguyen & Meltzer, 2003; Flores et al., 2007; Flores et al., 2008; Mora, 2011; Barniol & Zavala, 2014 and Barrera et al., 2016); the common denominator of these investigations is that students have difficulties mainly with the concepts of scalar quantity and vector quantity, magnitude and direction of a vector, etc. Knight (1995) and Nguyen & Meltzer (2003) agree that students' misconceptions about vectors is the absence of a clear idea about vector. However, despite the fact that the most recurring difficulties of students are known and have been reported to occur at the basic level (Knight, 1995), didactic proposals do not specify how to work with the vector concept at the basic level and it is not known what could enable the formalization of this concept as a mathematical object.

Consequently, the objective of this document was to design and implement a didactic proposal to address the notion of vector at lower secondary school level, emphasizing its characteristics: magnitude, direction and sense. And due to the educational context, the Planeación Didáctica Argumentada (PDA) model was used as a methodology to achieve the objective.

Method

The actions that were carried out to during the research are described below.

The curriculum

The Natural Sciences curriculum of basic education in Mexico was consulted to know the lower secondary school topics related to vectors, as well as to find out if the curriculum suggests any specific treatment for this concept and with this, compile elements to include in the didactic proposal, such as: the curricular standards, the didactic approach, the competitions, etc.

The results of the review indicated that the curriculum does not consider a specific topic on the vector concept, therefore no expected learning was found for this concept; however, it is stated that: "the student must be able to represent forces with vectors and add them by the parallelogram and polygon methods."

The textbooks

The textbooks of the following authors were reviewed: Barragán (2013); Chamizo (2014); González, Lluis and Pita (2014) and Cuervo (2015), to see the characteristics of activities involving vectors. This information was taken as a starting point for the design of activities in the didactic proposal and, to take the aspects that the textbooks do not deepen and that are necessary to address vectors.

We note that the vector concept is implicit in the topic of "motion" to represent displacements. In addition, in the topic of force, it is necessary to use vectors for the graphical representation and the graphical addition of forces. The revised textbooks lack of graphic examples and activities that promote vector learning, which is natural since the curriculum does not mention a particular type of work with the vector concept. We also note that different definitions of vector and the concept of direction are provided (based on the straight line that the vector contains, relative to a positive angle, and based on a reference angle).

Conceptual aspects for research

Through the reviewed literature, the fundamental concepts for studying vectors were identified, such as: magnitude, scalar magnitude, vector magnitude, vector, features of a vector (magnitude, direction and sense). These concepts were addressed in the activities of the didactic proposal.

The definition of vector depends on the context in which is being worked, in this case it was used in the context of mechanics, since it is the one that fits the contents of the basic level textbooks reviewed. So: Vector is a quantity that has magnitude, direction and sense, according to Dávila and Pajón (2015). In addition, the arrow was used as a vector representation (Hibbeler, 2004).

Planeación Didáctica Argumentada (PDA)

In this research, the Planeación Didáctica Argumenta (PDA) was used as a methodology to design and implement the activities on the vector concept. The PDA enables students to learn content of their interest, and teachers allow them to review what has been done and what is achieved (Sánchez, 2016).

To design the PDA, the following elements were considered (Sánchez, 2016): internal and external context of the class, diagnosis of the class, preparation of the class plan (in three moments: beginning, development and closure), material resources, organization of the group, space, time, assessment and the argumentation of the planning (justification of the chosen teaching strategies).

The elements mentioned above were organized in a planning format, which can be designed at the teacher´s discretion, provided that the essential characteristics of the PDA are considered. The following describes how the PDA was implemented.

Description of the internal and external context. The PDA was implemented in a secondary school with an eighth grade group of 16 students (9 girls and 7 boys) between the ages of 13 and 14, during the 2016-2017 school period. The institution is located in Zumpango del Río, Guerrero, Mexico.

Group diagnosis. At the time of the implementation of the PDA, the group examined was in the fourth school term and had no Physics teacher. Through an interview, a substitute teacher stated the existence of difficulties in mathematics, a lack of participation in class by students, and the fact of there had not been any work with vectors.

Students´ previous knowledge. Evidence was found in class notes that students had worked with displacement, velocity, and acceleration, but there was no mention of the vector characteristics of these concepts.

Class plan. Six activities were designed to be carried out in three phases: initiation, development and closure. In activities 3, 4 and 5, we worked with the graphic representation of vector, and in activities 1, 2, 3 and 6 with the definition of vector. Prior to the implementation of the activities, we worked with angle measurement and the use of the protractor. The material resources, organization, space and time were proposed accordingly to the characteristics of each activity.

To assess learning, a checklist with insufficient, sufficient and outstanding scales was used to determine the performance of the students based on the objectives of each activity. As an example, Activity 3 ("Jimena goes home and to school") is presented below. A time of 90 minutes was proposed to solve this activity following 4 objectives:

1. Establishing the graphical representation of vector quantities using arrows. Use the vector notation $\vec{X}$.
2. Applying the characteristics of a vector: magnitude (the distances that Jimena walks), direction (horizontal, vertical, inclined) and sense (up-down, left-right), based on the type of route Jimena takes.
3. Defining the vector as a quantity that has magnitude, direction, and sense.
4. Recognizing and express events around us that can be represented with vectors.

Planning Argument. The activities involved contexts known by the students and in accordance with the curriculum guidelines; for their resolution, inexpensive and easily available materials were required. The scenarios were chosen according to the needs of each activity and in the spaces of the educational institution. Individual, team and group participation was encouraged in order to contribute ideas to formalize concepts. The checklist for the evaluation record allowed continuous observation of the progress of students in the development of tasks, actions, procedures, skills and attitudes.

Results

The analysis of results was carried out based on the suggested objectives for each activity and taking into account a scale to assess performance (insufficient, sufficient and outstanding). Below are some results of Activity 3.

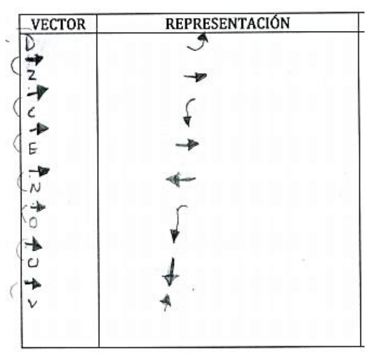

Figure 1: Student result who drew curves instead vectors.

The students managed to describe Jimena's route in words, considering the distance (magnitude), direction and sense; however, they did not discern that Jimena walked twice in the same direction but in a different route. Five students correctly used an arrow (vector) to represent the route, while two others drew "curves" instead of vectors (Figure 1).

To express the features of the distance traveled by Jimena, two students mistakenly determined the direction as "inclined" of some vectors and the sense as "lying down" instead of referring to "left or right". Three students correctly determined the magnitude, direction and sense of the vectors (see Figure 2).

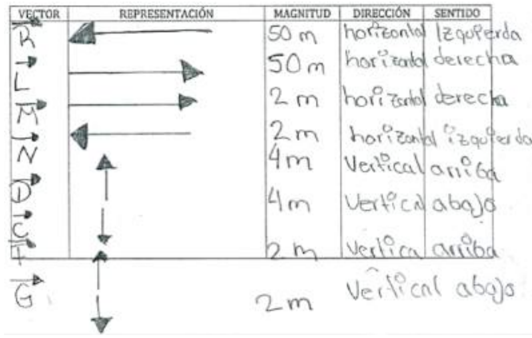

Figure 2: Student who obtained outstanding performance in determining the characteristics of a vector.

To achieve the formalization of the definition of vector, first, we mention that examples of everyday situations can be represented with vectors. Later, with the teacher's guidance, the vector concept was defined, and its features were also defined (Figure 3).

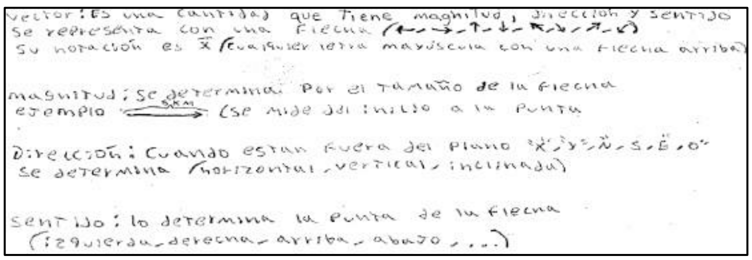

Figure 3: Student evidence in relation to the definition of vector and description of its features.

Conclusions

The reviewed literature made it possible to know aspects that students require to be able to work with vectors, know strategies that have been implemented and the possible difficulties that they may face.

The implementation of the PDA allowed us to reflect on the role of the teacher, since the fact of designing a class plan requires constant precision and adjustments in their practice, as well as identifying opportunities for improvement. In particular, this work made possible to make connections between Physics, Mathematics and everyday life.

This document suggests developing topics that are easier for students prior to working with vectors, involving different representations or contexts in the same topics, as we believe that those will allow us to know in more detail the learning styles of students. We propose, for the assessment, to implement the use of an evidence portfolio, in addition to the checklist, so that the student takes into account all the activities.

UNA EXPERIENCIA DE CLASE: CONCEPTO VECTOR

De acuerdo con varios estudios, trabajar con vectores es un problema para estudiantes de diferentes niveles educativos. En este documento proponemos una Planeación Didáctica Argumentada (PDA) para abordar el concepto vector en el nivel secundario, enfatizando sus características (magnitud, dirección y sentido) de tal manera que, se facilite la formalización del mencionado concepto en un contexto matemático. Luego de implementar la PDA, evidenciamos que con la instrucción adecuada, los estudiantes pueden desarrollar habilidades para trabajar con vectores. Luego de analizar los resultados, es posible establecer algunos aspectos que deben ser considerados en la enseñanza de vectores, por ejemplo: los aspectos del profesor, estudiantes, plan de estudios y los conocimientos previos de física y matemática necesarios.

Palabras clave: Actividades y prácticas docentes, Estudios interdisciplinarios.

Introducción

El vector es un objeto matemático cuyo operatividad va más allá de todo tratamiento numérico convencional (Zea, 2013), en Física se puede caracterizar en desplazamiento, velocidad, aceleración y fuerza. Trabajar con vectores en Física en una etapa temprana permitirá a los estudiantes desarrollar habilidades y tener una mejor comprensión del tema cuando posteriormente trabajen en un contexto matemático. (Poynter yTall, 2005). Existen investigaciones que se han centrado en identificar las dificultades al trabajar con vectores (Knight, 1995; Nguyen y Meltzer, 2003; Flores et al., 2007; Flores et al., 2008; Mora, 2011; Barniol y Zavala, 2014 y Barrera et al., 2016), el común denominador de estas investigaciones es que los estudiantes tienen dificultades principalmente en los conceptos de cantidad escalar y cantidad vectorial, magnitud y dirección de un vector, etc. Knight (1995) y Nguyen y Meltzer (2003) coinciden en los estudiantes no tienen una idea clara sobre vector. Sin embargo, a pesar de que se conocen las dificultades más recurrentes de los estudiantes y que se ha informado que estas ocurren en el nivel básico (Knight, 1995), no se ha especificado en propuestas didácticas cómo trabajar con el concepto vector en el nivel básico, lo que podría posibilitar la formalización de este concepto como objeto matemático.

En consecuencia, el objetivo de este documento fue diseñar e implementar una propuesta didáctica para abordar la noción de vector en el nivel secundaria, destacando sus características: magnitud, dirección y sentido. Y debido al contexto educativo, se utilizó el modelo de Planeación Didáctica Argumentada (PDA) como metodología para lograr el objetivo.

Método

Las acciones que se llevaron a cabo durante la investigación se describen a continuación.

El Plan de Estudios

Se consultó el Plan de Estudios de Ciencias Naturales de educación básica en México para conocer los temas relacionados con vectores señalados en el nivel secundaria, así como conocer si el plan de estudios sugiere algún tratamiento específico para el concepto vector y con ello, recopilar elementos a incluir en la propuesta didáctica, tales como: los estándares curriculares, el enfoque didáctico, las competencias, etc.

Los resultados de la revisión indicaron que el plan de estudios no considera un tema específico sobre el concepto vector, por lo que no se encontraron aprendizajes esperados sobre este concepto, sin embargo, se afirma que: "el alumno debe ser capaz de representar fuerzas con vectores y sumarlos por los métodos del paralelogramo y del polígono ".

Los libros de texto

Se revisaron los libros de texto de los siguientes autores: Barragán (2013); Chamizo (2014); González, Lluis y Pita (2014) y Cuervo (2015), para conocer las características de las actividades que involucran vectores. Esta información se tomó como punto de partida para el diseño de actividades en la propuesta didáctica y, para tomar los aspectos que los libros de texto no profundizan y que son necesarios para abordar el concepto de vector.

Observamos que el concepto de vector está implícito en el tema del "movimiento" para representar los desplazamientos. Además, en el tema de la fuerza, es necesario utilizar vectores para la representación gráfica y la suma gráfica de fuerzas. Los libros de texto revisados carecen de ejemplos gráficos y actividades que promuevan el aprendizaje de vectores, lo cual es natural ya que el plan de estudios no menciona un tipo particular de trabajo con el concepto de vector. También observamos que se proporcionan diferentes definiciones de vector y el concepto de dirección (basadas en la línea recta que contiene el vector, en relación con un ángulo positivo y con base a un ángulo de referencia).

Aspectos conceptuales de la investigación

A través de la literatura revisada, se identificaron los conceptos fundamentales para el estudio de vectores, tales como: magnitud, magnitud escalar, magnitud vectorial, vector, características de un vector (magnitud, dirección y sentido). Estos conceptos fueron abordados en las actividades de la propuesta didáctica.

La definición de vector depende del contexto en el que se esté trabajando, en este caso se utilizó en el contexto de la mecánica, ya que es el que se ajusta a los contenidos de los libros de texto de nivel básico revisados. Entonces: Vector es una cantidad que tiene magnitud, dirección y sentido, según Dávila y Pajón (2015). Además, se usó la flecha como representación gráfica de vector (Hibbeler, 2004).

Planeación Didáctica Argumentada (PDA)

En esta investigación se utilizó la Planeación Didáctica Argumenta (PDA) como metodología para diseñar e implementar las actividades sobre el concepto vector. La PDA permite a los estudiantes aprender contenidos de su interés, y a los profesores les permiten revisar lo hecho y lo logrado (Sánchez, 2016).

Para diseñar la PDA se consideraron los siguientes elementos (Sánchez, 2016): contexto interno y externo de la clase, diagnóstico del grupo, elaboración del plan de clase (en tres momentos: inicio, desarrollo y cierre), recursos materiales, organización del grupo, espacio, tiempo, evaluación y la argumentación de la planeación (justificación de las estrategias docentes elegidas).

Los elementos mencionados anteriormente se organizaron en un formato de planeación, que puede diseñarse a criterio del profesor, siempre que se consideren las características esenciales de la PDA. A continuación se describe cómo se implementó la PDA.

Descripción del contexto interno y externo. La PDA se implementó en una escuela secundaria con un grupo de octavo grado de 16 alumnos (9 mujeres y 7 hombres) de entre 13 y 14 años, durante el período escolar 2016-2017. La institución está ubicada en Zumpango del Río, Guerrero, México.

Diagnóstico del grupo. En el momento de la aplicación de la PDA, el grupo examinado estaba en el cuarto bimestre del período escolar y no contaba con profesor de Física. A través de una entrevista, un profesor suplente manifestó la existencia de dificultades en matemáticas, la falta de participación de los estudiantes en clase y el hecho de no haber trabajado con vectores.

Conocimientos previos de los estudiantes. En las notas de clase se encontró evidencia de que los estudiantes habían trabajado con desplazamiento, velocidad y aceleración, pero no se mencionaron las características vectoriales de estos conceptos.

Plan de clase. Se diseñaron seis actividades para ser desarrolladas en tres fases: inicio, desarrollo y cierre. En las actividades 3, 4 y 5 se trabajó con la representación gráfica de vector, y en las actividades 1, 2, 3 y 6 con la definición de vector. Previo a la implementación de las actividades, trabajamos con la medición de ángulos y el uso del transportador. Los recursos materiales, la organización, el espacio y el tiempo se propusieron de acuerdo con las características de cada actividad.

Para evaluar los aprendizajes se utilizó una lista de cotejo con escalas insuficientes, suficientes y sobresalientes para determinar el desempeño de los estudiantes en función de los objetivos de cada actividad. A modo de ejemplo, a continuación se presenta la Actividad 3 ("Jimena se va a casa y a la escuela"). Se propuso un tiempo de 90 minutos para resolver esta actividad siguiendo 4 objetivos:

1. Establecer la representación gráfica de cantidades vectoriales mediante flechas. Usar la notación de vector $\vec{X}$.
2. Aplicar las características de un vector: magnitud (las distancias que recorre Jimena), dirección (horizontal, vertical, inclinada) y sentido (arriba-abajo, izquierda-derecha), según el tipo de ruta que tome Jimena.
3. Definir vector como una cantidad que tiene magnitud, dirección y sentido.
4. Reconocer y expresar eventos que nos rodean que puedan representarse con vectores.

Argumentación de la planeación. Las actividades involucraron contextos conocidos por los estudiantes y de acuerdo con lo establecido en el plan de estudios, para su solución se requirieron materiales económicos y de fácil acceso. Los escenarios fueron elegidos de acuerdo a las necesidades de cada actividad y en los espacios de la institución educativa. Se incentivó la participación individual, en equipo y grupal con el fin de aportar ideas para formalizar conceptos. La lista de cotejo para el registro de evaluación permitió la observación continua del progreso de los estudiantes en el desarrollo de tareas, acciones, procedimientos, habilidades y actitudes.

Resultados

El análisis de resultados se realizó con base a los objetivos propuestos para cada actividad y teniendo en cuenta una escala para evaluar el desempeño (insuficiente, suficiente y destacado). A continuación se muestran algunos resultados de la Actividad 3.

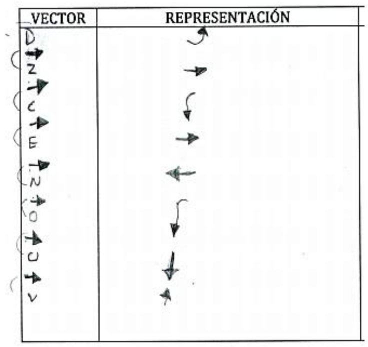

Figura 1: Los estudiantes dibujaron curvas en lugar de vectores.

Los estudiantes lograron describir en palabras la ruta de Jimena, considerando la distancia (magnitud), dirección y sentido, sin embargo, no distinguieron que Jimena caminó dos veces en la misma dirección pero en una ruta diferente. Cinco estudiantes utilizaron correctamente una flecha (vector) para representar la ruta, mientras que otros dos dibujaron "curvas" en lugar de vectores (Figura 1).

Al expresar las carcaterísticas de la distancia recorrida por Jimena, dos estudiantes determinaron erróneamente la dirección como "inclinada" de algunos vectores y el sentido como "acostado" en lugar de referirse a "izquierda o derecha". Tres estudiantes determinaron correctamente la magnitud, la dirección y el sentido de los vectores (ver Figura 2).

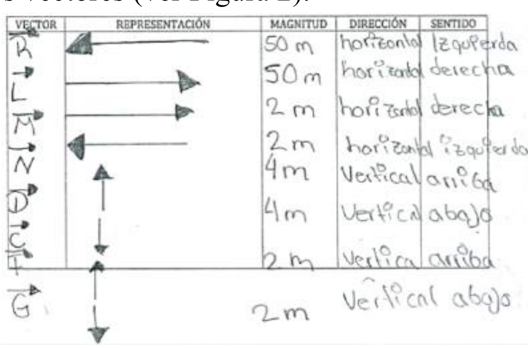

Figura 2: Estudiantes que obtuvieron desempeño destacado al determinar las características de un vector (actividad 3).

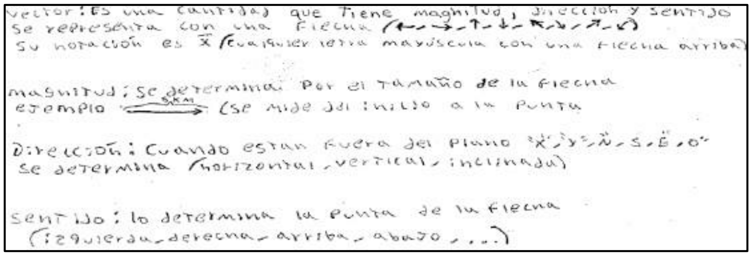
Para lograr la formalización de la definición de vector, primero se mencionaron ejemplos de situaciones cotidianas se pueden representar con vectores. Posteriormente, con la orientación del docente, se definió el concepto de vector y también se definieron sus características (Figura 3).



vector: Es una cantidad que tiene magnitud, dirección y sentido
se representa con una flecha (←, →, ↑, ↓, ↖, ↘, ↗, ↙)
su notación es $\vec{x}$ (cualquier letra mayúscula con una flecha arriba)

magnitud: se determina por el tamaño de la flecha
ejemplo $\xrightarrow{5KM}$ (se mide del inicio a la punta

Dirección: Cuando estan fuera del plano "x", "y", "N", S, E, O"
se determina (horizontal, vertical, inclinada)

sentido: lo determina la punta de la flecha
(izquierda, derecha, arriba, abajo, ...)

Figura 3: Producción de un estudiante en relación a la definición de vector y la descripción de sus características.

Conclusiones

La literatura revisada permitió conocer aspectos que requieren los estudiantes para poder trabajar con vectores, conocer las estrategias que se han implementado y las posibles dificultades que pueden enfrentar.

La implementación del PDA nos permitió reflexionar sobre el rol del docente, ya que el hecho de diseñar un plan de clase requiere precisión y ajustes constantes en su práctica, así como identificar oportunidades de mejora. En particular, este trabajo permitió establecer conexiones entre Física, Matemáticas y la vida cotidiana.

Este documento sugiere desarrollar temas que sean más fáciles para los estudiantes antes de trabajar con vectores, así como involucrar diferentes representaciones o contextos en los mismos temas, ya que creemos que lo anterior nos permitirá conocer con mayor detalle los estilos de aprendizaje de los estudiantes. Proponemos, para la evaluación, implementar el uso del portafolio de evidencias además de la lista de cotejo, con la finalidad que el alumno tenga en cuenta el total de actividades.

In this paper, we aim to explore how prospective elementary mathematics teachers (PMTs) learn to teach mathematics through their engagement in a pedagogically informative Making experience. Grounded in a commognitive perspective, we define learning to teach mathematics as changes in any of these four discourse activities: mathematizing and identifying (Heyd-Metzuyanim & Sfard, 2012), in addition to pedagogy and designing. We present our analysis of one PMT's discourse activity, exposing Making as an effective venue for provoking all four discourses and revealing their intertwined nature, further illustrating that one's identity is as central to learning to teach mathematics as is their learning of mathematics, pedagogy, and design. We conclude with a discussion of the implications of these findings for the research and practice of teacher education.

Keywords: Teacher Knowledge; Teacher Education - Preservice; Affect, Emotion, Beliefs, and Attitudes; Technology

Teacher knowledge literature continues to evolve, with recent conceptualizations building on previous characterizations of distinctive knowledge domains in order to promote a wider focus on their integration (Scheiner, Montes, Godino, Carrillo, & Pino-Fan, 2019). In the current study, we adopt this perspective by viewing *teachers as learners* and foregrounding their identities (Sfard & Prusak, 2005) in order to recognize what affective, interpersonal, and social matters can bring to this conversation. That is, by honoring the interrelationship between the learning of mathematics and the learners themselves, we hope to move beyond the "static, explicit and objective" (Scheiner, et al. 2019, p. 161) outlooks on knowledge to recognize the blended nature of knowing (Scheiner, 2015). And because our teachers are designing manipulatives to share with children with the intention of promoting their mathematical learning, the promise of this approach is suggested by the proposition that teachers' "invention[s] of 'objects-to-think-with'... [offer] the possibility for personal identification" (Papert, 1980, p. 11).

Adopting a communicational perspective on learning (Sfard, 2008), our objective is to explore the premise that learning to teach mathematics can be seen as changes in discursive activities that include narratives about mathematics and identity. The following question guides this research: *As practicing and prospective elementary mathematics teachers Make new manipulatives and corresponding tasks to support the teaching and learning of mathematics, what might their discourses reveal about the epistemology of learning to teach mathematics?*

Theoretical Framework

Our theoretical framing is organized around the learning theories of *commognition* and *constructionism*. Commognition encompasses both interpersonal "communication" and individual "cognition" (Sfard, 2007, p. 570). Discourse, with its affective and social aspects, is central to commognition, and learning is seen through changes in discourse (Heyd-Metzuyanim & Sfard, 2012). The constructionist perspective adds a dimension of participation in a discourse community

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

with a view toward the learning that can happen during the process of making a shareable object (Harel & Papert, 1991).

Heyd-Metzuyanim & Sfard (2012) take a commognitive perspective to frame mathematics learning as the interplay between talking about mathematical objects (*mathematizing*) and talking about participants of the discourse (*identifying*). Sfard (2008) defines discourse as "a special type of communication made distinct by its repertoire of admissible actions and the way these actions are paired with (re-)actions" (p. 297). Discourse can include speech, gestures, and visual mediators (e.g., graphs, symbols, manipulatives) (Sfard, 2008). From there, identity is viewed as a collection of "narratives about individuals that are reifying, endorsable, and significant" (Sfard and Prusak, 2015, p. 16), and identity discourse is viewed as integral to the learning of mathematics [see also Graven & Heyd-Metzuyanim (2019)]. We supplement mathematizing and identifying with two additional forms of discourse that also may be relevant to the learning of mathematics: *pedagogy* (narratives about teaching and learning) and *designing* (narratives about design decisions). Thus, this framework provides us with a lens through which to study how the process of making a manipulative can provoke the four discourse activities of mathematics, pedagogy, design and identity, and help us to see the intertwined nature of a teacher's learning.

Methodology

This project is part of a larger study that aims to test and refine the hypothesis that a pedagogically genuine, open-ended, and iterative design experience centered on the Making and sharing of a physical manipulative for mathematics learning would be formative for the development of practicing and prospective elementary mathematics teachers' (PMTs') inquiry-oriented pedagogy. That study took place in the spring of 2019 in a graduate-level mathematics course for PMTs at a mid-sized university in the northeastern United States. Thirteen participating students comprised ten groups (yielding ten projects). The PMTs were tasked with designing and 3D printing a manipulative that would be shared with a child to support their meaningful learning of mathematics. Written assignments provided autobiographical information of the PMTs' experiences as mathematics students, as well as reflections on clinical interviews they conducted throughout the semester. Snapshots of the PMTs designs in progress are included in the data, as are the physical "printouts" of their manipulatives and video recordings of the course's design sessions.

For this project, we took an exploratory case study approach (Yin, 2009) that focuses on "Moira," a PMT whose initial design was a tool intended to simulate the "keep change flip" algorithm for fraction division. She thought this tool would make fraction division meaningful by providing a concrete representation in which a child could *physically* "keep" the dividend, "change" the division symbol, and "flip" the divisor. However, the course's teacher educator pushed back on Moira's idea by asking her, "When dividing fractions, *why* do you flip the second fraction and multiply?" In re-action to this prompt, Moira becomes intent on figuring out "why we flip the second," a move that signals a change in her mathematical discourse. In a subsequent session, we noticed that she deviates from this intention, opting instead for a new fraction tool design that could support meaningful comparisons of fractions with a broader age-range of students. Effectively, her new design takes familiar fraction strips and connects them end to end to turn them into eight partitioned rings that can be stacked vertically on a cylindrical pedestal.

We chose Moira as an exploratory case because the change in her mathematical discourse constitutes learning, but we also sought to understand this learning through the lenses of the other discourses. Accordingly, we invited her back after the course ended for a voluntary, follow-up, semi-structured and task-based interview (Ginsburg, 1997). In addition to helping us understand Moira's rationale for abandoning her earlier fraction division design, we viewed the manipulative she had made for fraction comparison as an instance of her design discourse and sought to use it to assess her understanding of fraction division. This interview was video-recorded and added to the corpus of Moira's data, along with written artifacts from the interview. That data was then analyzed through the conceptual lenses of the four discourse activities: identifying, mathematizing, pedagogy, and designing.

Results

In this section, we present two central results from the follow-up interview. The first result concerns Moira's decision to change her tool design, and our analysis of this choice through the discourses of mathematizing [M], Pedagogy [P], Designing [D], and Identifying [I]. Moira reflects, "I wanted to make something that could be interpreted in many different ways [*M/P/D*], that wasn't something that I was just forcing them to, like, all right, you have to use it this way. I wanted it to be able to be manipulated [*M/P/D/I*]." As she considers her initial "keep, change, flip" tool, she articulates, "You basically were just, like, flipping the fraction upside down in my initial tool and ... it was just not useful [*M/P/D*] ... So I decided to switch to comparing fractions and then I came up with this [fraction comparison tool] [*M/D/I*]."

These reflections reveal how Moira's initial decision to abandon her fraction division design is not just about mathematizing, but also about identifying: as a teacher, it is important to her that her students have the opportunity to develop their own ways of thinking about fractions with a tool that can be used in a variety of ways. Moira acknowledged that the pedagogy promoted by the instructor in the classroom was also part of her decision to change her design:

> Moira: Well, [the change of design] was because we were talking and you [the teacher educator] said, "you're just teaching them how to – you're just giving them a way to solve the problem." And I realized, you're right ... It wasn't helping them learn how to do a problem [M/P/D/I].

By switching to a design for comparing fractions, Moira can participate in the discourse endorsed in the teacher education classroom and honor the teacher she wants to be.

A second result related to Moira's learning emerges from the interviewers' awareness that her current tool *could* be used to make sense of fraction division and a question about whether Moira realizes this capability in her tool. The interviewers ask her about this possibility, prompting Moira's in-the-moment reflections: "½ divided by 2. ½, this divides it into two equal parts, and I know this equals fourths, so this is ¼" [*M/I*]. Then, in investigating 1 divided by 1/3, Moira takes the 1 and 1/3 ring, guesses the answer is 3, and says, "I know I can do it, and I'm seeing it, but I don't know how to describe it" [*M/I*]. Moira is using her tool to make sense of this problem when the interviewers prompt her to explain whole number division (e.g., 6 divided by 3). As Moira reasons through whole number examples [*M*], she exclaims, "Oh! So, so, if I am dividing 1 by ⅓, there are three thirds in 1, so it's 3! Yes! You can do division with these … Wow! Fractions make so much sense now" [*M/I*].

Although Moira's reflections on the ½ and (later) ⅓ examples seem the same, the shift from her use of a partitive conception of division to a measurement one gives her sought-after language to "describe" her tool's utility in her understanding of fraction division. Moira's mathematical discovery is intertwined with an expression that reveals how emotionally invested she is in this realization. The moment culminates in self-reflection: "Honestly, I'm so impressed with myself [*I*]. I did not think that it had this capability. I thought it was only for comparing fractions [*M/P/D/I*]. So we've learned something today, haven't we all…" [*I*].

As she uses her tool to think through fraction ideas [*M*], Moira comes to recognize its potential not only for her own learning, but also for teaching fraction division in a way that aligns with her identity as a teacher [*P/I*]. Moira's body language and energy substantiate her enthusiasm for this discovery. Finally, the whole experience leads her to identify herself as part of a community of learners who can struggle and reason as part of a sense-making process.

Conclusion and Implications

As in a woven tapestry, learning to teach mathematics weaves together four threads or discourses that are unique to a PMT's discursive experiences and particular to a learning community where inquiry pedagogy is promoted. In this sense, to characterize Moira's learning to teach mathematics as a complex structure of discursive activities interwoven in dialectical unity is to illuminate the brilliance of a tapestry threaded by what she wants to teach (mathematizing), how she wants to teach it (pedagogy), decisions about what resources to make available (designing), and the kind of teacher she wants to be (identifying). Zooming in on that tapestry might provide a view on a single thread of Moira's understanding of fraction division, but focusing on a single thread obscures the others with which it is interwoven. Collectively, these threads contribute to a more intellectually honest depiction of the "organic whole" (Scheiner, 2019, p. 165) that is learning to teach mathematics.

This project set out to explore the proposition that learning to teach mathematics can be credibly conceived as changes in mathematizing, identifying, pedagogy, and designing discourses. Our analysis of data related to Moira's experiences making a physical manipulative for sharing with a child reveals how her experiences provoked all four discursive activities, and revealed the intertwined nature of these discourses. This finding resonates with a view of mathematics teacher learning that emphasizes the blending and transformation of constituent knowledge domains into emergent knowing. It also resonates with an acknowledgment of the complex dynamics of mathematics teacher knowledge in action (Scheiner, 2019).

Our study also establishes that identity is as central to learning to teach mathematics as is the learning of mathematics, pedagogy, and design. The ensuing changes of discourse have revealed that although sometimes viewed as distinct, teacher learning domains are inherently connected to a PMT's identity. In light of research by Pratt and Noss (2010), its centrality can be understood in the context of a design project carried out in a Maker community where PMTs were engaged in creative activity, leveraging their personal experiences and invoking personal design decisions, reflections, and articulations. All in all, implications of this finding speak to the potential of interdisciplinary experiences like the design experience as venues for the meaningful learning of learning to teach mathematics within teacher preparation coursework.

ELEMENTARY TEACHERS' DISCOURSE ABOUT MATHEMATICAL REASONING

Doris Jeannotte	Stéphanie Sampson	Sarah Dufour
UQAM	UQAM	Université de Montréal
doris.jeannotte@uqam.ca	stéphanie.sampson@courrier.uqam.ca	sarah.dufour.3@udmontreal.ca

Even though mathematical reasoning [MR] is at the heart of several elementary curricula around the world, very little is known about the meanings given to MR by teachers. In this paper, adopting a commognitive perspective (Sfard, 2008), we aim at better understanding the different meanings teachers give to MR. To do so, we used the Mathematical Discourse for Teaching framework (Cooper and Karsenty, 2018) to analyze elementary teachers' discourse about MR. Through individual and collective interviews, we gathered the data. We coded the data by first highlighting the vocabulary used to give meaning to mathematical reasoning by the teachers and, secondly, by identifying the utterances linked to their Mathematical Discourse for Teaching. Analyses revealed that elementary school teachers' discourse about MR is coherent with the prescribed curriculum.

Keywords: Teacher knowledge, Elementary School Education, Reasoning and Proof, Mathematical Knowledge for teaching.

This paper presents an analysis of teachers' discourse about mathematical reasoning [MR]. The MR is at the heart of several curricula around the world. In Quebec, where this project takes place, it is one of the three competencies of the elementary and secondary school curriculum (MEQ, 2001)[1]. According to Loong, Vale, Bragg and Herbert (2013), primary school teachers feel confused or uncertain about the task of defining Mr. Likewise, the meanings given to MR could play an important role in how teachers approach it in class (Stylianides and Ball, 2008). Taking a commognitive perspective, we aim at describing the discourse about MR of elementary teachers. In doing so, we want to better understand how MR can be fostered in classrooms from the teacher perspective.

What do we know about Mathematical Reasoning discourse at elementary level?

Despite a growing interest in MR and teachers' practices, very little is known about the meanings given to MR by teachers as well as how they promote its development in the classroom. Clarke, Clarke and Sullivan (2012) asked 104 elementary school teachers which MR related terms, from a given list, they frequently used in math class. Only four terms—explaining, justifying, proving and reasoning—were chosen by more than 50% of the teachers. To evaluate a professional development [PD] that aims at fostering MR in elementary classrooms, Herbert, Vale, Bragg, Loong and Widjaja (2015) explore the different meanings given to MR by teachers from Australia and Canada (Vancouver) involved in the PD. Their analysis highlights seven meaning categories that elementary teachers may attribute to MR: 1) thinking; 2) communicating; 3) solving problems; 4) validating thinking; 5) forming conjecture, 6) using logical arguments for validating conjectures; and, 7) connecting different mathematical aspects. Those categories emerged from the discourse developed during the PD. However, what about terms used and meaning given by teachers who never participate in this kind of PD? This study aims at investigating this question.

[1] The three competencies are 1) to solve a situational problem related to mathematics, 2) to reason using mathematical concepts and processes and 3) to communicate by using mathematical language.

Mathematical Discourse for Teaching

From a commognitive perspective, cognition and communication are two aspects of the same ontology, i.e. discourse. Discourses are constituted of keywords, visual mediators, rules of discourse, routines and generally endorsed utterances (Sfard, 2008). Knowledge and practices are two aspects of the discourse associated with the teaching of mathematics (Cooper and Karsenty, 2018). So, in the same way, the investigation of the meaning that mathematical reasoning can take in elementary school can be done by considering the teachers' discourse, rooted in practice.

Cooper (2014) reformulated the Mathematical Knowledge for Teaching framework of Ball et al. (2008) from a commognitive perspective: Mathematical Discourse for Teaching [MDT]. As the MKT framework, the MDT framework is divided into two types of discourse: Mathematical discourse and pedagogical discourse. Mathematical discourse [MD] consists of common content discourse (the mathematical discourse that is common to a large portion of educated society), specialized content discourse (mathematical discourse that is typical of teachers of mathematics) and discourse at the mathematical horizon (patterns of mathematical communication that are appropriate in higher grade levels). Pedagogical content discourse [PCD] consists of discourse about content and teaching, discourse about content and students and discourse about the curriculum and resources.

Adopting this framework, we can reformulate our aims as: What are the keywords, visual mediators, rules, routines and generally endorsed utterances that constitute MDT of elementary teachers in relation to MR?

Some methodological insights

The data used in this paper came from a larger project that aims to document how MR is defined and fostered by elementary and secondary teachers. Six elementary teachers with 2 to 16 years of experience participated in one 60 minutes individual interview (Pseudonymes: Martine, Gisèle, Aurélie, Jeanne, Alice, Agathe). Five of them participated in a 120 minutes collective interview. All interviews were video or audio recorded.

Three different moments constituted the individual interview. First, the interviewer asked the participant to recall a moment of her teaching or to present a task that she gives her students in which MR would be promoted. This allowed us to stay in an area known to the participant. Furthermore, it informed about the learning environment that teachers considered favourable to the development of MR. Then, two examples of tasks including one with a student's solution were presented to the participant. The participant was then invited to decide on the possibility for a student solving these tasks to develop MR or not and to justify their answer. If the answer was positive, she was asked to describe the possible reasoning processes in their own words. Finally, to close the meeting, the participant was invited to give in a few sentences her definition of MR.

The collective interview sought to encourage exchanges between practitioners around MR so as to bring out the discursive elements shared by them. The first part of the interview aimed at defining MR. The interview therefore began with the question that had ended the individual interview: "How do you define mathematical reasoning in a few words or sentences?" This was followed by an activity where participants constructed a conceptual map with vocabulary words widely used to define MR during individual interviews or in the literature. The second part of the interview was to see how the teachers could reinvest the conceptual map to comment on students' written work. Finally, the group interview ended once again by offering each participant the opportunity to add something related to their definition of MR.

In order to analyze the data, the videos and audiotapes were viewed/listened to repeatedly, and transcribed (Powell, Franscisco & Maher, 2003). Using Nvivo software, a first layer of coding made it possible to highlight the keywords used to give meaning to MR by the teachers. A second layer of coding made it possible to identify what seem as endorsed utterances linked to MDT for this group of teachers. By focusing mainly on keywords and endorsed utterances, discourse about the curriculum and resources [DCR] was particularly highlighted by the analysis.

Mathematical Discourse for Teaching and Mathematical Reasoning

When asked specifically to define MR, teachers use different keywords that seem to come from a common discourse about MR. For example, MR is linked to logic and argumentation, which are two words used to define reasoning in general dictionaries. But other keywords are more specific. For Martine, MR is to communicate and understand why. Similarly, Aurelie defines MR as explaining why. For Agathe it is also to communicate but to explain how. Gisele refers to MR as applying concepts and explaining what you have done. Alice used the metaphor of the toolbox. For her, MR is knowing when to use your toolbox, justifying and identifying and extrapolating patterns. Jeanne refers to organizing, thinking and making sense.

In relation to the PCD of the participants, generally endorsed utterances are usually embedded in DCR. Here are two illustrative examples.

Analyzing, making choices, applying, justifying and Mathematical Reasoning

In the teachers' discourse, analyzing, making choices, applying and justifying are important aspects of MR. Most teachers refer to those terms and they usually do so specifically by referring to the evaluation grid provided by school boards and based on MELS (2011) document.

> Aurelie: it's the evaluation criteria. 30 points for the analysis, 50 points for applying it … The last evaluation criterion is justifying, with 20 points.
>
> Gisele: Once I understand, I have analyzed the problem, then I have to make choices in what I know and what I think that will help me to reason with it.

This grid also *renders MR processes a linear structure* in the teachers' discourse as illustrated by Gisele's utterance above. Moreover, it is possible to draw a parallel between the grid and Pólya's problem-solving model: 1) understand the problem that is similar to analyzing; 2) develop a plan or make choices; 3) implement the plan or apply; and finally, 4) verify or justify. This is what Agathe feels in connection with MR:

> Agathe: Listen… I have the impression that reasoning with MR, well, this is the old one … this is the old problem solving from 15 or 20 years ago.

The criteria for assessing MR competency therefore play an important role in the discourse on MR. This role contributes to blurring the discourse on problem solving and MR.

Problem Solving and Mathematical Reasoning

In addition to being used as a quasi-synonym for MR, problem solving takes three other meanings for the teachers. First, it's a pedagogical method that can foster MR. Second, it's a competency evaluated with a particular type of task. Third, it's the type of task that evaluates problem solving. Those last two meanings are embedded as for both, problem solving is seen as more global and complex than MR.

> Alice: Well, that's why it's interesting to teach with problems too. So, not to make problems after the concepts, to bring the concepts with the problems.
>
> Martine: Well, the link I do between solving and reasoning is that… In fact, well, a situation to learn and evaluate, it should be complex. So, for sure, every child can have a different answer. Then, he [the child] uses the concepts uh that we include in reasoning [competency] because there is a need and then goes and solves it. So, I think reasoning is like a prior to solving [competency] because it is part of knowledge.

We can link those elements of discourse to the type of tasks used by teachers to evaluate each competency. Both types of task, namely situational problem and problem using application (MEQ, 2001), have different characteristics. The wording of the former is longer, includes a context, many steps to do, many concepts and processes to use and, as the students have to make choices in the data in order to solve the task, many solutions are possible (Lajoie & Bednarz, 2012). The wording of the latter is usually shorter, with one or two steps and the students have to choose the concepts and processes needed to solve it.

Discussion and Conclusion

Similarly to Herbert et al. (2015), the meanings given to MR by those 6 elementary teachers are broad and manifold. Likewise, as shown by the partial analysis presented, those meanings are tied to and somehow limited by teachers’ DCR. In fact, the discourse found in the Quebec curriculum (MEQ, 2001), just like the one in math education literature, is also quite blurry (author, year). As MR is a competency which must be assessed with a specific grid and so-called *problem using application* task, this grid greatly colours their whole discourse. However, the evaluation criteria seem to favour a linear vision of the MR activity. Although questioned by the teachers, this linear vision of MR conveyed by the grid could limit learning opportunities for students as it gives the impression that MR is a series of steps to follow. Moreover, the criteria make it difficult for teachers to differentiate problem solving competency from MR otherwise than by the type of task used.

Like the discourse in the mathematics education community, the discourse of teachers is formed from a set of discourses related to different fields: educational institutions, psychology, pedagogy, mathematics education. These discourses are sometimes incommensurable. Thus, as they point out, enriching and clarifying the vocabulary related to the MR, whether in the curriculum or in training could, among other things, open up new possibilities for developing it in the classroom:

> Agathe: But that proves that we have to have a common language… We teach mathematics differently depending on our understanding.

Acknowledgments

This research would not have been possible without the support of the FRQSC[197178] and the participation of six dedicated elementary teachers.

LANGUAGE: A HIDDEN RESOURCE IN PREPARING BILINGUAL PRE-SERVICE TEACHERS

LENGUAJE: UN RECURSO OCULTO EN LA FORMACIÓN DE MAESTROS BILINGUES

Gladys H. Krause	Juanita Silva	Jair J. Aguilar
William & Mary	Texas State University	UTRGV
ghkrause@wm.edu	jsilva@txstate.edu	jair.aguilar@utrgv.edu

We worked to identify how the availability of two languages, Spanish and English, facilitates the teaching of mathematics when students' mathematical thinking forms the basis of instruction. To this end we studied seven teachers in training, one expert teacher and seven bilingual elementary students working on learning and teaching fractions. Using a theoretical framework focused on the use of one-on-one interviews, translanguaging and responsive teaching, we identified two aspects of language in the teaching of mathematics in the bilingual classroom: (1) Language is a hidden resource that bilingual teachers possess and (2) the maintenance and furthering of linguistic abilities should not be isolated from the teaching of mathematics. We argue that these two aspects are situated and integrated into the practice of teaching and in this way should be part of the preparation of bilingual teachers.

Key Words: Elementary School, Bilingual Teacher Preparation Programs, Teacher Educators

Our article presents a study we conducted based on our interest to understand more deeply how to support the preparation of bilingual teachers, particularly those bilingual in Spanish-English. The study was conducted in the context of an extracurricular program with bilingual 5th grade students (Spanish-English). This extracurricular program focused on teaching fractions. Our focus on fractions has two theoretical foundations: (1) children's mathematical thinking (Empson & Levi, 2011; Carpenter et al., 2014; Jacobs & Empson, 2016), and (2) how students' mathematical thinking supports teacher training (Hunt et al., 2019; Krause & Maldonado, 2019).

Our work focuses on understanding what factors influence the linguistic negotiation between teacher and student during the teaching of mathematics. Specifically, our research focuses on identifying these factors when teacher educators and elementary students interact during the teaching and learning of fractions. In this specific context, this research answers the following question: How does the availability of two languages, Spanish and English, facilitate the teaching of mathematics when students' mathematical thinking is used as the basis for fraction instruction?

Theoretical Background

Recent proposed reforms in the field of mathematics education promote environments that encourage student participation in mathematical reasoning, problem solving, and the use of common sense when learning mathematics (National Council of Teachers of Mathematics, 2014). All these reforms have a research foundation that comes from monolingual classrooms. To date, there is little evidence to suggest that reforms that work in the monolingual context could also be carried out in bilingual contexts in the same manner. For example, decades of research confirm that instruction based on students' mathematical thinking improves student learning (Fennema et al., 1996; Simon & Schifter, 1993; Saxe et al., 1999; Jacobs et al., 2007). However, these investigations do not mention, or consider, the importance and influence of language in the way students express their mathematical ideas. Furthermore, as bilingual teachers we often have to adapt the use of language. This particular practice adds a level of difficulty in teaching due to the idiosyncrasy of how different speakers learn languages in multicultural contexts (Urciuoli, 1985).

Theoretical Framework

Next, we present the concepts that were considered as theoretical foundations for our study.

One-on-One Interviews as an Approximation of Practice

Grossman et al. (2009) presented a theoretical framework for teaching practice that includes three main components: approximation, representation and decomposition. Our work focuses on one of these central practices: approximation of practice. The teaching practice approach is defined by Grossman et al. (2009) as a way to provide opportunities for representation and experimentation through simulations of aspects of the teaching practice. Grossman et al. (2009) also make the case that engaging in approximation of practice allows the trainee to engage in repetition. Repetition allows pre-service teachers to gain fluency with common teaching moves, so that they can place greater attention on more nuances and individualized aspects of practice.

In our study we designed an approximation of practice by developing an after-school program where BPSTs worked on one-on-one interviews (Ginsburg, 1997) with a bilingual elementary student.

Translanguaging as a means of communication in the Bilingual Classroom

In addition to working in spaces where approaches to educational practice are available to BPSTs, we also focused our study around translanguaging. García et al. (2017) define a classroom where translanguaging can be observed as a "space built collaboratively" by teachers and students, where each has their own linguistic practices. In this space the main goal is to teach and learn in “deeply creative and critical ways” (p.2). Maldonado et al. (2018) have pointed out the lack of studies that focus on this practice when teaching or learning mathematics. They argue that it is necessary for mathematics educators to cultivate translanguaging and build classrooms in which teachers and students work and enrich the practice and culture of the language, involve families and communities as sources of knowledge, and create a democratic classroom that co-creates knowledge (Maldonado et al., 2018). We used this lens to understand the language practices of BPSTs and their students in order to understand the development of BPSTs instructional practices.

Responding in the Moment to the Mathematical Ideas of the Students

To illustrate how translanguaging is positioned during mathematics instruction and how BPSTs became involved in translanguaging while teaching mathematics, we used the theoretical framework of Jacobs and Empson (2016), responsive teaching. They conceptualize responsive teaching as a “type of teaching in which teachers’ instructional decisions about what to pursue and how to pursue it are continually adjusted during instruction in response to children’s content-specific thinking, instead of being determined in advance" (p.1). Their work establishes a framework of questions that identifies four categories of instruction: (a) ensure that the student understands the context of the problem, (b) explore details of the strategy the student uses to solve the problem, (c) encourage the student to consider other strategies, and (d) connect the student's mathematical thinking with symbolic notation.

These three principles provided the theoretical basis in the design of the extracurricular program in our study and in the data analysis.

Methods and Data Analysis

For the analysis we followed the parameters of an exploratory case study (Yin, 1984).

Data Collection

The data for this study comes from an extracurricular program for bilingual 5th grade students. BPSTs worked once a week for approximately 30 minutes at a time. We recorded a total of 20 sessions. We also held three interview sessions with each of the BPSTs. The first interview was conducted at the beginning of the extracurricular program, the second during the middle of the semester and the third at the end of the extracurricular program.

Participants

Seven BPSTs, one bilingual Latina teacher with more than 12 years of experience, and seven 5th grade students participated in this study. All teachers identified themselves as Latinx. All seven BPSTs had taken (the previous semester) the bilingual mathematics methods course that the first author of this article designed and taught.

Analysis

First, the three authors created a list of preliminary codes reported in our experience through the research project. This list was extensive and detailed (Saldaña, 2015). The three authors met to discuss the initial code list and we generated a common code list (Saldaña, 2015). After this coding process, we meet to compare the codes and carry out a triangulation process (Vallejo & de Franco, 2009).

Results and Discussion

The interactions between the teachers in training and the 5th grade students showed important aspects in the use of language in the teaching-learning process. The following represent a few reflections on the discoveries made during this analysis process.

Language: A Hidden Resource

The interactions between Aurora and her student, Yerina, allowed us to notice the fluidity with which each one changed from one language to another. For our study, we have defined fluency as the ability to move from one language to another. In the following transcript of Aurora interacting with Yerina, it can be seen that they both use English and Spanish, while Aurora makes sure that Yerina understands the context of the problem:

Aurora: *Carlos tiene una caja* [Yerina repeats with Aurora] *de comida de gato* [Carlos has a box of cat food]

Yerina: *Él le da a su gato un* [Aurora helps Yerina to read one-fourth] *un cuarto* [He feeds his cat one fourth]

Aurora: *One-fourth*

Yerina: *…de la caja para la comida. ¿Cuánto le queda de la caja?* […of the box. How much of the box is left?]

Aurora: [Aurora repeats the problem] *Entonces Carlos tiene una caja de comida de gato. Él le da a su gato un cuarto de la caja de la comida. ¿Cuánto queda de la caja?* [Carlos has a box of cat food. He feeds his cat ¼ of the box. How much of the box is left?]

This type of interaction is an example of what García and Sylvan (2011) has described as translanguaging. In the context of our study, this practice is particularly important for two reasons: 1) while Aurora made sure that Yerina understood the problem statement, she was able to see that any difficulty that might appear in relation to understanding the context of the problem, is not related with the ability to understand one language or another, that is, it is not a linguistic barrier, 2) providing the space to express mathematical ideas, as provided to Yerina, facilitated the communication of mathematical ideas and the interaction between Aurora and Yerina.

Language: Not an Isolated Resource

The following example shows how in the initial interactions between Aurora and Yerina, Aurora focuses on guiding Yerina towards a specific strategy. In this way Yerina's strategy becomes more like Aurora's strategy and Yerina's mathematical thinking is no longer the main source of instruction at that time.

Aurora: *So what number do we see? ¿Qué números ves?* [What numbers do you see?]
Yerina: *One fourth.*
Aurora: *One fourth, okay. Un cuarto ¿de qué?* [A fourth of what?]
Yerina: *¿De la caja?* [Of the box?]
Aurora: *Entonces ¿cuántas cajas tiene Carlos?* [Then, how many boxes does Carlos have?]
Yerina: *Una.* [One]
Aurora: *Una, nada más tiene una. ¿Podemos dibujar la caja? ¿Sí? …. y ¿es comida para Carlos? O ¿para quién?* [One, he only has one. Can we draw the box? Yes? … and is it food for Carlos?]
Yerina: *Gatos* [Cats]
Aurora: *Aja, para el gato. Y dice … él le da a su gato un cuarto de la caja para la comida. So, he gives one fourth.* [Aha, for the cat. And it says … he feeds his cat a fourth of the box. So,…]
Yerina: *So he gives her like this much.*
Aurora: *So, it would be, okay kind of like in the middle. So, let's draw one in the middle. Let's see.*
[Yerina draws a line]
Aurora: *Okay, ¿entonces cuántas partes tenemos ahí?* [Okay, then how many parts do we have there?]
Yerina: *Uno…dos.* [One … two]

In our experience as mathematics educators we have seen that teacher educators tend to guide the student towards a specific strategy. Typically, they suggest the use of a drawing, as we saw in this sample. At the same time, Jacobs and Empson (2016) have documented the same experience working with in-service teachers. Although, language seemed to help in the interaction between Yerina and Aurora, we noticed language was not the only resource needed in this instance to help Yerina express her mathematical thinking. Aurora, could have used this opportunity to uncover how Yerina was thinking, instead of suggesting that she draw the box.

Conclusions

We found that the availability of the two languages made it easier for BPSTs 1) to reach the same understanding of the context of the problems, ruling out the use of one language or another as an obstacle to reaching a common agreement, and 2) that the teacher also needs to develop the ability to respond instantly to the student's mathematical ideas. This practice in the case of bilingual interactions does not necessarily depend on the use of a specific language. Once language has been ruled out as a non-influencing factor in solving the problem, the teacher needs to have the ability to create the space for the student to freely express their mathematical ideas. In our study we investigated the language factors in one-to-one interactions between BPSTs and a bilingual student in the context of approximations, but we need more studies that investigate the representation and decomposition of practice.

En este estudio se identifica de que manera la disponibilidad de dos idiomas, español-inglés, facilita la enseñanza de las matemáticas cuando el pensamiento matemático de los estudiantes es la base para la instrucción. Identificamos dos aspectos intrínsecos del lenguaje en la enseñanza de las matemáticas en el aula bilingüe: (1) El lenguaje es un recurso oculto que poseen los maestros bilingües y (2) el lenguaje no debe ser estudiado como un recurso aislado en la enseñanza de las matemáticas. Argumentamos que estos dos aspectos están situados e integrados en la práctica de la enseñanza y de esta manera deben formar parte en la preparación de maestros bilingües.

Palabras clave: Educación Primaria, Preparación de Maestros en Formación, Educadores de Docentes

Nuestro artículo presenta un estudio que realizamos teniendo como base el entender más a fondo cómo apoyar la preparación de maestros bilingües en formación, particularmente aquellos en español e inglés. El estudio se realizó en el contexto de un programa extracurricular con estudiantes bilingües de 5to grado de primaria (español-inglés). Este programa extracurricular se enfocó en la enseñanza de fracciones. Nuestro enfoque en fracciones tiene dos fundamentos teóricos: (1) el pensamiento matemático de los niños (Empson & Levi, 2011; Carpenter et al., 2014; Jacobs & Empson, 2016), y (2) cómo el pensamiento matemático de los estudiantes apoya la preparación de maestros en formación (Hunt et al., 2019; Krause & Maldonado, 2019).

Nuestro trabajo se enfoca en entender qué factores influyen en la negociación lingüística entre el maestro y el alumno durante la enseñanza de las matemáticas. Específicamente nuestra investigación se centra en identificar estos factores cuando maestros en formación y estudiantes de primaria interactuaban durante la enseñanza y aprendizaje de fracciones. En este contexto especifico, la presente investigación responde la siguiente pregunta: ¿De qué manera la disponibilidad de dos idiomas, español e inglés, facilita la enseñanza de las matemáticas cuando el pensamiento matemático de los estudiantes es usado como base para la instrucción de fracciones?

Antecedentes Teóricos

Recientes reformas propuestas en el campo de la educación de matemáticas promueven entornos que fomentan la participación de los estudiantes en el razonamiento matemático, la resolución de problemas y el uso del sentido común al aprender matemáticas (National Council of Teachers of Mathematics, 2014). Todas estas reformas tienen un fundamento de investigación que proviene de aulas monolingües. Hasta la fecha, existe poca evidencia que sugiera que el éxito de estas reformas en el contexto monolingüe, podría trasladarse sin ningún cambio al aula bilingüe. Por ejemplo, décadas de investigación confirman que la instrucción basada en el pensamiento matemático de los estudiantes mejora el aprendizaje de los estudiantes (Fennema et al., 1996; Simon & Schifter, 1993; Saxe et al., 1999; Jacobs et al., 2007). Sin embargo, estas investigaciones no mencionan, o tienen en cuenta, la importancia e influencia del idioma en la manera cómo los estudiantes expresan sus ideas matemáticas. Por ejemplo, sólo lo que implica usar el pensamiento matemático de los estudiantes en la práctica, requiere que acomodemos estos pensamientos para nuestro propio entendimiento en el mismo momento en que recibimos las respuestas y explicaciones de los estudiantes sobre lo que piensan y entienden de una idea matemática. Además, como maestros bilingües muchas veces debemos adaptar el uso del lenguaje. Esta práctica en particular agrega un nivel de dificultad en la enseñanza debido a la idiosincrasia de cómo los diferentes hablantes aprenden idiomas en contextos multiculturales (Urciuoli, 1985).

Marco Teórico

A continuación, se abordan los conceptos que fueron considerados como fundamentos teóricos para el estudio que se presenta en esta propuesta.

Entrevistas Uno-a-Uno Como Aproximación de la Práctica Docente

Grossman et al. (2009) presentaron un marco teórico para la práctica docente que incluye tres componentes principales: aproximación, representación y descomposición. Nuestro trabajo se enfoca en una de estas prácticas centrales: aproximación de la práctica docente. La aproximación de la práctica docente está definida por Grossman et al. (2009) como una forma de proporcionar oportunidades para la representación y experimentación a través de simulaciones de aspectos de la práctica docente. Grossman et al. (2009) también exponen que participar en la aproximación de la práctica permite al aprendiz participar en la repetición. La repetición permite a los maestros en formación ganar facilidad y fluidez con movimientos de enseñanza comunes, para que puedan poner mayor atención en más matices y aspectos individualizados de la práctica.

En nuestro estudio, diseñamos una aproximación de la práctica educativa mediante el desarrollo de un programa extracurricular en el que los maestros en formación trabajaron en entrevistas individuales (Ginsburg, 1997) con un estudiante bilingüe de 5to grado de primaria.

TransLenguaje Como Medio Comunicación en el Aula Bilingüe

Además de trabajar en espacios donde aproximaciones de la práctica educativa están disponibles para los maestros en formación, también centramos nuestro estudio alrededor de el teórico de *TransLenguaje.* García et al. (2017) definen un aula en dónde se puede observar el uso *TransLenguaje* como un "espacio construido en colaboración" por docentes y alumnos, donde cada uno tiene sus propias prácticas lingüísticas, y que tiene como objetivo el de enseñar y aprender de manera "profundamente creativa y crítica" (pág. 2). Maldonado et al. (2018) han señalado la falta de estudios que se centran en esta práctica cuando se enseñan o aprenden matemáticas. Ellas argumentan que es necesario que los educadores de matemáticas cultiven *TransLenguaje* y construyan aulas en las que los maestros y los estudiantes trabajen y enriquezcan la práctica y la cultura del lenguaje, involucren a las familias y las comunidades como fuentes de conocimiento y creen un aula democrática que co-crea conocimiento (Maldonado et al., 2018). Usamos este lente para comprender las prácticas lingüísticas de los maestros en formación y sus estudiantes para comprender el desarrollo de las prácticas de instrucción de los maestros en formación.

Contestando en el Momento a las Ideas Matemáticas de los Estudiantes

Para ilustrar cómo se ubica *TransLenguaje* durante la instrucción de matemáticas y cómo los maestros en formación se involucraron en la práctica de *TransLenguaje* al hacer matemáticas, usamos el marco teórico de Jacobs y Empson (2016), enseñanza receptiva*.* Ellas, conceptualizan enseñanza receptiva como un "tipo de enseñanza en la que las decisiones de instrucción de los maestros sobre qué idea seguir y cómo seguirla se ajustan continuamente durante la instrucción en respuesta al pensamiento específico de los estudiantes, en lugar de determinarse de antemano" (pág. 1). Su trabajo establece un marco de preguntas que identifica 4 categorías de instrucción: (a) asegurar que el estudiante entienda el contexto del problema, (b) explorar detalles de la estrategia que el estudiante usa para resolver el problema, (c) animar al estudiante a considerar otras estrategias, y (d) conectar el pensamiento matemático del estudiante con notación simbólica.

Estos tres principios proporcionaron la base teórica en el diseño del programa extracurricular en nuestro estudio y en el análisis de datos.

Método de Análisis

Para el análisis seguimos los parámetros de un estudio de casos exploratorios (Yin, 1984).

Recopilación de datos

Los datos de este estudio provienen de un programa extracurricular para estudiantes bilingües de 5to grado. Los maestros en formación trabajaron una vez por semana por aproximadamente 30 minutos a la vez. Se realizaron un total de 20 sesiones durante el transcurso de un semestre.

También realizamos tres sesiones de entrevistas con los maestros en formación. La primera entrevista se realizo al inicio del programa extracurricular, la segunda durante la mitad del semestre y la tercera al final del programa extracurricular.

Participantes

En este estudio participaron siete maestros bilingües en formación, una maestra Latina bilingüe con mas de 12 años de experiencia y 7 estudiantes de 5to grado. Todos los maestros se identificaron como Latinx. Los siete maestros en formación habían tomado (el semestre anterior) el curso de métodos de enseñanza de matemáticas bilingües que el primer autor de este artículo diseñó y enseñó.

Análisis

Primero, los tres autores creamos una lista de códigos preliminares informados en nuestra experiencia a través del proyecto de investigación. Esta lista fue extensiva y detallada (Saldaña, 2015). Los tres autores nos reunimos para discutir la lista de códigos iniciales y generamos una lista común de códigos (Saldaña, 2015). Después de este proceso de codificación, nos reunimos para comparar los códigos y realizar un proceso de triangulación (Vallejo & de Franco, 2009).

Resultados y Discusión

Las interacciones entre los maestros en formación y los alumnos de 5to grado mostraron aspectos importantes en el uso del lenguaje en el proceso de enseñanza-aprendizaje. A continuación, se muestran algunas reflexiones sobre los descubrimientos que se obtuvieron durante el este proceso de análisis.

Idioma: Un Recurso Oculto

Las interacciones entre Aurora y su estudiante, Yerina, nos permitió notar la fluidez con la que cada una, cambiaba de una lengua a otra. Para nuestro estudio, hemos definido fluidez como la capacidad de moverse de un idioma a otro. En la siguiente transcripción de Aurora interactuando con Yerina, se puede notar que ambas usan el inglés y el español, mientras que Aurora se asegura que Yerina entienda el contexto del problema:

Aurora*: Carlos tiene una caja* [Yerina repite con Aurora] *de comida de gato*
Yerina: *Él le da a su gato un* [Aurora ayuda a Yerina a decir la palabra] *un cuarto*
Aurora: *One-fourth*
Yerina: *De la caja para la comida, ¿cuánto le queda de la caja?*
Aurora: [Aurora repite la pregunta] *Entonces Carlos tiene una caja de comida de gato. El le da a su gato un cuarto de la caja de la comida. ¿Cuánto queda de la caja?* [Aurora espera unos cuatro segundos]

Este tipo de interacción es un ejemplo de lo que García y Sylvan (2011) ha descrito como *TransLenguaje*. En el contexto de nuestro estudio esta práctica es particularmente importante por dos razones: 1) mientras Aurora se aseguraba que Yerina entendía el enunciado del problema, se pudo percatar que cualquier dificultad que pudiera aparecer con relación a comprender el contexto del problema, no está relacionada con la capacidad de comprender una lengua u otra, es decir no es una barrera lingüística. 2) El proveer el espacio para expresar las ideas matemáticas, tal como le fue facilitado a Yerina facilitó la comunicación de las ideas matemáticas y la interacción entre Aurora y Yerina.

Idioma: No es un Recurso Aislado

El siguiente ejemplo muestra como en las interacciones iniciales entre Aurora y Yerina, Aurora se enfoca en guiar a Yerina hacia una estrategia especifica. De esta manera la estrategia de Yerina se convierte mas en la estrategia de Aurora y el pensamiento matemático de Yerina, ya no es la fuente principal de la instrucción en ese momento.

Aurora: *So, what number do we see? ¿Qué números ves?*
Yerina: *One fourth.*
Aurora: *One fourth, okay. Un cuarto ¿de qué?*
Yerina: *¿De la caja?*
Aurora: *Entonces ¿cuántas cajas tiene Carlos?*
Yerina: *Una.*

Aurora: *Una, nada más tiene una. ¿Podemos dibujar la caja? ¿Sí? …. y ¿es comida para Carlos? O ¿para quién?*
Yerina: *Gatos*
Aurora: *A ha, para gato. Y dice … él le da a su gato un cuarto de la caja para la comida. So, he gives one fourth.*
Yerina: *So, he gives her like this much.*
Aurora: *So, it would be, okay kind of like in the middle. So, let's draw one in the middle let's see.* [Yerina dibuja una línea]
Aurora: *Okay, ¿entonces cuántas partes tenemos ahí?*
Yerina: *Uno…dos.*

En nuestra experiencia como educadores de matemáticas hemos visto que los maestros en formación tienden a guiar al estudiante hacia una estrategia especifica. Típicamente, sugieren el uso de un dibujo, como lo vimos en esta muestra. Al mismo tiempo, Jacobs y Empson (2016) han documentado la misma experiencia trabajando con maestros en servicio. En este instante notamos que el lenguaje no era el único recurso necesario para ayudar a Yerina a expresar su pensamiento matemático. Aurora podría haber aprovechado esta oportunidad para descubrir cómo estaba pensando Yerina, en lugar de sugerirle que dibujara la caja.

Conclusiones

Encontramos que la disponibilidad de los dos idiomas facilitó a los maestros en formación 1) llegar a un mismo entendimiento del contexto de los problemas descartando el uso de un idioma u otro como obstáculo para llegar a un acuerdo común, y 2) que el maestro necesita también desarrollar la capacidad de responder en el momento a las ideas matemáticas del estudiante. Esta práctica en el caso de interacciones bilingües no depende necesariamente del uso de una lengua especifica. Una vez que el lenguaje ha sido descartado como un factor que no influye en solucionar el problema, el maestro necesita tener la capacidad de crear el espacio para que el estudiante pueda libremente expresar sus ideas matemáticas. En nuestro estudio investigamos los factores del lenguaje en las interacciones individuales entre BPST y un estudiante bilingüe en el contexto de aproximaciones en la práctica. Sin embargo, necesitamos más estudios que investiguen las representaciones y la descomposición de la práctica docente.

INTRODUCING FRACTION MULTIPLICATION. A STUDY ON TEACHER'S PEDAGOGICAL KNOWLEDGE

INTRODUCIR LA MULTIPLICACIÓN DE FRACCIONES. UN ESTUDIO SOBRE EL CONOCIMIENTO DIDÁCTICO DEL PROFESOR

The aim of this article is to describe the characteristics of the pedagogical knowledge used by a teacher to introduce the multiplication of fractions in elementary education. In order to achieve this aim, a sixth-grade teacher was observed while she was teaching the multiplication of fractions according to the Mexican curriculum. Results show that the teacher defines the multiplication of fractions as a repetitive sum and she uses this notion to guide students in carrying out multiplications; however, this strategy creates difficulties since the curriculum presents the fraction also as a multiplicative operator.

Keywords: Culturally Relevant Pedagogy; Teacher Knowledge; Rational Numbers; Elementary School Education.

Background

The multiplication of fractional numbers is taught in basic education. Teaching this topic is aimed at helping children in developing their mathematical reasoning, and it is considered an essential topic for understanding further contents and for applying it in their daily lives (NCTM, 2013, 2014; Lamon, 2012; SEP, 2011). It is expected that children understand the fraction as a multiplicative operator, in terms of calculating a part *of* a whole (Son, 2012). However, the different meanings of the fraction and the relationship between the factors pose difficulties for students' understanding (De Castro, 2008; García, 2014; Lamon, 2012). These difficulties might be derived also from teaching practices focused on the repetition of the fractional numbers multiplication algorithm and from the students' belief that fractions and natural numbers share the same properties and laws (De Castro, 2008). Researchers like Isiksal and Cakiroglu (2011) point out that, in the classroom, the multiplication of fractions is reduced to a routine and mechanized procedure, instead of understanding its meaning and functionality.

In addition to the conditions mentioned above, teachers might hold misconceptions regarding this content; for example, believing that the product is bigger than the factors, understanding this multiplication as a repetitive sum (Isiksal & Cakiroglu, 2011; Rifandi, 2014; Thompson & Saldanha, 2003; Valdemoros, 2010), and dealing with it as a routine problem (Chinnappan & Desplant, 2012). Yasoda (2009) states that teacher knowledge to teach the multiplication of fractions is, mainly, of algorithmic nature, which makes difficult to students to comprehend its meaning and the relationship between the factors (Son, 2012). A didactic barrier is to take as a reference the natural numbers as a way of understanding the multiplication of fractions, specifically, the rule that the product is bigger than the factors (Prediger, 2008). Related to what has been stated before, the aim of this research is to describe the didactic knowledge related to the practice of a teacher who introduces and teaches the multiplication of fractions to children in basic education.

Reference Framework

To teach mathematics, the teacher requires, besides knowing mathematics, a didactic knowledge (Ball et al., 2008; Carrillo, Escudero & Flores, 2014; Carrillo, Climent, Contreras, & Muñoz, 2013; Shulman 1986). This knowledge refers to a group of strategies that the teacher has to represent ideas, analogies, examples, illustrations and explanations related to a mathematical content (Chick, Baker, Pham & Cheng, 2006). The teacher is expected "to hold clear concepts, images, structures and basic approaches related to a topic…, as well as knowing how to identify in his students the difficulties and conceptual errors that they could face (problems related to the derivation rules, for example the rules related to the product, quotient **or the chain**), as well as what this means in their learning. This knowledge also requires teachers to use activities or methodological strategies so that students can identify and build new understandings based on their previous ideas" (García, 2009, p. 42).

In addition to the relevance of understanding the didactic knowledge in mathematics, it is necessary to specify the concept of multiplication of fractions when using whole numbers. Son (2012) considers that this type of multiplication makes reference to the *part-part* or *part-whole*. When the fraction involves whole numbers as a first factor (*n out of a/b*), the multiplication points out a repeated sum, where the whole number is the number of times the fraction is repeated; on the other hand, if the fraction is the first factor (*a/b out of n*) the fraction is an operator and it refers to the part that will be taken from the whole number.

Methodology

The study is qualitative, and it was designed as a case study. Data was collected through non-participant observation in order to grasp the natural context where the mathematical teaching-learning process occurs. A sixth grade teacher participated in the research; she works in a rural school in Mexico and we have named her, Elena. Lessons related to the *Multiplication of fractions* were audio and video recorded, according to the current study plan (SEP, 2011). In total, two lessons were video recorded, each lasting three hours approximately. Recordings were carried out under the informed consent of the teacher, respecting the dates and timing established by the teacher, in order to avoid affecting de natural and cultural context. In addition to the recordings, notes were taken in a fieldwork journal, to support in triangulating information.

Video-recordings were transcribed and fragmented into units of analysis. The analysis was based on Miles and Huberman (2007) framework, this allowed to identify aspects related to the didactic knowledge that Elena used when teaching the multiplication of fractions. The syllabus (SEP, 2011) posits that the student should use the fraction as a multiplicative operator through problems type *a/b out of n.* The results of class observation are shown in the following section.

Analysis

To achieve the learning objective stated in the syllabus (SEP, 2011), Elena used specific and centered strategies to help students in constructing their knowledge through the interaction with their peers, working individually and under her guidance. Elena first taught the *part-whole* concept of the fraction and implemented an activity in which she presented the multiplication of fractions. The activity is described next.

To introduce the *part-whole* concept of the fraction, Elena gave the half of a sheet paper (1/2) to 18 out of the 24 students of the group, and asked them to identify which part of the group (3/4) had a piece of paper:

Elena: How many are in total?
Students: 24!

Elena: If you are 24 and I want to give half of a paper sheet to $\frac{3}{4}$ of the class. How many of you are going to get a piece of paper?
Students: 18!

In the construction of this interpretation of the fraction, Elena induces the answer that she wants to get from students by asking directly "I want to give half of a paper sheet to $\frac{3}{4}$ of the class. How many of you are going to get a piece of paper?" Students' responses evidence their use of their previous knowledge on fractions (SEP, 2011), since they first recognized the denominator, called "whole number", then they determine that $\frac{3}{4}$ from the total of students is the same as 18. With respect to Elena's knowledge, it was noticed that she does not only expects an answer but its validation:

Elena: If I wanted to know how many halves of paper sheets I used with $\frac{3}{4}$ of you, what do I have to do? Check it out, there you have the sheets of paper… stand up and count how many [children have $\frac{1}{2}$ of a piece of paper].

This validation leads students to work on the multiplication as a repeated sum ($8\times\frac{1}{2}$) where the fraction as an operator is left out. Elena gave suggestions, such as separating into two groups, one group with the students who had a piece of paper and the other group without it, she told them: "get together or count each other". Getting students into groups allowed Elena to construct the multiplication of fractions concept, however, she formalized and institutionalized the demonstration $\frac{3}{4}$ *out of the group = 18 students* (Chevallard, 1998), and she raised the meaning of the multiplication as a repetitive sum: "What have we been doing? Counting each… a half plus a half, plus a half, plus a half, plus a half, plus a half until I completed $\frac{18}{2}$. Therefore, in the same way as in the sum, [in the multiplication] I was adding a half, plus a half…" In her discourse, it is possible to see that the multiplication is 18 students per $\frac{1}{2}$ of a paper sheet.

Elena generalized the fraction multiplication as a repetitive sum, even though she did not point out the relationship between $\frac{18}{2}$ (total halves of paper sheets) and $\frac{3}{4}$ of the class. Based on this meaning, Elena introduced new activities; for example, she asked children to solve $4\times\frac{2}{3}$ by using paper strips:

Elena: How can I multiply $4\times\frac{2}{3}$? To make this simpler, we are always going to try to write the whole numbers first, ok? In a multiplication, it is the same if I write the numbers before [as a first factor] or if I write them after [as a second factor]. But now, to make it easier, I am going to write the whole number first. Then, what do I need? Out of this paper sheet, we are going to get whole number [she gives the paper sheets to the students]. The problem says that I need four strips… because we need four whole numbers.
Students: [They measure and cut the paper sheets to obtain the strips that represent the whole numbers, as it is shown in Figure 1].

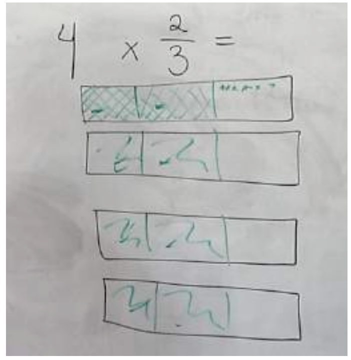

Figure 1: Graphic Representation to calculate $4\times\frac{2}{3}$.

In this activity, Elena allows students to discover the algorithm by themselves, which consists in $a\times\frac{b}{c}=\frac{a}{1}\times\frac{b}{c}=\frac{a\times b}{1\times c}$. In Elena's explanation, a limitation regarding content knowledge was identified, which could influence students' comprehension on the topic, we refer to the position of the whole numbers in the multiplication of fractions (commutation property). Although the product is the same, the meaning of the factors changes; when the whole number is the first factor ($4\times\frac{2}{3}$) the multiplication represents an abbreviated sum, but when the whole number is the second factor ($\frac{2}{3}\times 4$) it corresponds to a multiplication of fractions as an operator (Son, 2012). Elena's interpretation could be based on the commutation law.

It is possible to argue that for Elena there is no difference when using the whole number as a first or second factor. Elena's argument is focused on the product, as she tells their students when institutionalizing the algorithm "To make this simpler, we are always going to try to write the whole numbers first, ok? In a multiplication, it is the same if I write the numbers before [as a first factor] or if I write them after [as a second factor]. But now, to make it easier, I am going to write the whole number first". In doing so, the difference between a reduced sum and a fraction as a multiplicative operator is not recognized.

Conclusions

Results show that as part of her didactic knowledge (SEP, 2011), Elena uses strategies and tools according to the sixth graders academic level and to the syllabus requirements, which is identified in the examples to represent graphically and to work the multiplication algorithm with rational numbers. The use of paper, as didactic tool, allowed students to represent the algorithm and the multiplication of fractions product, as Elena does in class. It is evident that through students' interaction in the classroom, they can construct and validate this content knowledge. However, in Elena's practice, we identified that the meaning of this multiplication differs from the curricular objectives, because the fraction is considered only as a repetitive sum, which can, in turn, generate comprehension problems to students. Therefore, didactic and mathematical knowledge is fundamental to comprehend the difference in meaning of *a/b out of n* and *n out of a/b.*

INTRODUCIR LA MULTIPLICACIÓN DE FRACCIONES. UN ESTUDIO SOBRE EL CONOCIMIENTO DIDÁCTICO DEL PROFESOR

INTRODUCING FRACTION MULTIPLICATION. A STUDY ON TEACHER'S PEDAGOGICAL KNOWLEDGE

El artículo tiene como objetivo describir el conocimiento didáctico que una profesora utiliza para introducir la multiplicación de fracciones en educación básica. Para ello se observó a una profesora de sexto grado de educación primaria (México), enseñando este contenido de acuerdo con el Plan de estudios vigente durante la toma de datos. Los resultados muestran que la docente recupera el *concepto de fracción para definir y trabajar la multiplicación de fracciones como una suma reiterativa, pero esta estrategia genera dificultades dado que el Plan de estudios plantea la fracción como operador multiplicativo.*

Palabras clave: Pedagogía culturalmente relevante; Conocimiento del Profesor; Números Racionales; Educación Primaria.

Antecedentes

La multiplicación de números fraccionarios se enseña en la educación básica, con la finalidad de que los niños desarrollen un razonamiento matemático para comprender otros contenidos de mayor complejidad y para su vida cotidiana (NCTM, 2013, 2014; Lamon, 2012; SEP, 2011). Se espera que los niños entiendan la fracción como un operador multiplicativo, en términos de calcular una parte *de* un conjunto (Son, 2012). Sin embargo, para los alumnos es difícil comprender la multiplicación de fracciones debido a los diferentes significados de la fracción y de la relación entre los factores (De Castro, 2008; García, 2014; Lamon, 2012). Tal dificultad, en ocasiones, es producto de una enseñanza centrada en la mecanización y memorización del algoritmo de la multiplicación con números fraccionarios, y debido a que los niños creen que las fracciones presentan las mismas propiedades y leyes que los números naturales (De Castro, 2008). Investigadores como Isiksal y Cakiroglu (2011) apuntan que, en el aula, la multiplicación de fracciones se reduce a un procedimiento rutinario y mecanizado, en lugar de entender su significado y su funcionalidad.

Aunque existe el compromiso de enseñar la multiplicación de fracciones, el profesor llega a tener conceptos erróneos de este contenido, por ejemplo, que el producto es mayor que los factores o generalizar su definición como una suma reiterada (Isiksal & Cakiroglu, 2011; Rifandi, 2014; Thompson & Saldanha, 2003; Valdemoros, 2010), así como abordar problemas rutinarios (Chinnappan & Desplant, 2012). Yasoda (2009) afirma que el conocimiento del profesor para enseñar la multiplicación de fracciones es, principalmente, de naturaleza algorítmica, lo cual le dificulta a los estudiantes comprender su significado y la relación entre los factores (Son, 2012). Un obstáculo didáctico es tomar como referente los números naturales para entender la multiplicación de fracciones, en específico, la regla de que el producto es mayor que los factores (Prediger, 2008). En relación con lo anterior, la presente investigación tiene como objetivo describir el conocimiento didáctico inmerso en la práctica de una profesora que introduce y enseña la multiplicación de fracciones a niños de educación básica.

Marco de referencia

Para enseñar matemáticas el profesor requiere, además de saber matemáticas, un conocimiento didáctico (Ball et al., 2008; Carrillo, Escudero & Flores, 2014; Carrillo, Climent, Contreras, & Muñoz, 2013; Shulman 1986). Este conocimiento se refiere al conjunto de estrategias que el docente dispone para representar ideas, analogías, ejemplos, ilustraciones y explicaciones en torno a un contenido matemático (Chick, Baker, Pham & Cheng, 2006). Se espera que el profesor "tenga claro los conceptos, imágenes, estructuras y planteamientos básicos vinculados a un tema…, además sepa identificar en sus estudiantes las dificultades y errores conceptuales que enfrentarán estos (problemas con las reglas de derivación, como por ejemplo las del producto, cociente o de la cadena), así como lo que esto signifique en su aprendizaje. Este conocimiento también reclama al profesor que, mediante actividades o estrategias metodológicas, el estudiante pueda identificar y discernir sobre sus ideas previas" (García, 2009, p. 42).

Además de la relevancia de entender el conocimiento didáctico en matemáticas, es indispensable precisar el concepto de multiplicación de fracciones cuando se tiene números enteros. Son (2012) considera que este tipo multiplicación hace referencia a la *parte-parte* o *parte-todo*. Cuando involucra números enteros como primer factor (*n de a/b*), la multiplicación indica una suma reiterada, donde el entero es la cantidad *de veces* que se repite la fracción; en cambio, si la fracción es el primer factor (*a/b de n*) la multiplicación indica que la fracción es un operador y refiere *la parte que se tomará* del entero.

Metodología

El estudio es de corte cualitativo y está centrado en el estudio de casos. Se recurrió a la observación no participante con la finalidad de tener un acercamiento al contexto natural donde ocurre el proceso de enseñanza y aprendizaje de las matemáticas. En la investigación participó una profesora de sexto grado de educación primaria, quien labora en una escuela rural en México y a quien hemos llamado Elena. El acopio de datos comprendió la video y audiograbación de las clases en las que Elena trató el contenido *Multiplicación de fracciones* de acuerdo con el Plan de estudios vigente en ese momento (SEP, 2011). En total se videgrabraron dos sesiones de clases, totalizando 3 horas aproximadamente. Las videograbaciones se realizaron previo consentimiento de la docente, respetando las fechas y tiempos programados por ella, de tal manera que no afectaran el escenario natural y cultural del salón de clases. Además de las grabaciones en audio y video, en una bitácora se registraron aspectos puntales de la práctica de la profesora, esto facilitó la triangulación de la información.

Las videograbaciones fueron transcritas y fragmentadas en unidades de análisis, para ello se tomó como referencia la propuesta de análisis de Miles y Huberman (2007), lo cual permitió identificar aspectos relacionados con el conocimiento didáctico que Elena pone en juego al enseñar la multiplicación de fracciones. El Plan de estudios (SEP, 2011) apunta que el alumno debe usar la fracción como *operador multiplicativo* mediante problemas de tipo *a/b de n*. En la siguiente sección se muestran los resultados de la observación en aula.

Análisis

Para lograr el objetivo de aprendizaje dado en el Plan de estudios (SEP, 2011), Elena recurrió a estrategias específicas y centradas en que los alumnos construyeran sus conocimientos a partir de interactuar con sus compañeros, trabajar de manera individual y bajo la guía de la profesora. Para ello, Elena partió del concepto de fracción como *parte-todo* y de una actividad en la cual presentó la multiplicación de fracciones. A continuación, se describe esta actividad.

Para introducir el concepto de fracción como parte-todo, Elena proporcionó media hoja de papel (1/2) a 18 de los 24 estudiantes que conforman el grupo, para que posteriormente todos determinaran qué parte del grupo (3/4) tiene papel:

> Elena: ¿Cuántos somos en total en el grupo?
> Alumnos: ¡24!
> Elena: Si son 24 y yo les quiero dar a $\frac{3}{4}$ de ustedes media hoja de papel. ¿A cuántos les voy a dar?
> Alumnos: ¡18!

En la construcción de esta interpretación de fracción, Elena induce la respuesta que espera obtener al plantearles directamente "les quiero dar a $\frac{3}{4}$ de ustedes media hoja. ¿A cuántos [estudiantes] les voy a dar?" Las respuestas de los alumnos evidencian que partieron de sus conocimientos sobre fracciones (SEP, 2011), pues primero reconocen el denominador, llamado "entero" por los alumnos, y posteriormente determinan que $\frac{3}{4}$ del total equivalen a 18 alumnos. Como características del conocimiento de Elena, se observa que involucra no sólo obtener el resultado sino que el alumno lo sustente:

> Elena: Si yo quisiera saber cuántos medios de hoja me gasté en $\frac{3}{4}$ de mi salón, de mis alumnos, ¿cómo le puedo hacer? Compruébenmelo, ahí están las hojas… párense y cuenten cuántos [niños con $\frac{1}{2}$ de hoja de papel].

Esta validación le permite a Elena llevar a los estudiantes a trabajar la multiplicación como una suma reiterada ($8\times\frac{1}{2}$), donde deja de lado la fracción como operador. La profesora da sugerencias a los estudiantes, tales como hacer dos grupos, aquellos que tienen hoja de papel y quienes no la tienen, pues ella les dice: “júntense o cuéntense”. Agrupar a los estudiantes permite a Elena construir el concepto de multiplicación de fracción, sin embargo, ella es quien formaliza e institucionaliza la demostración $\frac{3}{4}$ *del grupo = 18 alumnos* (Chevallard, 1998), y plantea el significado de la multiplicación como una suma reiterativa: “¿[qué] tuvimos que ir haciendo? Contando cada… medio más medio, más medio, más medio, más medio, más medio hasta que completé los $\frac{18}{2}$. Entonces al igual que en la suma, [en la multiplicación] yo tendría que estar sumando medio, medio más…” En su discurso se evidencia que la multiplicación queda como 18 estudiantes por $\frac{1}{2}$ de hoja papel.

Elena generaliza la multiplicación de fracción como la suma reiterada, aunque no muestra la relación entre $\frac{18}{2}$ (total de medios de hojas) y $\frac{3}{4}$ de grupo. Con base en este significado de la multiplicación de fracciones, Elena introdujo nuevas actividades orientadas a que los estudiantes lo pongan en práctica; por ejemplo, les pidió resolver $4\times\frac{2}{3}$ mediante el uso de tiras de papel:

> Elena: ¿Cómo puedo multiplicar cuatro enteros por $\frac{2}{3}$? Para que se nos haga más fácil vamos a tratar siempre de poner primero los enteros, ¿sí? En una multiplicación es lo mismo si lo pongo acá [como primer factor] que lo ponga acá [como segundo factor]. Pero por lo pronto, para que se nos haga más fácil, voy a poner primero los enteros. ¿Qué es lo que necesito entonces? En esta hoja vamos a ir sacando enteros [reparte hojas de papel a los alumnos]. Dice que necesito cuatro enteros, yo necesito cuatro tiras… porque son cuatro enteros.
>
> Alumnos: [Miden y recortan las hojas de papel para obtener las tiras que representen los enteros, como se muestra en la Figura 1].

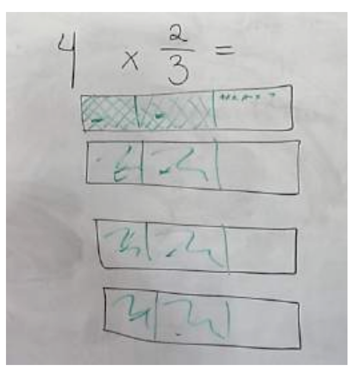

Figura 1: Representación gráfica para calcular $4\times\frac{2}{3}$.

Esta actividad Elena deja que los alumnos descubran el algoritmo de la multiplicación de fracciones por ellos mismos, el cual consiste $a\times\frac{b}{c}=\frac{a}{1}\times\frac{b}{c}=\frac{a\times b}{1\times c}$. En la explicación de Elena se evidencia una limitación en el conocimiento del contenido que podría afectar la comprensión del niño acerca del tema, nos referimos a la posición de los enteros en la multiplicación de fracciones (propiedad de la conmutación). Aunque el producto es mismo, el significado de los factores cambia; cuando el entero es el primer factor ($4\times\frac{2}{3}$) la multiplicación representa una suma abreviada, pero cuando es el segundo factor ($\frac{2}{3}\times 4$) corresponde a multiplicación de fracciones como operador (Son, 2012). La interpretación de Elena podría deberse a la prevalencia de la ley de conmutación.

Es notorio que para ella no hay una diferencia de significado en cuanto al entero como primer o segundo factor. El argumento de Elena está centrado en el producto, pues como ella les dices a los estudiantes al momento de institucionalizar el algoritmo: "Para que se nos haga más fácil vamos a tratar siempre de poner primero los enteros, ¿sí? En una multiplicación es lo mismo si lo pongo acá [como primer factor] que lo ponga acá [como segundo factor]. Pero por lo pronto para que se nos haga más fácil voy a poner primero los enteros". En este sentido no se reconoce la diferencia entre una suma reducida y la fracción como operador multiplicativo.

Conclusiones

Los resultandos muestran que, como parte de su conocimiento didáctico, Elena usa estrategias y recursos acorde con el nivel educativo de los estudiantes de sexto grado de educación primaria y a las exigencias del Plan de estudios (SEP, 2011), lo cual se refleja en los ejemplos para representar gráficamente y trabajar el algoritmo de la multiplicación con números racionales. El uso de papel, como recurso didáctico, le permite al alumno representar el algoritmo y el producto de la multiplicación de fracciones, tal como Elena lo hace en la clase. Es evidente que a través de la interacción que tienen los alumnos en el salón de clases se construye y se validan los conocimientos en torno a este contenido. Sin embargo, en la práctica de Elena se evidencia cómo el significado de la multiplicación difiere con los objetivos curriculares al considerarla sólo como una suma reiterada, los cual puede generar obstáculos de compresión en el estudiante. En este sentido es fundamental un conocimiento didáctico y matemático para comprender la diferencia en los significados *a/b de n* y *n de a/b.*

MATHEMATICS TEACHERS' PERCEPTION OF INDUCTIVE REASONING AND ITS TEACHING

PERCEPCIÓN DE PROFESORES DE MATEMÁTICAS DEL RAZONAMIENTO INDUCTIVO Y SU ENSEÑANZA

This paper presents the perception that middle school mathematics teachers attribute to inductive reasoning and its teaching from working with the concept of quadratic equation. The data was obtained from a questionnaire given to 16 teachers and from their expanded responses in a group conversation. Through the thematic analysis method, it was found that most teachers perceived this type of reasoning as a process to move from the particular to the general and as a way to guide teaching a concept through questioning. However, they encountered difficulties in using inductive processes to teach the concept and attach it to an inductive logic.

Keywords: Teacher Knowledge, Reasoning and Proof, Middle School Education.

Introduction

Inductive reasoning for learning mathematics in basic and middle school education is important for two reasons. On one hand, it is a means for the development of concepts and the resolution of mathematics problems (Molnár, Greiff, & Csapó, 2013; Papageorgiou, 2009; Sosa, Cabañas y Aparicio, 2019; Sriraman & Adrian, 2004) that assists the abstraction and generalization of the invariant characteristics of particular objects or situations. Klauer (1996) claims that it leads to "detecting regularities, be it classes of objects represented by generic concepts, be it common structures among different objects, or be it schemata enabling the learners to identify the same basic idea within various contexts" (p. 53). On the other hand, it supports processes to speculate, argue and generalize in mathematics (Cañadas et al., 2007; Cañadas, Castro and Castro, 2008; Conner et al., 2014; Martinez & Pedemonte, 2014).

This implies that middle school teachers should develop and interpret the inductive reasoning of students (AMTE, 2017; NCTM, 2000). NCTM (2000) establishes that this form of reasoning must progress in students throughout each grade and education level so that they can become more proficient in the formulation of conjectures and generalizations from specific cases. In this sense, it is desirable that teachers have clarity about inductive reasoning and the phases that go along with the transition from particular instances to the general. On the contrary, they may have difficulties incorporating it into their practice. Therefore, the goal of this study is to examine and describe the perception that middle school teachers show about the inductive reasoning in relation to the teaching of the quadratic equation concept.

Literature review

Much of the research on inductive reasoning and professional development of mathematics teachers has been conducted with preservice teachers and most of them focused on issues associated to the teacher cognition, such as ways of recognizing similarities by induction from numerical and figural representations (Rivera & Becker, 2003), levels of deepening understanding and strategies used to solve a generalization problem (Manfreda, Slapar, & Hodnik, 2012), the role of induction and abduction in making generalizations of classes of abstract objects (Rivera & Becker, 2007), and the relationship between inductive and deductive reasoning with learning styles (Arslan, Göcmencelebi, & Tapan, 2009). Results indicate that future teachers tend to induce numerically over strategies used based on the use of figures. Difficulties are also reported in generalizing quadratic patterns, even when a numerical pattern was identified. However, Sosa, Aparicio and Cabañas (2019) show that secondary school teachers who achieve generalization in these kinds of patterns are those who managed to connect inductive processes; they also identified difficulties to establish and abstract a pattern. This reinforces the need to study how teachers perceive inductive reasoning and its teaching.

Conceptual framework

In this study, inductive reasoning is understood as a means to produce generalizations from particular cases, be they ideas, qualities, objects, facts, phenomena or situations. This understanding is consistent with those who refer to it as a mental process oriented to infer laws or general conclusions through observation and connection of particular instances of a class of objects or situations (Glaser & Pellegrino, 1982; Haverty et al., 2000, Polya, 1957).

The works of Reid and Knipping (2010), Polya (1967) and Sosa et al. (2019) are examples of this understanding. Reid and Knipping (2010) identify three characteristics of inductive reasoning: it comes from specific cases to conclude general rules, uses what is known to conclude something unknown and, it is only likely but not true. Polya (1967) proposes the following four phases of such reasoning to discover properties, principles and general cases in mathematics: observing particular cases, formulating a conjecture, generalizing and verifying conjecture. More recently, from a cognitive approach, Sosa et al. (2019) report that the connection of the following three processes is necessary to achieve generalization inductively: observation of regularities, establishment of a pattern and formulation of a generalization.

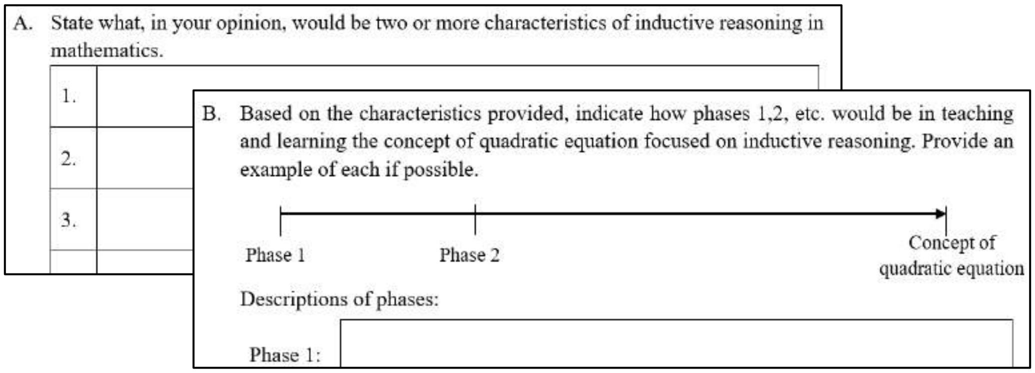
Methodology

Context and participants

This study is part of a professional teacher development program in mathematics, in which 16 secondary school teachers (10 women and 6 men) participated. The data was collected in the first of the five sessions that make up the program. Due to the relationship between inductive reasoning and generalization, as well as the difficulties of teachers to obtain a generalization of quadratic patterns as reported in the literature, the selection criteria for their participation was that they had at least one year of teaching experience in the third year of secondary school. This criterion is explained by the fact that, in the Mexican curriculum, "patterns and equations" is a topic associated with generalization, and the quadratic structure is studied in that education level.

Data collection

Data collection was conducted with a written questionnaire and audio recordings. The questionnaire had two items A and B (Figure 1). Item A asked for the enunciation of at least two characteristics of inductive reasoning in mathematics, and item B requested the description of the phases to be followed in order to teach some aspect of the quadratic equation in an inductive way. The replies were recorded in writing, and individually, and were subsequently communicated orally to the group for further information or clarification.



A. State what, in your opinion, would be two or more characteristics of inductive reasoning in mathematics.

1.	
2.	
3.	

B. Based on the characteristics provided, indicate how phases 1,2, etc. would be in teaching and learning the concept of quadratic equation focused on inductive reasoning. Provide an example of each if possible.

Descriptions of phases:

Phase 1:

Figure 1: Questionnaire for data collection

Data analysis

A thematic analysis was conducted to describe the perception of teachers considering the written and oral answers to item A. Then, the responses given to item B were associated to the categories of perception previously generated and contrasted with the conceptual framework in order to identify how teachers interpret inductive reasoning in teaching the concept of quadratic equation.

Thematic Analysis. This method consists of identifying, analyzing, organizing and systematically obtaining patterns (themes) in a data set by detecting and giving sense to the experiences and meanings shared in a group (Braun & Clarke, 2006; 2012). This helped to identify patterns of meanings in the common characteristics that teachers attribute to inductive reasoning and to form categories of their perception. To do this, the six phases of thematic analysis were followed: familiarize with the data, search for topics, review those that have potential, define and name themes, and produce a report (Braun & Clarke, 2012).

Results

Inductive reasoning perception categories

Five categories were identified on the perception of inductive reasoning, among them were *as a guide for mathematical knowledge* and *as a cognitive process.*

- **Category 1:** Inductive reasoning as a way to guide mathematical knowledge. This category consists in the fact that the students can be guided from their previous knowledge to new knowledge through questions. An example of this category is shown in the following excerpts of responses:

Teacher L: Give students an exercise and based on their previous knowledge draw their own knowledge. Create a brainstorm to learn what students know.

Teacher M: One of the characteristics is to begin asking key questions for the exercises and introducing students to the topic. Students begin to reason about the topic through questions and are able to visualize the previous knowledge. Guide questions. During the class, doubts may emerge [...] and questions may be asked [...], students can achieve the appropriation of concepts.

- **Category 2:** Inductive reasoning as a cognitive process. This category consists of perceiving it as a process to move from particular instances (ideas, particular cases or situations) to the inference of a general conclusion or result. For example:

Teacher E: It goes from the particular to the general...

Teacher N: It is a type of reasoning that consist of moving from particular to general ideas. Starting from concrete ideas to ideas in general. Generalize based on experiences of the given results.

Interpretation of inductive reasoning in teaching: logic and phases

Four different ways of interpreting teaching a concept based on inductive reasoning were identified. Eight teachers interpreted it as a guide for knowledge, such was the case of teacher M (Table 1). Five followed a deductive logic rather than inductive logic, for example teacher O; this means that they begin with the approach of general formulas or definitions of quadratic equations and conclude with a particular example. The deductive or inductive logic was not identified in the phases described by two teachers, they focused on "iconic" treatments based on the association of a quadratic property with the area of a square figure or the product of a number with itself. Strictly speaking, only the phases described by one teacher could be considered as an inductive logic. Overall, inductive processes were found to be absent in the phases proposed by the teachers for teaching quadratic equation, except for those described by teacher B (Table 1).

Table 1: Transcription of the phases proposed by two teachers

Phase	Teacher M	Teacher B
1	Previous knowledge: Introductory questions about algebraic expression, algebraic language, power, law of exponents.	Specific cases or situations which can be quantified, manipulated, or visualized are provided.
2	Application of the concept of "basic" shapes areas (with square shapes).	Different cases that meet the observed characteristic or property are asked.
3	Delete data and replace it with literals. Start with formulas.	It is required a prediction that this characteristic or property is fulfilled for other cases that are not tangible or directly observable.
4		A rule or formula that covers all possible cases is obtained; that is, a generalization.

Conclusions

Little clarity was identified in teachers about what inductive reasoning is. Most perceive or interpret it as a way of guiding mathematical knowledge in a teaching situation. However, this perception differs from the idea of inductive reasoning as a means for the construction of concepts; that is, to abstract and generalize the key characteristics of an object in specific situations (Sosa, Cabañas y Aparicio, 2019; Sriraman & Adrian, 2004; Klauer, 1996). It was also identified that few teachers perceive induction as a means to promote processes of generalization and resolution of problems. While reference is made to the transition from the particular to the general as a feature of this reasoning, the responses reveal a lack of clarity about the underlying processes because there is an inadequate interpretation when describing the phases to teach this mathematical concept; some of them even used a deductive logic. Therefore, it is necessary to compare and broaden teachers' knowledge of inductive reasoning through learning experiences in which they recognize and articulate inductive processes in contexts of mathematical generalization.

DEFINING KEY DEVELOPMENTAL UNDERSTANDINGS IN CONGRUENCE PROOFS FROM A TRANSFORMATION APPROACH

Julia St. Goar
Merrimack College
stgoarj@merrimack.edu

Yvonne Lai
University of Nebraska-Lincoln
yvonnexlai@unl.edu

Previous work by the authors (St. Goar et al., 2019) identified two potential key developmental understandings (KDUs) (Simon, 2006) in the construction of congruence proofs from a transformation perspective for pre-service secondary teachers in an undergraduate geometry course. We hypothesized the independence of the potential KDUs in previous work, meaning that students may have one potential KDU but not the other, and vice versa. We tested this hypothesis with analysis of an expanded data set and found that this hypothesis did not hold in general. We report on the expanded analysis and discuss implications for the scope and limitation of the potential KDUs.

Keywords: Teacher Knowledge, Geometry and Geometrical and Spatial Thinking, Reasoning and Proofs

A change has come to K-12 geometry instruction, and as a result changes to preparation of future teachers must follow. Many guidelines (Catalyzing Change in High School Mathematics: Initiating Critical Conversations [NCTM], 2018) and standards (National Governors Association Center for Best Practices, Council of Chief State School Officers, 2010) now recommend or require the teaching of geometry from a transformation perspective instead of the more traditional approach originating from Euclid's *Elements* (Sinclair, 2008). The concepts and proofs involving congruence and similarity now appeal to rigid motions: reflections, rotations, and translations. That is, two figures are said to be congruent if and only if there exists a sequence of rigid motions carrying one figure onto another. This definition is notably different from those in Euclid's *Elements,* where the criteria for congruence differs for each type of shape. Thus, the reader will note that the differences in mathematical structure between the transformation and *Elements* contexts are substantial.

The resulting danger is that some future teachers may lack the content knowledge to handle the new approach. Without sufficient content knowledge, they may struggle to know what can be proved in this new context and how these proofs may be structured. This lack may affect how they write lesson plans and course materials, adapt or modify materials for the context of their class, and evaluate student thinking and alternate approaches. Future teachers may need support in the transformation context to allow them to thrive in the teaching of geometry.

Relationship to Prior Literature

To answer the call, some undergraduate instructors are beginning to incorporate transformation geometry into their geometry courses for future teachers. Because transformation geometry is becoming a more prominent feature of geometry in post-secondary contexts, research on how pre-service teachers learn these topics are particularly salient. However, at this point research on how pre-service teachers learn transformation geometry is just beginning. Jones and Tzekaki (2016) noted the "limited research explicitly on the topics of congruency and similarity, and little on transformation geometry" (p. 139).

Some key results informing our work are the following. Edwards (2003) explained that students in middle school through undergraduate contexts tend to view transformations from a motion view, as opposed to a map view of transformations. A motion view is characterized by conceptualizing transformations as physical movements, such as picking up a figure and shoving it to where it needs to go. A map view is characterized in terms of inputs and outputs of transformation, and

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

distinguishes the preimage from the image. For instance, a person with a motion view may think of an image and preimage of a figure as being the same object, simply with a different location. But a person with a map view can hold the idea that the image and preimage as different objects, and hence compare them. Research conducted after Edwards' (2003) study with middle school students corroborate her results, even for high school teachers (Hegg et al., 2018; Portnoy et al., 2006; Yanik, 2011). These results also note the difficulty that a motion view may present to generating congruence proofs from a transformation approach.

Based on analysis of future teachers' work on two congruence proofs on a midterm examination, we previously highlighted the importance of supporting pre-service teachers in understanding *both* directions of the "if and only if" in the definition of congruence. Further, we identified two potential key developmental understandings (KDUs; Simon, 2006), stated below:

"Potential KDU 1: Understanding that applying the definition of congruence to prove congruence of two figures means establishing a sequence of rigid motions mapping one *entire* figure to the other *entire* figure" (St. Goar et al., 2019).

"Potential KDU 2: Understanding that using a sequence of transformations to prove that two figures are congruent means justifying deductively that the image of one figure under the sequence of transformations is exactly the other figure" (St. Goar et al., 2019).

As the results by St. Goar et al. (2019) were based on analysis of teachers' work from a single, timed assessment, more work is needed to interrogate the accuracy of these potential KDUs.

Further, *we previously hypothesized the independence of these potential KDUs, meaning that teachers might hold KDU 1 but not KDU 2, or hold KDU 2 but not KDU 1.* We generated this hypothesis empirically from examples of teachers' work in our previous analysis. In considering the literature, we might also support and refine this hypothesis as follows. First, potential KDU 1 pertains to constructing a sequence of rigid motions, and not explicit deductive reasoning about images and preimages, which is the scope of potential KDU 2. Second, constructing a sequence of rigid motions can be consistent with either a motion view or a map view. However, deductive reasoning as needed for congruence proofs might require distinguishing between overlapping figures. Although this could be done under a motion view, it seemed plausible to us that conceiving transformations as maps was more likely to support a teacher in careful work with images and preimages – particularly if the figure is disconnected. It seemed plausible that it is more difficult to conceive of "moving" a disconnected figure than "moving" a connected one. In lieu of the literature, although it is possible for these potential KDUs to be independently held, *the following is a better hypothesis: Teachers hold neither potential KDU (if neither motion or map view is developed), potential KDU 1 but not potential KDU 2 (representing a motion view), or both potential KDUs (representing a map view).*

Objectives

Hence, we proceeded with the following research questions, with the same teachers' work on different congruence proofs than previously analyzed: (1) Do we continue to see evidence of the previously identified potential KDUs? (2) What are the scope and limitations, including the independence, of these potential KDUs?

Conceptual Perspective

Based on Usiskin and Coxford (1972), a *transformation approach* assumes without proof that rigid motions (e.g., reflections, rotations, and translations) are bijections of the plane that preserve both distance and angle measure. Additionally, under such an approach, two subsets of the plane are considered to be congruent if and only if there exist a sequence of rigid motions mapping one subset to the other. Similarity is treated analogously, incorporating dilations.

Key developmental understandings (KDUs) are described by Simon (2006). A key developmental understanding has two primary aspects: (1) Achieving a KDU represents a conceptual advance by the student. A conceptual advance is "a change in a students' ability to think about and/or perceive particular mathematical relationships" (Simon, 2006, p. 362) and (2) Acquiring KDUs does not tend to happen "as the result of an explanation or demonstration. That is, the transition requires a building up of the understanding through students' activity and reflection and usually comes about over multiple experiences" (Simon, 2006, p. 362).

As Simon noted, KDUs generally cannot be found by a mathematician examining their own understanding of a topic, but rather through observing students' mathematical work. As a result, our first steps in identifying these potential KDUs have been through the analysis of future teachers' work. Simon noted also that KDUs may be identified with varying amounts of detail and that "the level of detail specified for a key developmental understanding is adequate if it serves to guide the effort for which it is needed (e.g. curriculum design, further research)" (Simon, 2006 p. 364). Hence our analysis here is meant to achieve this necessary detail so that the potential KDUs can be used to improve undergraduate geometry curricula and research.

We use the term "potential KDU" rather than "KDU" because we see our understanding of teachers' understanding as a work in progress that is only based on analysis of written work as opposed to cognitive interviews, which would be ideal and needed to substantiate a claim of being a KDU. We return to this critical piece in the discussion and questions to the audience.

Methods

We collected the coursework of twenty teachers in an undergraduate geometry course taught by Lai. We examined homework assignments and midterm exams from throughout the semester for tasks where teachers specifically worked on congruence proofs. Here we report analysis of four tasks. This resulted in 69 total proof submissions included in the analysis.

We coded teachers' work on tasks based on evidence of potential KDU 1 and KDU 2. During the course of this analysis, if some criteria had to be changed, then codes were reworked to reflect these updated criteria, consistent with constant comparison (Strauss & Corbin, 1994).

Results

Addressing the first research question, the basic statements of the potential KDUs remained intact after analysis of teachers' work on additional tasks. Addressing the second research question, this analysis provided possible disconfirming evidence for the independence of the potential KDUs. We begin this section by reviewing the scope and limitations of the potential KDUs, and then compare evidence of each potential KDU.

Scope and Limitations of Potential KDUs

Potential KDU 1 is primarily focused on the *construction* of the sequences of rigid motions. That is, in order to have this potential KDU, teachers must construct a sequence of rigid motions from one entire figure to another entire figure. This means that aside from the creation of the rigid motions themselves, the rest of the deductive logic in a transformation proof is not a part of this potential KDU.

Potential KDU 2 focuses on the *deductive reasoning* used in the proof. Specifically, teachers need to attempt to deductively show that their transformation extends to the entire figure. Note that a teachers' work need not show entirely correct logic in order to show evidence of this potential KDU so long as they are attempting to extend arguments about the image of a transformation to entire figures and are using deductive logic to do so.

(Non) Independence of Potential KDUs

We hypothesized previously the independence of potential KDU 1 and potential KDU 2, meaning that, teachers' capacity to engage in deductive reasoning about the correctness of a proof may not depend on their capacity to construct sequences of rigid motions. We refined our view in lieu of the literature to hypothesize that it is most likely that teachers may hold neither potential KDU 1 nor potential KDU 2, hold potential KDU 1 and not potential KDU 2, or hold both. Our analysis suggests that our initial hypothesis is not well-supported, but our new hypothesis is. For brevity, we limit discussion of this to a visual summary of the results of this analysis, shown in Figure 1.

Homework Task 1	Evidence of KDU 1	No Evidence of KDU 1
Evidence of KDU 2	12	2
No Evidence of KDU 2	2	0

Homework Task 2	Evidence of KDU 1	No Evidence of KDU 1
Evidence of KDU 2	9	0
No Evidence of KDU 2	1	6

Midterm Task 1	Evidence of KDU 1	No Evidence of KDU 1
Evidence of KDU 2	4	0
No Evidence of KDU 2	12	1

Midterm Task 2	Evidence of KDU 1	No Evidence of KDU 1
Evidence of KDU 2	7	3
No Evidence of KDU 2	5	5

Across all Tasks	Evidence of KDU 1	No Evidence of KDU 1
Evidence of KDU 2	32	5
No Evidence of KDU 2	20	12

Figure 1: The above is a summary of evidence of potential KDU 1 and potential KDU 2 across two homework tasks and two midterm examination tasks.

Discussion and Conclusion

In this report, we expanded on the research by St. Goar et al. (2019) by analyzing future teachers' work on transformation congruence from an undergraduate geometry course. The results confirm the viability of potential KDU 1 and potential KDU 2 as codes for teachers' written work on congruence proofs from a transformation approach. Moreover, the results do corroborate the authors' revised hypothesis that that teachers may hold neither potential KDU 1 nor potential KDU 2, hold potential KDU 1 and not potential KDU 2, or hold both. In other words, the *least likely scenario* is that teachers hold potential KDU 2 but not potential KDU 1. Indeed, across the tasks, there are only 5 out of 69 instances (7%) where teachers' work shows evidence of potential KDU 2 but not potential KDU 1.

While our work was able to corroborate part of our revised hypothesis described above, the revised hypothesis was based on the construct of map view and motion view. We were not able to deduce from the available written work which type of view a teacher might hold, and as a result further research is needed to investigate this possible role of motion view and map view.

Acknowledgements

Thank you to Rachel Funk for her work in the initial stages of this research by beginning analysis of student use of the definition of congruence.

USING TASK DESIGN METHODOLOGY TO UNPACK TEACHERS' (MIS)CONCEPTIONS ABOUT PROCEDURAL AND CONCEPTUAL KNOWLEDGE

Angelica Monarrez
University of Texas at El Paso
amonarrez5@utep.edu

Mourat Tchoshanov
University of Texas at El Paso
mouratt@utep.edu

Star (2005) argues that "current characterizations of the terms procedural knowledge and conceptual knowledge are limiting and are in fact impediments to careful investigation of these constructs" (p. 405). Addressing this argument, we examined secondary mathematics teachers' understanding of procedural and conceptual knowledge through the design of mathematical tasks. We asked 55 secondary mathematics teachers to design a procedural and a conceptual task on a given topic and explain why they think that the task they designed is a procedural and/ or conceptual task. The study results showed that 78% of teachers were able to design and correctly explain procedural tasks. However, only 5.5% of teachers were able to correctly design conceptual tasks. Teachers' narratives were examined to categorize emerging characteristics of procedural and conceptual tasks as well as to address teachers' (mis)conceptions about procedural and conceptual knowledge.

Keywords: procedural knowledge, conceptual knowledge, task design, secondary mathematics teachers.

Objective

Mathematics education reform calls for building students' and teachers' mathematical proficiency that, among other strands, include conceptual understanding and procedural fluency (Kilpatrick, Swafford, & Findell, 2001). Star (2005) suggests that the widespread use of the terms conceptual and procedural in learning and teaching mathematics can be attributed to Hiebert (1986) who defined procedural knowledge as knowledge of procedures (e.g., syntax, steps, conventions, rules) and conceptual knowledge as knowledge of relationships (e.g., connected web of knowledge, a network of linked information). However, there are different interpretations of the conceptual/procedural framework (Star & Stylianides, 2013). Therefore, teachers may agree that reform-oriented mathematics teaching and learning should focus on conceptual knowledge, but it could be difficult to implement "if teachers do not have a common understanding on what conceptual knowledge is" (Star & Stylianides, 2013, p. 5). Considering this challenge, the purpose of this study is to utilize task design methodology as a way to explore secondary mathematics teachers' understanding of procedural and conceptual knowledge. This study addresses the following research question: how do secondary mathematics teachers' operationalize the distinction between procedural and conceptual knowledge through task design methodology?

Perspectives

Procedural vs. Conceptual Knowledge

There is a vast existing literature on the differences between procedural and conceptual knowledge. Star (2005) argues that procedural and conceptual knowledge can have a superficial and/or a deep quality. Deep procedural knowledge is "knowledge of procedures that is associated with comprehension, flexibility, and critical judgment and that is distinct from (but possibly related to) knowledge of concepts" (Star, 2005, p. 408) while deep conceptual knowledge is about knowledge of concepts with rich connections.

In this study, we examine different ways secondary mathematics teachers express their procedural and conceptual knowledge by evaluating mathematical tasks that they designed. We view the superficial and deep quality of the two types of knowledge as an intersection between procedural and conceptual knowledge, as shown in figure 1. The arrows at the intersection show how the procedural knowledge can deepen into conceptual knowledge and how conceptual knowledge can be surfaced into procedural knowledge.

Task Design

We employed task design as a methodology to unpack teachers' understanding of procedural and conceptual tasks. Research on task design has been common to study teachers' content knowledge (Gellert et al., 2012). Several studies have focused on pre-service teachers' designing tasks as part of their training (Chinnappan & Forrester, 2014; Hannigan et al., 2013; Rayner et al., 2009). Some studies have focused on designing tasks aligned with technology (Gueudet et al., 2016; Hansen et al., 2016; Misfeldt & Zacho, 2016). Additionally, researchers have created tasks to be used by teachers (Jung & Brady, 2016; Tempier, 2016; Wake et al., 2016) while other researchers discussed the design of tasks with teachers (Coles & Brown, 2016; Johnson et al., 2016; Thanheiser et al., 2016). However, when examining mathematical tasks with in-service teachers, most studies have examined how in-service teachers choose mathematical tasks (Cartier et al., 2013; Roth McDuffie & Mather, 2006). The field lacks studies that use task design as a methodology to address teachers' misconceptions. By asking teachers to design their own tasks we can analyze further their reasoning (Cartier et al., 2013).

Methods of Data Collection

Context

This study was part of a larger project that took place during four years from 2013 to 2016. The larger project was a series of professional development workshops focused on mathematics content. This study took place at a university located on the U.S.-Mexico border. The vast majority of people in this area identify themselves as Hispanics (80%). Many of them are recent immigrants from Mexico. The population of the main school districts reflects the demographics of the city. The workshop was aimed to support the training and retention of secondary school mathematics teachers.

Participants

Workshop participants (N=55) were selected from local secondary schools. Teachers that attended the professional development workshop were from five different school districts across the region. Most of the teachers were female (62%). Also, the majority of the teachers reported their race/ethnicity as Hispanics (81%), 17% reported their race as White, Non-Hispanic, and 2% as African American. Years of teaching experience varied from half a year to 15 years.

Data Sources

All 55 teachers that participated in the study answered a survey that required them to design a procedural and conceptual task and explain their reasoning. The purpose of this survey was to examine the teachers' understanding of procedural and conceptual knowledge. Two topics were used for the survey: area and proportion. In addition, we conducted semi-structured interviews where teachers were asked to talk about their understanding of procedural and conceptual tasks.

Data Analysis

Once the survey data was graded, both researchers analyzed the tasks that the teachers designed and looked for patterns. We were interested in examining closely the types of tasks the teachers designed. The tasks were graded on whether they were surface or deep procedural or surface or deep conceptual. We also looked for patterns on their explanations. The interviews were coded to look for instances in which the teachers talked about the design of mathematical tasks. Emergent codes were extracted using linguistic analysis and meaning coding techniques (Kvale & Brinkmann, 2009). After the authors coded the data separately, the two researchers held meetings to reach a consensus on the codes to separate them into final categories.

Results

Teachers created a wide array of tasks as procedural and conceptual tasks. Table 1 shows the percentage of the types of tasks teachers designed. The table clearly shows that teachers were able to correctly design procedural tasks (78%) while the majority designed a procedural task when they intended to design a conceptual task (80%). There is also a percentage of teachers that created tasks that were ill-designed or provided no answer (i.e., 22% for procedural tasks and 14.5% for conceptual tasks). When the explanations were analyzed along with the tasks that teachers designed, we found different patterns. Tables 2 and 3 show the different codes that were created based on teachers' explanations and the types of tasks. The majority of teachers argue that their task is procedural because it includes a procedure (35%) or because it requires to substitute or "plug-in" values in a formula (29%). When they were designing the conceptual task they argued that their task is conceptual because: it is about finding a relationship (26%), it is a multi-step problem (26%), it is a word problem (23%) or it has a real-world connection (21%).

Besides designing a task teachers had to provide a solution as well as an explanation of why they think the task is either procedural or conceptual. For example, a teacher designed the following task: "solve the following, $\frac{x}{3} = \frac{7}{20}$" as a procedural task. This teacher wrote the following explanation: "Must find x using cross multiplication, then division, very procedural, no connection." For this teacher, this problem is procedural because is about just solving for x. Using Star's (2005) classification, we rated it as a superficially procedural task, The following task was intended as a conceptual task:

Laura types 168 words in 25 minutes, if she continues typing at this rate, how much time will she spend typing a 1500 word paper?

The explanation for this task written by the teacher was: "Because students need to apply what they learned on proportions by solving real-world problems in order to make connections." Based on this teacher's explanation, there is some understanding about conceptual knowledge by using words and phrases like "real-world problem" and "connections." However, upon further examination of this task, we can see that this task requires just procedural knowledge since, after setting up the equation, the solution would look very similar to the previous one. The main difference is that this is a word problem, which would require a student to read the problem, determine if this is a proportional situation, and set up the equation. Therefore, we rated it as a deep procedural task using Star's (2005) classification.

Another teacher designed the following task: "What is the maximum area of a rectangle if the perimeter is 20?" with an explanation that said, "it requires to use prior knowledge of area and perimeter". The use of "prior knowledge" in the explanation might imply that the teacher was thinking about how the student would have to make connections between fixed perimeter and changing area. This task was one of the few that was rated as a deep conceptual task following Star's (2005) classification. During interviews, teachers expressed the desire to design more conceptual tasks but said they need help. For instance, a teacher said about conceptual tasks, "to get them (students) to apply it to the real world and forces them to kind of make the connections, so it's something I think I am improving on, I don't think I am quite at the area but I am improving on it…"

Discussion and Conclusions

Teachers have an understanding of procedural knowledge related to the steps that require solving a mathematical task. While some teachers used language related to conceptual knowledge in their explanations, they face challenges in designing conceptual tasks. For the majority, the actual tasks that they designed illustrate some misconceptions about procedural and conceptual knowledge. This study adds to the growing literature about procedural and conceptual knowledge (Hannigan et al., 2013; Rayner et al., 2009; Rittle-Johnson et al., 2015; Star & Stylianides, 2013) by utilizing task design as a methodology. Based on teachers' (mis)conceptions of procedural and conceptual tasks, more studies need to be conducted to aid teachers not only in selecting tasks but in designing them as well.

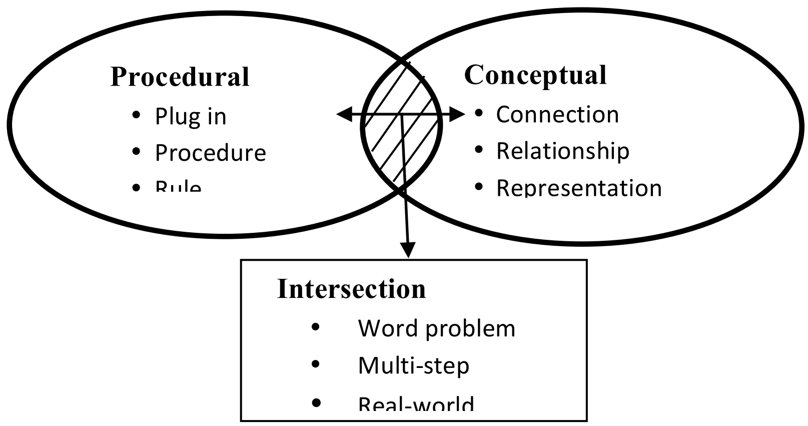

Figure 1: Relationship between Conceptual and Procedural Tasks

Table 1: Teacher designed tasks rated by experts as procedural and/or conceptual

	Procedural	Conceptual
Rated as Procedural	43 (78%)	44 (80%)
Rated as Conceptual	0 (0.0%)	3 (5.5%)
Ill-designed/no answer	12 (22%)	8 (14.5%)
Total	55 (100%)	55 (100%)

Table 2: Number and Percentage of Teacher Explanations for the Procedural Task

Procedure	Word-Problem	Substitute	Multi-step	No real world connections	No explanation	Total codes
18 (35%)	8 (16%)	15 (29%)	4 (8%)	6 (12%)	0 (0%)	51 (100%)

Table 3: Number and Percentage of Teacher Explanations for the Conceptual Task

Procedure	Word-Problem	Substitute	Multi-step	Real world connection	No explanation	Total codes
12 (26%)	11 (23%)	1 (2%)	12 (26%)	10 (21%)	1 (2%)	47 (100%)

MATHEMATICAL KNOWLEDGE FOR TEACHING:

POSTER PRESENTATIONS

A STUDY ON THE RELATIONSHIP BETWEEN TUTOR'S CONTENT KNOWLEDGE AND THEIR TUTORING DECISIONS

Jose Saul Barbosa
University of Texas at San Antonio
saulbarbosa45@gmail.com

Christopher James Duffer
University of Texas at San Antonio

Keywords: Mathematical Knowledge for Teaching, Informal Education, University Mathematics

When studying mathematics education and student success, most research tends to study the in-classroom teaching aspect. Another important aspect of mathematics education occurs outside the traditional classroom with tutors. While it has been shown that tutoring leads to student success (Xu, Hartman, Uribe, & Mencke, 2001), research has not necessarily focused on what tutoring is or what makes it effective. In recent years, efforts have been made to expand research in this field. Two major themes are the study of the types of knowledge necessary for effective tutoring and the interplay between these domains of knowledge to better understand the tutoring process.

Mathematical Knowledge for Tutoring

Burks and James (2019) began to create a theoretical framework for what constitutes "Mathematical Knowledge for Tutoring (MKTu)" (Burks & James, 2019) derived from Mathematical Knowledge for Teaching (MKT; Ball, Thames, & Phelps, 2008) model. What they determined is that a MKTu model would differ slightly from MKT in that the MKTu would include two overarching domains of *affect* and *self-regulation*. Additionally, certain domains shared by MKT and MKTu may not necessarily be implemented in the same manner. For example, while a classroom teacher is typically expected to be a master of their subject, a tutor is not, and thus, their common content knowledge tends to be more general, with a focus on *solving* problems rather than conceptual understanding. This new framework prompts a number of new avenues for research.

The Study

One such avenue is research into the relationship between a tutor's content knowledge and the pedagogical decisions they make while tutoring. In this poster, we present the results of a study in which we develop and facilitate mock-tutoring scenarios for tutors at a generalist-model tutoring center, and analyze their interactions with an actor-student (Jose Saul Barbosa) through the lens of MKTu, with consideration given to the dimensions for tutoring centers laid out by Byerly et al. (2019). In a generalist model, tutors are not experts in a single content area, rather they have a more general knowledge on a variety of subjects (Byerly et al. 2019). This variation provides an excellent opportunity to study how one's content knowledge interacts with the other domains of MKTu. In addition, we present the results of analyzing brief content assessments associated with the scenarios to draw comparisons between a tutor's content knowledge and the choices they make while tutoring. This study has implications not only for understanding the ways in which a tutor's content knowledge informs their tutoring, but also the ways it interacts with the other domains of MKTu. In studying this, we hope to contribute to future research into determining what factors and decisions can lead to effective tutoring.

NOVICE TEACHERS INTERPRETATION OF FRACTIONS

Brian Bowen
West Chester University
bbowen@.edu

Keywords: Teacher Knowledge, Teacher Education

Past research suggests that teacher's intentions to root mathematics instruction in conceptual understanding is impeded by their content knowledge and pedagogical beliefs (Borko et.al., 1992; Fuller, 1996). A significant source of this knowledge and beliefs may be attributed to their own experiences as mathematical learners (Chicoine, 2004). Implementation of the Common Core Mathematical Standards and Practices, launched in 2009, have emphasized the importance of instruction and learning focused on developing both mathematical procedural knowledge and conceptual understanding. Novice teachers have experienced the implementation of the Common Core during their own k-12 experience, as well as within their teacher preparation program. It may be that the renewed emphasis on productive mathematical dispositions and conceptual understanding present in the Common Core era may be realized in the content and pedagogical knowledge of these novice teachers.

In an effort to better understand novice teacher's mathematics knowledge and the potential influence of development of mathematical understanding under the Common Core, we have designed a study to examine one specific content area- the interpretation of fraction concepts. Fraction were chosen specifically due to the challenge they present to both pre-service and in-service teachers (Ma, 1999). Our data collection initially focused on how novice teachers across the k-12 grade level apply their own mathematical understanding to interpreting fractions and applying fraction operation. To address this area, artifacts of teacher work comparing, adding, and division of fractions was collected. We then compared the solution strategies utilized by the teachers in their own work was compared to the instructional strategies chosen by these teachers in their classrooms. Within this comparison, we questioned teachers to understand the impetus for these instructional decisions.

Results of the study suggest diverse solution strategies to the fraction problems within and across certification levels (e.g. elementary compared to high school). When choosing instructional strategies to apply for the instruction of fraction concepts the school curriculum was not often cites as a common resource. Instead, many of the teachers focused on their own backgrounds and experiences to determine their instructional approaches. This finding is of interest because of the potential for contradictions between teacher held beliefs on appropriate methods of instruction and instruction that exists in school and state curriculums.

ADVANCING REASONING AND PROOF IN SECONDARY MATHEMATICS CLASSROOMS: INSTRUCTIONAL MODULES FOR SUPPORTING TEACHERS

Keywords: Reasoning and Proof, Instructional activities and practices

Bringing to life a vision of mathematics teaching that emphasizes reasoning and proof across topics and grade levels can be a challenging task for teachers. To support and enhance teachers' content and pedagogical knowledge for teaching reasoning and proof, we developed and systematically studied a capstone course for preservice teachers (PSTs) *Mathematical Reasoning and Proving for Secondary Teachers.* The course emphasized integration of reasoning and proof with teaching secondary mathematics across *any* curricular topic, not just high-school geometry.

During our design-based research project, we developed and tested four instructional modules, each focusing on a particular proof theme: (1) direct reasoning and argument evaluation, (2) conditional statements, (3) quantification and the role of examples in proving, and (4) indirect reasoning. Each module comprised three types of activities: *crystalize, connect* and *apply*. The *crystalize* activities aim to help PSTs refresh their memory of a particular proof theme, within secondary school content. The PSTs enhance their knowledge by solving problems, as well as discussing and clarifying questions or misconceptions, e.g., the difference between proof by contradiction and by contrapositive. In the *connect* activities, the PSTs have an opportunity to connect their mathematical knowledge with knowledge of students' conceptions. The PSTs read cases or watch video or animations of classroom scenarios depicting students working on problems in a particular proof theme. For example, in the *connect* activity of the Quantification and the Role of Examples in Proving module the PSTs analyze a dialog between three students contemplating how to interpret a statement "There exist three consecutive even numbers whose sum is a multiple of four" and what kinds of examples can prove or disprove (if possible) this statement. Next, the PSTs envision possible pedagogical moves to support student thinking in the scenario. The *apply* tasks invite PSTs to identify opportunities in secondary curriculum to make proof themes explicit to students, and to develop a lesson plan that achieves that goal. In our course, we had PSTs implement these lessons in actual middle and high school classrooms, videotape themselves, and reflect of their teaching (Buchbinder & McCrone, 2018).

All four course modules were designed to be independent from each other and applicable for individual use in courses for PSTs or teacher workshops. The design of the instructional modules is grounded in the literature on best practices for teacher learning and professional development, such as focusing on deepening both content and pedagogical knowledge, engaging teachers in active learning experiences, and making direct connections to teachers' classroom practices (American Federation of Teachers 2002; Boston & Smith, 2009, 2011; Copur-Gencturk & Papakonstantinou, 2015). In our poster, we will show the four modules, explicate design features underlying their development, and provide evidence for the effectiveness of the modules.

Keywords: Mathematical Knowledge for Teaching, Technology, Teacher Educators, Teacher's Knowledge

Mathematics pre-service teachers must learn how to use tools like scientific calculators, Computer Algebra System (CAS), text processors and dynamic mathematical environments. These tools allow users to work with mathematical objects, perform specialized tasks, respond in a defined mathematical way, and transmit mathematical knowledge (Dick & Hollebrands, 2011). To achieve the integration of technology in Mathematics Education, the teacher's role is very important, since their beliefs and knowledge will dictate how they use technology in the classroom (Julie et al., 2010).

The goal of this research is to determine the beliefs and knowledge about technology and its integration into the teaching of mathematics by a group of pre-service teachers at the beginning of their first course of methodology in the teaching of mathematics at the secondary level (N=11). Interviews were conducted, and a questionnaire was administered to determine the profile participants use of technology at their schools and universities.

The results show that participants have used scientific calculators, content management software and online platforms. However, they have little experience with programs that allow them to work with mathematical objects (Dynamic Geometry or CAS). The participants have had a low level approach to technology, since both, they and their teachers, use the computer mainly for presentations, and calculators to corroborate results obtained with pencil and paper (Sacristán, 2017). 98% of the pre-service teachers that participate have used word processors, spreadsheets, presentations, emails, and cloud storage for academic purposes. Likewise, 59% of the participants indicated that they learned to use these technologies on their own. In the case their beliefs, participants indicated that the technology oriented to mathematical learning improves the quality of education, increases student participation, cooperative work experiences, individualized learning, and the motivation of students.

The participants have a positive perspective towards the use of technology in the mathematics classroom. However, their experiences and knowledge are not enough to do mathematical work or to teach mathematics. Therefore, it is necessary to expose pre-service teachers to experiences that allow them an integration that facilitates the learning of their students. (Julie et al. 2010; Önal, 2016; Sacristán 2017). We propose that, in the preparation of future teachers, a systematic and theoretical framework of the Technological Pedagogical Content Knowledge (TPACK), which is necessary to teach mathematics, is used (Harris et al., 2009; Rosenberg & Koehler, 2015).

Palabras clave: Conocimiento Matemático para la Enseñanza, Tecnología, Educadores de Docentes, Conocimiento del Profesor

Los maestros en formación deben aprender a utilizar herramientas como las calculadoras científicas, los sistemas algebraicos computadorizados, los procesadores de textos y los entornos matemáticos dinámicos. Estas herramientas permiten a los usuarios trabajar con objetos matemáticos, realizar tareas especializadas, responder de una forma matemática definida y trasmitir conocimientos matemáticos (Dick & Hollebrands, 2011). Para lograr la integración de la tecnología en la educación matemática el rol del maestro es muy importante ya que de sus creencias y conocimientos dependerá el uso que haga de ellas en el salón de clases (Julie et al., 2010).

El objetivo de este trabajo es determinar las creencias, el conocimiento sobre la tecnología y su integración en la enseñanza de las matemáticas de un grupo de maestros en formación al inicio de su primer curso de metodología de enseñanza de las matemáticas en el nivel secundario (N=11). Se realizaron entrevistas y se administró un cuestionario para determinar el perfil de uso de la tecnología en la escuela y en la universidad de los participantes.

Los resultados demuestran que los participantes han utilizado calculadoras científicas, programas gestores de contenido y plataformas en línea. Sin embargo, tienen poca experiencia en programas que les permitan trabajar con objetos matemáticos (Geometría Dinámica o "Computer Algebra Systems"). Los participantes de este estudio han tenido un acercamiento con la tecnología de bajo nivel ya que tanto ellos como sus maestros utilizaron la computadora principalmente para hacer presentaciones y las calculadoras para corroborar resultados obtenidos con lápiz y papel (Sacristán, 2017). El 98% de los maestros en formación ha utilizado para fines académicos procesadores de palabras, hojas de cálculo, presentaciones, correos electrónicos y nubes de almacenamiento. Igualmente, un 59% indica que han aprendido ha utilizar estas tecnologías por su propia cuenta. En relación con las creencias, los participantes indican que la tecnología orientada al aprendizaje matemático mejora la calidad de la educación, la participación, el trabajo cooperativo, el aprendizaje individualizado y la motivación en los estudiantes.

Los participantes tienen una orientación positiva hacia el uso de la tecnología en las matemáticas. Sin embargo, sus experiencias y conocimientos no son suficientes para hacer trabajo matemático o para enseñar matemáticas. Por ello, es necesario exponer a los futuros maestros a experiencias que les permita una integración que facilite el aprendizaje de sus estudiantes (Julie et al. 2010; Önal, 2016; Sacristán 2017). Proponemos que en la formación de maestros se utilice sistemáticamente un marco teórico del conocimiento pedagógico, tecnológico y de contenido necesario para enseñar matemáticas (Harris et al., 2009; Hollebrands, 2017; Rosenberg & Koehler, 2015).

EXPLORING MATHEMATICS TEACHER EDUCATORS' AVENUES FOR PROFESSIONAL GROWTH: A REVIEW OF THE RESEARCH LITERATURE

Dana Olanoff
Widener University

Priya Vinata Prasad
University of Texas at San Antonio
priya.prasad@utsa.edu

Rachael M. Welder
Texas A&M University
rachael@rachaelwelder.com

There is a growing consensus that mathematics teacher educators (MTEs) need a robust knowledge base in order to prepare prospective teachers (e.g., Chavout, 2008; 2009). However, research has shown that the majority of MTEs are not provided the support or training necessary to develop this knowledge (Masingila et al., 2012). Professional organizations have called for improved preparation of MTEs (AMTE, 2017; CBMS, 2012), but the ways in which *MTEs develop Mathematical Knowledge for Teaching Teachers (MKTT)* it is not yet understood.

For the past three years, our research group has been studying the literature on MKTT (Castro Superfine et al., in preparation; Olanoff et al., 2018; Welder et al., 2017). As part of this work, we have conducted an extensive literature search of research on the knowledge MTEs use in their work with prospective and practicing teachers and how this knowledge is developed. Thus far, we have organized the extant literature into five overall themes capturing the ways in which MTEs have developed MKTT. In this poster, we will offer the five themes, summarize pertinent research for each, and discuss implications this work has on the preparation and professional development of MTEs. Below we offer a sampling of our findings.

1. ***Learning through reflective self-study***. Many MTEs who are also researchers have conducted reflective self-studies of their teacher education practices (e.g. Alderton, 2008; Allen et al., 2018; Chavout, 2009; Marin, 2014; Muir et al., 2017; Taylan & da Ponte, 2016). These studies vary (for example, individual vs. collaborative efforts), including whether or not the researchers identified professional growth as a finding of their self-study.
2. ***Learning through communities of practice***. Some groups of MTEs (e.g., Applegate et al., 2020; Jaworski, 2003; Olanoff et al., in press) have formed communities of practice to improve the MKTT of all of the group members and/or initiate novice MTEs into the field.
3. ***Learning through graduate preparation and/or professional development activities***. Few studies describe how MTEs have taken graduate-level courses (Flores et al., 2017), or participated in formal professional development opportunities, as part of their own learning (Hauk et al., 2017; Castro Superfine & Li, 2014). Flores and colleagues (2017) suggest that taking graduate courses or participating in other forms of professional development can provide meaningful opportunities for MTEs to reflect on and build upon their own knowledge.
4. ***Learning through research***. Some authors (e.g., Chauvot, 2008, 2009; Chen et al., 2008) suggest that MTEs develop MKTT by being *Mathematics Teacher Educators/Researchers*. This work can involve studying one's own practices of teaching teachers as well as studying the literature involving the teaching and learning of MKT.
5. ***Learning through doing the work of teaching teachers***. Ball and her colleagues (2008) suggest that MKT is the knowledge required to perform the mathematical tasks of teaching. Building on this, some researchers (e.g., Zopf, 2010) define MKTT as the knowledge required to perform the mathematical tasks of teaching teachers. Zopf and others, such as Jankvist and colleagues (2019) suggest that MTEs develop MKTT on the job by performing the work of teaching teachers.

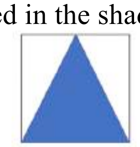
Keywords: Teacher knowledge, Concept of number and operations; Rational Numbers

The need to strengthen teachers' mathematical knowledge for teaching in Mexico has been identified as a recurrent topic in the literature (Eugenio & Zaldívar, 2019; García, et al., 2019; Juárez Eugenio & Arredondo López, 2017; OCDE, 2012). Addressing this need, we present results from a diagnostic study administrated to 355 elementary teachers in Mexico enrolled in a course focused on rational numbers. The results are contrasted with both a similar diagnostic administrated to 360 university students enrolled in other programs and the way in which this topic is addressed in textbooks in Mexico and Canada.

We focus our analysis on the distinct representations of mathematical objects, as well as the diverse images, metaphors and analogies related to rational numbers (Lakoff y Núñez, 2000; Núñez y Marghetis, 2014). For the case of rational numbers, we considered the division of objects in equal parts (Confrey et al., 2009). However, our review of textbooks from Canada and the official student resource in Mexico (Comisión Nacional Libro de Texto Gratuito, 2019) reveled that images and descriptions for fractions make emphasis on dividing a shape in congruent parts. However, the area model for fraction requires parts with the same measure of surface area, without the need of being congruent. Figure 1 shows two of the questions in the diagnostic test.

Question 1: Which fraction is represented in the shaded shape?	Question 2: If the area of the rectangle is 12, what is the area of the shaded part?
	


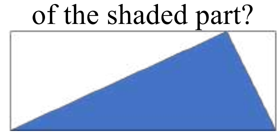


Figure 1: Diagnostic test questions related to rational numbers and the are model.

The results of the diagnostic test administrated to teachers suggest that many of them attended to the shape of the shaded part, instead of its area. The diagnostic to other undergraduate students, which included written justifications of their answers, was consistent with the suggested results from the diagnostic to teachers. In this sense, the answers to Question 1 were 1/2, 1/3 and 2/4. Although 1/2 and 2/4 are equivalent rational numbers, the justifications for 2/4 included the division of the shaded triangle in two equal parts, dividing the square in four congruent triangles. Many people who answered 2/4 did not answer Question 2 correctly, which suggests that they focused on the shape of the parts rather than the surface area.

These results plead for the need to clarify the meaning of "equal" in the definition of fractions, both in teachers' knowledge and textbooks. We consider that this analysis based on representations and metaphors can be extended to other school content.

Palabras clave: Conocimiento del profesor, Conceptos de Números y Operaciones, Números Racionales

La necesidad de fortalecer el conocimiento matemático para la enseñanza de los profesores en México ha sido identificada como tema recurrente en la literatura (Eugenio & Zaldívar, 2019; García, et al., 2019; Juárez Eugenio & Arredondo López, 2017; OCDE, 2012). Atendiendo esta necesidad, presentamos resultados de un estudio diagnóstico a 355 profesores de educación básica en México en el contexto de un curso enfocado en números racionales. Los resultados se comparan con un diagnóstico similar a 360 estudiantes universitarios en otras carreras, así como la forma en que se aborda el tema en libros de texto de educación básica en México y Canadá.

Enfocamos nuestro análisis en las distintas representaciones de objetos matemáticos, así como las diversas imágenes, metáforas y analogías relacionadas con los números (Lakoff y Núñez, 2000; Núñez y Marghetis, 2014). Para el caso de números racionales se considera la división de objetos en partes iguales (Confrey et al., 2009). Sin embargo, nuestra revisión de libros de texto de Canadá y del recurso oficial en México (Comisión Nacional Libro de Texto Gratuito, 2019), reveló que las imágenes y descripciones de fracción hacen énfasis en la división de una figura en partes congruentes. Sin embargo, el modelo de área para fracciones requiere que las partes compartan la misma medida de su área, sin ser necesario que sean congruentes. La Figura 1 muestra dos de las preguntas del diagnóstico.

Pregunta 1: ¿Qué fracción representa la figura?	Pregunta 2: Si el área del rectángulo es 12, ¿cuál es el área de la parte sombreada?
	

Figura 1: Preguntas correspondientes a números racionales usando el modelo de área

Los resultados de la evaluación diagnóstica a maestros sugieren que muchos pusieron atención a la forma de las partes en lugar del área. El diagnóstico a estudiantes universitarios, que incluyó respuestas escritas con justificación, fue consistente con los resultados sugeridos en el diagnóstico a profesores. En este sentido, las respuestas a la Pregunta 1 fueron 1/2, 1/3 o 2/4. Si bien 1/2 y 2/4 son equivalentes como números racionales, las justificaciones para 2/4 incluyeron la división del triángulo sombreado en partes iguales, dividiendo al cuadrado en cuatro triángulos congruentes. Muchas personas que respondieron 2/4 no respondieron correctamente la Pregunta 2, lo que sugiere que se enfocaron en la figura, no en el área.

Estos resultados dan cuenta de la necesidad de aclarar qué se entiende por “igual”, tanto en el conocimiento del profesor como en los libros de texto. Consideramos que este análisis basado en representaciones y metáforas se puede extender a otros contenidos escolares.

THE IDEAS OF GIORDANO BRUNO AS A TEACHING ALTERNATIVE, IN ORDER TO UNDERSTAND THE PRINCIPLE OF RELATIVITY

LAS IDEAS DE GIORDANO BRUNO, ALTERNATIVA DE ENSEÑANZA PARA LA COMPRENSIÓN DEL PRINCIPIO DE RELATIVIDAD

Felipe de Jesús Matías
CINVESTAV
fmatias@cinvestav.mx

Aurora Gallardo
CINVESTAV
agallardo@cinvestav.mx

Keywords: Giordano Bruno, Secondary Education, Relativity Principle.

We report what took place in our qualitative research in mathematics education and science teaching, on the Relativity Principle (RP) proposed by Giordano Bruno (GB), which, up until today, has been adjudicated to Galileo. De Angelis and Espirito (2015) report on that situation.

We considered the 1993, 2006, 2011 and 2017 curricula used in Mexico for science teaching, with emphasis in Physics, particularly of the free fall topic, which ask to contrast what was carried out by Aristotle and Galileo Galilei. Bruno's innovation of the relativity principle (1984/1972) is highlighted as follows: "TEO: With Earth move therefore, everything what is on it. Because of that, if, from one place outside Earth an object is launched toward it, it could lose the straightness due to its movement" (p.61).

In the Concept Models (CM) theory, invented by teachers, researchers, engineers, architects in order to facilitate the comprehension or teaching of physical systems, Mental Models (MM) are

> models that people build to represent physical states. They do not need to be technically accurate but they must be functional. They evolve naturally. They are limited by factors such as knowledge, previous experience and the own structure of information processing of human been. (Moreira, 1997, p. 45).

The following problem was given to 117 students of seventh grade in a public school of a metropolitan area near Mexico City:

> Imagine a ship that moves in a constant velocity. From the tallest mast a rock is released. Do you believe that the rock will fall exactly at the mast´s base where the rock was released? Justify your answer. The proposed problem is based on one of Bruno (1584/1972, p. 161).

The following is the most frequent Mental Model from the studied population:

> MM: "No, because, while it falls through the air, the ship moves and the rock doesn't fall in the same place"

Figure 1. Image retrieved from Matías & Gallardo (2019, p. 98).

The studied problem shows the need of analyzing important concepts for the comprehension of relativity principle, making it possible to use Giordano Bruno's proposal as a teaching alternative.

Palabras Clave: Giordano Bruno, Educación Secundaria, Principio de relatividad.

Se reporta lo acontecido en una investigación cualitativa en la enseñanza de la matemática y las ciencias, usando el Principio de Relatividad (PR) propuesto por Giordano Bruno (GB) hasta hoy adjudicado a Galileo. De Angelis, A. y Espirito, C. (2015) también reportan y reclaman dicha situación.

Se contemplaron los Planes y Programas de los años 1993, 2006, 2011 y 2017 usado en México respecto a la enseñanza de las ciencias con énfasis en física particularmente sobre la caída libre, los cuales piden contrastar lo realizado por Aristóteles y Galileo Galilei. Se resalta la primicia del PR en Bruno (1584/1972) como sigue: "TEO: Con la tierra se mueven por tanto, todas las cosas que se encuentran en ella. Por consiguiente, si desde un lugar fuera de la tierra se arrojara algún objeto hacia ella, perdería la rectitud debido al movimiento de ésta." (p. 61)

Se usó la teoría de los Modelos conceptuales (MC): "Aquellos inventados por los profesores, investigadores, ingenieros, arquitectos, para facilitar la comprensión o la enseñanza de sistemas físicos…" En ella, los Modelos Mentales (MM) son

> modelos que las personas construyen para representar estados físicos. No requieren ser técnicamente precisos, sino que deben ser funcionales. Evolucionan naturalmente. Están limitados por factores tales como conocimiento, experiencia previa y la propia estructura del sistema de procesamiento de información del ser humano. (Moreira, 1997, p. 45).

Se aplicó a 117 estudiantes de segundo grado de una escuela pública ubicada en el Estado México el problema siguiente:

> Imagina un barco que se desplaza a velocidad constante, desde el mástil más grande, se deja caer una piedra. ¿Crees que la piedra caerá justo en la base del mástil donde se dejó caer? Justifica tu respuesta. Problema propuesto con base en (Bruno, 1584/1972, p. 161).

A continuación se muestran los MM del grueso de la población analizada.

> **"MM.** No, porque mientras cae sobre el aire, el barco se mueve y la piedra no cae en el mismo lugar"

Figura 1. Imagen recuperada de (Matías y Gallardo, 2019, p. 98)

El problema usado, despierta la necesidad del análisis de conceptos importantes en la comprensión del PR pudiendo usar lo propuesto por Giordano Bruno como alternativa de enseñanza.

MATHEMATICAL PROCESSES AND MODELING

RESEARCH REPORTS

EXPLORING SECONDARY STUDENTS' PROVING COMPETENCIES THROUGH CLINICAL INTERVIEWS WITH SMARTPENS

Michelle Cirillo
University of Delaware
mcirillo@udel.edu

Jenifer Hummer
West Chester University
jhummer@wcupa.edu

Twenty students who earned A or B course-grades in the proof unit(s) of a secondary course that addressed proof in geometry were asked to work on two proof tasks while sharing their thinking aloud and using smartpens. Students were classified into two categories: those who were successful with both proofs and those who were unsuccessful with both proofs. Large differences were observed in how often students in the two groups exhibited certain competencies. The largest gaps occurred in the ways that students: attended to the proof assumptions; used warrants in their proofs; and demonstrated logical reasoning.

Keywords: reasoning and proof, geometry and geometrical and spatial thinking

Introduction

Proving is an important aspect of mathematical competence, and geometry is the site which has historically been considered to be a good starting point to teach and learn mathematical argumentation and proving in secondary mathematics (Reiss, Hellmich, & Reiss, 2002). Hoyles (2002) suggested that proving involves a range of non-trivial "habits of mind" such as looking for structures and invariants; identifying assumptions; and organizing logical arguments. These processes, she noted, must be coordinated with visual or empirical evidence and mathematical results and facts. The need to coordinate the linguistic and visual registers is a particularly distinguishable feature of proof in geometry (Sinclair, Cirillo, & de Villiers, 2017). Yet, a number of studies conducted in the context of secondary geometry provide evidence that the teaching and learning of proof in secondary geometry is a challenging endeavor (Balacheff, 1988; Cirillo, 2011; Healy & Hoyles, 1998; Senk, 1985). To make progress on this challenge, we sought to gain insight into the competencies and behaviors displayed by students who were successful and unsuccessful with two proof tasks.

Theoretical Framework

A number of studies have documented students' difficulties with proof in geometry. For example, Senk (1985) conducted a study wherein she administered six proof-writing tasks to 1520 students in the U.S. After scoring the tasks on a scale of 0-4 where scoring >3 deemed a student to be "successful" on an item, Senk concluded the following: only about 30% of students in a full-year geometry course reached a 75% mastery of proof, and approximately 29% of students could not write even one valid proof. In another study, in this case, a study of high-attaining 14-15 year-old students in England and Wales, Healy and Hoyles (1998) found that only 19% of students were able to construct a proof of a familiar geometry statement, and fewer than 5% of students could construct a proof of an unfamiliar geometry statement. Last, in their study of 81 German upper secondary students, Reiss, Klieme, and Heinze (2001) found that only 20% of students were able to construct correct Euclidean geometry proofs. Various recommendations and student difficulties were noted in these studies.

Based on study results, Senk recommended that we must look for more effective ways to teach proof in geometry, noting, for example, that we must find ways to support students to start a chain of reasoning. In the studies conducted by Healy and Hoyles (1998) and Reiss and colleagues (2001), the researchers found that students were better at judging others' proofs than they were at constructing their own proofs. Also, in Reiss et al.'s (2001) study, only 10% of students were able to provide a definition of the central concept of "congruence" and name a mathematical theorem related to congruence (i.e., a triangle congruence theorem). Furthermore, this study provided evidence that geometric competence with respect to proving is dependent on a combination of metacognition, spatial reasoning, methodological knowledge, and declarative knowledge (e.g., the notion of congruence).

Some researchers have elaborated on why proof is so challenging for students. For example, Healy and Hoyles (1998) explained that the process of building a valid proof is complex in that it involves sorting out what is "Given" from what can be deduced, and then organizing the conclusions that can be drawn from the "Given" into a coherent and complete argument that meets the proof goal. When considering the large number of possible inferences that could be made from the "Given(s)" in a typical school geometry proof problem, Koedinger and Anderson (1990) noted: "Geometry proof problem solving is hard" (p. 512). To better understand this "hard" situation, they observed geometry "experts" and found that, prior to writing up the details of their proofs, experts tended to quickly and accurately develop an abstract proof plan that skips many of the steps required in the full proof. In other words, they first applied global thinking (i.e., considered the "big picture") rather than local thinking (i.e., worked on one step at a time) at the start of the process. This conclusion is consistent with Cai's (1994) finding in a study of problem solving in geometry that the more-experienced participants spent the majority of their time on orientation and organization, while less-experienced students spent the majority of their time on execution (i.e., doing rather than thinking or planning).

In Battista's (2007) review of school geometry research, he posed several unanswered questions related to students' learning of proof, including: Why do students have so much difficulty with proof? What components of proof are difficult for students and why? and How can proof skills best be developed in students? (pp. 887-888). Ten years later, speaking back to these questions in their research review, Sinclair et al. (2017) concluded that while some researchers have attempted to address these questions, the reported studies tended to focus on only one or a few teachers or did not provide evidence of effectiveness at scale. They also suggested that more research is needed on students' development of geometric proof skills and their understanding of the nature of proof. The lack of research in this area led us to pursue this topic. Thus, this study addresses the following research questions: (1) What proving competencies and behaviors are observed in students who were successful with solving geometric proofs? and (2) How do these competencies and behaviors compare to those of students who were unsuccessful with the proofs?

Methods

The study reported on in this paper is part of a larger research project titled: *Proof in Secondary Classrooms: Decomposing a Central Mathematical Practice* (*PISC;* PI: Cirillo).The goal of the *PISC* project is to better understand the difficulties involved in the teaching and learning proof in secondary geometry and to develop a new and improved intervention to address these challenges. Students who earned high marks (grades of A or B) in the geometry proof unit(s) were selected for individual clinical interviews for this sub-study. The rationale for interviewing students with high marks was to understand what high-performing students were taking away from the proof unit(s). Because past studies have shown that even high-attaining students struggle with non-routine as well as routine proof tasks in geometry (see, e.g., Healy & Hoyles, 1998; Cirillo, 2018), two proof tasks that, in theory, should have been somewhat familiar to the students, were selected for data collection and analysis. We chose triangle congruence proof as a topic for exploration because it is considered to be a central concept in school geometry and because limited time to conduct the interviews in the school setting did not permit us to take up large amounts of students' time with longer problems.

The criteria for participant selection for this sub-study were as follows: (1) students were enrolled in a secondary course that addressed proof in geometry; (2) students earned an A or a B in the proof unit(s); (3) students were identified by their teacher as students who would be willing to share their thinking aloud during the interview; and (4) students completed the full interview protocol in the allotted time; (5) there were no technology glitches during the data collection, and (6) students' success results on each of the two proof tasks were the same (i.e., successful or unsuccessful on both proofs). This selection process reduced the sample size from 31 students interviewed to 20 selected. Participating students spanned Grades 8-11 (ages 13-17).

The first author conducted all student interviews. The goal was to spend about 35 minutes with each student; the mean interview length was about 32 minutes. The full interview protocol consisted of seven items. The first item was a simple "warm-up" task about geometric notation. The next four tasks were selected or adapted from Cirillo and Herbst (2011). The last two tasks, which were the ones selected for this analysis, were full-proof tasks (see Figure 1). Students spent an average time of 7.28 minutes on Task 6 and 5.95 minutes on Task 7. Students were asked to read each task aloud to ease them into talking through the task and guarantee that they had read the "Given" information for each task. Smartpen technology (i.e., Livescribe pens) was used to audio-record the students' explanations of their thinking and capture their pen strokes as they worked through the proofs. This methodology allowed us to capture students' thinking in the form of verbal explanations and simultaneous diagram markings and other written work.

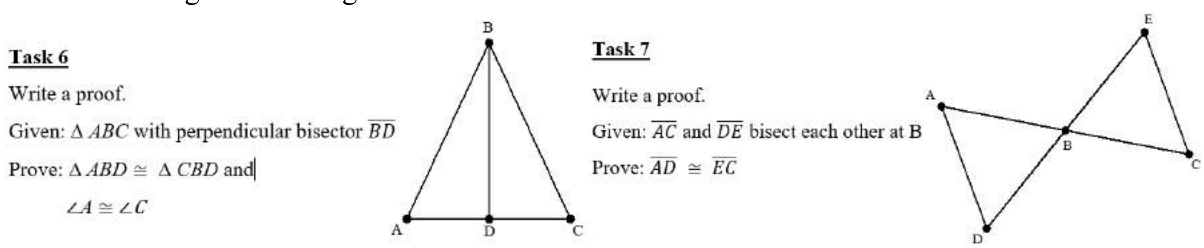

Figure 1: The two full-proof interview tasks analyzed for this study

Smartpen data were digitized to create a "pencast," or video, that simultaneously replays each student's handwriting and audio-recording (Livescribe, 2012). Prior to analyzing the smartpen data, students' final proofs were quantitatively scored from the paper hardcopies in ways that followed Senk's (1985) methods. Specifically, we adapted the rubrics for Senk's full-proof tasks so that every proof was scored on a scale of 0-4. Following Senk's approach, if students scored a 3 or a 4 on a proofs, they were considered to be Successful with the Proof tasks (abbreviated as SP; n=7). Students who scored less than 3 were considered Not successful with the Proof tasks (abbreviated as NP; n=13). The resulting data set consisted of two Proof Task Interviews (PTIs) from 20 students. The units of analysis are the individual proof tasks, resulting in 40 units of analysis. Tables 1 and 2 include age, grade level, course grade (A or B), and task scores (0-4) for each participant in the NP and SP groups.

We used constant comparative analysis (Boeije, 2002) to develop a coding dictionary. To develop the codes, the research team watched the PTI pencasts for six participants for both Tasks 6 and 7. Codes were developed for observed problem-solving behaviors and competencies that were exhibited through spoken and written work. This iterative process resulted in 45 possible codes for both NPs and SPs. After garnering an 86.59% interrater reliability and reconciling incongruent decisions, the second author coded the remaining data. The final phase of analysis involved looking across the coding results for patterns and themes.

Table 1: Study participants who were Not successful with both Proof tasks (NPs)

Participant Number	Age	Grade Level	Course Grade	Task 6 Score	Task 7 Score
P1	14	8	A	0	0
P2	16	10	B	0	0
P3	15	10	B	0	0
P4	15	10	B	0	0
P5	14	8	A	0	1
P6	14	8	A	1	1
P7	17	9	B	1	1
P8	17	10	B	1	1
P9	16	10	B	1	1
P10	15	9	A	1	1
P11	13	8	A	2	1
P12	17	11	B	2	2
P13	17	11	A	2	2

Table 2: Study participants who were Successful with both Proof tasks (NPs)

Participant Number	Age	Grade Level	Course Grade	Task 6 Score	Task 7 Score
P14	14	8	A	3	3
P15	14	8	A	3	4
P16	13	8	A	4	4
P17	13	8	A	4	4
P18	14	8	A	4	4
P19	14	8	A	4	4
P20	13	8	A	4	4

Findings

In reporting the findings, we first describe the most prevalent competencies and behaviors among the students who were **S**uccessful with both **P**roof tasks (SPs; n = 7). Because there were multiple competencies and behaviors that were exhibited by a high percentage of the SPs, we chose a threshold of 60% for the occurrences that would be reported. That is, we report on behaviors and competencies observed at least 60% of time for the SPs. This decision yielded five findings across the data set and includes behaviors related to working with the "Givens," marking the diagram, demonstrating logical thinking, and so forth.

Regarding the second research question about the competencies and behaviors of the students who were **N**ot successful with either **P**roof task (NPs; n = 13), the data were more inconsistent. We first compare NPs with SPs by reporting on the frequencies (as a percentage of the total occurrences for each PTI) with respect to the six findings from the SP group. Table 3 provides a summary of these behaviors and the frequency of occurrence. We then share three additional findings that relate to behaviors observed at least 20% of the time in the NP group.

Competencies and Behaviors of Students Who Were Successful with the Proofs

All seven SPs made productive and explicit use of the "Given" information for both tasks (i.e., 100% of the time). They did so either as they were planning their proofs or as they began to work on a proof. They explicitly identified the relevant mathematical objects from the assumptions (i.e., the "Given"). Here is an example of P14 thinking aloud about Task 7 (P14-T7; from here forward, we will use the notation PX-TY to denote each participant and task): "First thing we know is that ABC and DE bisect each other at B. Why? Because it's the Given. Next. Well you know that B, B is the midpoint. Why? Because definition of line segment bisector…"

Table 3: Frequencies of observed competencies and behaviors for both groups

Observed Competencies & Behaviors (rounded to nearest whole percentage)	**SPs (%)**	**NPs (%)**
***Students productively attended to the "Given" information**	**100**	**23**
Students correctly identified bisectors	100	12
Students indicated what object was being bisected	93	12
Students used the diagram as a resource	**100**	**47**
Students marked the diagram	100	65
Students used the diagram as a check list or planning tool	100	46
Students made valid claims supported by assumptions about the diagram	100	31
***Students identified warrants as postulates, axioms, definitions, or theorems**	**86**	**8**
Students clearly connected claims to definitions	86	12
Students stated or explained a definition	79	4
Students articulated a definition of congruent triangles	100	8
***Students demonstrated that they were thinking in a logical manner**	**93**	**8**
Students attended to important details while working through their proofs	**68**	**13**
Students articulated a plan for the proof prior to writing the proof	64	15
Students attended to rigor in sub-arguments	100	4
Students attended to triangle congruence criteria	79	15
Students attended to the "Prove" statement in explicit ways	64	23

* Indicates the main findings with the largest percentage gap between SPs and NPs (> 75%)

All SPs accurately marked the diagrams for both proofs (i.e., 100% frequency). The smartpen technology enabled us to see noticeable differences in the ways this occurred. For Task 6, SPs tended to mark the diagram in two distinct ways. Either they worked through the details of the proof, marking off congruent parts as they made their inferences, or they marked the congruent parts, using the diagram as a checklist to show that they had proven the triangles congruent. For Task 7, three SPs seemed to immediately recognize how to solve the proof, so they explained a plan for the proof *and* marked the congruent parts prior to beginning the proof (see Figure 2). Each proof task included some type of bisector in the "Given." SPs were clear about what type of bisector they were working with 100% of the time (e.g., line segment bisector). They explicitly indicated what was being bisected 92.9% of the time.

When SPs wrote or articulated their warrants (i.e., reasons for their statements), they typically indicated the typology in explicit ways 85.7% of the time. SPs appropriately connected claims to definitions 85.7% of the time, sometimes even stating the exact definition (78.6%). For both proofs, the concept of congruent triangles was critical toward developing a valid proof. All SPs wrote CPCTC as the warrant for their triangle congruence statements. When asked what it meant or stood for, 100% of SPs were able to articulate what CPCTC stood for or explain what it meant (i.e., Corresponding Parts of Congruent Triangles are Congruent).

As they were thinking aloud, SPs' explanations contained logical connectives, such as "next," "and then," and "we can conclude," in 92.9% of the PTIs. The P18-T6 excerpt above is a good example of this. Also, P20-T6 used logical connectives "then" and "so" in various ways:

> <u>So, we have</u> this is congruent to that and we have that this is perpendicular to that <u>so I guess we could use</u> the right angles theorem to prove that these are congruent <u>and then we could prove</u> that this is congruent by the reflexive property of congruence. <u>And then we can get</u> the angles congruent by C-P-C-T-C.

Although, in this explanation, P20 seemed to skip over the step of stating that the triangles were congruent, it was included in the written proof.

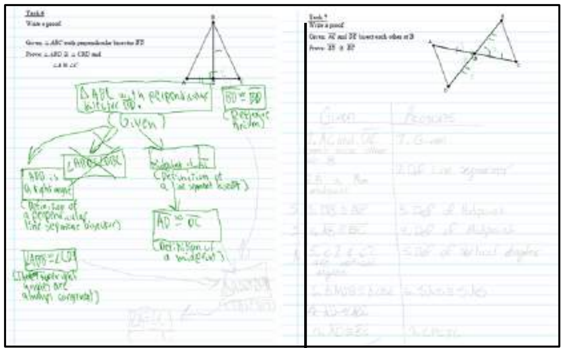

Figure 2: P15-T6 Used Diagram as a Checklist & P20-T7 Used Diagram as a Planning Tool

Arrow 1	Arrow 2	Arrow 3 and Triangle Congruence Statement
		

Figure 3: P16-T6 attends to sub-arguments and triangle congruence criteria

SPs attended to the details of their proofs in multiple ways. They articulated a plan for the proof before writing the proof 64.3% of the time. SPs attended to rigor in their sub-arguments 100% of the time. They attended to triangle congruence criteria in explicit ways 78.6% of the time. And they explicitly attended to the "Prove" statement 64.3% of the time. P16-T6's work provides evidence of attending to sub-arguments (i.e., branches of a proof claim and consequence) and triangle congruence criteria. His written work (see Figure 3) is very methodical in that he established three congruent parts prior to drawing in the arrows in his flow proof to connect the three congruent statements to the triangle congruence statement:

> Ok so then we have our three parts [draws three arrows]. So, we know that these are congruent and then we can say that triangle ABD is going to be congruent to triangle C, CBE. [Pause] I had to take a moment there to see which point was corresponding with point A. So, then we have our two triangles. And we can say this, because of S-A-S theorem. And after this, we can use my favorite theorem again to say that line segment AD is congruent to line segment EC because of C-P-C-T-C. So yeah.

The smartpen allowed us to see how the student worked out the three congruence statements prior to writing and then drawing arrows to the triangle congruence statement. We can see from the combination of transcript and smartpen images that he attended to triangle congruence criteria when he said: "we have our three parts," paused to accurately write the triangle congruence statement in a way that matched up the corresponding parts, and drew the three arrows before writing the triangle congruence statement.

Competencies and Behaviors of Students Who Were Unsuccessful with the Proofs

Large discrepancies between SPs' and NPs' behaviors were noted in the data. Table 4 includes frequencies from the PTIs (as percentages) for both groups for each finding and sub-finding. The differences in occurrences of the six main findings range from 35-92% with a gap of more than 80%

for 3 of the 6 main findings (as indicated in the table by *). For the second research question, it is not so productive to go through each finding one-by-one because there is little to say about the absence of something. Instead, we address the kinds of behaviors observed in NPs given the absence of many of the competencies exhibited by high percentages of SPs. Because the percentages of occurrences of common behaviors were much lower in this data set, we chose a lower threshold of >20% for the codes that we discuss in this section.

First, there were multiple issues noted with the ways in which students dealt with the "Given" information. In particular, 23.1% of the time, NPs incorrectly stated the "Given" when they read it aloud. The most common error for both tasks was saying "line" rather than "line segment." Second, 46.2% of the time, NPs omitted notation or information when they wrote the "Given" statement in the first line of their proof.

NPs' warrants were vague 61.5% of the time. They often did not identify warrants as postulates, definitions, or theorems, and they frequently did not seem to know definitions of relevant concepts. For example, P12-T6 wrote "Definition of bisect" as a reason for Line 3. Yet, in order for the corresponding statement, ∠ABD ≅ ∠CBD, to be true, $\overline{BD}$ would have had to have been an *angle* bisector rather than a *perpendicular* bisector. In the next line of the proof, the student's warrant references the particular diagram, rather than a definition.

NPs displayed a lack of confidence in 34.6% of the PTIs. They sometimes would say that they could not remember definitions or reasons for their statements. For example, when asked about a reason for one of the steps in her proof, one NP said, "I don't have one." This statement also indicates a lack of using logical reasoning. Other comments made by NPs as they shared their thinking included: "I don't know how to do this one" [P1]; "I don't know how to explain it" [P4]; and "I remember having a lot of trouble on this because I didn't understand" [P11].

Discussion and Conclusions

Making use of smartpen technology, we explored the competencies and behaviors of high-attaining students with the expectation that even high-attaining students would have gaps in their abilities to prove. Clear differences were noted in the approaches taken by students who were successful with the two proof tasks, compared to students who were unsuccessful with those tasks. These findings contribute to the research on the teaching and learning of proof in geometry, specifically, the first part of Battista's (2007) question: What components of proof are difficult for students and why? There are several important take-aways from these findings.

First, when we compare the frequency percentages of competencies and behaviors observed in the two student groups in Table 4, the differences are relatively large. For example, the difference between how often SPs were observed productively attending to "Given" information compared to how often NPs did so was 77%, with SPs doing so 100% of the time and NPs only 23% of the time. This finding indicates that more work is needed to support students to productively attend to proof assumptions.

With respect to geometric diagrams, 100% of SPs marked their diagrams, made valid claims supported by assumptions about diagrams, and used the diagrams as a check list or a planning tool, particularly when solving a proof at the "global" level (Koedinger & Anderson, 1990; Cai, 1994). In contrast, NPs did not always mark their diagrams; they sometimes used the diagrams to plan; and they rarely made appropriate assumptions about the diagrams. Rather than using the "Given" information to draw valid conclusions, NPs put forth inappropriate inferences which often seemed to come from what the diagram "looked like." Doing so follows the perceptual proof scheme described by Harel & Sowder (2007).

There was also ample evidence to suggest that SPs had strong understandings related to the typology of warrants and that they understood how to use them to develop proof arguments. In contrast, this competency was rarely observed in the PTIs of NPs. Instead, NPs were sometimes observed justifying statements using reasons related to particular diagrams (e.g., B is the midpoint). Additionally, at times, NPs simply wrote, as their warrants, some mathematical object (e.g., bisector) without writing anything further, such as clearly identifying the type of bisector or explicitly stating whether they were thinking about a theorem or definition. NPs explicitly connected claims to definitions, stated definitions, and were able to articulate a definition of congruent triangles less than 15% of the time. These issues connect to Reiss and colleagues' (2001) claims about the importance of coordinating declarative knowledge with higher order skills. Regarding higher order skills, evidence that students were reasoning through their proofs in a logical manner was observed 93% of the time for SPs, compared to only 8% of NPs.

The likelihood of SPs attending to important details in their proofs was also much greater than the likelihood of NPs doing so. The area of greatest difference was with respect to sub-arguments. SPs attended to sub-arguments in rigorous ways 100% of the time; NPs did so only 4% of the time. This finding relates to logical reasoning in that a sub-argument is a chain of reasoning that begins with an assumption and involves more than one deduction (Cirillo, Murtha, McCall, & Walters, 2017). SPs were also observed attending to other kinds of details in ways that were not observed in the NP data, such as: developing a plan for their proof (i.e., thinking at the global rather than local level); attending to triangle congruence criteria; and attending to the "Prove" statement. SPs were observed doing these things most of the time; while NPs were not. These findings are consistent with Healy and Hoyle's (1998) descriptions of what makes proving so complex. In particular, they argued that proving involves: sorting out what is "Given" from what can be deduced and then organizing the conclusions that can be drawn from the "Given" into a coherent and complete argument that meets the proof goal.

The use of smartpen technology allowed us to "see" and analyze the data in ways that we would not have been able to see or do without it. For example, the active ink feature in the pencast videos allowed us to track the ways in which students marked their diagrams and how they shifted back and forth between diagram and proof. We conjecture that this kind of analysis is only the tip of the methodological iceberg in terms of what is possible to do with this and other tracking technologies. What kinds of insights into student thinking might be gained from more studies like this one, is an open but exciting question.

Acknowledgments

The authors would like to thank the teachers and their students for allowing them to conduct this research. They would also like to thank Amanda Seiwell and Kevin Felice for supporting the data analysis as well as Keith Weber for his useful suggestions on methods. DEVELOPING A FRAMEWORK FOR CHARACTERIZING STUDENT ANALOGICAL ACTIVITY IN MATHEMATICS

Michael D. Hicks
Texas State University
mh1653@txstate.edu

This report proposes a framework for describing student analogical reasoning activities in abstract algebra that moves beyond the traditional literature-based treatment of analogical mapping. The Analogical Reasoning in Mathematics (ARM) framework captures the activities that students engage in when anticipating, creating, and reasoning from mathematical analogies. This considers activities along several dimensions including: inter/intra domain activity, foregrounded/backgrounded domain, and attention to similarity/difference. These dimensions are integrated with Gentner's (1983) analogical mapping framework to characterize student activity when they are presented with tasks where reasoning by analogy can productively support their mathematical investigations. By characterizing these activities, we can better develop tasks to support students in productively analogizing between mathematical domains.

Keywords: Advanced Mathematical Thinking, Algebra, Analogical Reasoning

Throughout history, analogies have played a vital role in the development of key mathematical concepts and connections such as Descartes' recognition of the analogical similarities between algebra and geometry (Crippa, 2017). In modern mathematics instruction, analogies have been argued to be useful in developing student conceptual understanding by assisting students in utilizing prior knowledge to make sense of new contexts and develop conceptual understanding rich in connections across mathematical domains. However, unguided analogical reasoning may result in unproductive mathematical reasoning (Sidney & Alibali, 2015). By investigating the nature of students' mathematical reasoning as they develop and reason from analogies in mathematical contexts, we can begin developing support for students to productively reason by analogy.

Outside of mathematics education, Gentner (1983) introduced the Structure-Map Theory (SMT) to describe analogical reasoning as mappings across domains. In particular, this notion of mapping requires attention to similarity across domains. This type of focus is consistent with much of the theories that followed (e.g. Holyoak & Thagard, 1989). Attending to similarity is crucial for generating analogies. Surface similarities provide an access point for the generation of analogies (Holyoak & Koh, 1989). These components of analogical reasoning are shown in Figure 1 below.

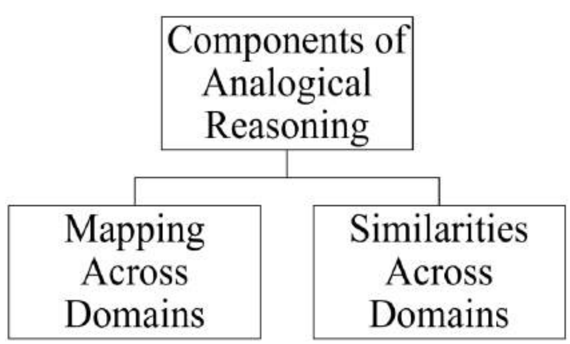

Figure 1: Components of Analogical Reasoning

Although the framework above is useful for categorizing a particular analogical mapping, there exist nuances of analogical reasoning within mathematical thinking that are not explicitly captured by

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

this framework. In this paper, I present the Analogical Reasoning in Mathematics (ARM) framework for characterizing the mathematical activity of students as they anticipate, create, and reason from analogies between mathematical domains. In particular, this framework expands upon the ubiquitous components of mapping across domains and attending to similarities, and introduces a new component of foregrounding a domain. This interpretive qualitative study seeks to contribute to answering the following research question:

What are the mathematical activities of students as they reason by analogy about structures between group theory and ring theory?

Theoretical Framing

I adopt Gentner's SMT as a foundation for developing a conceptual framework for identifying and describing analogical reasoning in mathematics. In particular, I borrow the concept of *domains* and the process of *mapping across domains* as a basis for identifying and describing analogical reasoning in mathematics. I define analogical reasoning as the act of identifying or conjecturing about a perceived correspondence between two (or more) domains. In addition, I define *analogical activity* as mathematical activity occurring within and around analogical reasoning.

A domain is a collection of knowledge held about a mathematical concept or situation. For example, one could reason specifically about the domain of two-digit addition problems, or more generally about the domain of binary operations. A key aspect of reasoning by analogy is to utilize knowledge in one domain in order to develop knowledge within another. This process occurs through mapping across domains. The domain from which knowledge originates is known as the *source domain*, while the domain to which source knowledge is being applied is the *target domain*.

I also adapt the content of mappings described by Gentner to this conceptual framework. Gentner proposed that three categories of content may be mapped between domains: objects, attributes and relations. Objects can be a single entity (e.g., a triangle), component parts of a larger object (e.g., the angles of a triangle), or coherent combinations of smaller objects (e.g., all equilateral triangles) An attribute is defined as a property or description of an object. This could include a definitional property of an object or a non-definitional descriptor of an object. Relations are properties that relate two or more objects, attributes or other relations together. A visual of these aspects in the context of an analogy between a ruler and a number line can be seen in Figure 2.

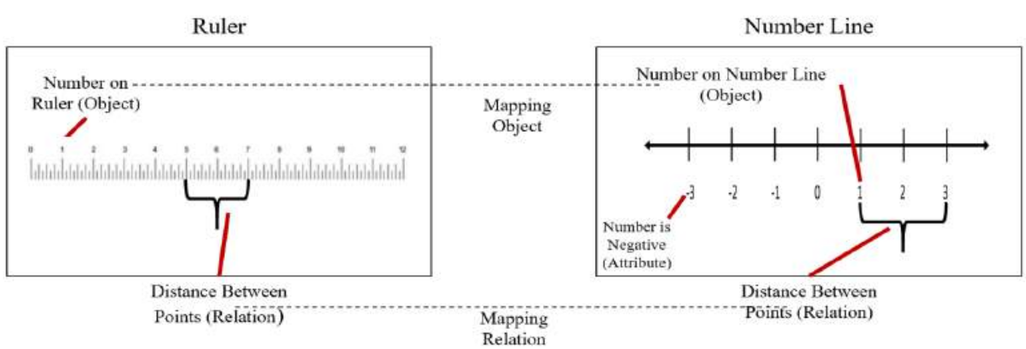

Figure 2: Mapping Between a Ruler and a Number Line

Methodology

Data Collection

The context of abstract algebra was chosen because of the existence of several naturally occurring structural similarities between group theory and ring theory. I conducted an initial pilot study with two mathematics students, one an undergraduate student in pure mathematics, and the other a graduate student pursuing a PhD in mathematics education. The participants in the present study included two undergraduate mathematics students who had previously taken a course in modern algebra emphasizing the theory of groups. Five 60-90-minute-long task-based interviews were conducted with the each participant. The initial interview helped to assess the participant's content knowledge of group theory before beginning to explore topics in ring theory. The ring interview provided the participants with the definition of ring and various tasks designed to acclimate the student to working with rings. The three subsequent interviews provided students with the analogizing task focused on reconstructing one of subrings, ring homomorphisms, or quotient rings by analogy with a structure in group theory. The interview tasks were constructed around three basic types: (1) Explicit elicitation of analogy generation, (2) example generation and checking (i.e., "give an example of a subring."), and (3) proof-writing (i.e., "Is the homomorphic image of a commutative ring commutative?") An example of a task meant to elicit explicit analogies is the following: *Make a conjecture for a structure in ring theory that is analogous to subgroups in group theory.*

Data Analysis

I used techniques outlined by Corbin and Strauss (2015) to analyze the data. First, the transcripts were segmented by identifying shifts in a particular mathematical idea or focus. Segments were identified by two criteria: (1) presence of analogical activity, and (2) shifts in mathematical focus. Each of the six interviews in which the analogizing task was given was coded for mapping activity and attending to similarity, as well as open coded for other aspects of analogical activity. Microanalysis was intermittently performed on segments when the nature of the analogical activity was unclear within a segment. Diagramming was incorporated to aid in making sense of how concepts fit together with one another. As a part of ongoing analysis, I wrote research memos to aid in explicating my thinking about concepts and generating new hypotheses. Results of microanalysis, diagramming, and memoing were regularly shared with colleagues to assist in ensuring the viability of my interpretations. Finally, the interviews focused on group theory and rings were used to help triangulate interpretations of the students' activity when possible.

From this process of coding and subsequent axial coding, two dimensions of activity related to analogical reasoning were identified in addition to the activity of mapping and attending to similarity, and one component of analogical reasoning was identified. These are each discussed at length in the following section.

Results

In this section, I share an overview of the Analogical Reasoning in Mathematics (ARM) framework with extended attention on categorizations that did not exist in the literature on analogy: intra-domain activity, and attending to differences. I then describe the component of foregrounding a domain which allows for deeper description of student mathematical activity while reasoning by analogy. Finally, I exhibit examples of mathematical activity during analogical reasoning that are characterized with the aid of the expanded framework.

The Analogical Reasoning in Mathematics (ARM) Framework

As shown in Figure 1, the literature on analogy is heavily focused upon mapping activity and attention to similarity. Within Gentner's (1983) framework, the heart of analogical reasoning is the process of mapping between domains. I refer to activity in which mapping occurs as inter-domain activity due to the nature of the activity as necessarily involving two or more domains along with activity occurring across those domains. However, there are times when a student may not engage with mapping activity. Instead, the student engages with activity that lies completely within a single domain. This category of activity is referred to as *intra-domain* activity. Intra-domain activities are those activities that operate within a single domain, either by focusing specifically on one domain, or by blending domains together. In addition, students may also attend to differences during the process of reasoning by analogy. Figure 3 exhibits the expanded framework for analogical reasoning including three components of analogical activity along with the dimensions of each component. Those marked with a '*' represent new aspects identified within the present study.

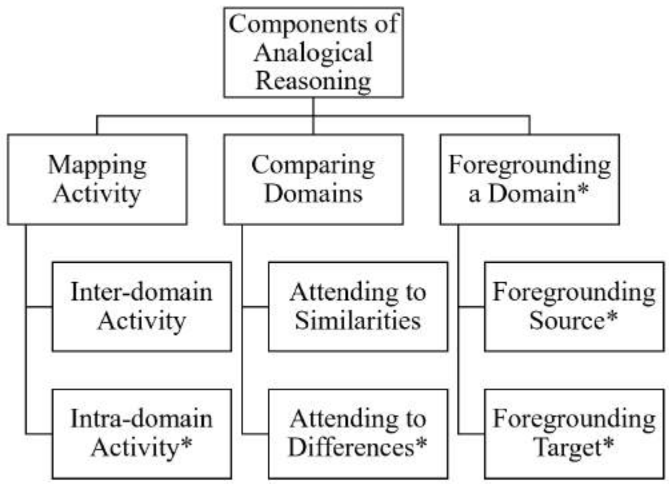

Figure 3: The ARM Framework

Foregrounding a Domain. The participants in this study were seen to place emphasis on different domains throughout the process of reasoning by analogy. This component of activity is referred to as *foregrounding a domain*. Consider the following quote from a student providing a rationale for their definition of what they call "normal subrings":

> Well I used the normal subgroup definition to apply it to normal subrings just because that act of using an operation I guess to apply it to your subring and making sure it's still and the ring itself is kind of the point of a normal subgroup so it's got to be important to use that for subrings or for normal subrings.

Within this first example, the student is justifying her definition of 'normal subring' by specifically pointing to the definition of normal subgroup and claiming that she "applied it to normal subring." The student is emphasizing the source domain as the motivation for her definition as is thus foregrounding the source domain of groups.

In contrast, consider the following exchange in which another student is reasoning about a proposed idea of normality in rings:

> Student B: I don't know. We didn't talk about normal rings, so I didn't even think about that. I don't know. Well, with rings, you do have a lot more conditions than you do with groups, so I don't think I would need this normal on my ring because that's already included in my ring. So, I don't think I would have to mess with it.
>
> Interviewer: Okay. Could you explain what you mean by that? Like you say, "It's already included in the ring."
>
> Student B: Groups have four conditions or something to be called a group, and then rings have seven of them. So, since rings have more conditions, I think being normal is already one of those conditions, in a sense.

Within the second example, the focus of the student's reasoning is on the concept of 'normal rings' to which he then draws comparisons to normal subgroups. Thus, in this second example, the student is foregrounding the *target* domain of rings.

Characterizing Activity Using the ARM Framework

Through reintegration with the widely identified dimensions of mapping activity and similarity, the dimensions of intra-domain activity and attending to differences, and the component of foregrounding domains offer insights into detailing ways in which student mathematical activity during analogical reasoning can be characterized and interpreted. In this section, I use the ARM framework to characterize several identified mathematical activities during analogical reasoning. Table 1 provides a brief overview of the activities characterized and described in this section.

Table 1: Overview of Identified Activities

Activity	Description of Activity	Dimensions of Activity
Exporting	Projecting known aspects of the source domain into the target domain.	• Inter-domain • Attending to similarities • Foregrounding source
Importing	Selectively pulling aspects of the source domain into the target domain.	• Inter-domain • Attending to similarities • Foregrounding target
Recalling	Recalling information that one possesses about the source domain.	• Intra-domain • Neither similarities or differences • Foregrounding source
Distinguishing	Recognizing an anomaly between the source and target domain.	• Inter-domain • Attending to differences • Foregrounding source
Adapting	Modifying the target to accommodate a distinction between the source and target.	• Inter-domain • Attending to differences • Foregrounding target

Exporting and Importing Across Domains. The activity of exporting across domains occurs when a student projects an aspect of the source domain over to the target domain. In contrast, importing occurs when a student selectively pulls aspects over from the source domain into the target domain. The terms "exporting" and "importing" are chosen purposefully to be analogous to the meaning of the words in the context of international trade in the sense that you export outward from the country in which you reside, but import into the country in which you reside.

Consider the following example of a student exporting attributes from the source domain of groups to the target domain of rings:

> So, normal subgroup… First condition is that H is a subgroup of G, and the second condition is that gHg^{-1} is a part of H, and then you can say, therefore, H is normal to G. So, now we're going to call this normal subring. We give this one a name. First condition is that S is a subring of R. Second condition, I don't know. Maybe we say rSr^{-1} is in S, just to copy it.

A visual of this student's work is seen in Figure 4 below. In this example, the student is constructing a definition for what they call "normal subrings." The student constructs a "normal subring" by copying over known aspects of normal subgroups into the context of ring theory.

To contrast with the activity of exporting, consider the following example from the pilot study in which a student is making a conjecture about what comes next in the study of ring theory after having developed the concept of subring:

> Like Abelian rings, or like... giving them that type of thing where you give them special names… Special types of rings, "This is the golden ring." So these, you gave me these properties on the last page. But I'm sure if you have all these properties, it's probably a special type of ring.

In this example, the student is importing the objects of “special” groups, such as Abelian groups, from the source domain into the target domain. The emphasis is on the target which is evident by the fact that the student does not immediately assume that there are Abelian rings just as there are Abelian groups. Rather, this student has discriminately chosen which aspect of group theory they wished to pull over into the target domain of rings.

Characterizing the activities of exporting and importing with respect to the components of mapping and comparing, it is clear that each of these activities are examples of inter-domain activity focused on attending to similarity. They are indistinguishable by examining these two components alone. However, a distinguishing feature can be determined by examining which domain is being foregrounded while engaging with the activity.

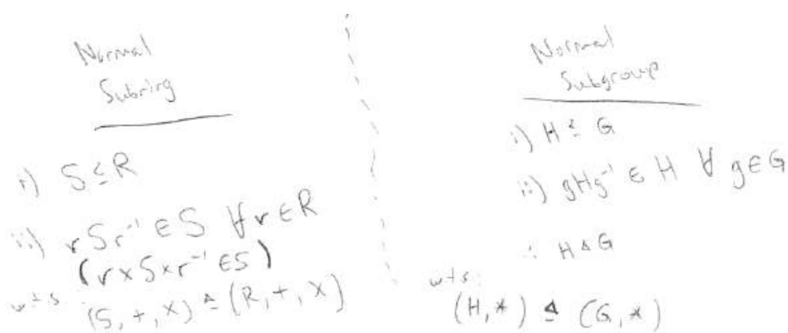

Figure 4: Student Exporting Properties from Source to Target

Recalling Source Knowledge. By expanding the component of mapping across to domains to include intra-domain activity, a greater range of mathematical activities during analogical reasoning become observable. One such activity is that of *recalling source knowledge*. Consider the following example of a student recalling attributes after being asked to make a conjecture for a structure in ring theory analogous to group homomorphisms:

> So, let me just try to recall that… So, group homomorphism. So, there exists a phi that maps from *A* to *B*. So, *A* ... or, I guess maybe it'd be easier to say phi maps from $(A,*)$ to $(B,*)$. So, phi of *a* equals some *b*.

In this case, the student is foregrounding the source and is neither attending to similarity or difference. Although the student is not explicitly engaging in reasoning by analogy in this example, the student is recalling information about the source domain with the intent of utilizing the information for the purpose of analogical reasoning. This is evidenced in the following quote from the same student in which the student exports from the source:

> So, now let's talk about ring homomorphism. Homomorphism. I don't know, I feel like it would be the same thing. There exists, let's just say psi or something from one ring to another ring such that psi is one-to-one. Or, I don't know what you say, onto.

Distinguishing and Adapting. Just as expanding the component of mapping to include intra-domain activity revealed new perspectives on analogical activity, so too does adding the dimension of attending to differences along with similarities provide new insight. One such activity is *distinguishing* between domains. Distinguishing occurs when a student recognizes an anomaly between the source and target domain. Consider the following example in which a student is making observations about the definition of ring:

> So it has ... what I noticed immediately is that, it has two binary operations addition and multiplication. Whereas with group theory we're only dealing with one binary operation at a time.

It is clear from this example that the student is attending to differences and mapping objects between the source and target domains. During distinguishing activity, the student is foregrounding the source. This is due to the nature of anomalies being detected within the target only by a direct comparison to what is already known about the source.

The attention to differences in examples such as this impacted the student's reasoning by analogy later on in the interview process through the activity of *adapting the target domain*. Adapting occurs when a student modifies the target to accommodate a distinction between the source and target. Consider the following statement from the student as they conjectured about the definition of ring homomorphism:

> What would be one for.... We have two [operations] here. Start with phi going from G to H. There's two operations here so I'm like, I don't exactly know if it should just be one of them, or both of them, or how I would do that here. Could I do like three elements, like *a*, *b*, and *c*, and then have like the addition and multiplication?

A visual of this student's work is seen in Figure 5. In this instance, the student is keying in on the difference she identified between the domains two interviews prior and attempting to adapt the homomorphism property she learned in group theory to the context of rings. Adapting activity is characterized by inter-domain activity and attending to differences. Unlike distinguishing activity, adapting activity foregrounds the target since the focus is on constructing new information within the target.

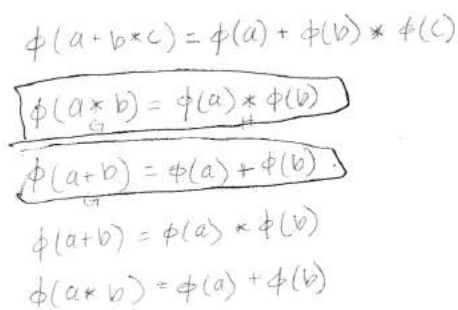

Figure 5: Student Adapting a Structure to the Target

Discussion

An Application to a K-12 Context

Although the ARM framework was developed in the context of abstract algebra, I argue the framework has utility across mathematical contexts. I use an example of students' reasoning about integer operations to illustrate the utility of the framework to capture analogical activity in other contexts. Consider the following statement in which a child is solving the problem -5 – (-3) = ☐ (Bishop et al, 2014).

> Five minus 3 is an easy fact for me. So, um, using negatives it will probably be the same thing like using normal numbers. It will probably be the same thing, but with negatives it'll probably be negative 2.

The child is mapping between the source domain of "normal" numbers and the target domain of negative integers. Because they are emphasizing their knowledge about how subtraction of positives work, they are foregrounding the source. In addition, it is clear that the child is attending to similarities (i.e., "…it will probably be the same thing…") This characterization of the child's activity allows us to see that the child is engaging in the activity of *exporting* from the source domain. To summarize this brief analysis, this child appears to be relying heavily upon their knowledge about "normal numbers" in order to understand a subtraction problem with negative numbers.

Conclusions and Implications

Analogical reasoning in mathematics provides students with the opportunity to develop their conceptual understanding in mathematics that is rich in connections across mathematical contexts (Sidney & Alibali, 2015). Within this study, students were provided the opportunity to leverage analogy and analogical reasoning to make comparisons across domains and reinvent mathematical structures by analogy. By characterizing mathematical analogizing activity, we can support students in coming to create connections across mathematical domains by providing a tool for carefully analyzing how students engage with analogical reasoning in mathematics.

For the purposes of research, the ARM framework provides a foundation for analyzing student analogical activity specific to mathematics. Thus, the framework can be used for generating insight into student's thinking involving analogical reasoning. The results in this paper have only shown a snapshot of students' analogical reasoning in an interview setting. Further research can focus on how student's leverage analogical reasoning over an extended period of time. Finally, the ARM framework and the analogical activities identified in this paper can aid instructors in developing tasks which leverage analogical reasoning by attending to the possible activities of their students while working the tasks. Future research should address ways in which to foster more productive reasoning by analogy in the context of instruction.

Jennifer Czocher
Texas State University
Czocher.1@txstate.edu

In this theoretical paper we compare the Piagetian perspective on knowledge construction to mathematical model construction, with the aim to understand how mathematical modeling enables learning of mathematics and learning of science, as is often claimed. We do this by examining data through two lenses:(i) examining the role of cognitive conflict as it arises during validation of a model and (ii) viewing model validation as a reflection on activity-effect relationship. We explain why we chose to look deeply into model validation specifically, present examples for each lens, and consider implications.

Keywords: Learning Theory, Modeling, Cognition

There has been much interest over the past few decades in the teaching and learning of mathematical modeling. Typically, investigations seek to understand the process of model construction. However, research has also looked into how learning of curricular mathematics beyond modeling may occur as students generate and validate their mathematical models (Zbiek & Connor, 2006). Taking on a Neo-Vygotskian, socio-cultural perspective, Zbiek and Connor elaborated on the cognitive processes that constitute modeling as to situate thinking about how learning takes place during mathematical modeling. In addition, empirical studies have also shown how a modeling approach to instruction may have an impact on student achievement (e.g. Czocher, 2017; Schukajlow et al, 2012). At the same time, two lines of inquiry have used mathematical modeling as an instructional paradigm to guide students' construction of mathematical knowledge. The first uses mathematical modeling tasks to teach mathematical concepts (Lesh et al., 2000) and the second uses the term model to capture the evolution of conceptual models through mathematical activity (Gravemeijer, 1999; Lesh, Doer, Carmona, & Hjlmarson, 2003). Both lines of inquiry agree that mathematics can be learned through constructing models. However, for one to know how mathematical modeling can best be leveraged to learn mathematical concepts, one first needs to understand how mathematical modeling may enable learning. In this paper, we illuminate data drawn from cognitive modeling task-based interviews using two theoretical lenses on mathematical modeling in order to elaborate how learning may enabled through mathematical modeling.

Perspective on Learning and Knowledge Construction

In order to understand how learning is occasioned through modeling we take on a Piagetian view on learning and knowledge construction. In this view, learning is considered as a process of transforming one's way of knowing and acting. According to Piaget, all construction consists of activity and all activity is goal-directed. In this sense, all construction (of cognitive structure) is goal directed (von Glasersfeld, 1983). Hence, we begin from the position that mathematical modeling is a goal-directed activity and the modeler is working towards an anticipated model as a goal. Two theories have been highlighted in the constructivist perspective as ways of learning to occur: the theory of equilibration and reflective abstraction. To support our view of modeling as a process of construction, we adapt both these views to mathematical modeling and compare their merits.

Theory of equilibration

One tenet highlighted in constructivist theory is that conceptual transformation is induced by a perturbing experience. *Perturbation* is experienced when the cognizing subject is met with a constraint or clash in the externalized world and therefore goes through adaptation to regain

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

equilibrium (absence of clashes). According to Piaget, disequilibria is stimulated by conflict, either between an individual's action schemes and external realities or among different schemes within an individual. The cognitive structure undergoes assimilation and accommodation repeatedly until it seems "fit" in the externalized world. A *scheme* is an intellectual structure that organize events as they are perceived and classified according to common characteristics. *Assimilation* is the cognitive process by which a person integrates new matter into existing schemata or patterns of behavior. Assimilation does not result in a change of schemata, but it does affect the growth and its part of the development. *Accommodation* modifies the cognitive structure (scheme) to make it "fit" the external world. According to Piaget, accommodation can happen in two ways: one can create a new scheme in which to place the new stimulus or modify an existing schema so that the stimulus fits into. Both forms of accommodation result in change in the configuration. Piaget refers to the process of assimilation and accommodation as *adaptation* (Wadsworth, 2004).

Scholars have since explored the contours of disequilibria and cognitive conflict in different ways. Limon (2001) defined cognitive conflict as something that occurs when a students' mental balance is disturbed by experiences that do not fit their current understanding. Zazkis & Chernoff (2007) stated cognitive conflict is "invoked when a learner is faced with a contradiction or inconsistency of his or her ideas" (p. 196). Berlyne (1970) elaborated cognitive conflict as "a condition in which mutually interfering processes occur simultaneously and in which selection of a motor response from a set of competing alternatives is therefore hampered" (p. 968), which is more amenable to empirical work seeking to understand it in the context of mathematics teaching and learning. Zazlavasky (2015) argued that perplexity, confusion and doubt are often associated with and evoked by cognitive conflict, suggesting that they may be used as proxies for identifying instances of cognitive conflict. Within the literature on mathematical modeling, Lesh et al (2003) identified three kinds of cognitive conflicts arise as models are constructed: within-model mismatches, model-reality mismatches, and between-model mismatches. Researchers have studied how cognitive conflict influences or changes a students' conceptual understanding (Chan, Burtis, & Bereiter, 1997; Ernest, 1996). At the same time, there is also a body of research questioning the role of cognitive conflict in the learning of a concept with evidence that cognitive conflict is only one of the many important factors contributing to learning a concept (Kang, et al., 2004; Zimmerman & Bloom, 1983).

Theory of Reflective Abstraction

The theory of equilibration only considers how a conceptual change is established when there is a presence of clashes between the cognizing subject and the stimuli. However, it is incapable of explaining how we learn during the absence of clashes. Reflective abstraction addresses this issue. Piaget's (2001) reflective abstraction is a process by which higher level mental structures could be developed from lower level structures. This is done in two phases. In the first phase, the structure at the lower developmental level is projected onto a higher level and in the second phase these structures are reorganized (Campbell,2001). Piaget (2001) acknowledged that reflective abstraction is not necessarily a conscious process.

Reflective abstraction was a significant contribution to addressing the learning paradox (Pascual-Leone, 1976) because it allows for knowledge to be constructed from already-existing knowledge. Simon and colleagues elaborated on reflective abstraction, offering a new explanation for conceptual learning in mathematics that not only addresses the learning paradox but also can contribute to the basis for the design of mathematics instruction (Simon, Tzur, Heinz, & Kinzel, 2004). The mechanism, Reflection on Activity-Effect Relationship (Ref*AER) builds on von Glaserfeld's (1995) tripartite model of a scheme: (1) recognition of a certain situation (S), (2) specific activity associated with that situation (A), and (3) the expectation that the activity produces a certain, previously experienced result or the anticipated the activity-effect relationship (A/E) (Tzur & Simon, 2004). According to Simon and colleagues, an occasion that can result in learning is present when a learner sets a goal (G). The goal is then assimilated into situations (S) that are part of the learner's existing conceptions. From the set of conceptions related to S, activities (A) are called upon to work towards the goal to which the learner anticipates the effect of these activities (A/E). While carrying out these activities, the learners' mental systems engage in continual monitoring, including distinguishing effects of the activity that advance the goals from effects that do not advance them. During the reflection, the learner identifies patterns in the outcomes and abstracts a relationship between the activity and the effect it had on reaching the goal. This abstraction results in a new activity-effect relationship. Here, activities refer to mental activities, the learners' goal are not necessarily conscious, and the effects are the assimilatory conceptions that the learner brings to the situation.

Perspective on Mathematical Model Construction

We view mathematical modeling as a goal-directed activity. To elaborate the modeling process, we appeal to the cognitive perspective on modeling (Kaiser, 2017) where a mathematical model is considered to be a cyclic process that transforms a real-world problem into a mathematical problem. From this perspective it is common to represent model construction through a mathematical modeling cycle (MMC) such as Blum & Leiß's (2007) characterization. Empirical studies have described dimensions along which a model can change as it is constructed (Czocher & Hardison, 2019) and different ways a modeler can validate her model (Czocher, 2018). Validation is a crucial part of mathematical modeling, because non-viable models are of little use for solving real-world problems. In many mathematical modeling cycles, validating occurs at the end of the process (e.g. Blum & Leiß's, 2007). However, Czocher (2018) argued that validating not only occurs when one checks the final results against the real-world phenomena, she attempted to model but in different ways throughout model construction. When a student attempts to validate her model, she holds two models in her mind: the model she is constructing and the model she anticipates constructing. As a consequence of this comparison, the modeler chooses to accept, revise, or reject the model she is constructing. In this way, validating is responsible for the iterative nature of modeling as well as ongoing monitoring (Czocher, 2018). Therefore, we conclude that since (a) the outcomes of validating lead to modifications of the model, and (b) modelers validate both their final products and monitor their evolving models, validating has a significant contribution in model construction.

For these reasons, we argue that looking deeply into model validation will lead us to understand how learning happens through modeling. To move the field forward, the paper focuses on what happens during validation that leads to the acceptance, rejection or revision of the model, specifically by looking at model validation through two related but different lenses: (1) cognitive conflicts during model validation and (2) viewing validation as a ref*AER. Informed by the review of the relevant constructs, we conceptualize cognitive conflict that arises during validating the model as a discomfort the modeler experiences due to a perceived discrepancy between the model under construction and the model she anticipates constructing. At the same time, validating can be seen as a reflection on Activity-Effect relationship. When a student engages in a modeling task, she is working towards a goal(G) of modeling a real-world situation. To reach this goal, she calls upon activities or activity sequences (A), which she had previously abstracted as having certain effects (A/E), that will help her to map her understanding of the real-world situation to a mathematical structure. While executing these activities, she then monitors the effects of these activities through the interpretation of her constructed model. Then, validation is the reflection that compares the anticipated effect to the constructed effect. As Simon and colleagues stated, "the ability to set the goal subsumes the ability judge the results" (2004, p.318).

We make the case that if cognitive conflicts and reflective abstraction contribute to the construction of knowledge, then in the mathematical modeling context, it is through model validation that cognitive conflict and ref*AER enable learning. This paper first presents an analysis using the first lens to investigate the decisions made during validation, addresses the constraints, and then presents the second lens that could address the limitations of the first.

Methods

Data for this study were drawn from a larger study of one-on-one modeling task-based interviews with undergraduate STEM majors at a large university in the United States. The students were enrolled in a semester course on differential equations. The overarching goal of the interviews were to explore and document students' mathematical reasoning during modeling. We present examples, to illustrate our case, from one student Jayden, working on the falling body problem.

> The falling body problem: On November 20, 2011, Willie Harris, 42, a man living on the west side of Austin TX died from injuries sustained after jumping from a second-floor window to escape a fire at his home. What was his impact speed?

Jayden was purposefully selected to look deeply into the mechanisms of model validation, because he employed multiple strategies to model the scenario and exhibited observable modeling mechanisms that helped us in explaining our lenses on model validation. Our primary research goal was to build second-order models (Steffe & Thompson, 2000) of his mental activities to explain the factors that shaped his decisions about revising his mathematical model (or not) as an outcome of his engagement in model validation. Since we did not have direct access to Jayden's mental activities, the second-order models are what we inferred from Jayden's observable activities including his language, verbal descriptions and discourse, written work, and on occasion gestures, when they were salient.

For our retrospective analysis of Jayden's engagement with the falling body task, we carried out five rounds of data analysis to arrive at examples that could serve for theory-building. First, we coded the interview for instances of validating, using the method of constant comparison and according to the operationalization in Czocher (2018). Next, we surveyed the validating instances for any identifiable cognitive conflicts and these instances were isolated. Third, we selected examples illustrating cognitive conflict to seek evidence of learning. Fourth, we catalogued instances of validation that failed to be instances of cognitive conflict. Fifth, we applied ref*AER to explain the failed examples. Below, we share illustrations of the third and fifth steps.

Findings

Lens 1 - Cognitive Conflicts during Model Validation

We offer two illustrations of when cognitive conflict arose for Jayden during model validation. We leverage the illustrations to explain how Jayden modified the model under construction to accommodate the anticipated model or otherwise left the conflict unresolved.

Jayden began from kinematics equations and successfully modeled the falling body situation without accounting for air resistance. He justified his choice, asserting that air resistance would be negligible "when there is either no air or no fluid to fall through, or you were infinitely close to the ground." The interviewer challenged Jayden to take air resistance into consideration. In response, he constructed a first order, linear, homogeneous equation to model the falling body. He wrote $\frac{dQ(t)}{dt} + \beta Q = 0$, where Q represented the position of the body and $\frac{dQ}{dt}$ represented its velocity. He then wrote the generic solution $Q(t) = Ce^{-\beta t}$. Jayden wrote $Q(t) = Ce^{-\lambda t}$ with the intention of figuring out "what λ has to equal". Jayden modeled the situation with the initial condition for position as $Q(0) = 0$. Later, Jayden indicated that he was not sure if the model he constructed was correct. Jayden stated, "I'm not sure if that's right, I'm not sure if there should be some sort of constant increase as you get faster". He drew two graphs showing an increasing relationship between velocity and the air resistance (figure 1). However, he was unsure which representation best matched the situation. He indicated that the linear relationship or the exponential relationship will determine if $\frac{dQ(t)}{dt} + \beta Q$ would equal zero or would equal a forcing term, respectively.

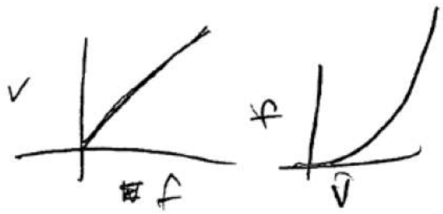

Figure 1: Students' representation of the relationships between drag force and velocity

He continued to solve the differential equation assuming the initial positions and initial velocity to be zero. He substituted the general solution $Q(t) = Ce^{-\beta t}$ in $\frac{dQ(t)}{dt} + \beta Q = 0$ and obtained the expression $\lambda Ce^0 + \beta Ce^0 = 0$ which resulted in$\lambda = -\beta$ (figure 2). He then engaged in validating the model he presented by commenting on the reasonableness of it by stating the following:

> it doesn't really tell me a whole lot because I don't know what the graph should look like. I feel like it probably equal some sort of forcing term…because I don't think that the solution would end up being…as he increases in position, I don't think it's going to be $Ce^{-\beta t}$ ... I don't think that this correctly models it.

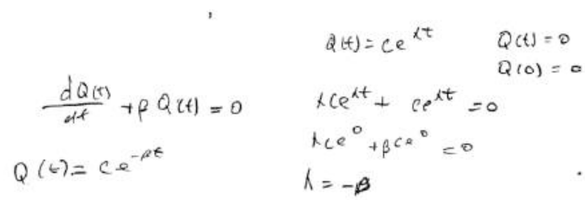

Figure 2: First order linear differential equation with initial conditions

Jayden engaged in model validation when he commented on the reasonableness of the model. Here, the model under construction is the mathematical expression based on the assumption that the velocity and force change linearly and the anticipated model is the mathematical expression based on his assumption that "as the velocity gets larger, the force might get greater and greater and greater". Jayden was experiencing a conflict between the model he constructed and the model he idealized, hence anticipated.

Jayden was able to resolve the conflict when he realized that "the wind is always just an opposing force [so] it could be treated like the force of friction." He then rejected his mathematical model by attempting a different solution that used Newton's laws of motion because they incorporated the surface area of the body and air resistance. In this episode, Jayden attended to the model under construction by modifying the assumptions that the model was based on in order to accommodate the anticipated model. We inferred, based on his sketches, that his anticipated model was his idealization (based on his real-world knowledge) that as the velocity increases the force due to air resistance should increase nonlinearly.

Next is an example where Jayden left the conflict unresolved. Assuming the presence of air resistance, Jayden modelled the falling body using Newton's laws of motion, taking into the consideration the surface area of the falling body and a coefficient to capture the influence of air resistance. He introduced the downward force that the body would experience as $F = ma,$ the air resistance as $F_{wr} = \mu_w \cdot s_a$, and the net force the body would experience as the addition of the two forces. Here μ_w is was the coefficient of air resistance and s_a was the surface area (Figure 2). However, he mentioned that the velocity should be somewhere in these equations as well. This was evidenced by the following statement he made:

> I just kind of thought of something. His velocity should be somewhere in here also. Because the faster you go the more the force will be…but I have no clue how to put that in.

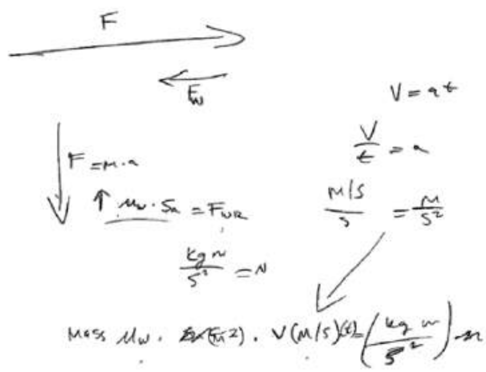

Figure 3: Student's model of the falling body including air resistance and surface area.

In order to incorporate velocity in his model Jayden performed a dimensional analysis to balance both sides of the equation in terms of units. He equated $1N = \frac{kg \cdot m}{s^2}$, to the units of $\mu_w \cdot s_a$. While performing the dimensional analysis, he decided that the surface area should not be there. He scratched out the symbol for surface area and instead added the "change in velocity for a time" of the body to the expression (Figure 3). He equated the mass of the body times the coefficient of air resistance times the "change in velocity for a time" of the body to net the force that the body would experience due to air resistance. After arriving at the aforementioned model, Jayden explained:

> Intuitively I don't think I trust that…I mean that's the answer that I reached, but I really think that has something to do with the surface area. Because this pencil will drop faster [drops his pencil from his hands] than a big piece of paper weighing the same amount…so I don't know.

In this instance, Jayden validated the model by commenting on the reasonableness of it, appealing to his lived experiences. Jayden's statement that the model was not trustworthy indicates that he experienced a cognitive conflict. In this case the model under construction was the mathematical expression he produced (without surface area) and the anticipated model was his idealized view of the world, where an object's surface areas affects its velocity through air resistance. Jayden indicated that he did not know how to rectify the dispute and therefore presented this as the final expression for wind resistance. He then discussed how he would set the force equal to $\frac{dQ(t)}{dt} + \beta Q$, obtained from earlier work, in order to find the falling man's impact speed. In this scenario, Jayden accepted his model. However, the conflict was left unresolved.

While analyzing cognitive conflicts during model validation was a useful way to look at what happened during model validation that led to the acceptance, rejection, and revisions of the model, there were limitations to it. First, taking this perspective assumes that learning during mathematical modeling only occurs during the rejection or/and revision of the model. This is not necessarily true. Learning could also happen when one is satisfied with the model and accepts it because accepting the model may also have transformed the modelers way of knowing and acting about the model. This perspective ignores this case. Second, not all validating instances coincide with instances of cognitive conflict. Therefore, it is necessary to explain such instances where model validation is present, but conflict is not. The second lens of looking at validating was drawn upon to address some of these limitations.

Lens 2 – Validation as a Ref*AER

The following is an example of model validation which could not be explained through the first lens, can now be explained by viewing validating as a Ref*AER. Recall the scenario where Jayden modelled the falling body with air resistance with the expression $\frac{dQ(t)}{dt} + \beta Q = 0$ and initial values $Q(0) = 0$. While considering the initial conditions to solve the differential equation, Jayden stated:

> I'm just trying to think what initial conditions I need to use. I guess I'll have to just say… $Q(0) = 0$ because his position is 0. But I guess it will be better if I said that this was [pause] let's see [long pause] … I guess this is fine [pointing at $Q(0) = 0$].

Jayden validated his model through evaluating the reasonableness of the initial condition $Q(0) = 0$. However, he was not experiencing a conflict because there was no evidence for a discrepancy between the model under construction and the anticipated model. When Jayden stated "I'm just trying to think what initial conditions I need to use" we take that as an indication of him recalling the activities that would lead him to the desired effect and filtering the ones that would not. Here the goal is to solve the differential equation (G), the activity is drawing on the appropriate initial condition (A), and the effect is what comes out of solving the differential equation using the selected initial condition (E). Jayden first considered the initial condition $Q(0) = 0$, and next he considered whether they would advance him toward his desired goal. This is evident when he said, "But I guess it will be better if I said that this was…" Through reflecting, Jayden ultimately conformed to his initial choice $Q(0) = 0$, and therefore accepted his model. In this instance, Jayden was continuously monitoring and reflecting on the effect of selecting $Q(0) = 0$ as the initial condition would have towards reaching his ultimate goal.

The following is an example where Jayden rejected his model, which can also be explained using the Ref*AER lens. Jayden's initial approach was to draw from the equations of motion from mechanics. To find the impact speed of the falling body, Jayden wrote the equation $s = ut + \frac{1}{2}at^2$, where s is the distance the body travelled, u is the initial velocity, a is the acceleration due to gravity, and t is the time it took to travel a distance s. As soon as he realized that the equation contains the time of fall t, Jayden scratched out the expression and resorted to $v^2 - u^2 = 2as$. The reason being the first expression required the time of fall, which was not given in the task. This was an instance of validation because he scratched out the first expression and attempted a different solution. However, there was no evidence of conflict. In this instance, the goal for Jayden was to find the impact speed without using the time of fall (G). He stated, "I could find the time of fall, but it's not necessary". His activity (A) was selecting $v^2 - u^2 = 2as$ over $s = ut + \frac{1}{2}at^2$ through cataloguing existing equations and reflecting on the effect they had in reaching the desired outcome (E). As a result of validating, he rejected his initial expression and selected another one to meet his desired effect.

Discussion & Conclusions

This study investigated the mechanisms of model validation through two lenses: (i) looking at cognitive conflicts that arise due to the discrepancy between the model under construction and the anticipated model, and (ii) viewing model validation as a reflection on activity-effect relationship. Our analysis offers insight into potential mechanisms for model construction and suggests a strong link between model construction and Piagetian explanations of knowledge construction. Studying the nature of cognitive conflicts students experience while engaging in mathematical modeling and viewing model validation as Ref*AER may be an avenue towards elaborating how learning occurs through mathematical modeling because it may inform us about how students make decisions about the viability of their models.

Given the preceding analysis, we close with two considerations: limitations and future directions. This study only informs us how learning may be enabled through mathematical modeling and is not capable to inform us on what was learned. At the same time, the paper does not discuss the explicit treatment of the two lenses and how they can be leveraged to analyze the mechanism of model construction, yet. Future analysis will investigate this. In order to understand what was learned through modeling, instances of validating will be analyzed closely, using the lenses presented in this paper, to see the following: why do modelers chose to accept, revise, and reject the models? how do they do so? and in what ways? However, this theoretical paper outlines the extent to which these learning theories are applicable to mathematical modeling. This we believe is a significant contribution as it sets us open to understanding what is it that is being learned through mathematical modeling. These mechanisms can then be leveraged to develop instructional theory that fosters mathematical conceptual learning through mathematical modeling.

In this report, we present how one prospective elementary teacher (PT) engaged in the Ant Farm Task, which we designed to investigate PTs' reasoning about coordinate systems. We highlight the cognitive resources the PT drew upon in solving the task via the establishment of a Cartesian coordination and consider educational implications.

Keywords: Geometry and Geometrical and Spatial Thinking, Representations and Visualization, Modeling, Coordinate System

From fifth grade onward, students and their teachers are often expected to represent and reason about various mathematical concepts (e.g., geometrical shapes, functions, etc.) using the Cartesian plane. However, coordinate systems are often taken for granted; meaning, students are assumed to develop proficiency in using this representational tool in relatively unproblematic ways, and teachers are assumed to have developed understandings of coordinate systems capable of supporting their students' mathematical activity. Additionally, textbooks and curricular standards (e.g., CCSSM) describe how to draw and use a Cartesian plane but rarely provide motivation for establishing a Cartesian coordination. Generally, the rules of "generating" a Cartesian plane are given with minimal explanation for *why* we construct it in such a way or *why* using an ordered pair of numbers locates a point. In this report, we present how one prospective elementary teacher (PT) engaged in the Ant Farm Task (AFT), a task we found helpful in motivating a Cartesian coordination. We highlight the cognitive resources the PT drew upon in solving the task via establishing a Cartesian coordination and consider educational implications of the task and our findings.

Theoretical Framing

By *coordinate system* we mean a representational space in which an individual systematically coordinates quantities (Thompson, 2011) to organize some phenomenon. A coordinate system does not represent by itself; it must be created and interpreted by a cognizing subject (cf., von Glasersfeld, 1987). Put differently, we consider coordinate systems to be constructed by an individual in goal-directed activity. Relatedly, we have distinguished between two types of coordinate systems depending on the goal they serve: spatial and quantitative (Lee, Hardison, & Paoletti, 2020).

Spatial coordinate systems are used to quantitatively organize a space in which a phenomenon is situated. Constructing a spatial coordinate system involves (mentally) overlaying a coordinate system onto some physical or imagined space being represented and tagging objects within that space with coordinates. For example, consider a Cartesian plane overlaid onto an amusement park from a bird's eye view where the axes are aligned with two streets in the park. On the other hand, quantitative coordinate systems are used to coordinate sets of quantities by constructing a geometrical representation of the product of measure spaces. Constructing a quantitative coordinate system involves an individual extracting quantities from the space in which a phenomenon occurs and projecting them onto a new space, different from the space in which the quantities were originally conceived. For example, imagine a Cartesian plane with one axis representing the amount of wait time for a ride in the amusement park and the other axis representing the number of people in line for that ride.

Both coordinate system types involve coordinating quantities. Our use of *spatial* and *quantitative* as modifiers is intended to foreground the different mental actions involved in establishing a coordination of quantities in each type of coordinate system. We use the Cartesian plane as an example to illustrate this distinction. When constructing a *spatial* Cartesian plane, an individual starts with a space they want to organize. In order to quantitatively describe the location of objects or points within this space, the individual can establish a reference point and orthogonal lines through the reference point and use these frames of reference to describe each point's location in terms of its horizontal and vertical distance from the reference point. In other words, the individual can establish a Cartesian coordination via decomposing the location of a point along two orthogonal lines in relation to a reference point (see Figure 1a). In this case, the point's location is conceived of as a logical multiplication (Piaget et al., 1960) of the horizontal and vertical displacement from the reference point.

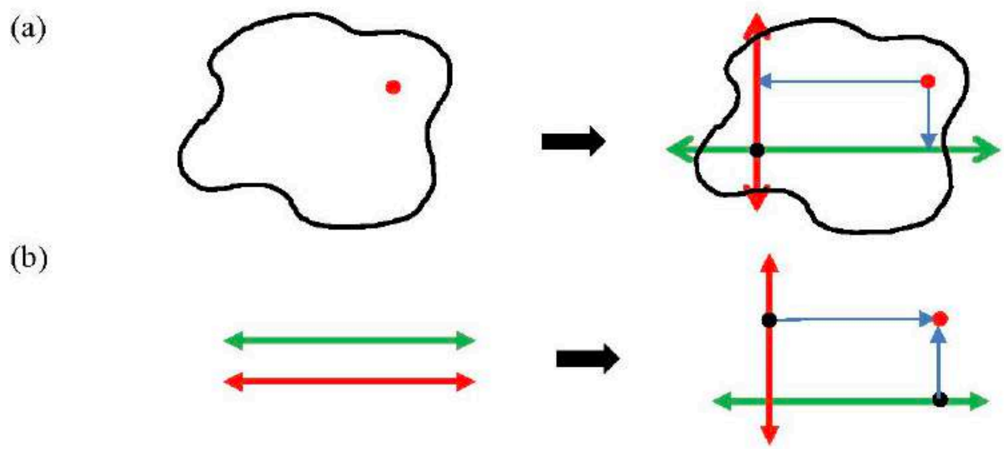

Figure 1: Model of the operations involved in establishing (a) a spatial Cartesian coordination and (b) a quantitative Cartesian coordination

In contrast, when constructing a *quantitative* Cartesian plane, an individual starts with two quantities they have disembedded (Steffe & Olive, 2010) from the space in which a phenomenon occurs (i.e., the individual has extracted them from the situation while maintaining an awareness of the quantities within the situation). Overlaying the quantities onto two number lines, and arranging the number lines orthogonally, the individual can produce a two-dimensional space, different from where the quantities were originally conceived. Finally, a point is constructed as the intersection of the perpendicular projections from each point/quantity on each number line (see Figure 1b) and a quantitative Cartesian coordination is established. In this case, the point is conceived of as a multiplicative object holding both quantities' values simultaneously (Saldanha & Thompson, 1998).

Students' Cartesian Coordinations in Literature

Several studies provide insights into students' Cartesian-like coordinations described above in graphing contexts. For example, Nemirovsky and Tierney (2004) presented a situation to Rose, an eight-year-old, in which blocks were added to or taken away from a paper bag over time. Rose was asked to show how the number of blocks in the paper bag changed over time using a line marked with Start and End. Rose produced a curve (Figure 2a) to represent the change in quantity over time.

This example shows a child spontaneously using the space above the line to show change in quantities over time. DiSessa et al. (1991) and Sherin (2000) presented a scenario describing the motion of a motorist over time to middle and high school students and asked them to produce a picture describing the motorist's motion. In solving this task, students tended to use a horizontal line representing the road and made marks such as dots and line segments to represent quantities (e.g., speed). Gradually, the horizontal line transformed into a number line representing time and some students produced a graph such as that in Figure 2b to describe the motorist's speed over time. This example demonstrates how middle and high school students utilized the vertical distance from a horizontal line to represent change in speed over time. Collectively, these examples illustrate how students, starting with a horizontal line, can use a vertical dimension to represent change in quantities over time and hence construct Cartesian-like systems. However, they do not explain how students might establish a Cartesian coordination starting with two (number) lines.

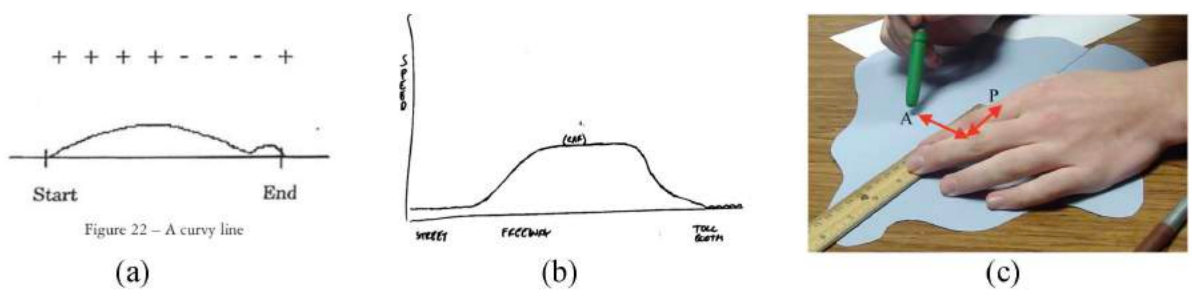

Figure 2: Two examples: (a) Rose's "time line" representation in Nemirovsky & Tierney (2004), p. 42 (b) Carl's representation in Sherin (2000), p. 432

In her previous work with four ninth-graders, Lee (2017) examined students' constructions of spatial coordinate systems and observed students establishing a spatial Cartesian coordination. For example, when asked to locate a missing person (point *A*) in reference to a rescuer (*P*) on a map, one ninth-grader described the location of *A* in relation to *P* by decomposing the straight motion from *P* to *A* into a horizontal and vertical movement from P to A (see Figure 2c). After observing students' constructions of spatial coordinate systems, we were motivated to explore how students might leverage their ways of coordinating spatially in order to coordinate quantitatively via the AFT (Lee & Hardison, 2016; 2017). The findings we present in this report extend the literature base by (a) examining PTs' constructions of coordinate systems which can inform educational support for PTs, which are scarcely documented and (b) identifying the cognitive resources that may be leveraged to engender a spontaneous Cartesian coordination starting with two (number) lines.

The Ant Farm Task

In previous work, we have hypothesized that spatial coordinations necessarily precede quantitative coordinations (Lee & Hardison, 2017). We designed the AFT as a possible way of bridging these two types of coordinations. In contrast to the above tasks, we designed the AFT to (a) be entirely situated in a spatial context in which PTs could leverage their spatial coordination, (b) start with two given lines, and (c) have the potential for engendering some of the mental actions involved in establishing a quantitative coordination. In the AFT, PTs were provided with two transparent tubes representing two ant farms (Figure 3a) and asked to imagine that each contained exactly one giant ant moving around haphazardly. Additionally, we provided a model of this situation in a dynamic geometry environment (DGE; Figure 3b); the DGE sketch contained two long, thin rectangles (ant farms), each containing a point (ant) moving haphazardly. The points' movement could be paused/activated by action buttons, and the rectangles could be moved or rotated within the DGE. Given this scenario and the DGE sketch, we asked PTs, “Can you make a single point to show the locations of both ants at any moment in time?” Following this prompt was an explanation that if we were to hide both ants, they should be able to use their new point to determine the location of the two hidden ants. We presented the spatial situation without referencing any quantities explicitly (e.g., an ant’s distance from the end of the tube). One possible solution to the AFT involves establishing a conventional Cartesian coordination. Through the AFT, we investigated (a) how PTs might modify their ways of coordinating spatially to coordinate quantitatively and (b) what cognitive resources PTs draw upon when constructing a two-dimensional coordinate system from two one-dimensional lines.

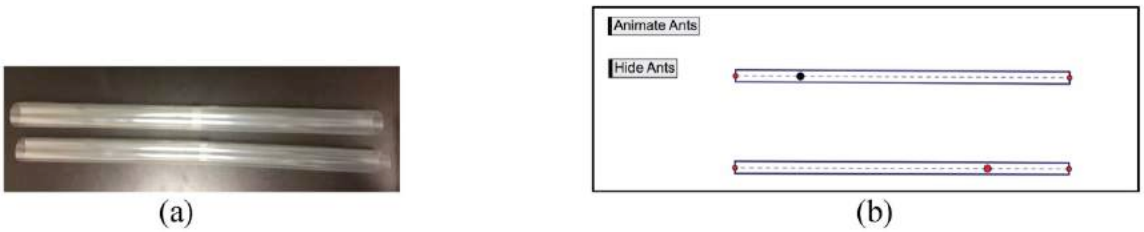

Figure 3: Ant Farm Task (a) plastic tubes representing the ant farms and (b) accompanying dynamic geometry environment sketch.

Methods

We draw on data from a teaching experiment (Steffe & Thompson, 2000) with four PTs. The overarching goal of the teaching experiment was to investigate how PTs construct and reason about coordinate systems, as well as how PTs’ ways of thinking changed throughout the teaching experiment. All four PTs were enrolled in an elementary or middle grades teacher preparation program at a university in the southern U.S. PTs participated in eight 60-minute long teaching sessions, which were conducted individually or in pairs. In this report, we present and analyze data from one teaching session wherein one PT, Ginny, and her partner, Hermione, solved the AFT. We focus our analyses on Ginny with occasional remarks regarding Hermione as appropriate. We focus specifically on Ginny because her solution to the AFT contained features common to other PTs’ activities on the task and a unique feature—introducing number lines.

Data Sources and Analysis Methods

Investigating PTs’ mathematical thinking, which is not directly accessible, requires making inferences from PTs’ observable activities. Therefore, the models of Ginny’s thinking we build are second-order models (Steffe & Thompson, 2000) of what we infer from her visual illustrations, verbal descriptions, and physical gestures. For each teaching episode, we collected video recordings of PTs’ actions, a screen recording of PTs’ activities in the DGE, and digitized written work.

We conducted both on-going and retrospective analyses and modeled PTs’ constructive activities (Steffe & Thompson, 2000). On-going analyses involved testing and formulating hypotheses during the teaching experiment based on ways PTs engaged in each teaching episode. We inferred, from PTs’ engagement, instances that corroborated or contraindicated our hypotheses. After the completion of the teaching experiment, we re-visited the data corpus to do an in-depth retrospective analysis. The retrospective analysis involved four main activities that collectively refined the initial explanatory models developed during the teaching experiment. The four activities were (a) watching the entire video set or subsets of the video holistically without interruption to observe recurring patterns in PTs’ activities or shifts in their reasoning, (b) identifying instances that offered insights in building working models of the recurring patterns or shifts in their reasoning, (c) constructing annotated transcripts of such instances with rich descriptions of PTs’ actions, and (d) constructing/refining explanatory models of PTs' constructions of coordinate systems. Specific to the AFT, we analyzed the cognitive resources PTs drew upon when constructing a two-dimensional system from two one-dimensional lines.

Findings

We present our findings regarding Ginny's reasoning about the AFT in four phases. We highlight Ginny's activities in each phase and analyze the cognitive resources that supported her in establishing a Cartesian coordination.

Attending to Variability and Locational Simultaneity by Superimposition

When first posed with the prompt in the AFT, Ginny reiterated the problem, asking, "So, we need to make one point *while they're moving* to show where they are while *they're moving*? *At any point in time*?" to which her partner Hermione added, "I think it's hard because they're moving around a lot." We took these initial comments to indicate that both PTs were attending to, and perturbed by, two things: variability in the ants' locations and locational simultaneity required in the desired single point.

Ginny and Hermione proposed some ideas to address these elements. For instance, Hermione suggested using the mid-points of each tube, since "the ants always pass the middle." However, both PTs noticed that the ants were not always at the middle of each tube. Instead, Ginny superimposed the tubes in various ways to observe where the ants crossed each other. Specifically, Ginny aligned the two ant farm rectangles on top of each other in the DGE so that one rectangle was perfectly overlaid onto another and animated the ants. Next, she observed instances where the ant points occupied the same location at the same time. She identified three such points and claimed that one of those could be used as the desired point. However, Ginny acknowledged that these three points do not capture all of the possible ants' locations.

Seeking alternative solutions, Ginny joined the ends of the two plastic tubes, making the two tubes into one long tube, and explained, "You know both of the ants are on the same path. In the direct center, I guess that would be the one point to describe where they both are," as she drew a circle and point in the circle's center. As such, Ginny assumed the ants were moving in the center of each tube and, taking a cross-sectional view, identified one point as a projection of both ants in each tube.

From her activities, we infer that superimposing and attending to the intersection of the two points was a way for Ginny to account for locational simultaneity. When she superimposed one tube onto another, she accounted for locational simultaneity for three different instances in time; when she superimposed the tubes by joining their ends, she accounted for simultaneity for all instances in time, but from a different perspective. Although these points did not indicate where the ants were in each tube, Ginny demonstrated flexibility in taking different perspectives in viewing the ants and tubes. Collectively, Ginny's activities indicated that she viewed the tubes as objects she could manipulate and rearrange to serve her goal; they were not fixed objects, which we viewed as a critical cognitive resource in her thinking.

Establishing the Single Point as Being Dynamic

Approximately 20 minutes into the session, Ginny placed the tubes in the DGE perpendicularly (see Figure 4a) and explained she wanted to see if the ants met in the middle, where the tubes intersected. With the ants animated in the DGE, Ginny and Hermione observed that the ants crossed each other at the middle, but Ginny was unsure how to proceed: "I still don't think [we can come up with just one point] because they're never, they're not always in the same place at the same time." Wondering if the PTs conceived of the desired point as being static, the teacher-researcher (TR) asked, "So, what if somehow that point might move appropriately with the ants?" To which Hermione expressed, "So, you're saying the point can move now?" Hermione's response suggested she had interpreted the initial prompt as requesting a static desired point and she was now considering whether the desired point could be dynamic. Although this interaction was occasioned by the TR, we view this interaction as critical because the PTs established the desired point as potentially being dynamic.

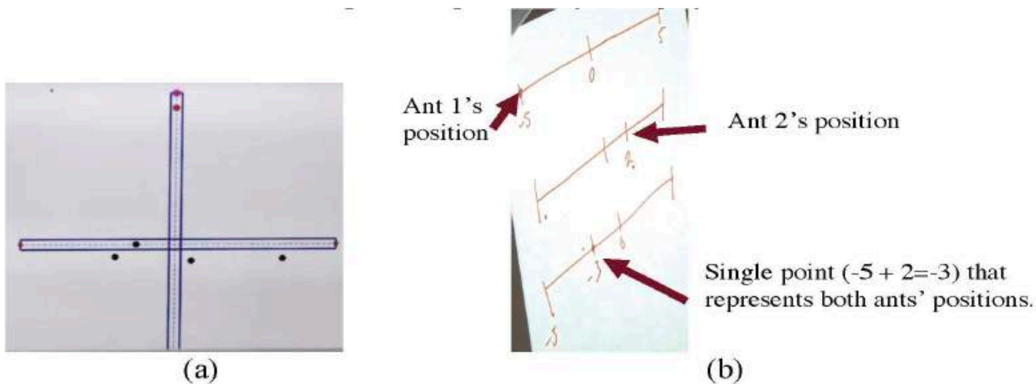

Figure 4: (a) Tubes arranged perpendicularly in the DGE and (b) Ginny's three number lines.

Using Number Lines

Approximately 30 minutes into the session, Ginny proposed a new idea: "What if we made the edges of the tubes a number line and the middle of the tube zero. So this [*pointing to the left side of a tube*] would be the negative side and this [*pointing to the right side of the same tube*] would be the positive side and this [*pointing to the center of the tube*] would be zero." Next, Ginny drew three number lines as shown in Figure 4b, explaining that the first and second number line each represented the ant's location in Tube 1 and Tube 2, respectively. Picking two locations as examples, she explained that if Ant 1 is at –5 and Ant 2 is at 2, then the single point –3 on the third number line, obtained by adding –5 and 2, should represent both ants' positions. When asked what the third number line was, Ginny explained, "[It is] corresponding to where the point is on, it would be I guess both of the tubes." As such, instead of superimposing one ant farm onto the other, Ginny created a third object to account for locational simultaneity.

Up to this point, we hypothesized that Ginny overlaid a number line onto each tube, and thus constructed a one-dimensional spatial coordinate system. Relatedly, there were two hypotheses to be tested: (a) whether Ginny's number lines were viewed as number lines superimposed onto the spatial situation, and (b) whether the numbers on her number lines were conceived of as distances (e.g., from the edge of the tube) or numerical values labeling each ants' location.

In Ginny's three number line representation (Figure 4(b)), although simultaneity was accounted for, the variability of the ants' positions yielded a non-unique point on the third number line. Relatedly, the TR asked, "what if Ant 1 is at –4 and Ant 2 is at 1?" Almost immediately, Ginny drew two perpendicular lines and explained, "So, if we had a graph and we do... negative five and then two, this point right here [*plotting the point in Figure 5a*] would describe where they are. So, instead of doing the adding them together you would graph it on a graph." She further explained that the point she plotted showed that the black ant is at 2 and the red ant is at –5. At this point, the two tubes in the DGE placed in front of the PTs were positioned perpendicularly (like in Figure 4a). We account for the sudden shift in her thinking to (a) Ginny's attention to locational simultaneity and attempting to capture both ants' locations and (b) recalling her previous graphing experience from the image on the DGE.

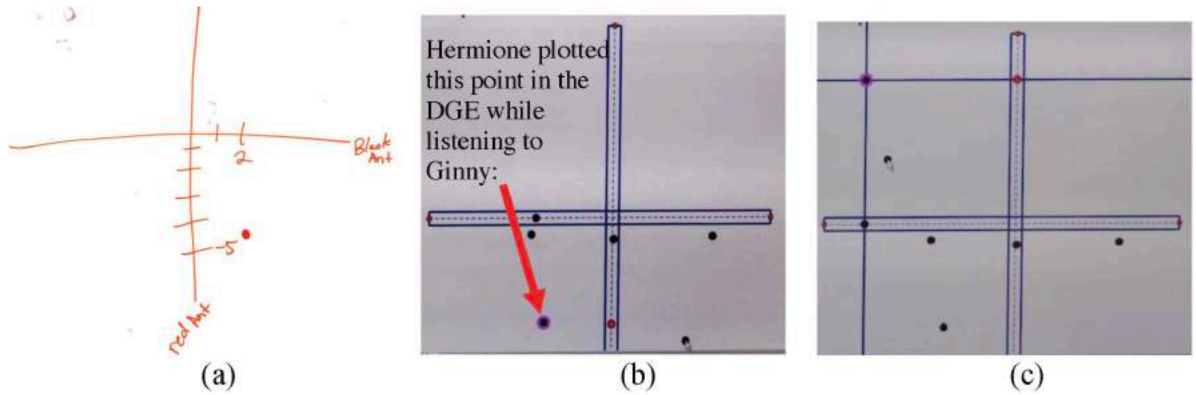

Figure 5: (a) Ginny's drawing of number lines arranged perpendicularly; (b) Hermione's point in the DGE; (c) Ginny's construction of the single point.

While Ginny was showing her new solution for finding the desired point, Hermione plotted the point shown in Figure 5b in the DGE and asked Ginny if the point she plotted would be the single point. Ginny explained "So, this [*pointing to her drawing in Figure 5a*] would be a totally different graph... so you'd get information from where the ants are on the number line on the tube. Then you would graph it on a different paper. So, it's not like a point on these [*pointing to the plastic tubes*] it's like a point on this [*pointing to her paper*].

Ginny's explanation in response to Hermione's question indicated Ginny has constructed number lines, disembedded from the Ant Farm situation, and arranged them to produce a different space from the original Ant Farm space. Thus, we inferred she constructed a quantitative coordinate system with her number lines in the sense that she viewed her "graph" as a space different from the space in which the number lines were initially conceived. Also, by the way she explained "getting information from where the ants are on the number line on the tube," we inferred her number lines consisted of numerical values indicating location in reference to the middle of the tube and that her number lines were not yet spatial coordinate systems superimposed onto the spatial situation.

Establishing the Cartesian Coordination

Noticing Ginny's differentiation between her "graph" and the ant farm space, approximately 35 minutes into the session, the TR commented, "I'm curious, so it sounds like you see this as a different space from that space, is what it sounds like." Ginny responded, "Yeah, I mean, I guess you can make it the same space but..." and sat in thought looking back and forth at the DGE screen and her sketch in Figure 5a for approximately 7 seconds. She then continued, "I guess you *could* make it the same space because...if put a number line on this," pointing to the ant farm tubes in the DGE. Pointing to each ant farm tube in the DGE, Ginny further explained, "So this [*referring to the horizontally placed tube*] would be your x and your y [*pointing to the vertically arranged tube*] of your graph and your dots [*referring to the ants*] would be your values and you just need to connect them to make your point [*moving her fingers in the air consistent with the blue arrows in Figure 1b*]."

Finally, Ginny constructed a line through Ant 1, perpendicular to Tube 1, and a line through Ant 2, perpendicular to Tube 2 and indicated that the intersection of the two lines would show the location of both ants in each tube (Figure 5c). After the TR hid the two perpendicular lines, both PTs verified their new method worked by considering several positions of ants by hiding the ants, animating the single point, guessing where the ants should be within each tube, and then checking the ants' locations. When the TR asked why they think this method works in general, Ginny explained that by placing the tubes perpendicularly, a horizontal line can be used to describe the red ant moving vertically and a vertical line to describe the black ant moving horizontally. In conclusion, Ginny established a Cartesian coordination leveraging her spatial coordinations.

Conclusion and Discussion

From Ginny's activities in the AFT, we highlight three cognitive resources we see as critical for establishing a Cartesian coordination given two lines that would enable holding a sustained image of two locations simultaneously for arbitrary positions of points on each line. First, Ginny's *attention to variability in the ants' locations* coupled with *imagining the single point as moving along with the two ants* was a critical development during the teaching session. Second, Ginny *recognized the tubes (or number lines) as objects that could be manipulated and rearranged* which supported her to arrange them in a particular way (e.g., perpendicularly) so that the locations of each ant could be accounted for simultaneously. Third, *drawing from her spatial coordinations*, Ginny utilized the two-dimensional space outside of the one-dimensional tubes spaces to construct a point outside of the tubes (or number lines). Specifically, she projected vertically from the horizontal tube in which the ant moved horizontally and projected horizontally from the vertical tube in which the ant moved vertically. Supported by these cognitive activities, Ginny successfully constructed a single point that simultaneously captured the location of both ants.

For Ginny and Hermione, devising a system to coordinate the location of two points using a single point appeared novel, meaning that establishing a Cartesian coordination by rearranging lines orthogonally and projecting from the two lines was non-trivial despite their prior school experiences. Recall that although Ginny eventually constructed a system she called a "graph," she initially viewed it as different from the ant farm space. We suspect this was due to her past experiences with coordinate systems focused predominantly on quantitative coordinate systems. Thus, viewing the Ant Farm space as a space analogous to her coordinated number line space was an additional critical realization for Ginny in solving the AFT.

Given the preceding findings, we close with two considerations: one limitation and one direction for further study. First, the wording of the initial AFT prompt may have hindered PTs from viewing the single point as being dynamic; therefore, variations of the prompt might be considered in future implementations. Second, the cognitive resources presented here that foster the establishment of a Cartesian coordination may be specific to Ginny and the AFT, which require further research with more PTs. Future research can also look into what engendered Ginny's transition from one phase to another (e.g., TR moves) and how these can be leveraged to support PTs and consequently their future students' constructions of coordinate systems.

PROSPECTIVE K-8 TEACHERS' PROBLEM POSING: INTERPRETATIONS OF TASKS THAT PROMOTE MATHEMATICAL ARGUMENTATION

Marta T. Magiera
Marquette University
marta.magiera@marquette.edu

This study examines pre-service teachers' (PSTs') views of tasks that engage students in mathematical argumentation. Data were collected in two different mathematics courses for elementary school education majors (n = 51 total PSTs). Analyzed were (a) written journals in which PSTs defined tasks that promote student engagement in argumentation, (b) tasks PSTs posed to engage students in mathematical argumentation, and (c) accompanying explanations in which PSTs motivated tasks they posed. The analysis revealed that PSTs interpret tasks that foster argumentation in terms of activities of argumentation that a task elicits and space for argumentation that the task provides. Several features that PSTs associated with each of the two major task characteristics were identified. While posing tasks to engage students in argumentation, PSTs did not place equal emphasis on all of the identified features.

Keywords: Reasoning and Proof, Mathematical Knowledge for Teaching, Teacher Education-Pre-service.

Background

Curricular standards in mathematics recognize mathematical argumentation as an essential disciplinary practice with which all students should engage and become proficient (e.g., National Governors Association Center for Best Practices and Council of Chief State School Officers [CCSSM], 2010; National Council of Teachers of Mathematics [NCTM], 2000). Engaging students in constructing viable arguments and critiquing the reasoning of others is the desired instructional goal (CCSSM, 2010). Past research on argumentation shows, however, that contrary to curricular recommendations and recognized importance of argumentation in student learning, teaching mathematics with a focus on argumentation is still far from a common practice (e.g., Bieda 2010; Staples, Bartlo, Thanhaiser, 2012).

Past research with practicing (and pre-service teachers, PSTs) documented challenges that teachers face while facilitating argumentation in their classrooms (e.g., Bieda 2010; Kosko, Rougee, & Herbst, 2014), explored the role of the teacher in promoting argumentation (e.g., Aylon & Even, 2016; Conner, Singlertary, Smith, Wagner, Francisco, 2014; Graham & Lesseig, 2018), and explored how teachers interpret argumentation in the context of mathematics classrooms (e.g., Park & Magiera, 2019). While overall, the research interest in argumentation is growing, research attention to teachers' views of tasks that promote student engagement in mathematical argumentation has been limited.

Researchers agree that tasks play an essential role in how students experience mathematics (Krainer, 1993; Simon & Tzur, 2004; Zaslavsky, 2008). However, research on curricular materials reveals that school mathematics textbooks, even textbooks designed to support mathematics curriculum reforms, offer limited collections of tasks that, by their inherent design, provide opportunities for engaging students in argumentation (e.g., Bieda, Ji, Drwencke, & Pickard, 2013; Dolev & Even; 2015; Stacey & Vincent, 2009). Understanding how teachers interpret tasks that engage students in argumentation could help gauge students' opportunities for experiencing argumentation in mathematics classrooms. Research-based information about teachers' views of tasks that engage students in mathematical argumentation can also aid the efforts of helping teachers develop a more comprehensive knowledge of argumentation. Thus, in a bid to address these existing gaps, this study uses problem-posing as a context for exploring elementary PSTs' views of mathematical tasks that engage students in the practice of argumentation. This research was guided by the following question: *What characteristics of tasks that promote mathematical argumentation emerge from the analysis of problems PSTs' pose to build students' capacities in mathematical argumentation, and PSTs' descriptions of problems that engage students in argumentation?*

Conceptual Framework

Problem Posing

Problem-posing, which includes designing new and modifying existing tasks, is recognized as an essential element of mathematical activity (Silver, 1994). Teachers' ability to design and pose mathematical tasks is one of the central aspects of mathematics teaching (Krainer, 1993; NCTM, 2000). Classroom problems provide students with the opportunity for thinking and learning (Smith & Stein, 1998). Thus problem-posing is perceived as integral to teaching a "high leverage" practice, a gateway to understanding that serves as a learning and instructional tool (Ball & Forzani, 2009). While posing problems, teachers go beyond thinking about problem-solution, they need to consider the overall goal of the task, think about what and how students can make sense of the mathematics they learn, and what understandings, skills, and attitudes they develop (Crespo, 2015; Lavy & Shriki, 2007; NCTM, 1991). Researchers recognize that the activity of problem-posing can provide a window into an understanding of teachers' mathematical and pedagogical content knowledge (Ellerton 2015; Lee, Capraro, & Capraro, 2018).

Mathematical Argumentation

Toulmin, Rieke, and Janik (1984) described argumentation broadly as "the whole activity of making claims, challenging them, backing them up by producing reasons, criticizing those reasons, rebutting those criticisms, and so on" (p. 14). This description is consistent with the notion of argumentation presented in the Standard for Mathematical Practice #3 (CCSSM, 2010). Mathematics education researchers generally agree that in school mathematics, argumentation involves a wide range of activities. These activities include constructing, validating, or refuting mathematical claims, producing and criticizing justifications, formulating conjectures, generalizing, representing mathematical ideas, constructing counterexamples, or communicating reasons, to name some. (e.g., Lakatos, 1976; Knudsen, Lara-Meloy, Stevens, & Rutstein, 2014; Krummheuer, 1995; Ramsey & Langrall, 2016). The existing frameworks that guide the examination of textbook tasks for their affordances of engaging students in argumentation (e.g., Bieda et al., 2014; Stylianides, 2009) classify the kinds of argumentation-related activities elicited by the task. Given that the focus of this research was on PSTs' interpretations of tasks that engage students in argumentation, not on the implementation of classroom tasks to engage students in argumentation, Toulmin et al. (1984) broad description of argumentation together with frameworks proposed to classify the types of argumentation-related activities elicited by written tasks provided an attractive guide for this study. They allowed negotiating a wide range of meanings that PSTs bring while thinking about tasks that engage students in argumentation and to place argumentation within the individual and social space a task might create for student engagement in argumentation.

Method

Participants and Study Context

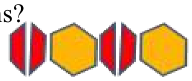
The study was conducted in the Midwestern university in the U.S. Participants were 51 PSTs preparing to teach grades 1-8 mathematics enrolled in two mathematics content and concurrent pedagogy with field experience set of courses for elementary education majors. The two pairs of courses were *Number Systems and Operations for Elementary School Teachers* and *Teaching Elementary School Mathematics* (n = 23) and *Algebra and Geometry for Teachers* and *Teaching Middle School Mathematics* (n = 28). Curricula of each set of courses were coordinated. In the context of their mathematics courses, PSTs studied concepts fundamental to the K-8 mathematics and engaged in mathematical argumentation as learners. In their corresponding pedagogy with field experience courses, they focused on teaching strategies that support students learning of K-8 mathematics and support students' mathematical reasoning skills. They conducted focused observations in their field placement classrooms to identify teacher moves, instructional strategies, and classroom interactions that supported student reasoning. In the context of their education and field experience work PSTs also prepared and conducted two problem-based interviews with students for the purpose of engaging students in the practice of mathematical argumentation and learning about student mathematical thinking.

Data and Data Analysis

Collected in the Number Systems and Operations for Elementary School Teachers course were (a) written journals in which each PST described tasks that engage students in argumentation, (b) two tasks each PST posed (one at a time) in preparation for their interviews of elementary school students, and (c) explanations in which each PST described why task they posed creates an environment for student engagement in argumentation.

Collected in the Algebra and Geometry for Teachers course were: (a) written journals in which each PSTs described tasks that engage students in argumentation, (b) PSTs' analyses and critiques of three instructor-provided tasks (completed one at a time) in which they discussed each task's potential to engage students in argumentation, and (c) revisions of instructor-provided tasks PSTs' proposed to enhance each task's potential to engage students in argumentation and PSTs' explanations for each revision. Instructor-provided tasks that provided context for PSTs' problem-posing activity are shown in Figure 1.

Task 1: How many red pattern blocks will be used if the pattern of figures is extended until there is a total of 13 polygons?



Task 2: Kay made summer lemonade from a mix using l2 tablespoons of lemonade mix and 20 cups of water. How many tablespoons of lemonade mix will she need if she plans to use 30 cups of water to make lemonade that tastes just the same?

Task 3: Below is a growing sequence of figures.

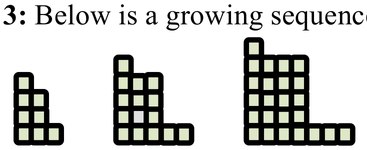


Fig 2 Fig 3 Fig 4

a) Draw the 1st, 5th, and 6th figures
b) How is the pattern changing?
c) What would the 100th figure look like? How many tiles it has? How can you justify your prediction?

Figure 1: Instructor-provided Tasks that PSTs Analyzed and Revised

Qualitative analytical-inductive methods were used for data analysis. In the first round of the analysis, a large subset of all data (about 25%) that consisted of all types of artifacts was first carefully annotated to discern PSTs' perceptions of tasks that engage students in argumentation. The goal was to create a code-book that could reliably capture task characteristics identified across PSTs' definitions, tasks they posed (designed or revised), journals in which they described why tasks they posed could engage students in argumentation, or interviews during which they discussed their tasks. To illustrate the coding process, consider included in Figure 2 task that PST A44 posed together with explanation PST A44 provided about her task. Following the initial round of the analysis, the annotations were further compared and contrasted, and their descriptions revised to formulate a final set of codes that were then applied to the entire corpus of data. If any new task characteristics were identified during this process, new codes were introduced, and the code-book was augmented. The final list of codes was further compared and contrasted until no new task characteristics were identified. In the final stage of analysis, all codes were again compared and contrasted, leading to the identification of two major task characteristics. Task features identified across each PST's responses were then tabulated to identify the overall patters in PSTs' interpretations of tasks that facilitate student engagement in mathematical argumentation.

PST A44's Task 1 (task posed)	Annotations
Kim has 5,372 songs on iTunes. She deletes 438 songs. How many songs does she have on iTunes now? A student solves this problem by subtracting the thousands, hundreds, tens, and one's from 5,372 by 438. Then she adds the sum of each number place together to get the final answer of 4,934 songs. Does this strategy work? Why or why not? Can this strategy work for any subtraction problem? Use examples to explain your reasoning. 	Call for justification of a strategy (Does this strategy work? Why or why not?) Call for evaluating reasoning of others Call for generalization (Can this strategy work for any subtraction problem?) Call for communicating thinking, reasoning (Use examples to explain your reasoning)
PST A44's Explanation about Task 1	Annotations
This task takes a simple subtraction problem and turns it into an engaging mathematical problem for the student. The student must understand how this subtraction problem was solved by someone else using what I assume will be a method that is different from how the student traditionally solves a subtraction problem. The task asks several questions of the student to clarify that they understand how the problem was solved and help them build upon their argumentation of how they got the solution and how it works. The task can be applied to other example problems to help the student with their understanding of the subtraction strategy and to help them explain their mathematical reasoning. I think the most likely problem that could occur is that the student may not fully grasp or understand the technique given to solve the subtraction problem. They may not get the idea of subtracting the place value or may struggle with the negative numbers that show up in this problem because they are not used to working with negatives in a standard subtraction problem. Lastly, it might be the wording of the problem, that stumps the student. However, with a little help, I do think that most sixth graders can absolutely understand this technique and argue how it works. The main math skill required to understand this task is place value and sixth graders should certainly have a strong understanding of this concept.	Task is engaging Task engages in evaluating the reasoning of others Task engages in generalizing Task is non-routine, requires deeper thinking, challenging Task builds on student existing knowledge, understanding

Figure 2: Example of Task Posed and Task Explanation (PST A44, Task 1)

Results

Table 1 summarizes the characteristics of tasks identified across PSTs' responses. The analysis revealed that while posing tasks to engage students in argumentation, PSTs considered (a) activities of argumentation in which students could engage given their task and (b) space for argumentation that their task provides. Overall across the analyzed tasks, task explanations, and PSTs' definitions of tasks that engage students in argumentation, individual PSTs included between 2 to 11 different task features.

Table 1: PSTs' views about tasks that promote mathematical argumentation

Major Task Characteristics	Task Features	(*n*, %*)
Activities of Argumentation	Task promotes providing justifications	48 (94%)
	Task encourages making generalizations	34 (67%)
	Task elicits explorations, generating conjectures, evidence, and claims	31 (61%)
	Task promotes evaluating arguments or reasoning of others	28 (55%)
Space for Argumentation	Task elicits communicating thinking and reasoning	47 (92%)
	Task enables the use of multiple solution strategies and ways of thinking	36 (71 %)
	Task draws on students' existing knowledge and allows them to make connections	34 (67%)
	Task engages in deeper thinking, is complex	33 (65%)
	Task supports the use of multiple representations, manipulative materials to guide thinking	31 (61%)
	Task requires that students reflect and make sense of their results	20 (39%)
	Task fosters the development of concepts	14 (27%)

* Rounded to the nearest %.

Activities of argumentation. As summarized in Table 1, PSTs associated argumentation with a broad range of activities in which a student could engage in the context of posed tasks. These activities, categorized as task features, were emphasized across the analyzed data to a different degree. For example, while almost all PSTs (94%), in at least one of their tasks, included an explicit call for justifying a result, claim or strategy, only about half of the participants (55%) designed tasks that would engage students in evaluating arguments or reasoning of others. About two-thirds of PSTs (67%) formulated tasks that engaged students in generalizing, and a little less than two-thirds of PSTs (61%) formulated tasks that encouraged explorations, generating conjectures, evidence, and claims.

Consider the presented earlier task posed by PST A44 (Figure 2). By its design, this task engages a student in evaluating the validity of a given strategy. The task statement requires that a student justifies his or her strategy assessment. The task also elicits thinking about the strategy generality by prompting the student to reason about whether or not the presented strategy can be applied to other subtraction problems. Consider also the following task which PST A15 posed modifying the instructor-provided Task 1 (Figure 1): "How many red pattern blocks will be used if the pattern is extended until there are 200 polygons? Justify your response." PST A15's task also includes an explicit call for justification. The intention to engage a student in generalizing was evident is explanation PST A15 included. PST A15 described her thinking about this task modification and her desire to engage a student in thinking about pattern generalization and exploring and developing a general conjecture about the pattern sharing:

> I increased the number of polygons in order to prevent the student from merely counting the blocks. Increasing the number requires that the student finds a general rule or equation. They can investigate the relationship between the blocks. I also asked the student to justify it. (PST A15, Task 1)

Space for argumentation. This category of task characteristics describes ways in which the PSTs thought about and designed their tasks to create an environment for student engagement in argumentation. As summarized in Table1, PSTs varied in approaches they used to generate a context for student engagement in argumentation within their tasks. For example, almost all PSTs (92%) designed tasks, so the task elicited communicating thinking and reasoning. A large group of PSTs (71%) described and proposed tasks that were open to diverse ways of thinking and solution strategies. The focus on the latter task feature is illustrated with the excerpts below:

> Mathematical tasks that foster argumentation must be challenging., directional, often have more than one specific answer and can be represented in multiple ways (PST A44)

> Flexibility is also very important in fostering mathematical argumentation. Understanding that there are multiple ways to view a problem or multiple solutions that could be found is important because it allows students to challenge ideas and use evidence to prove why their answer is efficient. (PST B17)

About a two-thirds of PSTs, (67%), thought about opportunities their task might give students for drawing on students' existing knowledge and making connections, for engaging in deeper thinking (65%), or for supporting student thinking by encouraging them to use multiple representations or manipulative materials (61%). For example, PST A23 shared:

> Using manipulatives in tasks helps students reason and make claims. When students are able to visualize and make structure of their work, they better understand the problem and are able to make and justify claims. (PST A23)

In contrast, only 39% of PSTs considered tasks that require students to reflect and make sense of their results as one that can engage students in argumentation, and only 27% of PSTs envisioned that tasks that facilitate concept development might engage students in argumentation. An excerpt from PST A18's journal presented below illustrates the former task feature:

> Tasks should encourage students to go back to their own work. A student should see if they used evidence or showed enough work to support their explanation. Are the equations and tables labeled? Can everything be proved? Tasks [that encourage reflection] can help and improve students' skills in making, justifying, and evaluating mathematical claims. (PST A18)

Presented below task posed by PST A2, together with accompanying task explanation, serve as an illustration of PSTs' thinking about how a task that provides space for concept development can engage students in argumentation. PST A2 shared:

> The mathematical task I designed is a word problem that will require students to think about multiplication- this task is designed for a third-grade student. Example task: Sue invited 8 friends to her birthday party. She was making goodie bags for each of her friends. If she puts 5 pieces of candy in each bag how many total pieces of candy does she need? Justify your answer.

While motivating her task PST A2 wrote:

> Mathematical argumentation requires a student to not only explain how they arrived at their answer but to think about the mathematical ideas, concepts, theories, and reasoning that are used in the problem. This task presents students with a fundamental multiplication property – equal-sized groups and repeated addition. Multiplication can be viewed as repeated addition of equal-sized groups. With this task, the student will be exposed to this idea because the task is asking them to find the total pieces of candy when there are 8 groups (bags of candy) with 5 pieces each (candy pieces). […] One potential error I could see with this problem is a student potentially grouping 8 pieces of candy 5 times. If this were to happen, this would still result in the correct solution of 40 and would be a great opportunity to talk about the commutative property of multiplication.

Summary and Discussion

This study contributes to the research on argumentation in school mathematics in two ways. First, it extends the existing analytical models for engagement in mathematical argumentation, which emphasize the structural or cognitive aspects of argumentation (e.g. types of arguments being generated, or degree of justification) and provide a framework that can serve as a guide for the design of tasks that support student engagement in argumentation. Second, it offers insights into PSTs' understanding of mathematical argumentation by describing the kinds of opportunities for argumentation that PSTs envision as they pose tasks to engage students in argumentation.

The analysis revealed that while posing written tasks and thinking about task affordances for engaging students in argumentation, PST considered (a) activities of argumentation in which a student might be involved while working on the task and (b) the space for argumentation that the task generates. PSTs viewed both of these task characteristics as contributing to the overall potential of the task for building students' capacities in argumentation. This finding extends previous conceptual frameworks for analyzing the potential of written tasks for engaging students in argumentation, which exclusively focused on the types of activities of argumentation that task elicits (Bieda et al., 2014; Stacey & Vincent, 2009; Stylianides, 2009).

The results also document task features related to the two identified major task characteristics and show that PSTs do not equally emphasize these features while designing tasks to engage students in argumentation. For example, concerning the activities of argumentation, almost all PSTs in this study posed tasks that elicited justifying. A large proportion of PSTs formulated tasks that promoted conjecturing and generalizing, but tasks that engaged students in evaluating arguments and reasoning of others were posed less frequently. PSTs' choices of task features identified as representative of the space of argumentation posed tasks afforded also varied. For example, the results suggest that PSTs might be more likely to associate opportunities for mathematical argumentation with tasks that elicit communicating thinking and reasoning, or tasks that allow for divergent ways of thinking and solution strategies. About two-thirds of PSTs in this study considered also task complexity, the extent to which task allows students to build on their prior knowledge and make connections, or facilitates the use of multiple representations as a viable task environment that offers space for engaging students in argumentation. Less frequently, PSTs envisioned that tasks that promote concept development or elicit students' reflections on their thinking might provide space for argumentation.

The results of this study provide important insights for mathematics teacher educators about supporting PSTs' visions of argumentation in mathematics classrooms. For example, it is likely that without intentional efforts focused on heightening PSTs' awareness of tasks that engage students in analyzing and critiquing the reasoning of others, PSTs might limit students' opportunities for experiencing this aspect of argumentation. Particularly, because, as reported by Bieda and colleges (2014) in their review of several elementary school textbooks in the U.S., tasks designed to engage students in evaluating claims were rarely present within the elementary school textbooks. This study did not examine how PSTs' envision classroom implementation of tasks for the purpose of engaging students in argumentation. To generate a more robust picture of PSTs' knowledge in the area of mathematical argumentation future research should investigate PSTs' interpretations of tasks that engage students in argumentation and the nature of opportunities for engaging students in argumentation PSTs see in classroom tasks, with concurrent attention to PSTs' visions of task implementation.

In this paper we present the results of an investigation related to the developing of mathematical knowledge and skills by first semester university students when solving a Model Eliciting Activity [MEA] which involves quadratic function knowledge. This was a qualitative research. The theoretical framework was Models and Modeling Perspective [MMP]. The results show that the students used their mathematical knowledge and skills related to linear and quadratic functions to describe the situation; they moved from a quantitative cycle of understanding (associated with linear and quadratic behaviors), to an algebraic cycle of understanding (associated with quadratic behaviors).

Keywords: Modeling, problem solving, university level.

Learning the concept of function has been studied by several researchers (Gutiérrez and Prieto, 2015; Hernández, 2013; Oviedo, 2013). Why is so important to learn the concept of function? López, Navarro and Fuchs (2018) answer that it is a necessary knowledge to model events and phenomena in different professional areas. Villarraga (2012) describes, for example, the type of situations that can be modelled using the quadratic function such as: optimization problems related to cost, demand, and areas, or physical problems. Despite the importance of understanding the quadratic function, difficulties have been identified in its learning, such as the poor articulation between algebraic and graphic representations (Díaz, Haye, Montenegro and Córdoba, 2013) needed to describe situations and phenomena.

Several authors (Gutiérrez and Prieto, 2015; Hernández, 2013; Oviedo, 2013) have created proposals to address the learning of the quadratic function. However, many of the proposals are reduced to the manipulation of parameters of algebraic expressions and the study of the transformations in the corresponding graph. Little research addresses the development of mathematical knowledge and skills associated with the quadratic function in the context of problem solving or modeling situations close to real life. One of the studies carried out in this direction was that of Aliprantis and Carmona (2003). They used the Models and Modelling Perspective framework (Lesh, 2010) to design and implement an activity to promote the development of knowledge of the quadratic function and associated concepts, such as variables, the relationship among them (quadratic and linear), the product of linear relationships, and the maximization; as well as to encourage students to develop skills for modeling and problem solving, such as conjecture, argument, description, and explanation. The participants in this study were high school students.

The research described in this paper has been carried out with students from the first university semester. The goal was to promote the development of mathematical knowledge and skills associated with the quadratic function during the process of solving situations close to real life. The research question is: What knowledge and skills do first-semester college students exhibit when performing an MEA in which the concept of quadratic function underlies?

(2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

Theoretical Framework

Learning mathematics, according to MMP (Lesh and Doerr, 2003), is based on the construction of models, which

> are conceptual systems (consisting of elements, relations, operations, and rules governing interactions) that are expressed using external notation systems, and that are used to construct, describe, or explain the behaviors of other system(s)—perhaps so that the other system can be manipulated or predicted intelligently. (Lesh and Doerr, 2003, p. 10).

These models can be internal and external, that is, they inhabit both the thinking of students and the equations, schemes, computer applications or other representational resources used by science experts or schoolchildren (Lesh and Doerr, 2003). Models can be created by carrying out Model Eliciting Activities (MEAs), which are simulations of "real life" situations. In carrying out MEAs, students go through iterative sequences where they express, test, and revise their own ways of thinking (Lesh and Caylor, 2007). During the knowledge development process students build and modify their models through the phases of differentiation and refinement of the conceptual systems they construct (Lesh and Doerr, 2003).

MEAs "involve sharable, manipulatable, modifiable, and reusable conceptual tools (e.g., models) for constructing, describing, explaining, manipulating, predicting, or controlling mathematically significant systems" (Lesh and Doerr, 2003, p. 3). Researchers mention that such descriptions, explanations, and constructions should not be considered as simple processes that students create to get 'the answer', but they are key elements in the learning process. Thus, the process is the product.

MEAs "involve mathematizing—by quantifying, dimensionalizing, coordinatizing, categorizing, algebratizing, and systematizing relevant objects, relationships, actions, patterns, and regularities" (Lesh and Doerr, 2003, p. 5). One feature that distinguishes MEAs from other problem-solving activities is the writing of a letter. In the letter, students must explain the method they used to find the solution to the problem; this method can be used by a client to solve other problems with similar characteristics.

Methodology

The methodology was qualitative. The MEA (Figure 1) whose results are described in this paper, is part of a didactical sequence (Lesh, Cramer, Doerr, Post and Zawojewski, 2003) designed during the research project. It was implemented in a two-hour session with a group of 12 undergraduate students, who were 18 years old. Students were organized in four teams of three members each. The participants had a laptop and Excel and GeoGebra software. The process of solving the problem was carried out in four phases. 1) students read an informative article related to the context of the problem (warm-up activity according to the MMP). 2) they read the problem (Figure 1) and worked as a team to solve it. 3) They presented their results in a plenary discussion. 4) Students solved the problem individually at home. In this paper, the results of the phase 2 are presented, based on the discussions generated during the plenary (phase 3). The data were obtained from the worksheets, Word, Excel and GeoGebra files, and from video recordings of the face-to-face session. The concepts associated with this activity are those mentioned before (Aliprantis and Carmona, 2003).

Students in the last semester of Mechanical Electrical Engineering at the University of Guadalajara's Centro Universitario de Ciencias Exactas e Ingenierías (CUCEI) want to organize a trip to the Mazamitla Cabins to raise funds to celebrate their graduation.

For this purpose, the University will lend them a bus with capacity for 49 passengers, so that the cost of the round trip from CUCEI (diesel and driver's fees) and the tours inside the magic town will be covered. In addition, Carlos, a partner of the students, has taken on the task of searching on the Internet for accommodation and activities in order to organize a tourist package and be able to offer a complete experience to the travelers who attend the tour.

The tourist package includes: accommodation for three days and two nights in a cozy cabin located in La Cañada; a tour of the Sierra del Tigre, with a guide; ice cream factory and tasting of typical products; a ride on a four-wheel-drive vehicle through the most striking places in the sierra. Also, for those who like adrenaline, the zipline, climbing wall, hanging bridges and gotcha are included.

Carlos budgeted the cost of $1300.00 for each tour package per traveler. But, in order to make a profit, he will offer it at a price of $3650.00. To encourage potential travelers, Carlos proposes to make a discount of $50 for each person who goes, except if only one goes. That is, if two people go, they get a $50 discount; if there are three, there is a $100 discount per passenger.

Help Carlos. Write him a letter explaining whether and how much organizing the trip will allow him to make a profit. Support your statements with clear and valid arguments.

Figure 1: MEA

Data analysis was based on two criteria: quantitative and algebraic cycles of understanding (Vargas, Reyes & Cristóbal, 2016). The quantitative cycle of understanding is one in which students are able to describe the variables and relations among them in a numerical way. The information and relationships can be organized in tables and graphs. In the Algebraic cycle of understanding, students exhibit some mastery of the language of algebra to solve the problem. Those who reach this last cycle have gone through different stages of differentiation, integration, and refinement of their conceptual systems and have a deeper domain of the representations. During each of the cycles, verbal representation was present to justify the conjectures and explanations.

Results

Students went through two cycles of understanding (Table 1). The first cycle was quantitative and the second one was algebraic. At the beginning, four teams (100% of the total) revealed a way of thinking related to linear variation (column 2, Table 1) during the quantitative cycle. Then, students from teams 1, 2 and 3 (75% of teams) moved from their procedures characterized by linear to a quadratic variation (column 3, Table 1). Only the members of the teams 1 and 2 extended their ways of thinking into an algebraic cycle of understanding. A detailed description is shown below.

Table 1: Student’s cycles of understanding to solve the MEA

	Cycle of understanding			Result	
	Quantitative		Algebraic	Correct	Incorrect
	Linear	Quadratic	Quadratic		
E1	✓	✓	✓		✓
E2	✓	✓	✓	✓	
E3	✓	✓		✓	
E4	✓				✓

First Cycle of Understanding: Quantitative

All the students identified the data: capacity of the bus, cost of the journey, initial price, and the discount. They also realized that they needed to write a letter that included the procedure for solving the problem. Two ways of addressing the situation in this cycle were distinguished: linear and quadratic behavior.

Linear behaviour. All the students calculated the value of the profit corresponding to the maximum number of passengers, i.e. 49 persons. Students' conjecture was that the more passengers, the greater profit, which denotes linear thinking. Two procedures were distinguished, one in which the profit per passenger was obtained, exhibited by teams 1, 2 and 3, and another in which the profit per group was obtained, realized by team 4. The procedures are discussed below.

Procedure to obtain the profit when 49 passengers travel (maximum capacity of the bus)

Procedure: profit per passenger. The procedure of the teams 1, 2 and 3 (75% of teams) was to subtract the corresponding discount for 49 passengers from the initial price, i.e. they carried out the operation: 3650-2400. The result (1250) was reduced by the cost of the trip, i.e. 1250-1300. Students interpreted this quantity (-50) as the profit per passenger. However, because the amount was negative, they expressed that it was a loss of $50 per person. Thus, $2450 would be the loss corresponding to the trip of 49 passengers, as shown in Figure 2.

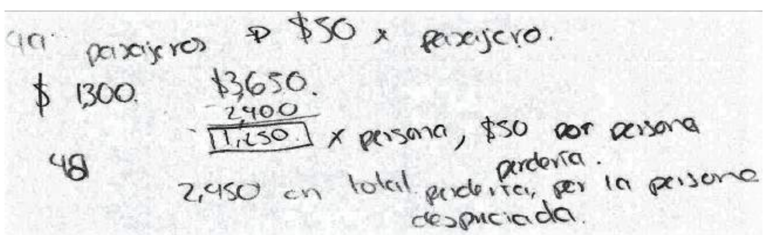

Figure 2: Operations carried out by Team 1 to obtain the Profit related to 49 Passengers. Procedure: Profit per passenger

Procedure to obtain the profit corresponding to 49 passengers (maximum capacity of the bus). Procedure: profit per group. Students of team 4 used the spreadsheet to operate with the cost of the trip, the maximum passenger capacity and the initial price, i.e., $1300, 49, and $3650, respectively (cells D6, E6 and D10 in Figure 3). They related these data using formulas (Table 2) to calculate the discount, the expenditure, the income related to the initial price, the income related to the discounted price, and the profit corresponding 49 passengers.

	A	B	C	D	E	F	G	H
1	2	50						
2	3	100		SUMATORIA DE LOS DESCUENTOS				
3	4	150			117600			
4	5	200						
5	6	250		PRECIO TOTAL DEL VIAJE				
6	7	300		$1,300	49			
7	8	350			63700			
8	9	400						
9	10	450		COBRO TOTAL		178850		
10	11	500		$3,650	61250			
11	12	550						
12	13	600						
13	14	650		GANANCIAS TOTALES				
14	15	700			-2450	COMO PODEMOS OBSERVAR ES UNA		
15	16	750				CANTIDAD NEGATIVA, POR TANTO SE		
16	17	800				PERDERIA ESE DINERO		

Figure 3: Procedure to obtain the profit corresponding to 49 Passengers by Team 4. Procedure: profit per group

Table 2: Formulas Used by Team 4

Cell	Formula
E3	=(B48*A48)
E7	=(D6*E6)
E10	=(D10*E6)-E3
E14	=(E10-E7)
F9	=(D10*E6)

Quadratic behavior. The members of teams 1, 2 and 3 (75% of the teams) made several operations using different amounts of passengers and analyzed how the results varied. Students from teams 1 and 2 (50%) used trial and error procedure, in a disorganized way. Students from team 3 (25%) performed a systematized procedure. Team 4 (25%) was the only team that did not perform many operations.

Trial and error procedure. Students from teams 1 and 2 (50% of the total) performed operations with different quantities of passengers. This allowed the students from team 1 to identify how income varied and to find out for what quantity of passengers a maximum income was produced (Figure 4). In turn, the students from team 2 identified in a more organized way how the profit varied and found the quantity of passengers that corresponded to the maximum profit.

Figure 4 shows the procedure developed by the team 1, as a representative example of the teams 1 and 2 procedures. Students calculated the income corresponding to 24, 28, 37, 36 and 38 passengers. However, they believed that they were finding the profit. They noted that there was a dependency relationship involving the number of passengers; they expressed that "the profit depends on the passengers".

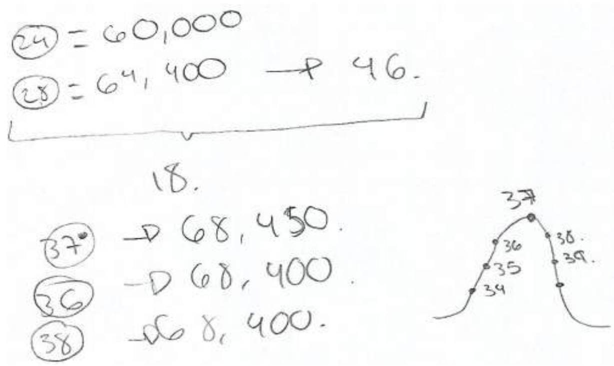

Figure 4: Procedure to obtain the Income and to analyze the Variation for Different Amounts of Passengers by the Team 1

Figure 4 shows how students made a graph that describes the way in which the income varies. Students noticed that an "income maximum value" or "peak" was obtained when they made operations with 37 passengers. They did not identify an interval where the function was increasing or decreasing. They pointed out that, from the maximum value (37), the income corresponding to 36 and 38 passengers "goes down the same", in the same way they mentioned that "35 and 39 have the same [corresponding income value]".

Exploration of results by systematized test. Students from team 3 constructed a table (Figure 5) with the labels: "Passengers", "Price per passenger", "Discount per passenger" and "Total Profit". They related the amounts of each row in a horizontal way, and obtained the profit, according to the quantity of passengers. They identified that the maximum profit, $28800, is obtained when 24 passengers are traveling. Figure 5 shows part of the table created by team 3.

Relación de clientes/ganancias

Pasajeros	Precio p/p	Descuento p/p	Ganancia total
1	$3650	0	2350
2	$3600	50	4600
3	$3550	100	6750
4	$3500	150	8800
5	$3450	200	10750
6	$3400	250	12600
7	$3350	300	14350
8	$3300	350	16000
9	$3250	400	17550
10	$3200	450	19000

Figure 5: Team 3 Procedure (passengers, price per person, discount per person, total profit)

Algebraic Cycle of Understanding

Students of teams 1 and 2 (50% of teams) generalized patterns. Students from team 3 (25% of the total) constructed syncopated expressions to perform the calculation. Students from team 4 (25%) did not generalize.

Generalization of patterns through algebraic expression. Figure 6 shows the expression obtained by the students of team 1 to calculate the profit. It is not identified as a function by the students, but as a formula. The quantities 3650 and 50 represent the initial price and the discount per person, respectively. The value 63700 is the result of multiplying 1300*49, that is, the cost per person multiplied by 49. Therefore, 63700 is the expenditure when attending the maximum passenger capacity.

The corresponding expenditure of n passengers would be $1300n$. The correct expression was $(3650-(n-1)*50)n-1300n)$. The algebraic model that the students had to construct to calculate the profit was $f(x)=-50x^2+2400x$, in its simplest form, where x represents the number of assistants.

(3650- (n-1)*50)n-63700

*Sea "n" el número de personas que asistan

Figure 6: Algebraic Expression of Team 1 for Calculating the profit

These students used the GeoGebra software to identify the number of passengers corresponding to the maximum profit. They found that 37 passengers were needed to produce a maximum value of 4750 (Figure 7). However, according to the problem data, the correct values were 24 passengers and $28800.

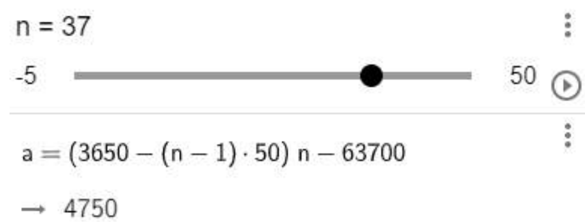

Figure 7: Team 1 procedure to obtain the maximum profit.

Generalization of patterns in a syncopated way. Students from team 3 (25% in the group) generalized their procedure relationships through natural language and mathematical symbols (Figure 8).

Número de personas -1 x 50 = Descuento por persona

Precio base(3650) - Descuento - Costo(1300) = Ganancia por persona

Ganancia por persona x N de personas = Ganancia total

Figure 8: Generalization of Patterns to obtain the profit by Team 3.

Plenary Discussion

During the plenary session the students presented their letters and discussed their results. Students from team 4, based on their letter, showed how they calculated the profit. They were challenged by the rest of the teams with questions such as "What if there were 10", "How many would have to attend so that I could earn a lot of money". Students from teams 2 and 3 mentioned that 24 passengers were needed to get a maximum profit of $28800. In the letters they wrote this result, however, they did not explain the method they used to find the solution so they did not develop a shareable and reusable model (Lesh and Doerr, 2003). Students from team 1 told their classmates that they "discovered a formula by trial and error". They wrote in the letter the quantities corresponding to the maximum profit (according to their expression), as well as the expression itself. In other words, they not only mentioned how many passengers were needed to obtain a maximum profit, but also presented the client with a shareable and reusable tool with which they could know the profit for any number of passengers. However, they also did not explain how they found their procedure.

Conclusions

What knowledge and skills do first-semester college students exhibit when performing an MEA in which the concept of quadratic function underlies? Students exhibited the knowledge mentioned by Aliprantis and Carmona (2003): variable recognition, variation, linear relation and quadratic relation, maximum. They were able to identify the data of the problem and relate them to obtain new data. The relationships were expressed verbally and in writing, through operations on paper and formulas in Excel. Regarding mathematical skills, they used trial and error procedures, and built tables and graphs to analyze the variation of quantities. They identified a maximum value denoted as "peak", "mountain" or "bell curve" in the graphical form as the maximum profit. Students were able to generate conjectures (associate profit with linear behavior), describe and explain the situation, and finally, evaluate their conjectures. The results showed how the students were able to identify patterns, generalize and express them in a rhetorical and symbolic way, and use the GeoGebra CAS system to find answers.

One aspect that is emphasized in the MMP is letter and, therefore, model building. Although students obtained solutions, it was difficult for them to describe the procedures they used to arrive at their answers, as well as to develop general procedures that would be useful for similar situations. Considering the process as the product was not easy, as it involved giving importance to the process of mathematization. Students are used to giving unique and accurate answers, and this is what happened when they carried out the MEA.

One thing that stands out in this study is that before students associated quadratic behavior to the situation, they associated linear behavior. In other words, the activity presented in this paper has the potential to give students elements to characterize each type of function and, based on the context, discuss the differences between linear and quadratic behaviors.

En este documento se presentan los resultados de una investigación relacionada con el desarrollo de conocimientos y habilidades matemáticas por estudiantes universitarios de primer semestre al resolver Actividades Provocadoras de Modelos [MEA] que implican conocimiento acerca de la función cuadrática. La investigación fue de tipo cualitativa. El marco teórico fue la Perspectiva de Modelos y Modelación [PMM]. Los resultados muestran que los estudiantes utilizaron sus conocimientos y habilidades matemáticas relacionadas con la función lineal y cuadrática para describir la situación; transitaron de un ciclo de entendimiento caracterizado por procedimientos cuantitativos (en el que asociaron comportamientos lineales y cuadráticos a la situación), a un ciclo de entendimiento algebraico (en el que asociaron comportamientos únicamente cuadráticos).

Palabras clave: modelación, resolución de problemas, matemáticas de nivel universitario.

El aprendizaje del concepto de función ha sido objeto de estudio en diversas investigaciones (Gutiérrez y Prieto, 2015; Hernández, 2013; Oviedo, 2013). ¿Por qué es importante aprender el concepto de función? López, Navarro y Fuchs (2018) responden que es un conocimiento necesario para modelar sucesos y fenómenos en distintas áreas profesionales. Villarraga (2012) da cuenta, por ejemplo, del tipo de situaciones que pueden ser modeladas mediante la función cuadrática como: circunstancias de optimización relacionadas con costo, demanda y áreas, o en problemas físicos como intensidad de iluminación sobre una superficie. Pese a la importancia de comprender la función cuadrática, se ha identificado que existen dificultades en su aprendizaje, como la escasa articulación entre las representaciones algebraica y gráfica (Díaz, Haye, Montenegro y Córdoba, 2013) necesaria para describir situaciones y fenómenos.

Diversos autores (Gutiérrez y Prieto, 2015; Hernández, 2013 y Oviedo, 2013) han creado propuestas para atender el aprendizaje de la función cuadrática. Sin embargo, muchas se reducen a la manipulación de parámetros de la expresión algebraica para estudiar transformaciones en la gráfica correspondiente. Son escasas las investigaciones en las que se atiende el desarrollo de conocimientos y habilidades matemáticas asociadas a la función cuadrática en el contexto de la resolución de problemas o modelación de situaciones cercanas a la vida real. Una de las investigaciones realizadas en esta dirección fue la de Aliprantis y Carmona (2003), quienes en el marco de la Perspectiva de Modelos y Modelación (Lesh, 2010) diseñaron e implementaron una actividad para promover el desarrollo del conocimiento de la función cuadrática y conceptos asociados como el reconocimiento de variables, relación entre ellas (cuadráticas y lineales), producto de relaciones lineales y maximización, así como para propiciar en los estudiantes el desarrollo de habilidades para la modelación y solución de problemas, como conjeturar, argumentar, describir y explicar. Los participantes en estudio fueron estudiantes de secundaria.

La investigación descrita en este artículo se llevó a cabo con estudiantes del primer semestre universitario. El objetivo fue propiciar el desarrollo de conocimiento y habilidades matemáticas asociadas a la función cuadrática durante el proceso de resolución de problemas cercanos a la vida real. La pregunta de investigación es: ¿Qué conocimientos y habilidades exhiben estudiantes universitarios de primer semestre al resolver un problema en el que subyace el concepto de función cuadrática?

Marco Teórico

Aprender matemáticas, de acuerdo con la PMM (Lesh y Doerr, 2003), se basa en la construcción de modelos, los cuales

> son sistemas conceptuales (que consisten de elementos, relaciones, operaciones y reglas que rigen interacciones) que son expresados al usar sistemas de notación externa y que son utilizados para construir, describir o explicar los comportamientos de otros sistemas –quizá de manera que el otro sistema pueda ser manipulado o predicho inteligentemente. (Lesh y Doerr, 2003, p. 10).

Estos modelos pueden ser internos y externos, es decir, habitan tanto en el pensamiento de los estudiantes como en las ecuaciones, esquemas, aplicaciones computacionales u otros recursos de representación que utilizan expertos en ciencia o bien escolares (Lesh y Doerr, 2003). Los modelos pueden ser creados al realizar Actividades Provocadoras de Modelos (MEA), las cuales son simulaciones de situaciones de la “vida real”. Al realizar las MEA los estudiantes pasan por secuencias iterativas donde expresan, prueban y revisan sus propias formas de pensamiento (Lesh y Caylor, 2007). Durante el proceso de desarrollo de conocimiento, los estudiantes construyen y modifican sus modelos mediante las fases de diferenciación y refinamiento de los sistemas conceptuales que construyen (Lesh y Doerr, 2003).

Las MEA implican el uso de “herramientas conceptuales que son compartibles, manipulables, modificables y reutilizables (por ejemplo, modelos) para construir, describir, explicar, manipular, predecir, o controlar matemáticamente sistemas significativos” (Lesh y Doerr, 2003, p. 3). Los investigadores mencionan que tales descripciones, explicaciones y construcciones no deben ser consideradas como simples procesos que los estudiantes crean para conseguir “la respuesta”, sino que son elementos clave en el proceso de aprendizaje. De manera que, el proceso es el producto.

Las MEA “usualmente involucran la matematización, es decir, cuantificar, dimensionar, coordinar, categorizar, algebrizar y sistematizar objetos relevantes, relaciones, acciones, patrones y regularidades” (Lesh y Doerr, 2003, p. 5). Una característica que distingue a las MEA de otras actividades de resolución de problemas es la escritura de una carta. En ella los estudiantes deben explicar el método que utilizaron para encontrar la solución del problema; este método puede ser utilizado por un cliente para resolver otros problemas de características similares.

Metodología

La metodología que se siguió en esta investigación fue de tipo cualitativa. La MEA (Figura 1) cuyos resultados se describen en este documento, forma parte de una secuencia didáctica (Lesh, Cramer, Doerr, Post y Zawojewski, 2003) diseñada durante el proyecto de investigación. Fue implementada con un grupo de 12 estudiantes universitarios de nuevo ingreso, de aproximadamente 18 años, en una sesión de dos horas. Los estudiantes trabajaron en cuatro equipos de tres integrantes cada uno. Cada participante tenía una laptop con la MEA, Excel y GeoGebra. El proceso de resolución del problema se llevó a cabo en cuatro fases. 1) los estudiantes leyeron un artículo informativo relacionado al contexto del problema (actividad de calentamiento de acuerdo con la PMM). 2) leyeron el problema (ver Figura 1) y trabajaron en equipo en la resolución de éste. 3) expusieron sus soluciones en una discusión plenaria. 4) los estudiantes resolvieron el problema de manera individual en casa. En este documento solo se presentan los resultados de la fase 2, sustentados en las discusiones generadas durante la plenaria (fase 3). Los datos del estudio se obtuvieron del trabajo hecho por los estudiantes (hojas escritas); archivos de Word, Excel o GeoGebra; y de videograbaciones de la sesión presencial. Los conceptos asociados a esta actividad son los mencionados en la introducción (Aliprantis y Carmona, 2003).

Los estudiantes del último semestre de Ingeniería Mecánica Eléctrica del Centro Universitario de Ciencias Exactas e Ingenierías (CUCEI) de la Universidad de Guadalajara, quieren organizar un paseo a las cabañas de Mazamitla con el fin de recaudar fondos para celebrar su graduación.

Para tal propósito, la Universidad ha puesto a su disposición un autobús con capacidad para 49 pasajeros, de manera que quede cubierto el costo del recorrido ida y vuelta desde las instalaciones del CUCEI (diesel y pago al chofer), así como los traslados dentro del pueblo mágico. Además, Carlos, compañero de los estudiantes, se ha dado a la tarea de buscar en internet alojamiento y actividades para formar un paquete y poder ofrecer una experiencia completa a los viajeros que asistan al paseo.

El paquete turístico incluye el hospedaje para tres días y dos noches en una acogedora cabaña situada en La Cañada; un tour por la Sierra del Tigre, con guía, hielera y degustación de productos típicos; un paseo en cuatrimoto en el que se recorren los lugares más llamativos de la sierra. También, para aquellos que gustan de la adrenalina, se incluye tirolesa, muro de escalar, puentes colgantes y gotcha.

Carlos presupuestó el costo de $1 300.00 para cada paquete turístico por viajero, pero con el fin de obtener una ganancia, lo ofrecerá a un precio de $3650.00. Para animar a los posibles viajeros, Carlos propone hacer un descuento de $50 por cada persona que vaya, excepto si sólo va una. Es decir, si van dos personas, éstas reciben un descuento de $50; si son 3, se hace un descuento de $100 a cada una de ellas.

Ayuda a Carlos. Escríbele una carta en la que le expliques si su propuesta de organizar la excursión les permitirá obtener ganancias, y de qué monto. Sustenta tus afirmaciones con argumentos claros y válidos.

Figura 1: MEA

El análisis de datos se realizó con base en los ciclos de entendimiento cuantitativo y algebraico (Vargas, Reyes & Cristóbal, 2016). El ciclo de entendimiento cuantitativo es aquel en el que los estudiantes son capaces de describir de manera numérica las variables involucradas en el problema.

La información y las relaciones pueden ser organizadas en tablas y gráficas. En el ciclo de entendimiento algebraico los estudiantes exhiben cierto dominio del lenguaje del álgebra para solucionar el problema. Quienes alcanzan este ciclo han transitado por distintas etapas de diferenciación, integración y refinamiento de sus distintos sistemas conceptuales y tienen un dominio superior en el manejo de las representaciones. Durante cada uno de los ciclos, la representación verbal estuvo presente para justificar las conjeturas y las explicaciones de los estudiantes.

Resultados

Los estudiantes transitaran por dos ciclos de entendimiento (Tabla 1). El primero fue cuantitativo y el segundo algebraico. Inicialmente, los cuatro equipos (100% del total) revelaron una forma de pensar relacionada con la variación lineal (columna 2, Tabla 1) durante el ciclo cuantitativo. Enseguida, los alumnos de los equipos 1, 2 y 3 (75% de equipos) transitaron de sus procedimientos caracterizados por la variación lineal a una de tipo cuadrática (columna 3, Tabla 1); sin embargo, el equipo 4 no lo logró. Solamente los integrantes de los equipos 1 y 2 extendieron sus ideas a un ciclo de entendimiento algebraico. Una descripción en detalle se muestra enseguida.

Tabla 1: Ciclos de entendimiento de los estudiantes al resolver la MEA

	Ciclos de entendimiento			Respuesta	
	Cuantitativo		Algebraico	Correcta	Incorrecta
	Lineal	Cuadrático	Cuadrático		
E1	✓	✓	✓		✓
E2	✓	✓	✓	✓	
E3	✓	✓		✓	
E4	✓				✓

Primer Ciclo de Entendimiento: Cuantitativo

Todos los estudiantes identificaron los datos del problema: capacidad del camión, costo del viaje, precio inicial y el descuento. También, se percataron que tenían que elaborar una carta en la que desarrollaran un procedimiento para solucionar el problema. Se distinguieron dos formas de abordar la situación en este ciclo, porque algunos equipos la asociaron a un comportamiento lineal y otros a uno cuadrático.

Comportamiento lineal. Los integrantes de los cuatro equipos (100% de los equipos) calcularon el valor de la ganancia correspondiente a la cantidad máxima de pasajeros, es decir, 49 personas. La conjetura de los estudiantes fue que, a mayor cantidad de pasajeros, mayor ganancia, lo que denota un pensamiento lineal. Se distinguieron dos procedimientos, uno en el que se obtuvo la ganancia por pasajero, exhibido por los equipos 1, 2 y 3; y otro en el que se obtuvo la ganancia por grupo, elaborado por el equipo 4. Enseguida se discuten los procedimientos.

Procedimiento para obtener la ganancia para 49 pasajeros (capacidad máxima del camión). Método: ganancia por pasajero. El procedimiento de los equipos 1, 2 y 3 (75% de equipos) consistió en sustraer al precio inicial el descuento correspondiente por 49 pasajeros, es decir, efectuaron la operación: 3650-2400. Al resultado (1250) le restaron el costo del viaje, o sea, 1250-1300. Los estudiantes interpretaron esta cantidad (-50) como la ganancia por pasajero. No obstante, debido a la naturaleza negativa, expresaron que se trataba de una pérdida, en este caso de $50 por persona. De esta manera, la pérdida por 49 pasajeros era de $2450, como se muestra en la Figura 2.

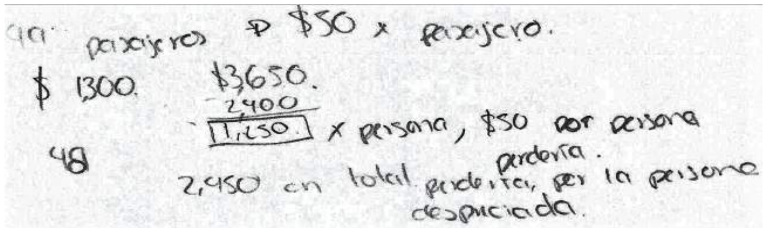

Figura 2: Operaciones llevadas a cabo por el equipo 1 para obtener la Ganancia relacionada a 49 Pasajeros por el Equipo 1. Método: Ganancia por Pasajero

Procedimiento para obtener la ganancia correspondiente a 49 pasajeros (capacidad máxima del camión). Método: ganancia por grupo. Los estudiantes del equipo 4 utilizaron la hoja de cálculo para operar con el costo del viaje por pasajero, la capacidad máxima de pasajeros y el precio inicial del paquete, es decir, $1300, 49 y $3650, respectivamente (celdas D6, E6 y D10 en la Figura 3). Relacionaron estos datos mediante fórmulas (Tabla 2) para calcular el descuento, el egreso, el ingreso relacionado con el precio inicial, el ingreso relacionado con el precio con descuento y la ganancia correspondiente a 49 pasajeros.

	A	B	C	D	E	F	G	H
1	2	50						
2	3	100		SUMATORIA DE LOS DESCUENTOS				
3	4	150			117600			
4	5	200

6	7	300		$1,300	49			
7	8	350			63700			
8	9	400						
9	10	450		COBRO TOTAL		178850		
10	11	500		$3,650	61250			
11	12	550						
12	13	600						
13	14	650		GANANCIAS TOTALES				
14	15	700			-2450	COMO PODEMOS OBSERVAR ES UNA		
15	16	750				CANTIDAD NEGATIVA, POR TANTO SE		
16	17	800				PERDERIA ESE DINERO		

Figura 3: Procedimiento para obtener la Ganancia correspondiente a 49 Pasajeros por el Equipo 4. Método: Ganancia por Grupo

Tabla 2: Fórmulas Utilizadas por el Equipo 4

Celda	Fórmula
E3	=(B48*A48)
E7	=(D6*E6)
E10	=(D10*E6)-E3
E14	=(E10-E7)
F9	=(D10*E6)

Comportamiento cuadrático. Los integrantes de los equipos 1, 2 y 3 (75% de los equipos) hicieron varias operaciones, usaron diferentes cantidades de pasajeros y analizaron cómo variaban los resultados. Los estudiantes de los equipos 1 y 2 (50%) recurrieron al ensayo y error, de manera desordenada. Los estudiantes del equipo 3 (25%) exhibieron un procedimiento sistematizado. El equipo 4 (25%) fue el único que no realizó varias operaciones.

Procedimiento de ensayo y error. Los estudiantes de los equipos 1 y 2 (50% del total) realizaron operaciones con cantidades distintas de pasajeros. Esto permitió que los integrantes del equipo 1 identificaran la forma en cómo variaba el ingreso y encontraran para qué cantidad de pasajeros se producía un ingreso máximo (Figura 4). Por su parte, los alumnos del equipo 2 identificaron de manera más organizada cómo variaba la ganancia y encontraron la cantidad de pasajeros que correspondía a la ganancia máxima.

En la Figura 4 se muestra el procedimiento elaborado por el equipo 1, como ejemplo representativo del trabajo de los equipos 1 y 2. Los estudiantes calcularon el ingreso que se generaba si viajaban 24, 28, 37, 36 y 38 pasajeros. No obstante, creían que habían obtenido la ganancia. Observaron que existía una relación de dependencia en la que estaba involucrada la cantidad de pasajeros; expresaron que "la ganancia depende de las personas que vayan [pasajeros]".

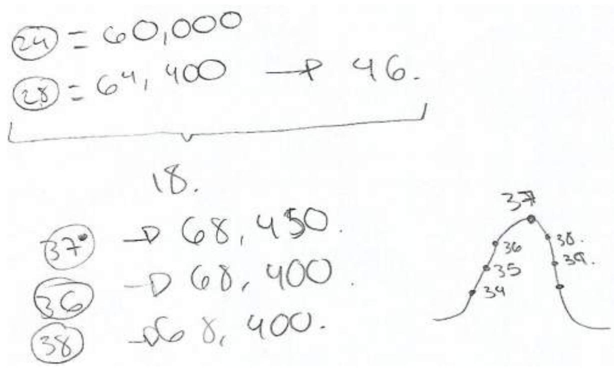

Figura 4: Procedimiento para obtener el Ingreso y para analizar la Variación para Distintas Cantidades de Pasajeros por el Equipo 1

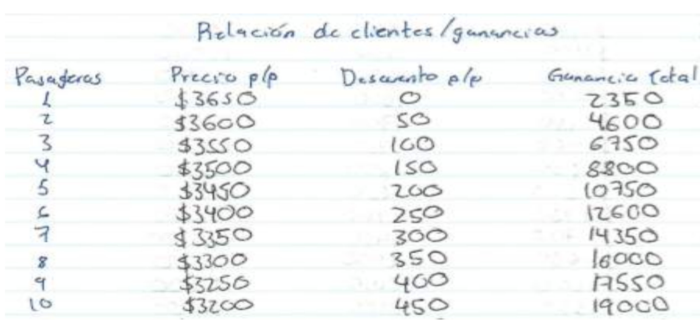
En la misma Figura 4 se observa el bosquejo de una gráfica que describe la forma en cómo varía el ingreso. Los estudiantes notaron que se obtenía un ingreso "máximo" o "cúspide" para 37 pasajeros. No identificaron un intervalo de crecimiento o decrecimiento. Señalaron que, a partir del valor máximo, los ingresos correspondientes a 36 y 38 pasajeros "van bajando igual", del mismo modo mencionaron que "35 y 39 tienen el mismo [correspondiente valor de ingreso]".

Exploración de resultados por ensayo sistematizado. Los estudiantes del equipo 3 construyeron una tabla (Figura 5) con los rótulos: "Pasajeros", "Precio p/p", "Descuento p/p" y "Ganancia Total". Relacionaron las cantidades de cada fila de manera horizontal, y obtuvieron la ganancia, según la cantidad de pasajeros. Identificaron que la ganancia máxima, $28800, se obtiene cuando viajan 24 pasajeros. En la Figura 5 se muestra parte de la tabla creada por el equipo 3.



Relación de clientes/ganancias

Pasajeros	Precio p/p	Descuento p/p	Ganancia Total
1	$3650	0	2350
2	$3600	50	4600
3	$3550	100	6750
4	$3500	150	8800
5	$3450	200	10750
6	$3400	250	12600
7	$3350	300	14350
8	$3300	350	16000
9	$3250	400	17550
10	$3200	450	19000

Figura 5: Procedimiento del Equipo 3

Ciclo de Entendimiento Algebraico

Los estudiantes de los equipos 1 y 2 (50% de equipos) generalizaron patrones. Por su parte, los estudiantes del equipo 3 (25% del total) construyeron expresiones sincopadas para realizar el cálculo. Los estudiantes del equipo 4 (25%) no presentaron generalizaciones.

Generalización de patrones mediante expresión algebraica. En la Figura 6 se muestra la expresión obtenida por los estudiantes del equipo 1 para calcular la ganancia. No es identificada como función por los estudiantes, sino como una fórmula. Las cantidades 3650 y 50 representan el precio inicial del paquete y el descuento por pasajero, respectivamente. El valor 63700 es el resultado de multiplicar 1300*49, es decir, el costo del paquete por pasajero por 49 pasajeros. De manera que 63700 es el egreso cuando asiste la capacidad máxima de viajeros.

El egreso correspondiente a n pasajeros sería $1300n$. La expresión correcta era $(3650 - (n-1) * 50)n - 1300n$. El modelo algebraico que los estudiantes debían construir para calcular la ganancia era $f(x) = -50x^2 + 2400x$ en su forma simplificada, donde x representa la cantidad de asistentes.

(3650- (n-1)*50)n-63700

*Sea "n" el número de personas que asistan

Figura 6: Expresión Algebraica del Equipo 1 para Calcular la Ganancia

Estos estudiantes emplearon el software GeoGebra para identificar la cantidad de pasajeros con la que se producía la ganancia máxima. Encontraron que eran necesarios 37 pasajeros para producir un valor máximo de 4750 (Figura 7). Sin embargo, de acuerdo con los datos del problema, los valores correctos eran 24 pasajeros y $28 800.

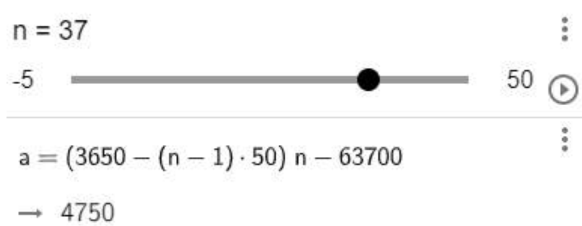


Figura 7: Procedimiento del equipo 1 para obtener la Ganancia Máxima

Generalización de patrones de manera sincopada. Los estudiantes del equipo 3 (25% en el grupo) generalizaron su procedimiento mediante lenguaje natural y símbolos matemáticos (Figura 8).

Número de personas-1 x50 = Descuento por persona

Precio base(3650) - Descuento - Costo(1300) = Ganancia por persona

Ganancia por persona x N de personas = Ganancia total

Figura 8: Generalización de Patrones para el Cálculo de la ganancia por el Equipo 3.

Discusión Plenaria

Durante la plenaria los estudiantes expusieron sus cartas y discutieron sus resultados. Los integrantes del equipo 4, con base en su carta, mostraron cómo calcularon la ganancia. Fueron cuestionados por el resto de los equipos con preguntas como "¿Qué pasa si van 10?", "¿Cuántos tendrían que asistir para que pudiera ganar mucho dinero?". Los alumnos de los equipos 2 y 3 mencionaron que eran necesarias 24 personas para obtener una ganancia máxima igual a $28800. En sus cartas escribieron este resultado, sin embargo, no explicaron el método que utilizaron para encontrar la solución por lo que no elaboraron un modelo compartible y reutilizable (Lesh y Doerr, 2003). Los estudiantes del equipo 1 comunicaron a sus compañeros que "descubrieron una fórmula al tanteo". Mostraron en su carta las cantidades correspondientes a la ganancia máxima (de acuerdo con su expresión), así como la expresión misma. Es decir, no sólo mencionaron qué cantidad de pasajeros eran necesarios para obtener una ganancia máxima, sino que presentaron al usuario una herramienta compartible y reutilizable con la que podrían conocer las ganancias para cualquier cantidad de pasajeros. No obstante, tampoco explicaron cómo encontraron su procedimiento.

Conclusiones

¿Qué conocimientos y habilidades exhiben estudiantes universitarios de primer semestre al resolver un problema en el que subyace el concepto de función cuadrática? Los estudiantes exhibieron los conocimientos mencionados por Aliprantis y Carmona (2003): reconocimiento de variables, variación, relación lineal y relación cuadrática, máximo. Fueron capaces de identificar los datos del problema y relacionarlos para obtener nuevos datos. Las relaciones las expresaron de manera verbal y escrita, mediante operaciones en papel y fórmulas en Excel. Respecto a las habilidades matemáticas, emplearon procedimientos de ensayo y error, y construyeron tablas y gráficas para analizar la variación de las cantidades. Identificaron un valor máximo denotado como "cúspide", "montaña" o "campana de Gauss" en la forma gráfica, el cual relacionaron con la ganancia máxima. Los alumnos fueron capaces de generar conjeturas (asociar a la ganancia un comportamiento lineal), describir y explicar la situación, y finalmente, evaluar sus conjeturas. En los resultados se observó cómo los estudiantes lograron identificar patrones, generalizarlos y expresarlos de manera retórica y simbólica, y utilizar el sistema CAS de GeoGebra para encontrar respuestas.

Un aspecto que se enfatiza en la PMM es la carta y, por lo tanto, la construcción de modelos. Si bien los estudiantes obtuvieron soluciones, les fue difícil describir los procedimientos que utilizaron para llegar a sus respuestas, así como desarrollar procedimientos generales que fueran útiles para situaciones similares. Considerar que el proceso es el producto no fue sencillo, ya que implicaba darle importancia al proceso de matematización. Los estudiantes están acostumbrados a dar respuestas únicas y exactas, y ello fue lo que ocurrió cuando realizaron la MEA.

Algo destacable en este estudio, es que antes de que los estudiantes asociaran a la situación un comportamiento cuadrático, asociaron un comportamiento lineal. Es decir, la actividad que se presentó en este documento tiene el potencial de dar elementos para que los estudiantes caractericen cada tipo de función y, con base en el contexto, discutan las diferencias entre comportamientos lineales y cuadráticos.

Humberto Gutiérrez Pulido
Universidad de Guadalajara
humberto.gutierrez@cucei.udg.mx

This report describes the models that students from the Electronics Engineering Division of the University of Guadalajara built with the implementation of a model eliciting activity (MEA) called Nanomaterials. The purpose was to document and analyze the underlying ideas and relationships that the students exhibited when solving a near-real-life problem in which various concepts of statistical inference emerge. The theoretical framework used was the Models and Modeling Perspective (MMP). The results indicate that the implementation of the activity generated hypothesis testing models, which integrated various means of representation, decision making and the use of concepts such as: null hypothesis, alternative hypothesis, confidence level, mean, sample, among others associated with statistical inference.

Keywords: Experiment design, Modeling, Problem solving, STEM.

Introduction

Nowdays there is a lot of information in print and digital formats. This demands the mastery of tools to analyze and understand that information, and use it to make decisions for the benefit of society (Lesh & Doerr, 2003). People who understand the information around them in their different economic, social, political or cultural contexts can make sense of it and reap its benefits.

Hypothesis testing is considered to support data interpretation, decision making and statistical inference, which "is where the power of statistics lies" (Makar & Rubin, 2018, p. 264). However, there are conceptual complications associated with statistical inference, especially in hypothesis testing, such as: a) confusion in the logic of hypothesis testing, b) the way in which the null hypothesis and the alternative are combined, c) the construction of a statistical hypothesis (Inzunsa & Jiménez, 2013; Lesh, 2010; Alvarado, Estrella, Retamal & Galindo, 2018; López, Batanero & Gea, 2018). These complications illustrate the complexity of the logic and fundamental concepts of hypothesis testing (Makar & Rubin, p. 269).

This study presents the results obtained in the implementation of a Model Eliciting Activity (MEA). It was developed under the Models and Modeling Perspective (MMP) (Lesh & Doerr, 2003; Lesh, Hoover, Hole, Kelly & Post, 2000). The activity simulated a problem close to real life where students could build mathematical interpretations and manipulate information to make decisions. With it, an alternative is sought to generate better access to statistical inference.

The questions that guided this research were: 1) what are the models that engineering students create to give meaning and solution to a real life problem situation, which is related to hypothesis testing, 2) what mathematical concepts emerge during the implementation of the activity associated with statistical inference?

Theoretical framework

In the MMP "models are expected to be among the most important kinds of knowledge that students" (Lesh, 2010, p.17). According to Lesh & Doerr models are considered as:

> conceptual systems (consisting of elements, relations, operations, and rules governing interactions) that are expressed using external notation systems, and that are used to construct, describe, or explain the behaviors of other system(s)—perhaps so that the other system can be manipulated or predicted intelligently. (Lesh & Doerr, 2003, p. 10)

Furthermore, "models are assumed to be highly situated, continually adapting, richly distributed, and socially shaped human constructs " (Lesh, 2010, p. 19), where modeling, as the process of building and developing models, includes a "series of parallel, interactive sequences of interactive cycles in which current forms of thought are repeatedly expressed, tested and revised" (Lesh, 2010, p. 17). In the framework of MMP, MEAs are proposed in order to motivate students to solve real-life problems through the construction of mathematical models that allow them to generate solutions, and they can "repeatedly revealing, testing and refining or extending their ways of thinking " (Lesh et al., 2000, p. 597).

Methodology

The MEA, named Nanomaterials, developed from Ramirez, Yu, Xu & Chen (2015), poses a situation of uncertainty related to a production process. The activity consists of four pages, the first two of which present a newspaper article describing the manufacturing process (printing) of nano circuits for biosensors. The third page contains a section of warm-up questions that introduce the student to the production process and uses of biosensors in health. The fourth page introduces the students to the problem, which refers to the discrepancy that exists between the molds and the magnitude of the printed circuits, and asks them to support the production process technicians to determine with certainty and with the information they have, the type of discrepancy that exists between the molds and the printed circuits.

The activity was refined with five previous implementations with different students (April-October 2019), where several aspects were adjusted. It is until the sixth implementation that we consider that we achieved an activity that meets the attributes of the MPA.

The implementation of the activity was developed according to Lesh & Doerr's (2003) suggestions which are: 1) reading a newspaper article that introduces the student to the context (production of biosensors), 2) construction of interpretations developed in teams, and 3) exposition and discussion of constructed models. The teacher performs the roles of facilitator and observer.

The six principles for the design of MEAs were used in the construction and refinement of the activity. 1) Reality: the situation is likely to occur in the students' real life; 2) Model construction: the activity generates in students the need to build, modify or refine a model; 3) Documentation of the model: the students' constructions explicitly reveal how they are thinking about the situation and its resolution (initial, intermediate and final interpretations); 4) Self-evaluation: the students are clear how to evaluate if their constructions are useful or good enough; 5) Generalization of the model: the model built by the students can be used for other situations and shared with other people; 6) Simple prototype: the activity solution provides a useful prototype for interpreting other structurally similar situations (Lesh et al. 2000; Lesh & Doerr, 2003). However, for the analysis of results only the first four design principles could be evaluated, due to the availability of resources.

The initial, intermediate and final ideas outlined by Lesh and Doerr (2003) were integrated into the principle of documentation of the model, and these were characterized in the MEA as follows. a) The initial ideas were proposals about what data are important, how to address the problem, and what steps for solution are most useful, and may or may not be associated with the use of statistics. b)

Intermediate ideas were those focused on the identification and explanation of patterns, relations or specific behavior of the data of the situation to be solved; it includes the use measures of central tendency and dispersion, construction of descriptive graphs or simple operations such as obtaining differences between the data, among others. c) Final ideas were the formal approaches of null and alternative hypothesis, confidence levels to decide, making the decision to reject or accept the null hypothesis, and includes possible suggestions to improve the production process according to the results obtained.

The study was of a descriptive qualitative nature. The means of collecting information were: videos, audios, and the written (physical and digital) of seven students from the Electronic and Computer Engineering Division of the University of Guadalajara, who were finishing the Probability and Statistics course (second semester). The final information was obtained in a 60-90 minute session, where the implementation of the activity took place. Three work teams were organized, Team 1 with two members (1A, 1B), Team 2 with three (2A, 2B, 2C) and Team 3 with two students (3A, 3B).

Results

The main results of the study are summarized below. They have been grouped according to the six principles for the design of MEAs, which were outlined above.

Reality principle. The reading and discussion of the newspaper article on biosensor production allowed the students to engage with the context of the activity, and revealed the knowledge they had about biosensors. This was done by relating the activity to some biosensors that they already knew about: "Apple Watch, exercise band, cardio exercise machines, heart rate sensor, temperature sensor and step counter".

Model construction principle. Team 1 made a graph to visualize the behavior of the data (mold measurements and impressions), which helped them to understand and interpret the situation visually. Team 2 proposed procedures such as: obtaining differences between the measurements of the shapes and impressions, determining an average of each of the measurements, calculating the standard deviation and variance of the data in order to analyze the information.

Model documentation (initial, intermediate, and final ideas). The students during the implementation developed a series of interpretations that went through several modifications and refinements, which helped them to orient their work towards what they considered to be the best answer.

Initial interpretations. The teams in their first working dialogues mentioned ideas of how to analyze the information of the problem, but without arguing why they were useful: 1A: "What if we make a graph", 2B: "What if we take out the differences between the mold and the print", 2B: "Let's make a bell graph", 2A: "Let's make a scatter graph". It was identified that students initially resort to data analysis with graphs and manipulate them with simple operations (differences); with the idea of making sense of the information of the problem.

Intermediate interpretations. Students identified patterns and relationships after graphing the data set and calculating some statistics (mean, variance, standard deviation).For example, Team 1 looked at their line graph and noted a dependency relationship between the mold and print measurements; 1B: "the mold is larger than the print," 1B: "look at the means are different," but without formally making a correlation or hypothesis to prove the differences, they only made some informal statements that could lead them to make the null and void hypothesis; 1A: "in fact the measurements should be the same," 1B: "the mold is larger than the print".

Final interpretations. The final model in all teams was a hypothesis testing procedure, which integrated graphic, tabular, algebraic, written and verbal representations. Here they posed the relationship between the measurements of the molds and the prints, for example: 1A: "the null hypothesis is that the measurements of the molds are equal", posed by the student that defines the type of contrast to be developed. 1B: "the other hypothesis is that the moulds are larger than the impressions". The approach of this alternative hypothesis complemented and guided the construction of his model, in addition to using other concepts such as: sample and confidence level to refine and define their model.

Principle of self-evaluation. Team 1, modified their decision to use graphs and linear regression to explain their proposed model. This was because, after a second analysis of the activity specifications, they felt that their proposal was not sufficiently useful. This redirected their work towards building a hypothesis test, a decision that they felt allowed them to test with greater certainty whether their guess was acceptable or not. In other words, the students self-evaluated the usefulness of their answer and modified it in search of a better one.

Conclusions

The MEA Nanomaterials contributed to the study of MMP, specifically in topic of hypothesis testing of inferential statistics, being an original design for electronic engineering students.

According to the research questions, the MEA Nanomaterials promoted the construction of models to perform the hypothesis testing procedure; which integrated different mathematical concepts such as: sample, mean, variance, null and alternative hypothesis, confidence level, scatter plot, among others. In addition, it made evident that the hypothesis test is not a trivial issue, since students had to develop a series of interpretations (initial, intermediate and final) (Lesh et al. 2000). They used various means of representation (graphical, tabular, written, algebraic, spoken language) (Lesh & Doerr, 2003) to refine, modify and extend their ways of thinking about this relevant procedure within statistical inference. In addition, access to the web and the use of Excel made it easier for students to build visual, manipulable and dynamic representations (Lesh, 2010).

En este reporte se describen los modelos que estudiantes de la División de Ingeniería en Electrónica y Computación de la Universidad de Guadalajara, construyeron con la implementación de una Actividad Provocadora de Modelos (APM) llamada Nanomateriales. El propósito fue documentar y análizar las ideas y relaciones subyacentes que los alumnos exhibieron al resolver una problemática cercana a la vida real en la que emergen diversos conceptos de inferencia estadística. El marco teórico utilizado fue la Perspectiva de Modelos y Modelación (PMM). Los resultados indican que la implementación de la actividad generó modelos de prueba de hipótesis, que integraron diversos medios de representación, la toma de decisiones y el uso de conceptos como: hipótesis nula, alternativa, nivel de confianza, media, muestra, entre otros asociados con la inferencia estadística formal.

Palabras clave: Diseño de experimentos, Modelación, Resolución de problemas, STEM.

Introducción

La gran cantidad de información en formatos impresos y digitales en la era actual demanda el dominio de herramientas de interpretación, análisis y toma de decisiones para poder comprender esa información y utilizarla en beneficio de la sociedad (Lesh & Doerr, 2003). Las personas que comprenden la información que les rodea en sus diferentes contextos económicos, sociales, políticos o culturales pueden darle sentido y aprovechar sus beneficios (Lesh, 2010, p.27).

Se considera que la prueba de hipótesis apoya la interpretación de datos, la toma de decisiones y la inferencia estadística, que "es donde reside el poder de la estadística" (Makar & Rubin, 2018, p. 264). Sin embargo, se han identificado varias complicaciones conceptuales asociadas con la inferencia estadística, especialmente en prueba de hipótesis, tales como: a) confusiones en la lógica del contraste de hipótesis, b) la forma en la que se combinan la hipótesis nula y la alternativa, c) la construcción de una hipótesis estadística (Inzunsa & Jiménez, 2013; Lesh, 2010; Alvarado, Estrella, Retamal & Galindo, 2018; López, Batanero & Gea, 2018). Estas complicaciones ilustran aún más la complejidad de la lógica y los conceptos fundamentales de las pruebas de hipótesis (Makar & Rubin, 2018; p. 269).

El presente estudio expone los resultados obtenidos en la implementación de una Actividad Provocadora de Modelos (MEA por su nombre en inglés: Model Eliciting Activities). Misma que fue desarrollada bajo la Perspectiva de Modelos y Modelación (PMM) (Lesh & Doerr, 2003; Lesh, Hoover, Hole, Kelly & Post, 2000). La actividad simuló una problemática cercana a la vida real donde los alumnos pudieron construir interpretaciones matemáticas y manipular información para tomar decisiones. Con ella se busca una alternativa para generar un mejor acceso a la inferencia estadística.

Las preguntas que guiaron esta investigación fueron: 1) ¿cuáles son los modelos que los estudiantes de ingeniería crean para dar sentido y solución a una situación problemática de la vida real, que está relacionada con la prueba de hipótesis?, 2) ¿qué conceptos matemáticos emergen durante la implementación de la actividad asociados con la inferencia estadística?

Marco teórico

En la PMM, se "espera que los modelos se encuentren entre los tipos de conocimiento más importantes que desarrollan los estudiantes" (Lesh, 2010, p.17), de acuerdo con Lesh & Doerr los modelos son considerados como:

> Sistemas conceptuales (consisten en elementos, relaciones y reglas que gobiernan las interacciones) expresados mediante el uso de sistemas de notación externa, y utilizados para construir, describir, o explicar los comportamientos de otros sistemas de tal forma que el otro sistema pueda ser manipulado o predicho de manera inteligente (Lesh & Doerr, 20003, p. 10)

Además, "se asume que los modelos están altamente situados, adaptándose continuamente, ricamente distribuidos y con construcciones con formas sociales" (Lesh, 2010, p. 20), donde la modelación, como el proceso de construcción y desarrollo de modelos, incluye una "serie de secuencias paralelas e interactivas de ciclos interactivos en los que las formas actuales de pensamiento se expresan, prueban y revisan repetidamente" (Lesh, 2010, p.17). La PMM, propone MEAs, para que los estudiantes se motiven a resolver problemas de la vida real a través de la construcción de modelos matemáticos que les permitan generar soluciones y puedan "revelar, probar y refinar repetidamente o ampliar sus formas de pensamiento "(Lesh et al., 2000, p. 597).

Metodología

La APM, nombrada Nanomateriales, desarrollada a partir de Ramirez, Yu, Xu & Chen (2015), plantea una situación de incertidumbre relacionada con un proceso de producción. La actividad consta de cuatro páginas, en las dos primeras se presenta un artículo de periódico que describe el proceso de fabricación (impresión) de nano circuitos para biosensores. La tercera página contiene una sección de preguntas de calentamiento que introducen al estudiante con el proceso de producción y usos de los biosensores en la salud. En la cuarta página se les presenta a los estudiantes la problemática, que se refiere a la discrepancia que existe entre los moldes y la magnitud de los circuitos impresos, y se les solicita que apoyen a los técnicos del proceso de producción para determinar con certeza y con la información que tienen, el tipo de discrepancia que existe entre los moldes y los circuitos impresos.

La actividad fue afinada con cinco implementaciones previas con diferentes alumnos (abril-octubre de 2019), donde se ajustaron varios aspectos. Es hasta la sexta implementación en la que consideramos logramos obtener una actividad que reúne los atributos propios de las APM.

La implementación de la actividad se desarrolló de acuerdo con las sugerencias de Lesh & Doerr (2003) que son; 1) lectura de un artículo de periódico que introduce al estudiante en el contexto (producción de biosensores), 2) construcción de interpretaciones desarrolladas en equipo y 3) exposición y discusión de los modelos construidos. El docente asume los roles de facilitador y observador.

Los seis principios de diseño de APM se utilizaron en la construcción y refinación de la actividad: 1) Realidad: la situación es posible que ocurra en la vida real de los alumnos; 2) Construcción del modelo: la actividad genera en los estudiantes la necesidad de construir, modificar o refinar un modelo; 3) Documentación del modelo: las construcciones de los alumnos revelan explícitamente cómo están pensando en la situación y su resolución (interpretaciones iniciales, intermedias y finales); 4) Autoevaluación: los alumnos tienen claro cómo evaluar si sus construcciones son útiles o suficientemente buenas; 5) Generalización del modelo: el modelo construido por los alumnos puede utilizarse para otras situaciones y compartirse con otras personas; 6) Prototipo simple: la solución para la actividad proporciona un prototipo útil para interpretar otras situaciones estructuralmente similares. (Lesh et al. 2000; Lesh & Doerr, 2003). Sin embargo, en el análisis de resultados sólo se pudieron evaluar los primeros cuatro principios de diseño, debido a la disponibilidad de los recursos.

Las ideas iniciales, intermedias y finales que señalan Lesh y Doerr (2003) se integraron en el principio de documentación del modelo, y se caracterizaron en la APM como sigue. a) Ideas iniciales, fueron las propuestas acerca de qué datos son importantes, cómo abordar el problema y qué pasos para la solución son más útiles, pudiendo o no estar asociadas con el uso de la estadística. b) Ideas intermedias, son aquellas centradas en la identificación y explicación de patrones, relaciones o comportamiento específico de los datos de la situación a resolver; incluye el uso de medidas de tendencia central y de dispersión, construcción de gráficas descriptivas u operaciones sencillas como obtener diferencias entre los datos, entre otras. c) Ideas finales, son los planteamientos formales de hipótesis nula y alternativa, niveles de confianza en la decisión, tomar la decisión de rechazar o aceptar la hipótesis nula, e incluye posibles sugerencias para mejorar el proceso de producción en función de los resultados obtenidos.

El estudio fue de carácter cualitativo descriptivo. Los medios de recolección de información fueron: vídeos, audios, y los escritos (físicos y digitales) de siete estudiantes de la División de Ingeniería en Electrónica y Computación de la Universidad de Guadalajara, que estaban terminando el curso de Probabilidad y Estadística del segundo semestre. La información final se obtuvo en una sesión de 60-90 minutos, donde se llevó a cabo la implementación de la actividad. Se organizaron tres equipos de trabajo, el Equipo 1 con dos integrantes (1A, 1B), el Equipo 2 con tres (2A, 2B, 2C) y el Equipo 3 con dos alumnos (3A, 3B).

Resultados

A continuación, se resumen los principales resultados del estudio. Se han agrupado de acuerdo a los seis principios para el diseño de APMs, que ya antes se señalaron.

Principio de realidad. La lectura y discusión del artículo de periódico (sobre producción de biosensores) permitió a los estudiantes involucrarse con el contexto de la actividad, y reveló el conocimiento que tenían sobre biosensores al relacionar la actividad con algunos que ellos ya conocían como: "Apple Watch, banda de ejercicio, máquinas de cardio para el ejercicio, sensor de ritmo cardiaco, sensor de temperatura y contador de pasos".

Principio de construcción de modelo. El Equipo 1 hizo un gráfico para visualizar el comportamiento de los datos (medidas de molde e impresiones), que les ayudó a entender e interpretar la situación visualmente. El Equipo 2 propuso procedimientos tales como: obtener las diferencias entre las medidas de las formas e impresiones, determinar un promedio de cada una de las medidas, calcular la desviación estándar y la varianza de los datos para analizar la información.

Documentación del modelo (ideas iniciales, intermedias y finales). Los estudiantes durante la implementación desarrollaron una serie de interpretaciones que transitaron por varias modificaciones y refinamiento, que les ayudó a orientar su trabajo hacia lo que consideraban como mejor respuesta.

Interpretaciones iniciales. Los equipos en sus primeros diálogos de trabajo mencionaron ideas del cómo analizar la información del problema, pero sin argumentar el por qué eran útiles: 1A: "¿Y si hacemos una gráfica?", 2B: "Y si sacamos las diferencias entre el molde y la impresión", 2B: "hagamos una gráfica de campana", 2A: "hagamos una de dispersión". Se identificó que los alumnos recurren inicialmente al análisis de datos con gráficas y a la manipulación de éstos con operaciones sencillas (diferencias); con la idea de dar sentido a la información del problema.

Interpretaciones intermedias. Los alumnos identificaron patrones y relaciones después de graficar los datos y calcular algunos estadísticos (media, varianza, desviación estándar). Por ejemplo el Equipo 1 observó su gráfica de líneas y señaló una relación de dependencia entre las medidas de moldes e impresiones; 1B: "el molde es más grande que la impresión", 1B: "mira las medias son diferentes", pero sin llegar a plantear de manera formal una correlación o el planteamiento de hipótesis para probar las diferencias, solo realizaron algunas afirmaciones informales que pudieran llevarlos al planteamiento de la hipótesis nula y alternativa; 1A: "de hecho las medidas deberían ser iguales", 1B: "el molde es más grande que la impresión",

Interpretaciones finales. El modelo final en todos los equipos fue un procedimiento de prueba de hipótesis, que integró representaciones gráficas, tabulares, algebraicas, escritas y verbales. Aquí ellos plantearon la relación entre las medidas de los moldes y las impresiones, por ejemplo: 1A: "la hipótesis nula es que las medidas de los moldes son iguales", planteamiento por el alumno que define el tipo de contraste a desarrollar. 1B: "la otra hipótesis es que los moldes son más grandes que las impresiones". El planteamiento de esta hipótesis alternativa complementó y orientó la construcción de su modelo, además de utilizar otros conceptos como: muestra y nivel de confianza para refinar y definir su modelo.

Principio de autoevaluación. El Equipo 1, modificó su decisión de usar gráficas y regresión lineal para explicar su modelo propuesto. Esto debido a que, después de analizar por segunda vez las especificaciones de la actividad, consideraron que su propuesta no era lo suficientemente útil. Esto reorientó su trabajo hacia la construcción de una prueba de hipótesis, decisión que, según ellos, les permitía probar con mayor certeza si su conjetura era aceptable o no. En otras palabras, los alumnos autoevaluaron la utilidad de su respuesta y la modificaron en búsqueda de una mejor.

Conclusiones

La APM Nanomateriales contribuyó al estudio de la PMM, específicamente en el tema de prueba de hipótesis de la estadística inferencial, al ser un diseño original para los estudiantes de ingeniería electrónica. De acuerdo con las preguntas de investigación la APM Nanomateriales propició la construcción de modelos tipo procedimiento de prueba de hipótesis que integraron diferentes conceptos matemáticos como; muestra, media, varianza, hipótesis nula y alternativa, nivel de confianza, gráfica de dispersión, entre otros. Además, dejó en evidencia que la prueba de hipótesis no es una idea trivial, ya que los alumnos tuvieron que desarrollar una serie de interpretaciones (iniciales, intermedias y finales) (Lesh et al. 2000) donde usaron varios medios de representación (gráfico, tabular, escrito, algebraico, lenguaje hablado) (Lesh & Doerr, 2003) para refinar, modificar y ampliar sus formas de pensar acerca de este procedimiento relevante dentro de la inferencia estadística. En adición, el acceso a la red y uso de Excel les facilitó a los alumnos la construcción de representaciones visuales, manipulables y dinámicas (Lesh, 2010).

Agradecimientos

Agradecemos al proyecto Campus Viviente (http://campusviviente.org), la Universidad de Guadalajara y el programa de becas CONACYT por apoyar este estudio.

This paper describes a modeling task designed to improve students' understanding of music and related unit structures (e.g., whole note, half note). Fourteen upper elementary students were asked to build models of melodies using Cuisenaire rods and make arguments about how their models represented what they heard. Our analysis of students' models suggested four categories of models. Students exhibited one- or two-dimensional reasoning with either (or both) height and length correspondence that varied in terms of duration and/or pitch features.

Keywords: Modeling, Representations and Visualization, Measurement

Background and Literature Review

Mathematical modeling focuses the relevance of mathematics through the use of authentic contexts where students use their mathematics to solve relevant problems (COMAP & SIAM, 2016). There is a growing emphasis on the inclusion of mathematical modeling in school mathematics (e.g., National Council of Teachers of Mathematics, 2000; National Governor's Association Center [NGAC] & Council of Chief State School Officers [CCSSO], 2010). While the phrase *mathematical modeling* has been used in many ways, we consider the description of mathematical modeling from the Common Core State Standards, which describes modeling as "the process of choosing and using appropriate mathematics and statistics to analyze empirical situations, to understand them better, and to improve decisions" (NGAC & CCSSO, 2010). In this description, the main focus of mathematical modeling is learning to make decisions and assumptions when interpreting a real-world scenario using a mathematical lens. These scenarios are often posed using open-ended tasks where students have the freedom and flexibility to create their own non-prescribed models (COMAP & SIAM, 2016). Because mathematical modeling requires creativity and allows for varied solution strategies, modeling tasks inherently provide multiple entry points and differentiation opportunities (Cirillo et al., 2016).

Prior research studies showed that mathematical modeling tasks were helpful in revealing student thinking and that modeling tasks enable students of differing performance levels to interpret, invent, and find solutions (e.g., Aguilar Battista, 2017; Carmona & Greenstein, 2007; Koellner-Clark & Lesh, 2003; Mousoulides, Pittalis, Christou, & Sriraman, 2010). Despite the existing literature on mathematical modeling, there is a need for further research in the elementary grade levels. An analysis of 29 articles (published between the years 1991-2015) that focused on elementary mathematical modeling (ages 10 and below) revealed that more research (as well as teacher training) related to mathematical modeling in the elementary grades is needed (Stohlman & Albarracin, 2016).

In the modeling task that we share in this report, students are expected to use "the language of mathematics to quantify real-world phenomena and analyze behaviors" (COMAP & SIAM, 2016, p. 8). The real-word phenomena is the representation of musical notes. We chose to develop a modeling task for music because musical notes are inherently mathematical due to the proportional relationship of their size (i.e., duration of each note). Additionally, integrating music and mathematics appears to be a particularly effective intervention for students to improve students' conceptual understanding of

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

fractions, especially for high needs students (Courey et al., 2012). In order to contribute to the understanding of framing instruction with modeling tasks in earlier grades, we focused on the following research questions in our study: *What were the mathematical assumptions and decisions students made when creating physical models to represent musical melodies? What were the underlying mathematical characteristics of their models and were there any similarities and/or differences between models?*

When learning a mathematical concept, children use actions. While these actions can initially be physical or mental, ultimately, the actions are mental that may or may not have been derived from physical actions or words (Sarama & Clements, 2009). When creating our own models during the design phase of the task, we determined that our own mental actions included unitizing: defining a unit and a sub-unit (i.e., whole and half notes). Unitizing is defined as "the process of constructing chunks in terms of which to think about a given commodity" (Lamon, 2012, p. 104). Because unitizing is a subjective process, encouraging flexibility and highlighting the relationship between unitizing and understanding fractions and equivalence is important (Lamon, 2012). We focused on students' unitizing mental actions while analyzing their models.

Methodology

The motivation for the *Modeling Music* task was to utilize the multiple ways in which music can be represented to emphasize the proportional relationship of musical notes. To show the different representations of music as well as how these different representations are related, we developed a framework which had the components of song, sound wave, sheet music, and physical tools. This particular modeling task attended to the bi-directional relationships between melody, sheet music, and physical tools representations.

Four melodies (Melodies A, B, C, and D) were created and then purposefully sequenced to highlight differences in the length of the notes (Figure 2). The first two melodies (A and B) were solely comprised of either whole or half notes. The third melody (C) was a combination of whole and half notes and the fourth melody (D) was a combination of whole, half, and quarter notes.

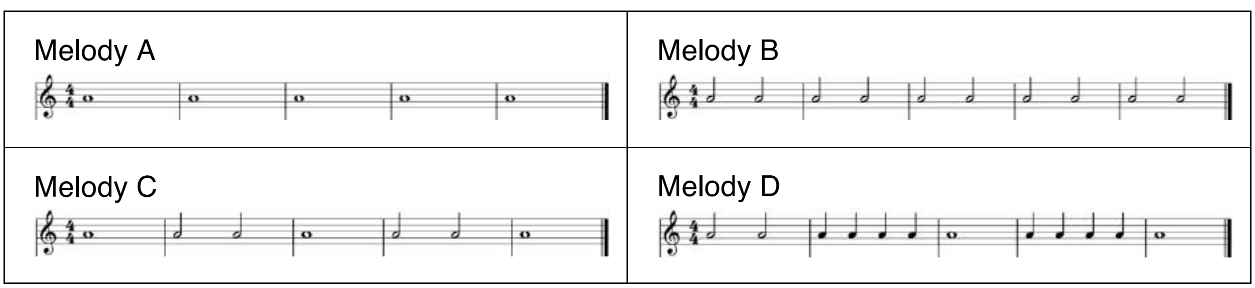

Figure 1. Sheet music for Melodies A, B, C, and D

Participants and Implementation

Fourteen upper-elementary (fourth and fifth grade) students participated in the *Modeling Music* task during a summer ice skating camp in July 2019. The daily schedule of the camp limited the time allotted for the *Modeling Music* task to 45 minutes and as a result, students were only able to create models for the first three melodies. The activity sequence for the *Modeling Music* task consisted of three parts: (1) listening to the melody, (2) recording and sharing notices and wonders about the melody, and (3) building the model using Cuisenaire rods. Students were not provided with any guidance or direction when building their models, which required them to make their own assumptions and decisions during the modeling process, as well as identify the underlying mathematical relationships in their models.

Data Collection and Analysis

In order to better understand students' modeling strategies, the data we collected during task implementation included students' individual written responses to the notices and wonder prompts for each melody, a written record of students' verbal descriptions of each melody, and photographs of the Cuisenaire rod models students created for each melody. The students' models and their written descriptions were analyzed using comparative analysis (Merriam, 1998). The similar models were first categorized into similar chunks (e.g., models using one-dimensional reasoning). In the next revision, this classification was elaborated into more defined categories and we looked for the unitizing structures involved in the models. We used measurement ideas to analyze the multiple representations of proportional relationships and we used basic principles of measurement (e.g., relating size and units) to explore how these relationships were connected within the context of music.

Results and Discussion

Students' notices and wonders for each of the melodies highlighted several common themes. Some of these themes revealed the underlying mathematics students observed (e.g., distance between notes, length of notes). Other themes revealed students' perceptions of the sound (e.g., pitch, tempo). Students' Cuisenaire rod models of the melodies revealed their modeling strategies, including the assumptions and decisions they made for mathematizing the melodies.

Modeling Single Note Melodies (Melody A and B)

When modeling single note melodies, students built either a single rod model or a collection of rods model to represent one note (see Table 1). The main difference between these models was how students decided to represent one unit. With the single rod model, students decided to define one note with one rod, whereas with the collection of rods model, students decided to define one note with a collection of rods in a staircase shape. With both the single rod model and collection of rod models, students assumed that the notes in the melody were identical and chose to iterate their unit to reflect this assumption.

Table 1: Student Models of Single Note Melodies (Melody B)

Single Rod Model	Collection of Rods Model
	

Modeling Two-Note Melodies (Melody C)

When modeling the two-note melody, students had to decide how to represent both whole and half notes in a single model. Students' models were categorized based on which characteristics of the rods they attended to when representing the different notes as summarized in Table 2.

Table 2: Categories for Two-Note Melodies (Melody C)

Category and Sample Model	Defining Characteristics
(1) 1-D: Length Correspondence (Duration) 	Attended to rod length to represent each note. Length of half note (red) corresponded to length of whole note (purple).
(2a) 2-D: Height Correspondence (Duration) 	Attended to horizontal length (number of rods) and height (length of rods) to represent each note. Length of starting rod of half note (yellow) corresponded to length of starting rod of whole note (orange).
(2b) 2-D: Length Correspondence (Duration) 	Attended to horizontal length (number of rods) and height (length of rods) to represent each note. Number of rods representing each note had a 4:2 proportion.
(3) 2-D: Height, Length Correspondence (Duration) 	Attended to horizontal length (number of rods) and height (length of rods) to represent each note. Length half note (yellow) corresponded to length of starting rod of whole note (orange) and number of rods representing each note had a 2:1 proportion.
(4) 2-D: Height, Length Correspondence (Duration and Pitch) 	Attended to horizontal length (number of rods), height (length of rods), and pitch (starting rod) to represent each note. Number of rods representing each note had a 4:2 proportion. Used same starting rod for both whole and half notes.

Conclusion

The *Modeling Music* task clearly provided students with multiple entry and exit points as evidenced by the sheer variety in students' models. In addition, unpacking students' mental actions when building their models revealed commonalities in students' thinking related to unitizing and proportional reasoning (e.g., half/whole note relationships). Our analysis provided a method of categorizing students' models based on their defining characteristics, which brought to light the assumptions and decisions made by students during the modeling process.

Research related to students' mathematical modeling strategies provides opportunities for rich descriptions of student thinking. Our findings are promising in terms of further study of modeling tasks and the value of using modeling tasks to explore students' reasoning and strategies, including application of prior knowledge, when solving open-ended problems. The *Modeling Music* task also suggests a framework for task design and model categorization that can allow for further mathematical modeling research in the elementary grades.

Our findings can also inform instructional decisions. Having a framework for model categorization (in terms of underlying mental actions) allows us to anticipate student thinking, which can help educators better prepare instruction related to both mathematical modeling and the development of measurement concepts.

BEYOND PATTERNS: MAKING SENSE OF PATTERNS-BASED GENERALIZATIONS THROUGH EMPIRICAL RE-CONCEPTUALIZATION

Amy B. Ellis
University of Georgia

Elise Lockwood
Oregon State University
elise.lockwood@oregonstate.edu

Identifying patterns is an important part of mathematical reasoning, but many students struggle to justify pattern-based generalizations. Some researchers argue for a de-emphasis on patterning activities, but empirical investigation has also been shown to support discovery and insight into problem structures. We introduce a phenomenon we call empirical re-conceptualization, which is the development of a generalization based on an empirical pattern that is subsequently re-interpreted from a structural perspective. We define and elaborate empirical re-conceptualization by drawing on data from secondary and undergraduate students, and identify three major affordances: Empirical re-conceptualization can serve as (a) a source of verification, (b) a means of justification, and (c) a vehicle for generating insight.

Keywords: Reasoning and Proof, Cognition, Algebra and Algebraic Thinking

Objective: Leveraging the Power of Pattern-Based Generalizations

Recognizing and developing patterns is a critical aspect of mathematical reasoning. Many students are adept at recognizing and formalizing patterns (Pytlak, 2014), but they can also struggle to understand, explain, and justify those very patterns they develop (Čadež & Kolar, 2014). One source of students' difficulties may rest with the empirical nature of those generalizations. Students can become overly reliant on examples and infer that a universal statement is true based on a few confirming cases (Knuth, Choppin, & Bieda, 2009). One potential solution is to help students understand the limitations of empirical evidence and thus recognize the need for deductive arguments (e.g., Stylianides & Stylianides, 2009). These approaches have shown some success in helping students see the limitations of examples, but they also frame empirical reasoning strategies as stumbling blocks to overcome.

In contrast, we have identified a phenomenon that we call *empirical re-conceptualization*, in which students identify a pattern, form an associated generalization, and then re-interpret their findings structurally. From this perspective, students can bootstrap their pattern-based generalizations into mathematically meaningful insights and arguments. In this paper, we describe and elaborate the construct of empirical re-conceptualization and address the following questions: (a) What characterizes students' abilities to leverage pattern-based generalizations in order to develop mathematical insights? (b) What are the conceptual affordances of empirical re-conceptualization? We offer a secondary example, discuss the affordances experienced, and consider ways in which instruction can support the practice of empirical re-conceptualization.

The Drawbacks and Opportunities of Empirical Reasoning

While an emphasis on patterning that lacks meaning can promote the learning of routine procedures without understanding (Fou-Lai Lin et al., 2004), there are also a number of affordances that can arise from empirical investigation. The act of developing empirically-based generalizations can foster the discovery of insight into a problem's structure, which could consequently support proof development (de Villiers, 2010). The degree to which pattern generalization is an effective route to proof is an open question, but there is evidence that students can and do engage in a dynamic interplay between empirical patterning and deductive argumentation (e.g., Schoenfeld, 1986).

Students lack sufficient experience with developing meaning from patterns. Curricular materials emphasize patterning activities that end with a generalization, typically an algebraic rule; developing an associated justification is seldom emphasized in standard classroom tasks. In fact, students typically receive little, if any, explicit instruction on how to strategically analyze examples in developing, exploring, and proving generalizations (Cooper et al., 2011). We propose that empirical re-conceptualization can be one way to provide opportunities to develop mathematical insight and deductive argumentation from pattern-based generalizing activities.

Theoretical Perspectives: Structural Reasoning

Harel and Soto (2017) identified five major categories of structural reasoning: (a) pattern generalization, (b) reduction of an unfamiliar structure into a familiar one, (c) recognizing and operating with structure in thought, (d) epistemological justification, and (e) reasoning in terms of general structures. The first category further distinguishes between result pattern generalization (RPG) and process pattern generalization (PPG) (Harel, 2001). RPG is a way of thinking in which one attends solely to regularities in the result. The example Harel gave is observing that 2 is an upper bound for the sequence $\sqrt{2}$,$\sqrt{2 + \sqrt{2}}$, $\sqrt{2 + \sqrt{2 + \sqrt{2}}}$, … because the value checks for the first several terms. When we refer to empirical re-conceptualization and the identification of a pattern based on empirical evidence, we are referring to RPG. In contrast, PPG entails attending to regularity in the process. Harel discussed how one might engage in PPG to determine that there is an invariant relationship between any two consecutive terms of the sequence, $a_{n+1} = \sqrt{a_n + 2}$, and therefore reason that all of the terms of the sequence are bounded by 2 because $\sqrt{2} < 2$.

We define empirical re-conceptualization as the process of re-interpreting a generalization based on RPG from a structural perspective. By structural perspective, we mean engaging in any of the following activities: (a) shifting from RPG to PPG; (b) reducing an unfamiliar structure into a familiar one; (c) carrying out operations in thought without performing calculations; (d) forming and reasoning with a new conceptual entity; or (e) shifting from figurative to operative activity. In short, re-interpreting a generalization from a structural perspective entails the ability to recognize, act upon, and reason with general structures.

Methods

Barney (a 7th-grade student) and Homer (a 9th-grade student) participated in a paired teaching experiment (Steffe & Thompson, 2000), which took place across five sessions averaging 75 minutes each. An aim of the teaching experiment was to investigate the students' generalizations about the areas and volumes of growing figures, and then to study their development of combinatorial reasoning by exploring the growing volumes of hypercubes and other objects in 4 dimensions and beyond.

All teaching sessions were videoed and transcribed. We first drew on Ellis et al.'s (2017) RFE Framework to identify generalizations, and then used open coding to infer categories of generalizing activity based on the participants' talk, gestures, and task responses. We then identified an emergent set of relationships between the participants' patterning activities and the types of generalizations they formed; this yielded the category of empirical re-conceptualization. In a final round we re-visited the data corpus in order to identify all instances of empirical re-conceptualization, the generalizations that led to each instance, and the subsequent explanation or justification. In this manner we were able track the changes in students' activity after engaging in re-conceptualizing, which led to the identification of the affordances detailed below.

Results

We found three major affordances of engagement in empirical re-conceptualization. Namely, empirical re-conceptualization can serve as (1) a source of *verification*, (2) a means of *justification*, and (3) a vehicle for *generating insight*. Within the third category, we identified three types of insight: (3a) re-interpretation within a different context or representational register, (3b) the creation of a new generalization, and (3b) the establishment of a new piece of knowledge. In order to characterize the phenomenon of empirical re-conceptualization and its associated affordances, we present an exemplar case.

Secondary Case: Growing Volumes in Three Dimensions and Beyond

Barney and Homer explored the added volumes of three-dimensional, four-dimensional, and other n-dimensional "cubes" that grew uniform amounts in every direction. They began by determining the added volume of an n by n by n cube that grew 1 cm in height, width, and length. The students worked with physical cubes to consider the component pieces and determined that the added volume would be $3n^2 + 3n + 1$. When they then investigated the added volume of a cube that grew x cm in each direction, the students simply generalized from their prior result. Homer wrote "$(3x)n^2 + (3x)n + x^2$", replacing the 3 in the first two terms of his original expression with a $3x$, and replacing the 1 in the last term, which he had conceived as 1^2, with an x^2. Unsure about the correctness of this expression, Barney said, "let me model on the cube", which he used to verify that the first term, $3xn^2$, was correct because it represented three additional rectangular prisms, each with a volume of xn^2. Both students then realized errors in the next two terms. Barney explained that the second term should actually be $3x^2n$ "because you're adding 3 of x by x by n." Both students also realized the final term would have to be x^3.

The students' original generalization was based on the *result* of their prior activity in building up additional volume components, rather than attending to the *process* by which they grew the cube's volume. However, Barney then experienced a need to verify Homer's result, which led to re-conceptualizing the generalization within the context of volume. He took the algebraic structure and made sense of it geometrically, in the process coordinating his mental activity of constructing component volumes and translating those quantities to algebraic representations.

The students eventually went on to determine expressions of added volume for the 2nd, 3rd, and 4th dimensions, which the teacher-researcher wrote in Figure 1. Homer then saw a pattern in the expressions, exclaiming, "Oh, I know what's happening!":

> Homer: It is simple, as 2 – sorry I'm writing on it. [Begins to draw the blue lines.] Two plus 1 is 3, and 2 plus 1 is 3, 3 plus 3 is 6, 3 plus 1 is 4, 1 plus 3 is 4. [Writes the red numbers.]
> TR: Whoa. Huh.
> Barney: Wow. It's just that one triangle, Pascal's triangle, right?

Homer recognized the pattern in which each coefficient could be determined by adding the sum of the coefficients of the prior consecutive terms. Pascal's triangle then became a mechanism for determining the additional volume of a 5th-dimensional solid, which the students wrote as "$5n^4 + 10n^3 + 10n^2 + 5n^1 + 1^5$". They then decided to check their answer by listing the arrangements of three ns and two 1s (the $10n^3$) case, which served to verify that the coefficient was indeed 10. Barney then realized that given that they had verified the $10n^3$ case, they did not need to check the $10n^2$ case: "We can basically just take this and switch all the ns to 1s and 1s to ns." This explanation of symmetry caused Homer to then extend that finding to new cases: "Oh, and you know what? You can do the same for these (pointing to the $5n^4$ and the $5n^1$ terms)…you can just replace these 1s for ns."

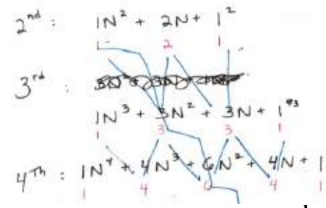

Figure 1: Expressions for added volume in the 2nd, 3rd, and 4th dimensions

Homer and Barney initially developed a generalization based on Pascal's triangle, which allowed them to determine the expression for added volume. Their subsequent listing activity enabled the students to re-interpret that expression combinatorially. That pattern allowed the students to engage in a verification process and subsequently reason about outcomes to develop a new insight, that there must be symmetry in the coefficients. Barney was able to reflect on his operations in listing the ten outcomes and realize that there was nothing special about the characters n and 1, and that they could simply be reversed in the case of determining the combinations of two ns and three 1s. This then supported Homer's new generalization.

Discussion

Empirical re-conceptualization can serve as a source of *verification*, such as when Barney checked the algebraic expression for adding x cm to a cube by appealing to the notion of volume. It can also serve as a source of *justification*, which we saw when Barney justified Homer's pattern of xs in the expression $3xn^2 + 3x^2n + n^3$. We also saw the students developing *insight*. They developed new knowledge and understanding, such as when Barney generated the idea that the coefficient of n^3 must be identical to the coefficient of n^2, which then supported Homer's ability to establish a new generalization that could be extended to the other terms, $5n^4$ and $5n$.

These affordances suggest that empirical re-conceptualization can serve as a vehicle to transform empirical patterns into meaningful sources of verification, justification, and insight. Certainly, students may also identify and generalize patterns that they do not understand or cannot justify. A danger is that students will engage in empirical investigation but then not seek to re-conceive their findings structurally. We find it useful to explore the conditions that can best support students' transition to the productive next step, that of empirical re-conceptualization. Our data suggest that directing students back towards the contextual genesis of the patterns they generalize may be an effective strategy for supporting empirical re-conceptualization. With the support of concrete contexts for meaning making, the activity of generalizing empirical patterns can serve as a bridge to more generative and productive mathematical activity.

Promoting students' mathematical creativity while problem solving is critical to prepare students for future learning and careers. In this paper, we introduce the Creativity-in-Progress Rubric (CPR) on Problem Solving as a tool to enhance mathematical creativity while cultivating problem-solving heuristics and fostering metacognition. With its two categories, Making Connections and Taking Risks, the CPR aims to develop mathematical discourse centered around aspects of creativity involving fluency, elaboration, flexibility, and originality.

Keywords: Advanced Mathematical Thinking, Assessment and Evaluation, Metacognition, Problem Solving

Mathematical creativity and problem solving are two interrelated research constructs in that "[t]rue problems need the extra-logical processes of creativity, insight, and illumination, in order to produce solutions" (Liljedahl, Santos-Trigo, Malaspina & Bruder, 2016, p.19). Numerous research studies and curriculum documents have emphasized the importance of mathematical creativity in mathematics and mathematics courses (e.g., Borwein, Liljedahl, & Zhai, 2014; CUPM, 2015; Leikin, 2009; Silver, 1997; Sriraman, 2009). Similarly, many research studies (e.g., Carlson & Bloom, 2005; Pólya, 1957; Schoenfeld, 2013) have emphasized the importance of problem-solving practices and identified a need to foster skills (e.g., metacognition, creativity) beyond accumulation of facts or procedural steps during problem solving. It seems that exploring mathematical creativity and problem solving together at the tertiary level in mathematics courses is rare (e.g., Zazkis & Holton, 2009). As a first step towards understanding ways to foster and enhance students' mathematical creativity at tertiary level, our research team designed a formative assessment tool, the Creativity-in-Progress Rubric (CPR) on Problem Solving that capitalizes on interactions between creativity and problem-solving constructs. In this paper, we introduce the CPR on Problem Solving and its development. We provide empirical examples from undergraduate Calculus 1 student interviews to illustrate potential benefits of using CPR.

Theoretical Background

In our work, we view mathematical creativity as a process of offering new solutions or insights that are unexpected for the student with respect to their mathematics background or the problems they have seen before (Liljedahl & Sriraman, 2006; Savić et al., 2017). In contrast to examining final products of those processes, this definition is process-oriented, providing a dynamic view of creativity rather than a static one. This definition also encompasses creativity relative to the student versus creativity relative to the field of mathematics (Leikin, 2009).

Our conception and development of the Creativity-in-Progress Rubrics (CPR) was guided by this operational definition of mathematical creativity and situated within two theoretical perspectives: *Developmental*, and *Problem Solving and Expertise-Based* (Kozbelt, Beghetto, & Runco, 2010). The primary assertion of the *Developmental* theory is that creativity develops over time, and the main

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

focus of investigation is a person's process of creativity. This perspective also emphasizes the role of environment, in which interaction takes place, to enhance the creativity. The *Problem Solving and Expertise-Based* theory with the emphasis on the role of an individual's problem-solving process brings forth key concepts such as problems and heuristics.

In our work, we adopted Schoenfeld's (1983) formulation of a problem as a task that the problem solvers "don't know how to go about solving it" (p. 41). Thus, problem solving becomes a process in which the problem solver tries to attain some outcomes without having an immediate access to known methods (to that particular individual) (Schoenfeld, 2013). This description of problem solving aligns with our mathematical creativity definition as both of them focus on a process relative to the individual.

Creativity-in-Progress Rubric

In our previous research studies (see Creativity Research Group, n.d.), we explored the ways in which mathematical creativity could be explicitly valued and fostered in tertiary level proof-based mathematics courses. The CPR on Proving was rigorously constructed through triangulating research-based rubrics, mathematicians' and students' views on mathematical creativity, and students' proving attempts (Karakok et al., 2015; Savić et al., 2017; Tang et al., 2015). Following the development, the CPR on Proving was implemented as a formative assessment tool in several proof-based courses. Some instructors used it to facilitate in-class discussions on proof construction and evaluation of this process (El Turkey et al., 2018) whilst others gave it to students to be used on homework problems and write-ups of solutions (Omar et al., 2019). For example, one instructor, in an elective proof-based combinatorics course asked students to reflect on their proving process of assigned problems using the CPR. One of the students of this course, when asked to discuss the use of the CPR, stated "The reflection process – the rubric itself helped kind of outline where you should go if you were lost, in a very general sense." Another student said, "I think it's helped me …reflect on the sort of creative process that I have and it's kind of helped me understand the ways that I can be mathematically creative."

We have expanded our research program by modifying the CPR on Proving to problem solving by utilizing existing studies in problem solving. This effort allowed us to include more tertiary mathematics courses and student populations in our exploration of creativity. The CPR on Problem Solving has two categories: *Making Connections* (Figure 1) and *Taking Risks* (Figure 2). These categories are divided into subcategories that are reflective of the different aspects of creativity found in prior research. The rubric provides three general levels: Beginning, Developing, and Advancing, each of which serves as a marker along the continuum of a student's progress in that subcategory. This continuum among levels of the rubric communicates the possible states of growth, aligning with the theoretical constructs of the Developmental perspective.

Making Connections Category

The category of *Making Connections* is defined as a process of connecting the problem with definitions, formulas, theorems, representations, and examples from the current or prior courses and connecting the attempted problem solutions to each other. Various researchers (e.g., Schoenfeld, 2013; Silver, 1982) have highlighted the importance of prior knowledge in problem-solving processes acknowledging that such knowledge helps the problem solver to understand the problem and influences the choices of approaches and tools to be used (e.g., examples, representations). The subcategories in Making Connections communicate these ideas to the problem solver and encourage them to push their processes in these areas forward along the continuum. Furthermore, the Between Solutions subcategory encourages the solver to examine their different solution attempts, connect them, and generalize them for thorough understanding.

MAKING CONNECTIONS

	Beginning	Developing	Advancing
Between Definitions/Formulas/ Theorems	Recognizes some relevant definitions/formulas/theorems from the course with no attempts to connect them in a solution	Recognizes some relevant definitions/formulas/theorems from the course and attempts to connect them in a solution	Uses relevant definitions/formulas/theorems from the course or other resources outside the course in a solution
NA ☐			
Between Representations[1]	Provides a representation with no attempts to connect it to another representation	Provides multiple representations and recognizes connections between representations	Provides multiple representations and uses connections between different representations
NA ☐			
Between Examples	Generates one or two specific examples with no attempt to connect them	Generates one or two specific examples and recognizes a connection between them	Generates several specific examples and uses the key idea synthesized from those examples
NA ☐			
Between Solutions	Attempts to connect multiple solutions to each other	Connects multiple solutions to each other	Connects multiple solutions to each other and generalizes common properties
NA ☐			

Figure 1: Making Connections Category of the CPR on Problem Solving

This category encompasses the *fluency* and *elaboration* components of Torrance's definition of creativity (Leikin, 2009). As *fluency* describes flow of associations and use of basic knowledge, with its subcategories of between definitions, formulas, theorems, between representations, and between examples and continuum levels, Making Connections provides opportunities to enhance fluency. As *elaboration* relates to generalization of ideas, moving in rubric's the continuum toward advancing levels of each subcategory provides opportunities for generalization.

Taking Risks Category

The category of Taking Risks in our rubric is defined as a process of actively attempting a solution, demonstrating flexibility in using multiple solution paths, posing questions about reasoning within solutions, and evaluating solution attempts or solutions. The subcategories of Flexibility, Posing Questions, and Evaluation of Solution Attempt align with Pólya's (1957) problem-solving heuristic. In the third step of this heuristic, Pólya discusses the process of carrying out a plan and in the fourth step, the solver examines the reasoning and results of their solution attempt and tries to solve the problem in different ways. In addition, the continuum levels of the Posing Questions subcategory provide ways for the solver to move from the state of being stuck to less stuck by explicitly asking various types of questions.

TAKING RISKS

	Beginning	Developing	Advancing
Tools and Tricks[2]	Uses a tool or trick that is usual for the course or the student	Uses a tool or trick that is partly unusual[3] for the course or the student	Creates a tool or trick that is unusual for the course or the student
NA ☐			
Flexibility[4]	Introduces one solution path	Introduces more than one solution path	Uses more than one solution path
NA ☐			
Posing Questions	Recognizes there should be a question asked, but does not pose a question[5]	Poses questions clarifying a step within a solution	Poses questions about reasoning within a solution
NA ☐			
Evaluation of Solution Attempt	Checks surface-level[6] features of a solution attempt	Checks an entire solution attempt for reasoning	Revises or validates an entire solution attempt for reasoning
NA ☐			

Figure 2: Taking Risks Category of the CPR on Problem Solving

We note that the Tools and Tricks and Flexibility subcategories directly relate to the *originality* and *flexibility* components of Torrance's definition of creativity (Leikin, 2009), respectively. Torrance describes *originality* as a unique way of thinking, which could be evident in the process of using a trick (e.g., adding one and subtracting one) or introducing a mathematical object (e.g., defining a new function) that is unconventional for a student or a course that the student is in. Torrance defined *flexibility* as approaching a problem in multiple ways and producing multiple solutions, which is captured in our Flexibility subcategory. Within the Taking Risks category, we claim that the process of moving forward in the continuum of levels towards the advancing level requires a problem solver to take an intellectual risk in their problem-solving process.

Discussion

In our research project, instructors of Calculus 1 at several different institutions were asked to use the CPR on Problem Solving with tasks that we designed (El Turkey et al., in press). Each instructor decided how to implement these tasks and the CPR, where some used them as part of assignments and others had in-class sessions. We conducted interviews with students from these courses. In our preliminary analysis, we noted that students' experience and the usage of the CPR align with four themes of a problem-solving activity that Schoenfeld (2013) claimed to be necessary and sufficient for the analysis of the success of a problem solver's problem-solving attempt: a) The individual's knowledge; b) The individual's use of problem solving strategies, known as heuristic strategies; c) The individual's monitoring and self-regulation (an aspect of metacognition); and d) The individual's belief systems (about him- or herself, about mathematics, about problem solving) and their origins in the students' mathematical experiences.

We claim that the first two themes (a & b) directly relate to the CPR. When students utilize the CPR during their problem-solving attempt, they demonstrate their knowledge and use of problem-solving strategies. For example, one Calculus 1 student stated that the rubric prompted her to think about class work during problem solving. Discussing her required use of the CPR on an assignment during an interview, she said, "I was trying to think about the definitions we used in class and like drawing pictures with that" and continued by discussing that the flexibility and evaluation subcategories guided her problem-solving approach.

We believe the third theme (c) was encompassed by the usage of the rubric as a reflection tool as the problem solver tried to move forward on the continuum. The CPR connects to the fourth theme (d) as it may increase students' awareness and shift in their perception about their own creative processes (Cilli-Turner et al., 2019). For example, a student from another Calculus 1 course at a different institution stated that, "So, I feel like [the rubric has] definitely improved my creativity the way that …made me think a little bit more about what I'm actually writing down instead of just doing the problem." Our preliminary analysis seem to indicate that as a reflective tool, the CPR can help facilitate discussions on students' attempts and provide guidance on how to enhance students' mathematical reasoning and creative potentials. Ultimately, it may serve to make the link between problem solving and mathematical creativity more salient and accessible in any classroom context.

A QUANTITATIVE REASONING STUDY OF STUDENT-REPORTED DIFFICULTIES WHEN SOLVING RELATED RATES PROBLEMS

Thembinkosi P. Mkhatshwa
Miami University
mkhatstp@miamioh.edu

This paper extends work in the area of quantitative reasoning at the undergraduate level. Task-based interviews were used to examine 16 calculus students' difficulties when solving three related rates problems. Analysis of students' verbal responses and written work revealed several difficulties, including dealing with several time-dependent quantities. The paper concludes with a recommendation for the teaching of related rates problems at the undergraduate level.

Keywords: quantitative reasoning, related rates problems, derivatives, problem solving.

Related rates problems involve at least two rate quantities (i.e., instantaneous rates of change) that can be related algebraically by an equation, function, or formula. Although related rates problems constitute an essential part of any first-semester calculus course in the United States, several researchers have argued that there is a shortage of research that has examined students' thinking about related rates problems at the undergraduate level (e.g., Engelke, 2007; Mkhatshwa, 2020; Speer & King, 2016). Of the few studies involving related rates problems, Mkhatshwa (2020) reported on students who exhibited poor calculational knowledge of the product and quotient rules of differentiation, something that limited their success in a non-routine related rates problem they were asked to solve. Engelke (2007) described beneficial components of a successful solution to a related rates problem, including drawing a diagram, determining a functional relationship (algebraic equation), and checking the answer for reasonability. Other studies have found that mathematizing (Freudenthal, 1993) related rates problems is problematic for students (Martin, 2000; White & Mitchelmore, 1996).

While these studies have provided useful information about how students set up and solve related rates problems, there is still much to be explored about what different modes of reasoning, such as quantitative reasoning (Thompson, 1993, 1994b, 2011) might reveal about students' difficulties with solving related rates problems that have real-world contexts such as kinematics. Quantitative reasoning seems a particularly important lens for studying students' understanding of related rates problems since they inherently deal with quantities. In addition, students' difficulties with solving related rates problems in these studies have all been reported from a researcher's perspective (i.e., observed difficulties), and have not considered a student perspective (i.e., student-reported difficulties). Thus, in order to build on these studies, the present study investigated students' difficulties with solving related rates problems from a student perspective. The research question we investigated is: What do calculus students identify as difficulties when engaged in reasoning quantitatively about solving related rates problems?

Related Literature

Evidence from studies that have examined students' reasoning about geometric related rates problems (Mkhatshwa, 2020) shows that students who are able to visualize and perform physical enactments of situations described in related rates problems tend to be successful in solving these problems (Carlson, 1998; Carlson, Jacobs, Coe, Larson, & Hsu, 2002; Monk, 1992). Several researchers have identified lack of facility with implicit differentiation as a major cause for students' failure to solve related rates problems successfully (Clark et al., 1997; Engelke, 2004; Mkhatshwa, 2020; Piccolo & Code, 2013). Piccolo and Code (2013) argued that students' difficulties with solving

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. related rates problems stem from a weak understanding of implicit differentiation, rather than a misunderstanding of the physical context of such problems. Hare and Phillippy (2004) posited that "implicit differentiation is a difficult concept for many students to understand because the level of difficulty of the concept is higher than the level of difficulty of explicit functions" (p. 7). Conflicting findings have been reported on calculus students' ability to mathematize related rates problems (cf., Martin, 2000; Mkhatshwa, 2020; White & Mitchelmore, 1996). Analysis of students' written responses to geometric related rates problems by Martin (2000) revealed that overall performance was poor, and that "the poorest performance was on steps linked to conceptual understanding, specifically steps involving the translation of prose to geometric and symbolic representations" (p. 74). Findings of a recent study (Mkhatshwa, 2020) on students' thinking about related rates problems in real-world contexts indicated that mathematizing routine related rates problems is straightforward for students.

Theoretical Perspective

This study draws on the theory of quantitative reasoning (Thompson, 1993, 1994b, 2011). Quantitative reasoning is the act of analyzing a problem in terms of the quantities and relationships between the quantities involved in the problem (Thompson, 1993). In this study, quantitative reasoning refers to how students interpreted rate quantities (i.e., instantaneous rates of change) when solving related rates problems, and how they reasoned about quantities and relationships between quantities when engaged in talking about difficulties they had with solving these problems. What is important in quantitative reasoning is making sense of quantities and relationships between quantities (Smith III & Thompson, 2007; Thompson, 1993). Thompson (2011) described three tenets that are central to the theory of quantitative reasoning, namely a quantity, a quantitative operation, and quantification. A quantity is a measurable attribute of an object (Thompson, 1994b). Examples of quantities in this study include the speed of an airplane, the area of a puddle, and the volume of a balloon. A quantitative operation is the process of forming a new quantity from other quantities (Thompson, 1994b). We designed three tasks (Task 1, Task 2, and Task 3 in the methods section) that provided opportunities for students to perform quantitative operations by creating new quantities through the process of implicit differentiation. Quantification is the process of assigning numerical values to quantities (Thompson, 1994b). The three tasks used in this study provided opportunities for students to engage in quantification.

Methods

Task-based interviews (Goldin, 2000) were used to investigate calculus students' quantitative reasoning while solving related rates problems. The interviews covered three tasks:

> **Task 1 [motion context]:** Two small planes approach an airport, one flying due west at a speed of 100 miles per hour and the other flying due north at a speed of 120 miles per hour. Assuming they fly at the same constant elevation, how fast is the distance between the planes changing when the westbound plane is 180 miles from the airport and the northbound plane is 200 miles from the airport?
>
> **Task 2 [non-motion context]:** A leak from the sink is creating a puddle that can be approximated by a circle, which is increasing at a rate of $12\ cm^2$ per second. How fast is the radius growing at the instant when the radius of the puddle equals 8 cm?
>
> **Task 3 [non-motion context]:** For the next problem, let me give you a little background on a formula that we will use. Suppose a gas is inside a container. Many gases under normal conditions follow the "ideal gas law," $PV = kT$, where P is the pressure the gas exerts on the container, V is the volume of the container, T is the temperature of the gas, and k is a constant. P is measured in "atmospheres," V is measured in cubic meters, and T is measured

> in Kelvins. Kelvins is a lot like Celsius, except that it is scaled so that 0 means absolute zero (lowest possible temperature), which makes water's freezing point to be $273\ °K$. Do you have any question(s) about this formula, or any of the quantities [like temperature in Kelvins] before we proceed?
>
> In a laboratory, an experiment is being done on a gas inside a large flexible rubber balloon. For the experiment, the temperature of the gas is being heated at a rate of 8 degrees Kelvin per second. At one point, when the temperature of the gas is $300\ °K$, the pressure is 1.5 atmospheres, the volume of the gas is one cubic meter, and the volume of the gas is increasing at a rate of 0.01 m^3 per second. At that moment, is the pressure in the balloon increasing or decreasing? What is the rate of that increase/decrease?

After students concluded their work on each task, the interviewer asked the following questions: (i) What does your answer [derivative] tell you in the context of this task? (ii) How would you answer the question posed in this task? (iii) What was the easy part for you when solving this task? and (iv) What was the difficult part for you when solving this task? With these questions, our goal was two-fold. First, we wanted to examine students' interpretations of derivatives in motion and non-motion contexts (questions i. and ii.). Second, we wanted to gain an insight on what is straightforward and what is difficult about solving related rates problems from a student perspective (questions iii. and iv.).

Setting, Participants, Data Collection, and Data Analysis

The study participants were 16 undergraduate students at a research university who were enrolled in five different sections of a calculus I course taught by three different professors. Details about the participants, including opportunities they had to learn about related rates problems during classroom instruction are provided in Mkhatshwa (2020). Data for the study consisted of transcriptions of video-recordings of the task-based interviews and work written by the students during each interview session. On average, each interview session lasted for about 65 minutes. The data was analyzed in two stages. In the first stage, we used two emergent codes i.e., student actions that evolved from the data. These codes are: (1) the difficulty of dealing with several time-dependent variables (quantities), and (2) the difficulty of finding the value of the constant k in Task 3. In the second stage of the analysis, we tallied the number of students in each of codes found in the first stage of the analysis.

Results, Discussion, and Conclusions

Since Task 3 was the only non-routine task, and one that most of the students were least successful in solving, we limit our discussion of student-reported difficulties with solving related rates problems to this task. There are three findings from this study. First, when asked about the difficult part about solving the task, six students stated that everything about the task was hard. Amos' reasoning about the difficulty of solving Task 3 is representative of the six students.

> Researcher: What was the easy part for you when solving this task [Task 3]?
> Amos: None of the problem was easy for me.
> Researcher: What was the difficult part for you when solving this task?
> Amos: Reading the task, differentiating the given equation [$PV = kT$], and figuring out where to plug in the given values [quantities in the task, e.g., the temperature of the gas given as $300°K$] in order to solve the problem.

In response to the first question (i.e., the easy part), Amos stated that "none of the problem was easy" for him. When asked about the difficult part, he noted reading the task, differentiating the equation given in the task, and using all the given information in the task to solve the problem posed in the task. When probed about the type of differentiation he would use in this task, Amos stated that he would "have to use implicit differentiation." Two other students identified implicit differentiation as the challenging part when solving the task. Students' difficulties with implicit differentiation (i.e., performing quantitative operations) when solving related rates problems have been reported by other researchers (cf., Clark et al., 1997; Mkhatshwa, 2020; Piccolo & Code, 2013).

Second, four other students stated that there were several variables (quantities) to keep track of, and that this was the main challenge for them when solving the task. The following excerpt illustrates how Felix, whose reasoning is representative of these students, commented about the difficult part when solving the task.

Researcher: What was the difficult part for you when solving this task?
Felix: There are more than two variables [quantities], P, V, and T in the same equation [$PV = kT$].

Felix remarked that having several quantities, namely pressure (P), volume (V), and temperature (T) in the same problem was problematic for him when solving the problem posed in the task. He, however, did not elaborate on this. We argue that the unfamiliar context may have been the challenge for Felix more than having several variables. This is because in Task 1 (a familiar task to Felix and one that has several variables as well), Felix did not claim that having several variables in the problem was the difficult part. Instead, he said the difficult part was finding an equation that relates the quantities in the task, that is, mathematizing the problem. On the contrary, 10 students claimed that Task 2 (a routine task) was easy to solve because it had fewer variables compared to Task 1 and Task 3. When asked about the easiest part about solving Task 2, one of the 10 students, James, commented, "we only had one variable to track and that's the radius, so it was fairly easy to solve." When asked about the difficult part when solving Task 2, he said, "I don't think there were any challenges." We argue that the number of variables play a huge role in students' ability to solve related rates problems successfully.

Third, four students stated that finding the value of the constant k was the difficult part for them when solving Task 3. We note that although only four students identified solving for the constant k as the problematic part in Task 3, half of the 16 students in this study were unsuccessful in finding the value of k. Since finding the value of the constant k entails engaging in the process of quantification i.e., substituting the given values of the quantities of P, V, and T in the equation $PV = kT$ and then solving for k, we argue that substituting known quantities and solving for an unknown quantity in an equation is perhaps not only problematic for secondary school students, but also for undergraduate students. Based on the student-reported difficulties when solving related rates problems in this study, we recommend that calculus instruction should provide more opportunities for students to make sense of, and to solve non-routine related rates problems that have several quantities. The interested reader is referred to Mkhatshwa (2020) for observed (i.e., researcher-reported) difficulties that were exhibited by the students when solving the three tasks used in the present study.

Reasoning-and-proving is viewed by many scholars to be a crucial part of students' mathematical experiences in secondary school. There is scholarly debate, however, about the necessity of formal proving. In this study, we investigated the notion of "proof for all" from the perspective of secondary mathematics teachers and we analyzed, using the framework of practical rationality, the justifications they gave for whether or not all students should learn proof. Based on interviews with twenty-one secondary teachers from a socioeconomically-diverse set of schools, we found that teachers do not share the same opinion on who should learn proving but they expressed obligations toward individual student learning as justifications both for teaching proving to all students and for not teaching proving to some students.

Keywords: Reasoning and Proof; Teacher Beliefs; High School Education; Equity and Diversity.

Reasoning-and-proving, the broad mathematical practice of conjecturing, justifying, critiquing arguments, constructing proofs and more (Stylianides, 2008), is central to the discipline of mathematics and can also be a powerful process through which students learn mathematics (de Villiers, 1995; Stylianides et al., 2017). Policymakers (National Governors Association & Council of Chief State School Officers, 2010; Secretaría de Educación Pública, 2014) and scholars (e.g., Mariotti, 2006) alike have called for reasoning-and-proving to be a part of all students' learning experiences in school. But there are also critiques of this general framing of learning "for all" such as Martin (2003) who pointed out that "for all" often comes as impositions on underserved groups, and Battey (2019) pointed out that "for all" can gloss over learners' individuality, proposing "for each and every" as a replacement framing. With regard to formal proof in particular, Weber (2015) noted that it may be unnecessary at the secondary level to explicitly develop "proving" and that it may be sufficient to push for clear explanations and valid justifications and that doing so may more easily integrate with students' mathematical experiences prior to secondary school.

Where do mathematics teachers, as the ones directly responsible for enacting curricular recommendations, stand on this issue of "proof for all"? How are teachers thinking about the scope and appropriateness of proof for students? Past studies have examined teachers' views of proof (e.g., Ko, 2010) or their views on mathematical processes including proof (e.g., Sanchez et al., 2015) but the question of who they think should learn proof is fundamental. In this study, we interviewed 21 secondary mathematics teachers from an economically-diverse set of schools in Cape Town, South Africa. Although outside North America, it has similarities to North American contexts in terms of mathematics teaching being heavily influenced by European colonization and having typical instruction that is procedural in nature (Webb & Roberts, 2017). Moreover, the question of who should experience proof is one with worldwide relevance as we consider broadly students' mathematical experiences.

(2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

Personal and Theoretical Perspectives

Because this study involves our analysis of teachers' perspectives on proving, it is important that we reveal salient information about our own perspectives for the sake of transparency. Samuel is an American white man of Western European descent who attended rural public schools and then public universities where he earned degrees in both mathematics and education. Mitchelle is an African woman who attended the Kenyan elementary, secondary, and undergraduate education system, and is currently in the U.S. pursuing a doctoral degree. Rajendran, an Indian born in South Africa, attended urban primary and secondary public schools during the apartheid era and then proceeded to study at public universities where he earned degrees in both mathematics and education. Although from diverse backgrounds, we all share a view that proving—in the sense of constructing reasonably complete and logically valid arguments for mathematical claims—is important for all students in the general education system as well as most students in the special education system. Although this is our opinion, we value hearing the voices of teachers and taking seriously their perceptions of what is possible and why.

In terms of our approach to teachers' perceptions, we see teachers as participants in a cultural practice of teaching governed by norms (i.e., tacitly expected behaviors or unquestioned historical practices) and obligations (i.e., requirements perceived as inherent to their role as a mathematics teacher) (Herbst & Chazan, 2011). These norms and obligations influence the choices that teachers make in their own teaching (e.g., Webel & Platt, 2015). Obligations, in particular, can be used to categorize the justifications that teachers provide for their instructional choices. For example, a teacher may decide to present a proof to students rather than have them construct the proof independently because she feels an obligation to complete the lesson in a single class period and stay "on pace." Or a teacher may decide to emphasize formal terminology in a proof because he feels an obligation to the mathematics discipline to maintain "rigor."

We have two central research questions. RQ1) According to secondary mathematics teachers, who should learn proving in their formal mathematics education? RQ2) What justifications do secondary mathematics teachers provide for their answer about who should learn proving?

Method

The study was conducted in the Cape Town metropolitan area of South Africa, which is a port city on the southwest coast. South Africa, since its democratization in the 1990s, has pursued curricular reforms centered on universal education (Webb & Roberts, 2017). Its official standards call for elements of reasoning-and-proving to be taught to all learners. The 21 teachers participating in this study varied in their professional preparation and experience (from 1 year to 15 years teaching) but they all were mainly involved in teaching mathematics to grades 10–12 leaners. Their five schools were in drastically different socio-economic neighborhoods.

The first author, sometimes with the third author, conducted two types of semi-structured interviews. All 21 teachers participated in focus group interviews (approx. 20–40 minutes), organized by school, focused on the purposes of mathematics education and curricular issues related to proving. Ten of the 21 teachers also participated in individual interviews (approx. 10– 30 minutes) focusing on proving tasks and their experiences with proof learners. The analysis reported here specifically addresses the question of "who should learn proof in school?"

The interviews were transcribed and coding was in two phases. Phase 1 involved reading the transcripts and applying broad codes to any segments that related to the overarching research questions. We noted the groups of learners that teachers identified as who should learn proving. Phase 2 involved qualitative coding based on the practical rationality framework (Herbst & Chazan, 2011), particularly the professional obligations. We briefly describe these codes here:

- *Disciplinary*: teachers' perceived obligations related to mathematics as a subject area (e.g., proving is the "core" of mathematics)
- *Institutional*: teachers' perceived obligations related to the educational system, school policies, or administrators (e.g., proving is included on official assessments)
- *Individual*: teachers' perceived obligations related meeting the needs and expectations of specific learners (e.g., proving can help learners gain deeper understanding)
- *Interpersonal*: teachers' perceived obligations to balance the needs of a diverse class of learners and managing productive interactions (e.g., proving promotes respectful critique)
- *Worldly obligations*: teachers' perceived obligations related to the real-world usefulness of what is being taught (e.g., proving will help learners use logic beyond mathematics)

The *worldly obligation* code emerged from our own data set. Overall, multiple authors coded the obligations and met regularly to clarify (e.g., code two obligations within the same justification statement) and reconcile any discrepancies in the coding.

Findings

Several of the teachers expressed the opinion that some students should be exempted from the opportunity to learn proving (see below), but more than twice as many teachers expressed that all students should have an opportunity to learn proving. Others (i.e., some who only participated in the focus group interviews) did not express an opinion on this question, but the sections below provide brief findings with regard to the rationality that the teachers exhibited.

Teachers' Rationality for All Students Learning Proving

Teachers who stated that all students should learn proving provided a variety of justifications for that position. The most common justification related to the teachers' obligation toward *individual* student learning. Teachers explained that proving can help students to understand mathematical content in deeper or more inter-connected ways. For example, Panyanga said:

> All of [the students] should know how we get to things, not just the application… I'll just make an example with Pythagoras' theorem, you find that they know how to use it but they don't really understand it properly [without proving it].

An implicit obligation here is for the teacher to support students in understanding mathematics "properly," not just execute applications, and proving is something that promotes an understanding of "how we get to things." A similar point was raised by another teacher, Rhyan, who said about proving opportunities, "You have to give people space to experience the idea" because this helps them to move beyond knowing just "that a parallelogram has opposite sides equal" to understanding how that result connects with other pieces of knowledge in geometry.

Other teachers, in justifying that all students should learn proving, looked beyond the classroom. Specifically, teachers expressed a *worldly obligation* by connecting mathematical proving to students' current or future lives beyond mathematics. For example, Portia said that

> …to prove something is not just a mathematical skill, it's a skill in logic, it's a skill in trying to figure out and to validate your arguments. And that is not confined to only mathematics… I think it is a valuable skill and I think that everybody has the ability to do it. You don't need to say, 'Okay, this is exclusively for those who score high marks [in mathematics].'

Shabeer made a similar point that "being able to prove something in geometry, it helps you even being able to prove it in something unrelated to geometry." We also viewed references to general "critical thinking" as part of this worldly obligation.

Beyond individual and worldly obligations, a few teachers cited disciplinary or institutional obligations. We turn now, however, to those who had different opinions altogether.

Teachers' Rationality for Not All Students Learning Proving

Although one teacher commented that, were it in her power, she would remove proof from the official curriculum, we focus in this section on the several teachers who stated that only certain groups of students should learn proof. The most frequent justification that teachers provided for this position had to do with their *individual obligation* to support or cater to students' needs. For example, when asked who should learn proof, Shannon said the following:

> I think our students must learn proofs but not all the students. Because … with a particular class I can prove a theorem or I can do a proof. But with another particular class I will see that if I want to prove this theorem, I will do more harm than good… For those learners whom I can say they may be average to above average, yes. If we say let us prove it and let us use it, they will acutely enjoy the proving and the using of the proof.

For Shannon, she wants to teach proof when the result, as she perceives it, is an enjoyment of learning and students who see the usefulness of the proof. She has identified these benefits as being attached to some "but not all" students. For the other students, she refers to proving as doing "more harm than good," which we interpret to refer to confusion and struggles that can occur when she teaches proving. Other teachers expressed a similar obligation to help students avoid struggle. One said that proofs can cause students to become "discouraged" and another mentioned that those who "shouldn't learn the proofs are those learners [who] at the beginning are struggling… it's not going to be worth it to learn the proofs," whereas "those learners who excel should be focusing on the proofs because it'll help them understand actually most of the math much better." In this excerpt, avoiding proof and teaching proof were both rooted in individual obligations to either help students avoid struggle or help them achieve understanding.

Another justification that teachers mentioned had to do not with students' struggles but with their future plans after secondary school. For example, Shabeer said that "there is a certain group of students [who] should learn proofs and it depends maybe on what that student plans to do when he's done with school." This life-after-school idea connects with the *worldly obligation* in our framework. A similar point, but with different underpinnings, came from Trevelyan who said that proof should be "for the other students who are going to do something with the mathematics… are going to go and study further with the mathematics… because that's the core of what mathematics is." In this instance, a *disciplinary obligation* is evident as proof is an essential part of mathematics and thus is relevant for those who will pursue higher mathematics.

Discussion

Our goal was to recognize teachers' rationality because this is important as we attempt to work collectively to improve proof learning. As scholars, it is not safe to presume that all teachers necessarily view proving as worthwhile for all students. Yet, our findings suggest that teachers on both sides of the issue were deeply attuned to individual obligations. Thus framing proof as a way to support individual learning, and in particular addressing the idea (not expressed by the teachers) that proving can be fruitful for "struggling" students may be a way to find common ground. Conversely, appeals to the disciplinary obligation of proving may inadvertently send the message that proving is only for students who are on a pathway to higher mathematics. The worldly obligation may be an opportunity to promote more universal opportunities for proof learning. Or in listening to some teachers we may, like Weber (2015), have to take seriously the notion that *formal* proof may not be the most productive approach to reasoning for all students.

Acknowledgments

We thank the teachers for sharing their perspectives and their generosity of time. This work was supported by the University of Missouri South African Education Program and the University of Missouri College of Education.

THE ROLE OF THE RESEARCHER'S QUESTIONS IN A CLINICAL INTERVIEW ON STUDENTS' PERCEIVED PROBLEM SOLVING

Reyhan Safak, The Ohio State University
Karoline Smucker, The Ohio State University
Azita Manouchehri, The Ohio State University

In this work we considered interactions between researcher/interviewer and two case subjects in the context of two task-based interviews to isolate ways that subjects' problem-solving performance was influenced by the choice of interventions that researcher opted to employ. In order to capture shifts in the students' actions that could be attributed to specific interventions a problem-solving map was constructed for each individual. Shifts and transitions in actions were then corresponded to the nature of exchanged taking place prior to the shift. In the case of Tuna, probing guidance lead her struggle to a productive end. For Sam, suggesting the use of a two-way table as scaffolding shifted his struggle in a productive manner.

Keywords: Problem Solving, Intervention, Clinical Task-Based Interview

The goal of the research reported here was twofold. First, we examined problem solving processes of two 5th grade students when working on a task that entailed algebraic thinking. The goal was to identify junctions where students' progress on the task was constrained. The second goal was to identify ways in which the researchers' modes of interventions seemingly impacted the problem solvers' performance, particularly at constrained junctions. Our research was motivated by the desire to better unpack ways in which researchers' choices of questions might influence results concerning children's problem-solving abilities and performance, an area rarely explored in mathematics education. With increased interest in using clinical interviews and teaching experiments that rely on direct interactions between subjects and researchers such an exploration is both timely and needed.

Literature Review

Mathematical problem solving is defined as "an activity that relies heavily on the problem solvers' in-the-moment decision making and improvising and the type of insights that they may develop in the course of their actions" according to Manouchehri & Zhang (2013, p.68). What remains unknown is how students decide what strategies to use and what might contribute to shifts in their approaches. Much of the literature concerning the mathematical problem-solving performance of learners relies on task-based interviews, either in structured or semi-structed setting. Rarely has the interviewer's role and their comments in the course of problem-solving process has been scrutinized, linking learners' performance to potential impact of the probing questions the interviewer might have asked. This considers even in occasions where questions may consist of eliciting the learners' own thinking (i.e. explain what you were thinking, why did you do this, etc.) All these comments are forms of intervention that force reflection, either implicitly or explicitly and elucidate cognitive reactions resulting to some kind of mathematical outcome.

Methodology

Videotapes of two task-based interviews (Litchman, 2012) with two 5th grade students were used as data sources to carefully unpack researcher/participant interactions as one task was used towards capturing students' problem-solving performance. During these interviews, the researcher had used a common task focused on capturing students' algebraic thinking (see Figure 1). Each interview lasted approximately 20 minutes.

Analysis consisted of two phases. First, Using Schoenfeld's (1985) problem solving path as a platform we traced the learners' actions throughout their encounters with the problem with the goal of launching a solution. Phases included reading the problem, analyzing the problem, exploring, planning, implementing and verifying the solution method. Of particular interest was determining stages at which progress seemed constrained.

Task 1: Where am I?

The seats in the auditorium of Joyful Elementary School with a capacity of 300 people are labeled as follows and the rest of the seats follow the same pattern.

Front

Row 1	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**
Row 2	**11**	**12**	**13**	**14**	**15**	**16**	**17**	**18**	**19**	**20**
Row 3	**21**	**22**	**23**	**24**	**25**					

Figure 1

1. Chris is in seat 48? What row is he in?
2. Tyler is two rows behind and four seats to the right of Seat 42. What is his seat number?

During the second phase of data analysis we considered the influence of the researcher/interviewer's comments on the problem solvers' transitions along the problem-solving map. Note that during the interviews, as a protocol, the researcher was allowed to ask "why" and "how" questions to understand the reasoning of students' problem solving strategies. Further, common to task-based interview tradition, students were asked whether their answer made sense and to explain their reasons. Additionally, questions regarding how students assessed their own progress, what may have caused them to be stuck or what they found confusing were considered ways that the research could gain a better understanding of sources that contributed to the problem solvers' choices. Indeed, we examined how these seemingly "unobtrusive comments" impacted the mathematical work that problem solvers produced.

Preliminary Findings

Our findings will be grounded in illustrations of shifts in two students' problem-solving practices in the presence of interactions with the interviewer. Due to the limitation of space, we consider only two examples to highlight ways that the task-based interactions influenced the learners' problem-solving actions and progress.

Sam and Tuna both encountered the same impasse during the episodes of exploring and planning, but their resolutions were different. Sam and Tuna both struggled as they worked on the task but there were significant differences in the nature of their struggle. Sam directly implemented his solution method after analyzing the problem based on his understanding from the task. On the other hand, Tuna asked analytical questions to the interviewer to clarify her understanding from the question and then she went back and forth between either correcting or recalling her prior knowledge and creating new knowledge in the exploring phase. While Sam struggled making sense of the 1st question, Tuna's constraint was misinterpreting her prior knowledge of multiplication for the 2nd question.

Initial actions

Figure 2 illustrates problem solving maps of the two interviewed subjects (Sam and Tuna). Figure 2(left column) depicts a map of Sam's problem-solving process. He first reads the problem and analyze the pattern going by ten then implement his strategy of counting by 10 backwards from 48 until he reaches 8. Then, he verifies his solution by his multiplication fact. (6x8=48). Once he was asked how he had arrived the number 6, he we went back to planning phase and adjusted his solution method. Then, he verified his new solution with another multiplication fact. (8x5=40). Lack of reliance on an organizational scheme hindered his ability to move forward in generalizing his answers. However, once Sam was provided with two-way table, he analyzed the problem again, relied on his initial interpretation of the task and solved it. The transcript below shows Sam’s shift in his struggle with multiplication facts to a productive end. Using two-way table reminded him his first interpretation of the task and obtained the final result. However, once he was suggested to use a two-column table to organize his data, he managed to successfully launch a solution.

S: So then, if you are like 6 rows over, it will probably be 48 because if he is if he is wait, if it says he was 48?

I: Yeah! Chris is in seat 48. It is asking for uhm what row is he in? **What we can do is I can give you this table Ok? Did you use two-way table before?**

S: Yeah

I: Ok. Just go with that.

(C is filling in the table as Row: 5 Seat Number: 41,42,43, 44…)

S: (While he is writing the number 44) AHA!

I: What happened?

S: It is row 5.

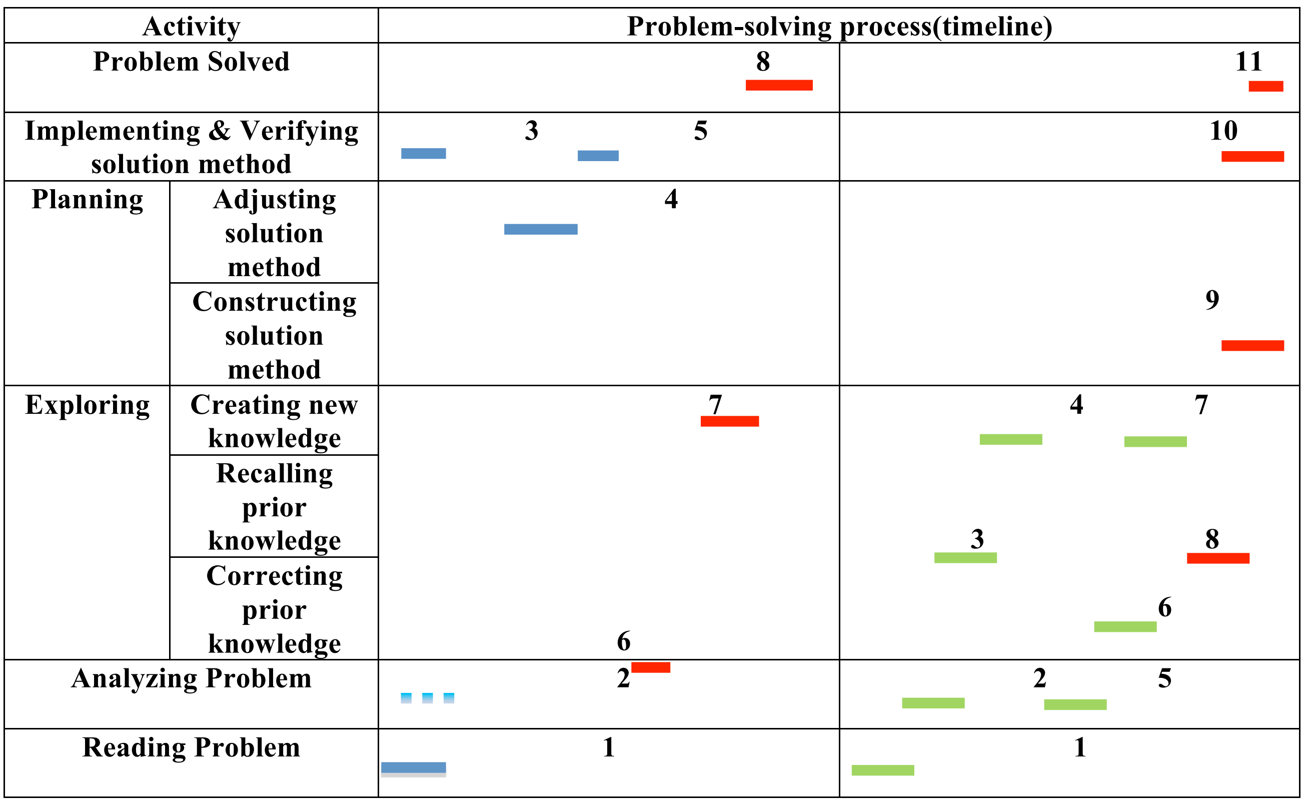

Figure 2: Tracking of Sam and Tuna’ s problem solving (Red lines represent intervention)
Sam: Blue lines 1-5 & red lines 6-8
Tuna: Green lines 1-7&red lines 8-11

I: Uhm how do you know that? Why did you use 6 times 7 is equal to 42? How did you decide to use that?

T: Uhm. Uhm yeah, uhm wait oh wait never mind. I will just solve it never mind. Because I was thinking like going like that uhm wait. I think it will be row 6 because like seat 42. Because in each row, one of the multiples are in 7 are (inaudible) in it. So, 42 will be in the row 6.

I: So, in each row, there are multiples of what?

T:7 and uhm because I know. Wait no! You are actually in row 5. Because in row 4, last seat will be 40 and row 5, seat 42 will be in it needs to keep going through and you find in in row 5.

Transcript above shows Tuna's transition from her previous strategy to the new solution due to the interactions with the interviewer. Immediately after the interviewer re-voiced her claim as in each row there are multiples of seven, Tuna recalled her prior knowledge of last seat in each row is 10 times the row number and she constructed new solution method based on her first interpretation of the task. She then implemented her solution method as adding 2 rows to row 5 and claimed that Tylor will be in row 7 and she said that "since it will be in row 7 last seat in row 7 will be 70 but the seat it is in row 7 so I know that his seat would be the 6^{th} seat in row. If 70 is the last seat you have to take away 4 will get you to 66.". She finally obtained the correct response after going back and forth between problem solving phases.

Conclusion

Our results highlight several important theoretical considerations. While clinical interviews are widely used as vehicles to learn about what students know and how they work mathematically around selected tasks with the desire to identify gaps and strengths in their approaches, little attention has been paid to how these actions may have been influenced by the researchers' choices of questions. It is commonly assumed that interviewer's role is to be an objective observer that asks why and how questions without a careful examination of how such interventions might have influenced the work that learners produce in the course of interactions. In our analysis we offered how students' problem-solving pathways were influenced by the interviewer's comments. As such, we problematize we perceived notions of students' problem solving competencies reported in the literature without a careful examination of interactions in the course of interviews that could have impacted participates' work either through provoking reflection or prompting schemes that may not have been recalled during their work on tasks.

sofia.vazquez@cinvestav.mx

The theme of proportionality begins formally in the last years of primary school, and involves the mastery of notions such as comparison of ratios, fractions, and percentages. In this research, a study was carried out with 18 students of fourth and fifth grades of primary education between the ages of 9 and 13, with the objective of assessing their performance in solving problems that involved comparing ratios and having relative thinking. Both types of problems involve proportional thinking. The purpose is to know what is the difference between the two groups, as well as to identify if there is a difference between performance in the two types of problems. It was found that students in both grades have more difficulty in solving relative thinking type problems and that there is no substantial difference between the two groups that participated

Keywords: Problem solving, Reasoning and Proof.

In research aimed at studying proportional reasoning in children who attend primary school, the difficulty they face in solving problems that involve operating with notions such as ratio, fraction and developing relative thinking is recognized.

This report presents the results of a study carried out with children in 4th and 5th grade of primary school using computer software in which two types of problems were presented that required the use of reasoning and relative thinking for their resolution.

Background and theoretical framework

Among the studies that focus on the comparison of ratios, Fishbein, Pampu, and Manzat, (1970) investigated the influence of the total number of marbles, in any set, when comparing ratios between sets, noting the possibility of estimating using W1/B1 and W2/B2 type ratios. Sing (2001), based on studies with sixth graders students on the understanding of concepts of proportion and ratio when solving problems such as buying sweets, delivering pizzas and a situation of enlarging and reducing a rectangle, emphasizes that it is necessary to have built multiplicative structures and iteration schemes for proportional thinking. Boyer, Levine, and Huttenlocher (2008), conducted two studies using computer programs, based on the application of a proportional equivalence task. They examined where students make mistakes in processing proportions involving discrete quantities.

The interpretation of the results of this study is made within the framework of the following theoretical approaches. Vergnaud (1991), mentions that the first acquisitions of numerical structures are made during the first years of primary school: additive structures and multiplicative structures. Addition is associated with grouping situations, which make it possible through directed situations to know the rules and procedures of the additive structures, necessary for the acquisition of the multiplicative structures. With respect to multiplication, it establishes that the first great form of a multiplicative relation, implies establishing a relation between two quantities of the same type with other two of the same type, that is, there are four quantities put in relation.

Multiplication requires an understanding of functions that assume the quantities involved, notions such as scalar operator, fractional operator, unit value, etc., Vergnaud (1991). According to this approach it is possible to write relationships and representations between quantities in the form of proportions and arrive at the notion of fraction, ratio and consequently the comparison of ratios. On the other hand, Lamon (1999) defines two types of thinking in the field of proportionality: relative thinking, in which the comparison between two quantities is made from one with respect to the other and not independently, which is what characterizes additive thinking. Noelting (1980), based on his experiment of comparing mixtures of orange juice and water, established a hierarchical differentiation of stages of development of proportional reasoning, based on the comparison of ratios.

Research questions, objectives and method

General objective

To assess whether there is a difference between fourth and fifth grade students in terms of their performance on two types of problems that involve recognizing relationships of proportionality and having relative thinking.

Specific objectives

Recognize how the results of reason comparison problems differ from relative thinking problems.

Observe what difference there is between the results of the fourth grade of primary school students with respect to the fifth grade of primary school students.

Research questions

What is the difference between the results of ratios comparison problems and relative thinking problems?

What is the difference between the results of the fourth grade of primary school students with respect to the fifth grade of primary school students?

Hypothesis

H0= There is no difference in results between ratios comparison problems and relative thinking problems.

H1= There is a difference in the results between the problems of comparison of ratios and the problems of relative thinking.

H0= There is no difference in the answers of 4th grade students compared to 5th grade students in primary education.

H1= There is a difference in the answers of 4th grade students compared to 5th grade students.

A total of 18 students participated in this research, 10 fourth graders and 8 fifth graders from a private school in Mexico City. The participants were between the ages of 9 and 13, with a mean of 10.17 years and a standard deviation of 0.89.

A program was designed in the PsychoPy software version v.3 .2.3. The program that was carried out in PsychoPy, is the instrument that allowed obtaining the data in the present investigation, it was made up of three general parts, the first one presented the instructions of the activity to the students, in the following part of the instrument eight problems of the type comparison of reasons were presented to the students, the activities carried out by Noelting (1980) were taken as a model, in the third part of the instrument eight problems in the category relative thought were proposed, some activities carried out by Lamon (1999), referring to relative and absolute thought were taken into account and others were adapted. For the implementation the institution provided access to the computer room and the test was done twice to each student, when the children arrived at the room they were informed that it was an investigation that was being done for a university and that it was not to qualify them.

Results and discution.

The procedure implemented to evaluate the answers was to calculate the percentage of correct answers per student in the first moment, then to calculate the percentage of correct answers per student in the second moment and finally to calculate the average of moments one and two.

With the mean of the moments one and two of the students, an analysis of variance (ANOVA) of repeated measures (grade five vs. grade four) X2 (Types of problems: Comparison of ratios vs. relative thinking) was performed in the statistical program called JASP. The school grade is defined as the inter-subject variable and the problem type variable is defined as the intra- subject variable.

For the main effect with respect to the types of problems, within subjects, a large statistic of $F(49,201)$, $(0.001<p)$ is reported, it can be said that without considering the group that responded to the instrument there are significant differences with respect to the two types of problems presented, the problems of comparison of reasons with respect to the problems of relative thinking. That is to say, the students of both courses respond better to the problems of comparison of reasons than to those of relative thinking, in this way the null hypothesis is rejected and the alternative hypothesis is accepted which mentions that if there is a difference between both types of problems.

On the other hand, another effect within subjects in relation to the two school grades is reported as a statistic $F(0.274)$, $(p= 0.608)$ this indicates that there is no difference between the two groups that answered the instrument. The ANOVA test suggests that in this case, regardless of the grade level of the students, both grades show a higher percentage of correct answers in one type of problem than in the other, thus accepting the null hypothesis.

On the other hand, as an effect of the test between subjects, there was no effect between the factors degree and types of problems $F(.411)$, $p=0.53$. That is, the grade does not affect performance on either type of problem. The analysis of variance does not reveal any significant interaction.

Figure 1 shows the lack of interaction between problem type and grade, both perform better in answering problems of the comparison of reasons type and lower in solving problems of the relative thinking type, fourth graders are slightly above correct answers relative to fifth graders.

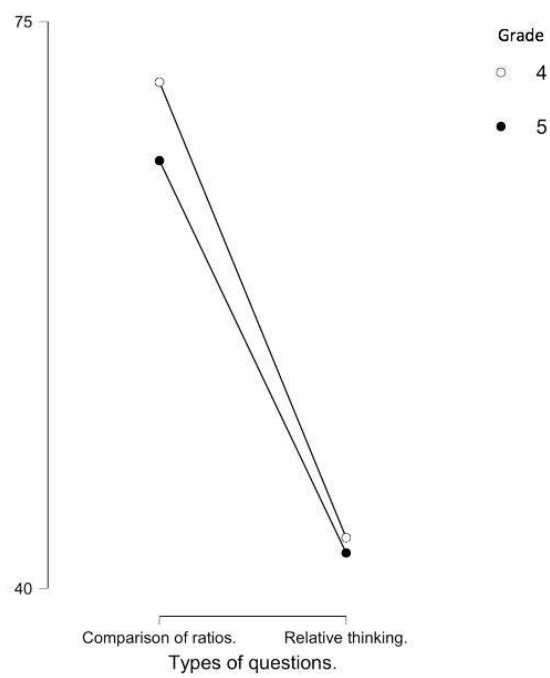

Figure 1: Comparative chart between the results of two types of problems in two school grades.

The results of the statistical test indicated that if there are differences between students' responses to the two types of problems, both problems show very large differences in student responses, even though proportional reasoning is at play in both.

It is believed that problems of the Relative Thinking kind present a greater level of difficulty to students because, as reported by Lamon (1993), students are more familiar with *using* additive structures and when facing situations that involve the use of multiplicative structures, they cannot perceive the multiplicative nature of situations involving ratio and proportion. Unlike problems of the comparison of ratios, it is not necessary to give meaning to any quantity, "in these problems the notion of ratio is the very object of the question, by means of a certain quality: which orange tastes more like orange? Which vehicle goes faster?" (Block, Mendoza and Ramírez, 2010, p 67).

It is necessary to provide students with opportunities to develop relative thinking, to create contexts in classrooms to encourage multiplicative thinking while giving meaning to the notion of ratio, and to find the value of ratio where necessary.

Future research should seek to link students' relative thinking and their understanding of ratio and proportion. It is essential that bridges be built between these two issues related to proportional thinking, so that it can contribute to the creation of new educational programs that favor understanding in proportionality. Work must also be done on the training of teachers, who face various challenges in teaching proportional reasoning (Hilton and Hilton, 2018).

mike.saldana@cinvestav.mx

Sofía K. Vázquez Gómez
Cinvestav
sofia.vazquez@cinvestav.mx

El tema de la proporcionalidad se inicia formalmente en los últimos años de la escuela primaria, implica el dominio de nociones, como la comparación de razones, fracciones y porcentajes. En esta investigación se realizó un estudio con 18 alumnos de cuarto y quinto grado de educación primaria con una edad entre los 9 a 13 años, con el objetivo de evaluar su desempeño al resolver problemas que implicaron comparar razones y tener un pensamiento relativo. Ambos tipos de problemas conllevan tener un pensamiento proporcional. El propósito es conocer cuál es la diferencia entre los dos grupos, así como identificar si existe diferencia entre la ejecución en los dos tipos de problemas. Se encontró que los alumnos de ambos grados presentan más dificultad al resolver los problemas del tipo pensamiento relativo y que no hay una diferencia sustancial entre los dos grupos que participaron.

Palabras clave: Resolución de problemas, razonamiento y demostraciones

En las investigaciones dirigidas a estudiar el razonamiento proporcional en los niños que asisten a la primaria, se reconoce la dificultad que enfrentan ante la resolución de problemas que implican operar con nociones como razón, fracción y el desarrollo del pensamiento relativo.

En este reporte se presentan los resultados de un estudio realizado con niños de 4° y 5° grado de primaria a través de un software informático en el que se plantearon dos tipos de problemas que para su resolución requería el uso de comparación de razones y del pensamiento relativo.

Antecedentes y marco teórico

Entre los estudios que focalizan la comparación de razones, Fishbein, Pampu, y Manzat, (1970) investigaron acerca de la influencia del número total de canicas, en cualquier conjunto, al comparar razones entre conjuntos, señalando la posibilidad de estimar utilizando razones del tipo W_1/B_1 y W_2/B_2 . Sing (2001), con base en estudios con alumnos de sexto grado sobre la comprensión de conceptos de proporción y razón al resolver problemas como la compra de dulces, reparto de pizzas y una situación de ampliar y reducir un rectángulo, enfatiza que se necesita tener construidas estructuras multiplicativas y esquemas de iteración para el pensamiento proporcional. Boyer, Levine, y Huttenlocher (2008), realizaron dos estudios mediante el uso de programas de computadora, basados en la aplicación de una tarea de equivalencia proporcional. Examinaron dónde se equivocan los estudiantes al procesar proporciones que implican cantidades discretas.

La interpretación de los resultados de este estudio, se realiza en el marco de los siguientes planteamientos teóricos. Vergnaud (1991), menciona que en el curso de los primeros años de la escuela primaria se hacen las primeras adquisiciones de las estructuras numéricas: las estructuras aditivas y las estructuras multiplicativas. La adición está asociada con situaciones de agrupamiento, que posibilitan a través de situaciones dirigidas conocer las reglas y procedimientos de las estructuras aditivas, necesarias para la adquisición de las estructuras multiplicativas. Respecto a la multiplicación, establece que la primera gran forma de una relación multiplicativa, implica establecer una relación entre dos cantidades del mismo tipo con otras dos del mismo tipo, es decir, hay cuatro cantidades puestas en relación.

En la multiplicación se requiere de la comprensión de funciones que asumen las cantidades implicadas, nociones tales como operador escalar, operador fraccionario, valor unitario, etc., Vergnaud (1991). De acuerdo a este planteamiento se da la posibilidad de que las relaciones y representaciones entre cantidades se escriban en forma de proporciones y se arribe a la noción de fracción, de razón y en consecuencia a la comparación de razones. Por otra parte, Lamon (1999), define dos tipos de pensamiento en el campo de la proporcionalidad: pensamiento relativo, en el que la comparación entre dos cantidades se hace de una respecto a la otra y no de manera independiente que es lo que caracteriza al pensamiento aditivo. Noelting (1980), con base en su experimento de comparar mezclas de jugo de naranja y agua, estableció una diferenciación jerárquica de etapas de desarrollo del razonamiento proporcional, basándose en la comparación de razones.

Preguntas de investigación, objetivos y método

Objetivo General:

Evaluar si existe diferencia entre los alumnos de cuarto y quinto grado de primaria en cuanto a su desempeño en dos tipos de problemas que implican reconocer las relaciones de proporcionalidad y tener un pensamiento relativo.

Objetivos específicos:

Reconocer qué diferencia existe entre los resultados de los problemas de comparación de razones con respecto a los problemas de pensamiento relativo.

Observar qué diferencia hay entre los resultados de los alumnos de cuarto grado de primaria con respecto a los alumnos de quinto grado de primaria.

Preguntas de investigación:

¿Qué diferencia existe entre los resultados de los problemas de comparación de razones con respecto a los problemas de pensamiento relativo?

¿Qué diferencia existe entre los resultados de los alumnos de cuarto grado de primaria con respecto a los alumnos de quinto grado de primaria?

Hipótesis

H0= No hay diferencia en los resultados entre los problemas de comparación de razones y los problemas de pensamiento relativo.

H1= Existe diferencia en los resultados entre los problemas de comparación de razones y los problemas de pensamiento relativo.

H0= No hay diferencia en las respuestas de los alumnos de 4º grado respecto a las de los alumnos de 5º grado.

H1= Existe diferencia en las respuestas de los alumnos de 4º grado respecto a las de los alumnos de 5º grado.

Un total de 18 alumnos participaron en esta investigación, 10 niños de cuarto grado y 8 niños de quinto grado de educación primaria de una escuela privada de la Ciudad de México.. Los participantes cuentan con una edad comprendida entre los 9 a 13 años de edad, con una media de 10.17 años y una desviación estándar de 0.89.

Se diseñó un programa en el software PsychoPy versión v.3.2.3. El programa que se realizó en PsychoPy, es el instrumento que permitió obtener los datos en la presente investigación, se conformó de tres partes generales, la primera de ellas presentó a los estudiantes las instrucciones de la actividad, en la siguiente parte del instrumento se presentaron a los estudiantes ocho problemas del tipo comparación de razones, se tomaron como modelo las actividades realizadas por Noelting (1980), en la tercera parte del instrumento se proponen ocho problemas en la categoría pensamiento relativo, se tuvieron en cuenta algunas actividades realizadas por Lamon (1999), referentes al pensamiento relativo y absoluto y otros se adaptaron. Para la implementación la institución brindó el acceso al aula de cómputo y la prueba se hizo dos veces a cada estudiante, cuando los niños llegaban al aula se les informaba que era una investigación que se estaba realizando para una universidad y que no era para calificarlos.

Resultados y discusión.

El procedimiento implementado para evaluar las respuestas fue calcular el porcentaje de respuestas correctas por alumno del primer momento, posteriormente calcular el porcentaje de respuestas correctas por alumno en el segundo momento para finalmente calcular la media del momento uno y dos.

Con la media de los momentos uno y dos de los estudiantes se realizó un análisis de varianza (ANOVA) de medidas repetidas (grado escolar: quinto de primaria vs. cuarto de primaria) X2 (Tipos de problemas: Comparación de razones vs Pensamiento relativo) en el programa estadístico llamado Jasp. El grado escolar se define como la variable inter-sujeto y la variable tipo de problema se define como la variable intra-sujeto.

Para el efecto principal con respecto a los tipos de problemas, dentro de sujetos, se reporta un estadístico grande de $F(49.201)$, $(0.001<p)$, se puede decir que sin considerar el grupo que respondió el instrumento hay diferencias significativas respecto a los dos tipos de problemas presentados, los problemas de comparación de razones con respecto a los problemas de pensamiento relativo. Es decir, los alumnos de ambos cursos responden mejor los problemas de comparación de razones que los de pensamiento relativo, de esta manera se rechaza la hipótesis nula y se acepta la hipótesis alternativa que menciona que si existe diferencia entre ambos tipos de problemas.

Por otra parte, otro efecto dentro de sujetos en relación con los dos grados escolares se reporta un estadístico $F(0.274)$, $(p= 0.608)$ esto indica que no existe diferencia entre los dos grupos que respondieron el instrumento. La prueba ANOVA sugiere que en este caso sin tomar en cuenta el grado escolar que cursen los alumnos, ambos grados muestran tener un porcentaje mayor de respuestas correctas en un tipo de problema que en el otro, aceptando así la hipótesis nula.

Por otro lado, como efecto de la prueba entre sujetos, no hubo efectos entre los factores grado y tipos de problemas $F(.411)$, $p=0.53$. Es decir, el grado escolar no afecta el rendimiento en ninguno de los dos tipos de problemas. El análisis de varianza no revela alguna interacción significativa.

La figura 1 muestra la falta de interacción entre el tipo de problema y el grado, ambos tienen un mejor rendimiento al responder problemas del tipo comparación de razones y un rendimiento más bajo al resolver problemas del tipo de pensamiento relativo, los alumnos de cuarto grado están ligeramente por encima con respecto a las respuestas correctas en relación con los alumnos de quinto grado.

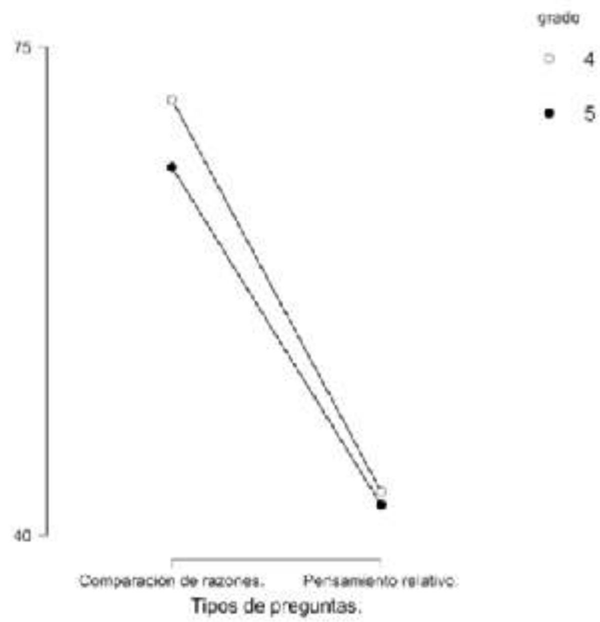

Figure 1: Gráfica comparativa entre los resultados de dos tipos de problemas en dos grados escolares.

Los resultados de la prueba estadística realizada indicaron que si hay diferencias entre las respuestas de los alumnos de los dos tipos de problemas, ambos problemas muestran diferencias muy grandes en las respuestas de los estudiantes, aunque el razonamiento proporcional está en juego en ambos.

Se cree que los problemas del tipo Pensamiento Relativo presentan un nivel de dificultad mayor a los estudiantes debido a que como reporta Lamon (1993), los estudiantes están más familiarizados con utilizar estructuras aditivas y al enfrentar situaciones que implican el uso de estructuras multiplicativas, ellos no pueden percibir la naturaleza multiplicativa de las situaciones que implican la razón y proporción, a diferencia de los problemas de tipo comparación de razones, en los que no es necesario dar significado a ninguna cantidad, "en estos problemas la noción de razón es el objeto mismo de la pregunta, mediante determinada cualidad: ¿qué naranjada sabe más a naranja? ¿Qué vehículo va más rápido?" (Block, Mendoza y Ramírez, 2010, p 67).

Es necesario brindar a los estudiantes oportunidades para desarrollar un pensamiento relativo, crear contextos en las aulas de clase para incitar el pensamiento multiplicativo a la par de dar significado a la noción de razón y encontrar el valor de la razón en los casos en los que sea necesario.

Futuras investigaciones deben buscar vincular el pensamiento relativo de los estudiantes y su comprensión de la razón y la proporción. Es indispensable que se construyan puentes entre estos dos temas relacionados al pensamiento proporcional, de modo que se pueda contribuir a la creación de nuevos programas educativos que favorezcan la comprensión en la proporcionalidad. También se debe trabajar en la capacitación de los profesores, los cuales enfrentan varios desafíos en la enseñanza del razonamiento proporcional (Hilton y Hilton, 2018).

STAGES IN USING PROOF TECHNIQUES: STUDENT DEVELOPMENT IN THE TRANSITION TO PROOF

ETAPAS EN EL USO DE TÉCNICAS DE PRUEBA: DESARROLLO DE LOS ESTUDIANTES EN LA TRANSICIÓN A LA PRUEBA

V. Rani Satyam
Virginia Commonwealth University
vrsatyam@vcu.edu

The transition to learning how to prove is difficult for undergraduates. We are aware of the many varied struggles students have, but we know less about their development as they are learning. This is vital as development is more than just an accumulation of competencies. To examine these developments, a series of four task-based interviews across a semester were conducted with (N=11) undergraduate students enrolled in a transition to proof course. Video of students constructing proofs was analyzed qualitatively; changes in how students chose what proof technique to use were common. Stages in students' rationales are illustrated using two students as cases. The results show students' decision-making in starting a proof and remind us that such judgement takes time to grow. Instructors and curriculum developers may use these results in designing tasks and supports for the transition-to-proof.

Keywords: Reasoning and Proof, Post-Secondary Education

The transition-to-proof is difficult for undergraduate students (Moore, 1994; Selden & Selden, 1987). Students struggle with learning how to prove (Iannone & Inglis, 2010; Selden & Selden, 2013). The transition-to-proof is a shift in the "game" of mathematics, from answering "exercises" that are largely procedural (Schoenfeld, 1992) to now writing arguments and justifications. Researchers have identified the types of errors students make (Selden & Selden, 1987) and their struggles (Selden & Selden, 2003): use of examples, notation and symbols, quantifiers, and general logic (Epp, 2003; Selden & Selden, 1987). Students also struggle with larger issues, such as providing empirical rather than deductive arguments (Harel & Sowder, 2007) and having difficulty writing formal arguments (Alcock & Weber, 2010). Another strand of research has focused on students' strategies and approaches to the proving process (Karunakaran, 2014; Savic, 2012).

We know then students' struggles and strategies while proving at singular points in time, but few have looked at how students develop, at how their strategies change over the course of the learning process. Development is not necessarily about accumulating competencies: "For some psychologists, development is reduced to a series of specific learned items, and development is thus the sum, the culmination of this series of specific items. I think this is an atomistic view which deforms the real state of things" (Piaget, 1964, p. 38). Thinking about proving as the sum of skills and assessing whether or not students have those skills is not enough for us to understand students' learning process. We do not yet know *how* students put the pieces together while they are learning how to prove nor the *order* in which they occur. We lack models of students' cognitive development in this domain.

In response to this gap, the research question guiding this work is: How does undergraduate students' proving develop over the duration of a transition to proof class? The purpose of this study is to understand how students come to learn how to prove. In this paper, I examine one prevalent development that occurred and illustrate it through two participants.

Conceptual Framework

Proving as Problem Solving

While there are multiple ways to think about proving as an activity, I take the conceptualization of proving as a form of problem solving (Stylianides et al., 2017). I further take problem solving to be the activity a person engages in when stuck, reaching an impasse (Savic, 2012). Under this definition, a task can elicit problem solving in one student but not another, depending on whether or not they become stuck at any point. There are a lack of robust frameworks for characterizing a student's proving (Savic, 2012), but by considering proving as problem solving, we can look to work on problem solving. I focused on the components of strategies (heuristics) and monitoring and judgement of problem solving (Schoenfeld, 1985b; 1992). Moreover, the focus here was on proving as a *process* (Karunakaran, 2014), rather than on the product, the correct proof.

Development at its most base level may refer to change over time. Development does not happen in a vacuum; it is undoubtedly informed by instruction. A common way to consider development is in terms of stages, in which a person passes through each stage on their way to full mastery (e.g. Lo, Grant & Flowers, 2008; van Hiele, 1959). I conceptualize development simply as taking a "snapshot" - a characterization of some construct at a point in time - and looking across these at multiple timestamps for change (Figure 1).

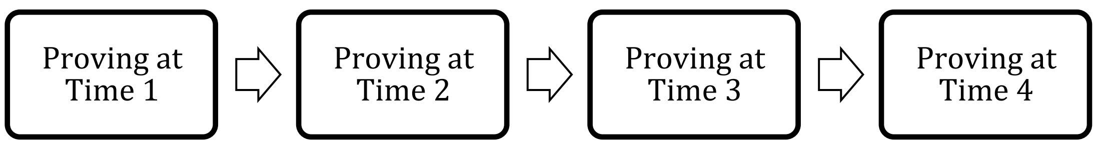

Figure 1: Conceptualization of development, by capturing snapshots of student's proving and comparing over time.

The purpose in taking this simple view of development is to provide as much description as possible and look for natural change, which may then inform the creation of potential frameworks and models for how students develop in a transition to proof course.

Method

A series of four semi-structured interviews were conducted with N=11 undergraduate students in a transition to proof mathematics course at a large Midwestern university. Their ages were 18 and up. This transition to proof course was designed to ease the transition from calculus-based to upper-level math courses that involved writing proofs. This course was a prerequisite for Linear Algebra, so a variety of STEM (science, technology, mathematics, and engineering) majors were enrolled in this course as well. The first half of the course focused on logic, including direct proof, proof by contradiction, proof by contrapositive, and proof by cases. The second half introduced basic concepts in real analysis, linear algebra, and number theory.

Data Collection

The four interviews were spread across a semester. Each interview was also task-based, consisting of two proof construction tasks. Participants worked for no more than 15-20 minutes on each proof construction and debriefed their thought process after with the interviewer. All eight tasks were from one content area, basic number theory. Tasks were selected by the researcher to not be heavily dependent on content knowledge nor a singular specific proof technique. Interviews were audio- and video-recorded, and interview notes and student work were collected.

In order to capture their strategies and reasons for using certain strategies, I used a think-aloud protocol (Ericsson & Simon, 1980; Schoenfeld, 1985a), where participants voice their thoughts aloud about a task. Based on the affordances and constraints of asking probing questions (Schoenfeld, 1985a), I minimized interviewer intervention during task performance. Because the phenomenon of interest was the proving *process* itself, keeping the process intact without interruption as much as possible was of the utmost importance.

Analysis

Qualitative analysis was conducted on video data of participants working on the proof construction tasks. First, video was analyzed for moments when students became stuck. Then, in those moments, I recorded students' strategies, termed proof-specific intentions (Satyam, 2018). Students' strategies were refined using open coding and constant comparison. Lastly, I looked for change in each student's strategies over the eight tasks spanning the semester.

Indicators of an impasse. Through watching videos of students' attempts to prove, certain observable behaviors contributed to my judgment of when a student was stuck. A list of these include: silence, no writing, staring at paper, holding paper closer to one's face, sitting back from the paper to look at it as if from a distance, tapping/playing with their pen/pencil, and touching face with hand or pencil. These behaviors were not exhaustive and individuals exhibited different behaviors specific to themselves, but they cover much of what we see when a person is stuck.

Results: Shifts in How Students Chose A Proof Technique to Use

A common development that occurred across participants was change in how they chose what proof technique to pursue, when trying to construct a proof. By *proof technique*, I mean tools such as direct proof, cases, etc. Proof by contradiction may be referred to here as just contradiction and proof by contrapositive as contrapositive for brevity sake. Eight of eleven participants (pseudonyms used) showed this development, based on interview notes and across all tasks (see Table 1). I discuss two participants here, to illustrate this development.

Table 1: Select Developments in Proving by Participant

	Rationale for a proof technique	Harness awareness of solution attempt	Check examples w/ other strategies	Explore and monitor
Amy				X
Charlie	X		X	
Dustin	X			
Granger		X	X	X

Joel		X		
Jordan	X			
Leonhard	X			
Stephanie	X			
Shelby	X			
Timothy	X	X	X	X

Case: Favoring One Proof Technique

Stephanie was chosen here to illustrate the early stages, of where a student uses one proof technique predominantly. From the beginning, Stephanie favored proof by contradiction over all other techniques when constructing a proof. In Interview 1 – Task 1, she jumped to trying proof by contradiction: She immediately identified the assumption as “A,” the conclusion of the statement as “B,” and wrote the negation.

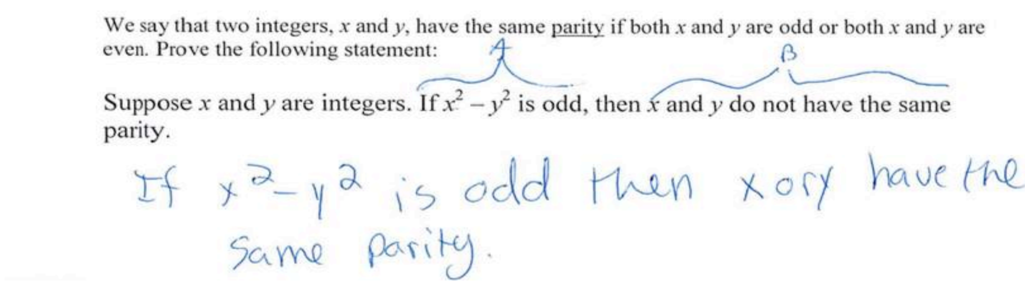

Figure 2: Beginning of Stephanie’s work on Interview 1 – Task 1

She explained that she used contradiction because the statement was an implication, having an “if-then” structure: “When I see the if-then statement, I immediately think I can do this by contradiction.” She explained further that she felt comfortable using this technique. Note that Stephanie technically wrote the negation incorrectly; the correct negation is “A and not B,” i.e. “$x^2 - y^2$ is odd and x or y have the same parity.” Instead, she wrote the negation as an implication, a common error. However, this error did not affect the rest of her proof and her reasoning for picking contradiction was unaffected by her execution.

In the next interview, Stephanie’s go-to method was still contradiction. Upon starting the second task of Interview 2, she said, "I can see that this is an if-then statement, so automatically I'm going to try to use contradiction, but I don't know if it will work or not." She explained that “When I read an if-then statement, I'm most comfortable using negation or a contradiction. So then I just try that, even though I know it doesn't always work, but I just try it." The use of contradiction was automatic for her, saying outright she does not always know if proof by contradiction will lead to a correct solution. The general structure – of a statement having “if” and “then” clauses – was enough to determine that she could use her favored technique, but she did not make use of the statement in any further way to guide her choice of technique.

Stephanie did get stuck on her proof by contradiction, so she switched to contrapositive. She explained during the debrief, “I'll try contrapositive and then I felt a little better after I tried contrapositive just because I thought [out of] both of them, probably one of them was gonna be right." Stephanie did not give a rationale for why, just that it was another technique.

Summary. Stephanie’s articulations and work during Interviews 1 and 2 show how a student can favor one proof technique and use it whenever they can. Stephanie did have a condition for when to use proof by contradiction, whenever she saw an if-then statement, but this applied to nearly all statements to be proven in the course. Stephanie becomes less dependent on proof by contradiction and her rationale did become more sophisticated over time, but her work was unfortunately incorrect on all four tasks on Interviews 3 and 4 so they are not presented here.

Case: Recognizing When Best to Use A Certain Proof Technique

We turn now to a different student, Timothy, to see how rationales shift over time. Timothy was similar to Stephanie in having favored proof techniques in the beginning, but his rationales became more sophisticated and based on the statement itself as his interviews progressed, in addition to producing correct or partially correct proofs.

Timothy began his interviews similar to Stephanie in terms of his rationales. Figure 3 shows Timothy’s attempt in Interview 1 - Task 1 (same as Stephanie’s task). When stuck in the beginning, he re-read the question and wrote what was known. At this point he switched from his direct proof attempt to proof by contrapositive.

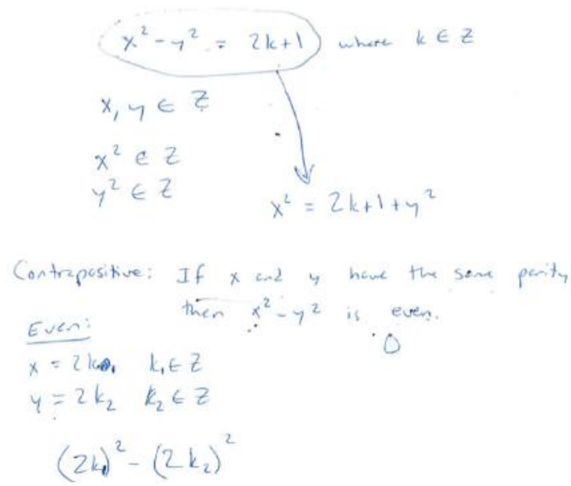

Figure 3: Beginning of Timothy's work on Interview 1 - Task 1

When asked why he selected contrapositive, he explained it was a method from class but also that it was a tool logically equivalent to direct proof that he could use:

> Timothy: It was confusing me when I'd try to think of it the normal way so I knew the contrapositive is true, it's basically the equivalent, logical equivalent.
>
> …
>
> Interviewer: So actually, so how did you come up with contrapositive?
>
> Timothy: Looking at it straightforward didn't…it wasn't working for me so I know we learned in class that the contrapositive is basically not B implies not A. I knew we said that was logically equivalent, so if I could prove the contrapositive was true, then I could prove the original statement was true was kinda my thinking with that.

He explained that direct proof was not helpful for generating a proof, but he gave no specific rationale for choosing contrapositive over other proof techniques. His explanation implied that contrapositive was a legitimate tool from class, so why not use it? While it is possible he may have had some internal reason for using contrapositive, he neither mentioned this on his own nor articulated any further reasons when questioned.

Later in this interview, he talked more about contradiction being one of his "go-to" methods and why:

> Timothy: I always go about it with either contradiction or induction or straight up [direct proof] so I kinda knew that I might be able to contradict this never equaling that, so I wrote out the contradiction...I guess contradiction is a little easier for me to think about. You just say the first part of the implication is true and the second part is false. So it's just easier in my head, I guess, just to think about rather than switching around the implication, negating both parts.
>
> Interviewer: Okay.
>
> Timothy: So I guess that's why I go to that first.

Timothy expressed here that contradiction was easier for him than contrapositive, which involves switching and negating both the assumption and conclusion. He did have some rationale for why he might use contradiction, but it was couched in terms of ease of use, first and foremost.

The notion of "ease of use" as determining choice of proof techniques showed up in latter interviews. In his work for Interview 2 - Task 1 (Figure 4), Timothy started by defining x and y using the definition of consecutive numbers but in calculating xy, he became stuck over what to do next. He then switched to contrapositive because "sometimes that's an easier way for me to look at it." He knew that contrapositive was easier on some level for him but not for any reasons specific to the statement and did not further articulate why. Ultimately, his contrapositive proof was not to his liking and also not correct.

If x and y are consecutive integers, then xy is even.

$x = k$ where $k \in \mathbb{Z}$

$y = k+1$ where $k \in \mathbb{Z}$

Then $xy = k(k+1)$ Goal: $2(m)$ where $m \in \mathbb{Z}$

$= k^2+k.$

Contrapositive: If xy is odd, then x and y are not consecutive integers.

Figure 4: Timothy's work for Interview 2 – Task 1

By the end of the interviews, however, Timothy showed sophisticated rationale when considering which proof techniques to use. In Interview 4 - Task 1 (Figure 5), Timothy became stuck after computing the goal, a+b, directly.

If a and b are odd perfect squares, then their sum a + b is never equal to a perfect square.

$a = n_1^2$ where $n_1 = 2k_1+1$ for some $k_1 \in \mathbb{Z}$

$a = (2k_1+1)^2$ for some $k_1 \in \mathbb{Z}$

$b = (2k_2+1)^2$ for some $k_2 \in \mathbb{Z}$

Then $a+b = (2k_1+1)^2 + (2k_2+1)^2$

$= (4k_1^2+4k_1+1) + (4k_2^2+4k_2+1)$

$= 4(k_1^2+k_1+k_2^2+k_2) + 2$

Let $k_1^2+k_1+k_2^2+k_2 = m \in \mathbb{Z}$ since $k_1, k_2 \in \mathbb{Z}$

Contradiction: a and b are odd perfect squares and $a+b$ is a perfect square.

Then $4m+2 = n^2$ for $m \in \mathbb{Z}$

$4m = n^2-2$

$m = \frac{n^2}{4} - \frac{1}{2}$

Figure 5: Timothy's work on Interview 4 – Task 1

He explained that he used contradiction because "it's easier when I know something like is equal to something or is something." He then gave this further rationale for why contradiction:

> I was trying to prove that it's not equal to a perfect square and I know from past experiences, *it's easier when I know something is equal to something or is something.* So I tried to use contradiction because *I knew I could say then it is a perfect square.*

His argument was that he wanted to be able to work with an equality. Timothy also gave a reason for why he did not use another method, contrapositive:

> I thought about contrapositive, too, but then it would say that A and B are not perfect squares and that's again, like something's *not* so I mean, it's easier for me to work when I know like a straight definition of something. So if I could keep this, I knew if I could keep this, like they are perfect squares and say this is a perfect square, then it'd be easier to work with.

This explanation was similar to his prior one about equality of objects being easier, i.e. knowing things are not equal is not as helpful. His sub goal then was to find a proof technique that would give him a+b *is* a perfect square. This task is also notable for drawing out Timothy's observations on contradiction:

> I never really thought about it this way but I realized when you use the contradiction, you don't really have the assumption and conclusion anymore…*you can actually pick any part of that statement you want and work with it. Rather than with an if/then statement, you start with the assumption and try to work to the conclusion.* So you're not as limited, I guess.

Timothy gave a high-level explanation of the nature of proof by contradiction. He found proof by contradiction freer than other techniques, due to being able to work with all parts of the statement. This is in contrast to starting with the assumption and trying to prove the conclusion, as is done in direct proof but also to an extent proof by contrapositive. Note that this revelation came during this interview context, based on his "I never really thought about it this way but..." clause. The interview served as a vehicle for reflection on proof techniques for Timothy.

Summary. Timothy went from picking a proof technique because (1) it existed as a tool, to (2) having a general sense that certain ones would be easier, to (3) explaining how the content of the statement can drive the approach, to (4) articulating understanding at the meta-level of how a technique functions as logical tools. His later interviews revealed insight on when to use contradiction that did not depend on statement content but instead meta-level structure.

Discussion

Both Stephanie and Timothy showed similar growth in how they chose a proof technique to pursue through most of their interviews. Both discussed liking and being drawn to certain techniques, as their go-to method. Timothy's latter interviews especially illustrated weighing the utility of different techniques, to think about which would be *better*, whether it be a cleaner proof or just easier. He noticed that being able to set things equal provided more to work with and often preferred proof by contradiction for this reason.

The difference between these two cases lies in where they ended: by the end of the interviews, Timothy articulated a general insight for when contradiction was useful. Across all the students, a general trajectory for how students grew in how they chose which techniques to use emerged. Conceptualizing this specific development as a series of stages, Figure 6 illustrates the stages students tended to step through.

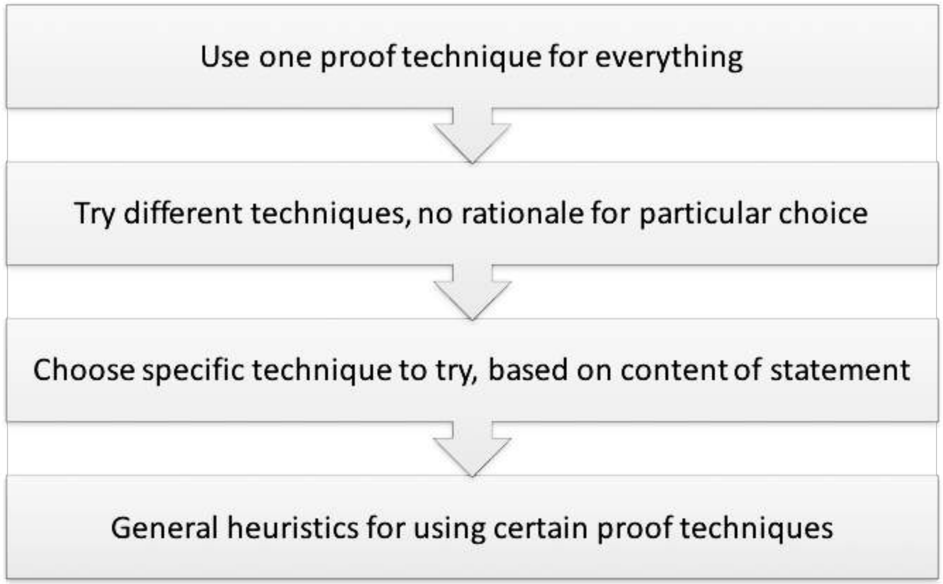

Figure 6: Stages of development in how students choose proof techniques to pursue

This development reveals the amount of decision-making that can go into writing even the first line of a proof. Timothy took the content of the statement to be proven into account when deciding how to begin a proof. This suggests a revisiting of the distinction between formal-rhetorical and problem-centered aspects of proving (Selden & Selden, 2007). Acts that we expect to be formal-rhetorical, such as writing the first line of a proof, may retain some of the problem-solving aspects too for students new to proving, as they consider the content as well. It is important that the interplay between these two aspects – formal-rhetorical and problem-centered parts of proving – not be lost when teaching students.

This development is significant because it shows that students do over time grow in their sense of when certain proof techniques are best suited for a problem and that there are general stages. One limitation is that becoming better at using tools is not necessarily reflective of deeper mathematical understanding, as Guin and Trouche (1999) noted about students using calculators as tools. But the cases here shows it is natural for even this kind of judgment to take a while to develop; noticing what proof technique works best for a given statement does not happen instantly but also it must be nurtured. This means that as instructors, we cannot expect students to have this reasoning immediately. Development is of course informed by instruction, so this may be an area that can be supported via instruction, by designing tasks that probe students to consider the strengths and weaknesses of each proof technique. Through this, we can better help students understand and learn how to prove, as a mathematical activity that makes sense.

ATTEND TO STRUCTURE AND THE DEVELOPMENT OF MATHEMATICAL GENERALIZATIONS IN A DYNAMIC GEOMETRY ENVIRONMENT

Xiangquan Yao
xzy73@psu.edu
The Pennsylvania State University

Central to mathematical generalization is the development of structural thinking. By examining the relationship between structural thinking and mathematical generalization, this study found that learners' attention to different elements of a problem can result in different mathematical generalizations and structural generalization occurs only when learners reason based on identified properties. These findings imply that learners should be cultivated to attend to mathematical structures and to generalize beyond numerical patterns.

Keywords: Advanced mathematical thinking

Generalizing involves transportation of a mathematical relation from a given set to a new set for which the original set is a subset, perhaps adjusting the relation to accommodate the larger set. It has been argued that generalizing should be at the heart of mathematics activity in school (e.g., Mason, Johnston-Wilder, &Graham, 2005). Within the past a few decades researchers have differentiated different forms of mathematical generalizations (Dörfler, 1991; Yerushalmy,1993; Mason, Burton, & Stacey, 2010), among which are *empirical* and *structural* generalizations. Empirical generalization is the process of forming a conjecture about what might be true from numerous instances. It occurs when a learner looks at several, sometimes many, cases or instances and identifies the sameness among these cases as a general property. Structural generalization arises when a learner recognizes a relationship from one or very few cases by attending to the underlying structure within these cases and perceives this relationship as a general property. The distinction implies the need for learners to move from empirical to structural generalization. Central to this advancement is the development of structure thinking, which can be defined as a disposition to use, explicate, and connect mathematical properties in one's mathematical thinking (Mason, Stephens, & Watson, 2009). However, most studies on generalizing were conducted in the context of pattern recognition. More importantly, by providing the first few terms of a pattern, the tasks used in these studies tend to promote generalization that does not necessarily demand structural thinking (Küchemann, 2010). To extend the study of mathematical generalization beyond the context of pattern recognition and to bring structure thinking to the forefront of the development of mathematical generalization, this study aimed to examine the relationship between structure thinking and mathematical generalization in a dynamic geometry environment (DGE). It was guided by one research question: How does learners' structure thinking evolve and influence their generalizing activity when working on a carefully designed sequence of tasks in DGE?

Theoretical Framework

Mason et al. (2009) described mathematical structure as the identification of general properties that are instantiated in a particular situation as relationships between elements and differentiated five states of learner's attention to mathematical structure. *Holding wholes* involves a certain way of looking at a whole situation that produces a global image that will undergo further analysis. In this awareness state, a learner attends to an object as a whole without explicit regard to its components. *Discerning details* shift the learner's attention toward further analysis and deep description, in which parts begin to be discerned and described in detail based on what the learner finds meaningful to inspect. The attention can focus on parts that either change or remain invariant. *Recognizing* *relationships* occurs when changing or invariant relationships are detected and analyzed critically. In this awareness state, the learner attends to relationships between parts or between part and whole. *Perceiving properties* occurs when the learner perceives the discerned relationships as instantiations of general properties which can apply in many different situations. It involves the transition from seeing something in its particularity to seeing it as representative of a general class. This state enables a further categorization of different (classes of) objects. The separation of stages three and four indicates a subtle but vital difference between recognizing relationships in particular situations and perceiving relationships as instantiations of general properties which can apply in many different situations. *Reasoning on the basis of the identified properties* is the critical phase in which inductive and abductive reasoning about specific objects transforms into deductive reasoning by examining what other objects may belong to the perceived structure. In this awareness state, the learner attends to properties as abstracted from and independent of any particular objects and forms axioms from which deductions can be made. This model provides a useful tool to examine the development of structural thinking.

Methodology

The data for this study was collected from a series of task-based interviews that were a part of a larger research project aimed to investigate preservice secondary mathematics teachers as learners and teachers of mathematical generalizations in a technology-intensive learning environment. The task-based interview was chosen to gain knowledge about individual preservice teacher's processes to generalize mathematical ideas and the mathematical knowledge resulting from it. Each task in this study consisted of a sequence of closely related problems that aimed to promote learners to generalize a mathematical idea to a broader domain. These tasks were design to engage learners in not only empirical but also structural generalizations.

The participants were 8 undergraduate preservice secondary mathematics teachers enrolled in a course that focused on teaching mathematics with various types of mathematical action technologies. The course took a problem-solving approach and engaged the preservice teachers in the processes of representing, conjecturing, generalizing, and justifying by solving and extending mathematically rich problems in technology-rich learning environments. Outside the class each participant participated in four task-based interviews, each of which was about 2 hours. During each interview, a participant would solve one or two mathematical tasks with the technologies they had learned in class. Participants' interactions with technology were screen-recorded. During each session, the interviewer frequently asked the participant to articulate his/her thinking process and to make general statement based on his exploration. Those interactions between the interviewer and the participant were recorded with a camera.

Data analysis consisted of three stages. First, the generalizations a participant constructed while solving each mathematical task were identified and categorized into empirical and theoretical generalizations. A generalization was coded as empirical if it was constructed on the basis of perception or numerical pattern by comparing numerous instances; it was coded as structural if it was constructed based on the generality of the inferred ideas, methods, or processes. Second, Mason et al. (2009)'s model was used to analyzed a participant's evolution of the state of attention to mathematical structure when constructing each mathematical generalization. The final stage involved coordinating the analysis in the first two stages to look for patterns about the evolution of structural thinking and the development of generalization.

Results and Discussion

Results from data analysis indicated a close relationship between the state of attention to mathematical structure and the forms of mathematical generalization that can potentially emerge.

More specifically, the study found that (1) learners' attention to different elements of a problem can result in different mathematical generalizations and (2) structural generalization occurs only when learners can reason on the basis of identified properties. I will use participants' work on task to illustrate the findings from this study. In the task, participants were asked to decide the conditions under which the area of the square created from the largest side of a triangle is equal to the sum of the areas of the squares created from the other two sides of the triangle (Part 1) and to further extend this relationship to quadrilateral (Part 2) and other polygons (Part 3).

When solving Part 1 of the task, Although Joe quickly connected it with the Pythagorean theorem, he focused his attention on the relationship of square from a right leg and the square from the hypotenuse, conjectured that the areas of the two squares grew proportionally and the vertex A shared by the two squares moved along a line, and then validated his conjecture by perception and measurement (Figure 1a). When solving Part 2 of the task, Joe made one interior angle of the quadrilateral a right angle by dragging and then dragged the vertex opposite to the right angle such that the area of the largest square was equal to the sum of the areas of the other three squares. After creating multiple instances of the desired diagram through dragging, informed by his knowledge gained from earlier exploration, he conjectured that the vertex D opposite to the right interior angle moved along a line and the areas of the two squares that share the vertex A grew proportionally (Figure 1b). Here, Joe attended to the relationship between the areas of the two squares and generalized this relationship from triangle to quadrilateral.

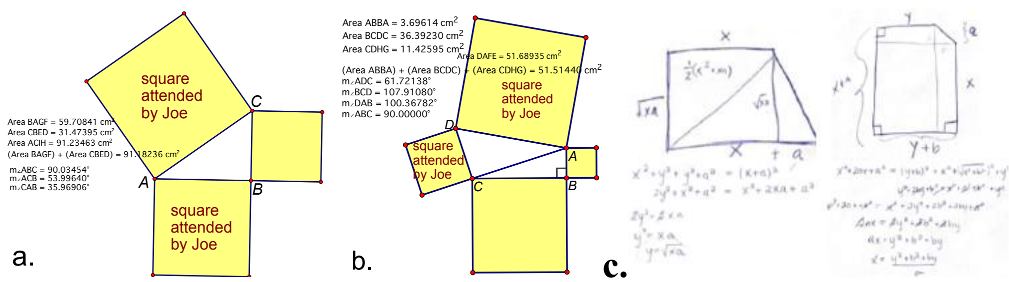

Figure 1: Snapshots of participants' work

In contrast, when exploring Part 2 of the task, Jen considered a right isosceles trapezoid, made two right triangles inside the trapezoid, and labeled the shorter base as x, the longer base as $x + a$, and a lateral side as y (see Figure 1c). By using the fact that the area of the largest square should be equal to the sum of the areas of the three squares and the Pythagorean theorem, she created an equation $x^2 + y^2 + y^2 + a^2 = (x + a)^2$ and concluded that $y = \sqrt{ax}$ after symbolic manipulations. When asked how to further extend the relationship to other polygons, Jen drew a pentagon with three right interior angles as shown in Figure 3 and labeled $x, y, x + a, y + b$ as the length of its four sides. By using the fact that the area of the largest square should be equal to the sum of the areas of the four squares and the Pythagorean theorem, he created an equation $x^2 + 2ax + a^2 = (y + b)^2 + x^2 + (\sqrt{a^2 + b^2})^2 + y^2$ and concluded that $x = \frac{y^2+b^2+by}{a}$ after symbolic manipulation. Moreover, Jen noticed that there was one right angle in the case of triangle, two right angles in the quadrilateral, three right angles in the pentagon and concluded that there would be $n - 2$ right angles by extending the perceived numerical pattern. Here, Jen attended to the desired symbolic relationship between the sides of a polygon and the algebraic identity expressed in the Pythagorean theorem to search for a class of polygons that would satisfy the problem condition. What was generalized was a symbolic relationship rather than the underlying structure expressed in the Pythagorean theorem.

Different from both Joe and Jen, Jack made generalizations by attending the underlying structure of the Pythagorean theorem. The following excerpt shows his generalization of the Pythagorean theorem when solving Part 2 and Part 3 of the problem.

> Interviewer: Now let's think a little bit of what we have done here. What if it is a nonagon, decagon, or an n-sided polygon, how can you create the polygon such that the area of the largest area is equal to the sum of the areas of the other squares drawing from each side of the polygon?
>
> Jack: From one of the vertices of the octagon, the vertex on the largest square, I need the side of each square and the line connecting A to each vertex of the nonagon or the n-gon to form a 90-degree angle. So, you need to make $n - 2$ right angles because the only ones that aren't are the two vertices from the largest square.

The above excerpt provides evidence that Jack extended the Pythagorean theorem to any polygon and generalized that the area of the largest square is equal to the sum of the areas of the n-1 squares created from each side of an n-sided polygon when the polygon is created by sequentially drawing n-2 right angles from a vertex of the polygon to the sides of the polygon.

This study found a close relationship between the elements that the participants attended to and the possible mathematical generalizations they might develop. As shown in the above examples, when solving the task, Joe focused on the covariation of the areas of the two squares, Jen attended to the algebraic identity expressed in the Pythagorean theorem, and Jack focused on the structure underlying the Pythagorean theorem. As a result, Joe generalized the proportionality of the areas of the two squares from triangle to quadrilateral, Jen applied the algebraic identity to deduce algebraic equations that specify a given set of quadrilaterals and pentagons that satisfy the problem condition, and Jack extended Pythagorean theorem and used it to decide the particular shape of an n-sided polygon that satisfies the problem condition. One productive way of helping learners to identify mathematical useful relations is to engage them to examine the generalizability of the perceived mathematics relations and the structures behind them.

Pattern generalization is a typical generalization activity in school mathematics, in which a figurative, numerical, or tabular pattern is usually presented in the form a systematic sequence of elements, and learners are expected to generate a systematic set of ordered pairs from which an empirical relationship can be induced. This approach allows learners to identify and express a numerical relationship without necessarily seeing the mathematical structure that produces it. This study found that although the inductive nature of the dynamic geometry environment made it relatively easy for the participants to observe, conjecture, validate, and generalize mathematical relations based on perception and numerical patterns, identifying structure underlying these relations and generalizing them to broader contexts proved to be challenging. For instance, when solving the above task, the participants produced various generalizations relying on measurement and dragging, but only two of them were able to generalize the Pythagorean theorem from triangle to other polygons. A similar result was found in other tasks given to the participants. Therefore, engagement in pattern generalization does not necessarily support learners' development of structural thinking. One plausible reason that many participants in this study were not able to generalize on the basis of mathematics structure is that they were not provided sufficient opportunities to engage in this way of thinking in their own mathematics learning experience. In order to develop learners' ability to make structural generalization, they should be provided opportunities to initiate into structural thinking.

HOW TO POSE IT: DEVELOPING A PROBLEM-POSING FRAMEWORK

José N. Contreras
Ball State University
jncontrerasf@bsu.edu

Posing problems is an important mathematical activity. In fact, Halmos (1980) views problems as the essence of mathematics and he, as well as other mathematicians (e.g., Polya, 1973) and mathematics educators (e.g., Brown & Walter, 1983, 1993; Silver 1994), argue that we should prepare our students to become better problem posers. It is not surprising then that professional organizations (e.g., Australian Education Council, 1991; National Council of Teacher of Mathematics [NCTM], 1989, 1991, 2000) have called for increased attention for students to be given opportunities to "create new problems by modifying the conditions of a given problem" (NCTM, 1991, p. 95). The research community still continues to investigate the different aspects of teaching and learning how to pose mathematical problems (Felmer, Pehkonen, & Kilpatrick, 2016; Silver, 2013; Singer, Ellerton, & Cai, 2013, 2015).

To help my students and I to become better problem posers within dynamic geometry environments, I developed a problem-posing framework. The problem-posing framework includes the following systematic strategies to pose new problems by modifying the conditions of a given problem: reversing, proving, specializing, generalizing, extending, and further extending. The problem-posing framework has been a powerful tool that has helped both my students and I to create new problems related to a given problem within dynamic geometry environments. The initial problem from which we created new problems was the following: What type of quadrilateral has as vertices the points of intersection of the angle bisectors of the angles of a parallelogram? I will refer to this problem as the base problem.

During the poster presentation, I will display the problem-posing framework and illustrate its usefulness with some of the problems that I and my students have generated by systematically varying the attributes of the base problem. Examples of posed problems include the following:

Problem 1: The vertices of quadrilateral EFGH are the points of intersection of the angle bisectors of a quadrilateral ABCD. If EFGH is a rectangle, what sort of quadrilateral is ABCD? (Converse or reverse problem)

Problem 2: Let E, F, G, and H be the points of intersection of the angle bisectors of the angles of a rectangle. Prove that EFGH is a square or a point. (Special and proof problem)

Problem 3: What kind of quadrilateral has as vertices the points of intersection of the angle bisectors of the consecutive angles of a quadrilateral? (General problem)

Problem 4: Prove that the angle bisectors of the angles of a kite are concurrent. (Extended and proof problem)

Problem 5: The vertices of quadrilateral EFGH are the points of intersection of the consecutive exterior angles of an isosceles trapezoid ABCD. Characterize EFGH. (Further extended problem)

Problem 6: Let E, F, G, and H be the points of intersection of adjacent angle trisectors of the interior angles of a parallelogram. What type of quadrilateral is EFGH? (Further extended problem)

The author will also provide solutions to problems that are supported by proofs in some cases or conjectures supported by empirical evidence in other cases (such as geometric diagrams created with Dynamic Geometry Software or numerical examples).

DOMAIN APPROPRIATENESS AND SKEPTICISM IN VIABLE ARGUMENTATION

Robert Ely
University of Idaho

David Yopp
University of Idaho

Anne E. Adams
University of Idaho

Keywords: Reasoning and Proof, Empiricism, Argument

Several recent studies have focused on helping students understand the limitations of empirical arguments (e.g., Stylianides, G. J. & Stylianides, A. J., 2009, Brown, 2014). One view is that students use empirical argumentation because they hold empirical proof schemes—they are convinced a general claim is true by checking a few cases (Harel & Sowder, 1998). Some researchers have sought to unseat students' empirical proof schemes by developing students' *skepticism*, their uncertainty about the truth of a general claim in the face of confirming (but not exhaustive) evidence (e.g., Brown, 2014; Stylianides, G. J. & Stylianides, A. J., 2009). With sufficient skepticism, students would seek more secure, non-empirical arguments to convince themselves that a general claim is true. We take a different perspective, seeking to develop students' awareness of *domain appropriateness* (DA), whether the argument type is appropriate to the domain of the claim. In particular, DA entails understanding that an empirical check of a proper subset of cases in a claim's domain does not (i) guarantee the claim is true and does not (ii) provide an argument that is acceptable in the mathematical or classroom community, although checking *all* cases does both (i) and (ii). DA is distinct from skepticism; it is not concerned with students' confidence about the truth of a general claim.

We studied how ten 8th graders developed DA through classroom experiences that were part of a broader project focused on developing viable argumentation. One important classroom task in the project was the Circle-and-Spots problem (Stylianides, G. J. & Stylianides, A. J., 2009, Brown, 2014), which was meant to develop DA and to provide a rationale for why empirical arguments are not considered viable. Semi-structured interviews were conducted, in which we provided students with the claim "For every whole number value of n, if you compute $7n - 1$ you will not get a perfect square," and "Thomas'" empirical argument that checked the first seven cases in the claim's domain. Students were asked questions such as if they thought the claim was true, whether the argument was viable, and what they would have to do to make the argument viable. Thematic analysis was used to develop themes among the student responses (*Braun & Clarke, 2006).*

After collapsing themes, we found that five of the ten students displayed robust understanding of DA. They said that Thomas' argument was not viable because it did not account for all cases in the claim's domain. All of them suggested both of the following ways to make Thomas' argument viable: (a) restrict the domain to just the seven cases that were checked or (b) find some sort of "equation," "pattern," or "relationship" to show why the claim was always true. Two students nonetheless expressed confidence that the claim was true, supporting our view that DA is distinct from skepticism. Two other students showed partial understanding of DA; the other three displayed empirical reasoning. The results provide evidence of how DA can develop in middle grades, and raise the question of how robustly DA can develop without students having significant prior experience with viable general arguments.

EXAMINING JUSTIFICATION OF THIRD-GRADE CHILDREN WHEN THEY ENGAGED IN EQUAL-SHARING PROBLEMS

Hochieh Lin
The Ohio State University
lin.2532@osu.edu

Keywords: Elementary School Education, Fractions, Justification, Problem Solving

Justification is a crucial practice that involves conjecturing and justifying mathematical claims. Researchers have shown that elementary children are able to provide sophisticated arguments for their conjectures during generalizing activities (e.g., Ball, 1993; Reid, 2002). To understand the justification of children in the context of fractions tasks, this study examined four third graders' discourse when they justified their claims in solving equal-sharing problems.

Four third-grade children in the Midwestern United States participated in this study. Through prior interviews, they showed only limited understanding of fraction concepts, particularly part-whole relationships, as is typical for this age. Provided with a tablet, pencils, and paper, the participants worked in pairs to solve equal-sharing story problems (e.g., Mary, Sam, and you are sharing eight pizzas; how do you share the pizzas so that each of you gets the same amount?). During the videotaped sessions of each pair, I facilitated the participants' interactions and observed how they used their intuitive knowledge for justification. Here presents an example that illustrates the arguments of two children when they engaged with the aforementioned task:

> Amy: …3 wholes, 3 wholes, 3 wholes [repeats her answer with confidence]. **[claim]**
> Betty: 1, 2, …2 wholes…and 2 halves [counts the wholes and slices of pizzas]. **[claim]**
> Amy: Therefore the 2 halves equals 1 whole.
> Betty: But the 2 halves do not make 1 whole. One half is here, and it takes two more (halves) to make 1 whole [explains while pointing to Amy's drawing]
> Amy: [Writes down numerical values inside the wholes and parts of the pizza figure]. The 2 slices should be counted as 1 whole. Here one slice is 5, and there one slice is 5 [points to graphics]. 5 added by 5 is 10, so together is 10. Since each person has 2 wholes already, then (the total is) 10, 10, and 10. Therefore, it's 3 (wholes) (for each person).
> Betty: Mine is kind of different. I would put 15 and 15 [writes down 15 for each circle that represents a whole pizza]. Everyone wants 3 slices to make 15, but the two slices are not sufficient (to make a whole). Since each person would take 2 slices. Those make a 10.…Each person gets 15, 15, and 10.

These results demonstrate informal strategies the children employed for justification. Particularly, whole number magnitudes were used to reason and describe part-whole relationships. Further analysis of Betty's discourse found that she seemingly followed a reasoning pattern similar to a proving technique, namely proof by contradiction. This technique first assumes the opposite of a claim and then uses the established facts to invalidate the claim.

This study reveals that some third-grade children created distinct strategies to justify or refute their claims for fractions problems. The finding of Betty's reasoning approach resonates the findings of Reid (2002) that specified logical patterns the fifth graders implicitly used for generating and testing conjectures. Since many U.S. elementary textbooks were found lacking written justification tasks (Bieda, Ji, Drwencke, & Picard, 2014), it is imperative for elementary teachers to consider enacting such practice in typical problem-solving fractions tasks.

Researchers have developed design categories or classification schemes for modeling problems (Bock, Bracke, & Kreckler, 2015; Czocher, 2017; Maaß, 2010) to make appropriate task choices for the target group of students and mathematical objectives. The task design around mathematical modeling needed to be carefully studied to evoke students' modeling process so that those processes could be traced systematically (Albarracin, Arleback, Civil, & Gorgorio, 2019). The goal of this study aimed to provide a task classification system to examine secondary students' modeling behaviors and decision-making processes while they are engaged in mathematical modeling tasks that draw on the content of Quantities.

The choice of mathematical content for this work was deliberate for two reasons: (1) the content of Quantities under the Number and Quantity section (CCSSM, 2010) plays a foundational role in the development of advanced mathematical domains (e.g., algebra, functions, vectors); and (2) the content naturally implicates to study modeling since it requires choosing, interpreting quantity units, and defining appropriate quantities to create descriptive models while coordinating both mathematical and non-mathematical knowledge to solve problems.

National and international research resources were reviewed to compile a list of modeling tasks (85 tasks). Two task design heuristics were followed in this project. First, by adopting Maaß's (2010) modeling task design framework, I examined modeling tasks under the five categories: the scope of modeling (whole process or sub-process), the amount of data provided (superfluous, inconsistent, missing, matching), the nature of the task's relationship to reality (level of authenticity or artificiality), the contextual situation (personal, occupational, public, scientific), and the type of model used (descriptive or normative). I used these categories along with the target mathematics content. Second, following Czocher's (2017) task selection method, the modeling cycle (Blum & Leiß, 2007) was utilized to filter the tasks from the list in order to map each task with the anticipated stages and transitions of the modeling expected to be evoked.

The final list of modeling tasks (14 tasks) was evaluated and critiqued by a panel of mathematics educators and field-tested by two researchers in high school classrooms. The tasks ranged from targeting specific steps to whole steps of the modeling cycle (Blum & Leiß, 2007) to study closely how secondary students might move between mathematical modeling stages and how their cognitive resources might influence their problem-solving process. This task scheme can be used for identifying modeling problems for the use of one-on-one clinical interviews or implemented in classrooms for tracking the kinds of mathematical thinking among high schoolers.

EXPLORING HIGH SCHOOL STUDENTS' VALIDATION METHODS IN THE MATHEMATICAL MODELING PROCESS

Ayse Ozturk

Keywords: Modeling, Cognition, Advanced Mathematical Thinking, High School Education

Calls have been made for the need to understand and advance students' mathematical modeling behaviors (Cai et al., 2014). Validation is a crucial step of the modeling process that occurs when modelers compare their mathematical results to a real-world situation that they attempt to understand (Blum & Leiß, 2007), and helps them to decide whether the model needs revisions or fulfills the need of the problem (Zawojewski, 2013). In this study, I investigated how high school students evaluate and validate their models in the mathematical modeling process.

The framework for this study stems from the two integrated theoretical stances—embodied cognition perspective (Lakoff & Núñez, 2000) and cognitive mathematical modeling perspective (Kaiser, 2017). Students' model-based problem-solving is influenced by their internal resources (i.e., mathematical knowledge and beliefs) (i.e., Stillman, 2011) and external relationships with the environment and other individuals (Lesh & Doerr, 2003). Prior experiences might be difficult to communicate at times for students, but linguistic tools can be rich with representational elements (Kövecses & Benczes, 2010) that can be turned into a validation method in the mathematical modeling process (Czocher, 2018). As a result, students embody experiences, intuitions, and means to support transfer through language, thought, and action while engaging cognitive steps of the mathematical modeling process (Manouchehri & Lewis, 2017).

This research was a qualitative, descriptive account of the validation ways employed in the mathematical modeling problem-solving process by eight high school students from different grade levels (2 ninth-graders, 2 tenth-graders, 2 eleventh-graders, and 2 twelfth-graders). Each participant completed 4 interviews lasting approximately 1 hour each based on one-on-one think-aloud tasks (Ericsson & Simon, 1998) at a public university in a Midwestern state. The selection of the participants was deliberate, targeting variability in mathematical backgrounds and self-efficacy toward solving mathematical problems. The common requirement of the interview tasks was choosing and interpreting quantity units and defining appropriate quantities to create descriptive models while using both mathematical knowledge (i.e., estimation) and non-mathematical knowledge to solve problems. Each interview was audiotaped and transcribed. The ongoing data analysis focused on the categorization of the forms of reasoning employed by the students while they were evaluating and validating their models, and then deciding whether their mathematical models needed more revisions or not. A content analysis of the transcripts (Patton, 2002) was used to detect themes in the students' validation methods.

The preliminary findings provided evidence in support of two of the themes identified by Ferri (2006)—*knowledge-based validation* and *intuitive-based validation*—and described three additional validation elements of implementation that appear to support those identified two themes: *formalistic validating* (the focus is on abstraction, formulas, mathematical correctness), *realistic validating* (the focus is on references to real situations that are enriched with verbalized or visual representations), and *formalistic–realistic validating* (the focus is on a balance between formal mathematical aspects and reality-based aspects of the problem).

PROMPTING QUANTITATIVE REASONING PATTERNS WITH MATHEMATICAL MODELING PROBLEMS

Patti Brosnan
The Ohio State University
brosnan.1@osu.edu

Ayse Ozturk
The Ohio State University
ozturk.25@osu.edu

Keywords: Problem-Solving, Number and Operation, Modeling, High School Education

Contributing to the call for improving secondary instruction, the National Council of Teachers of Mathematics (NCTM, 2000) emphasized that students should gain quantitative reasoning abilities that lead to work with quantitative information and be able to use formulas and graphs to represent how quantities in real-life phenomena are related to one another and change together. Ellis (2007) suggested that one way to support students' quantitative reasoning is by engaging them in problem-solving activities that require (a) exploring how changing initial quantities will affect the emergent quantities, (b) determining how to adjust the initial quantities while keeping the emergent quantities constant, and (c) determining how to adjust the emergent quantities with the initial quantities (p. 475). In that sense, mathematical modeling problems naturally provide an environment for fostering and nurturing quantitative reasoning skills (Carlson, Larsen, & Lesh, 2003; Thompson, 2011).

In this poster presentation, a partial report of a larger study, we examined two tenth-graders'—Carlos and Ahmad (pseudonyms)—quantitative reasoning patterns and quantification processes while they solved mathematical modeling problems. Each student was interviewed one-on-one and given four modeling problems. Each interview was approximately 60 minutes long, and the students were encouraged to explain their reasoning processes (Ericsson & Simon, 1998). In the data analysis, we adopted the quantitative reasoning in context (QRC) framework (Mayes, Peterson, & Bonilla, 2013), which has four elements: (a) the quantification act (QA), the ability to identify the mathematical objects and their unit measures; (b) quantitative literacy (QL), the ability to identify, compare, manipulate, and draw conclusions from variables; (c) quantitative interpretation (QI), the ability to discover patterns and trends; and (d) quantitative modeling (QM), the ability to create representations to explain the problem and to revise them based on their fit into reality (p. 130).

The initial findings indicate that both the students were comfortable when identifying variables and their unit measures. Both recognized that they had assigned numbers as assumptions. Two distinct patterns emerged when comparing and manipulating the unit measures throughout the four modeling problems: (a) when Carlos assigned numbers, he primarily used the smallest unit as a measure and made calculations from the part to the whole *(inductive thinking approach)* (Simon,1996), whereas Ahmad always simplified the whole unit to reach the smallest unit at the end and made calculations from the whole to the part (*deductive thinking approach*) (Simon, 1996), (b) those thinking approaches impacted their quantitative interpretations on the mathematical models they had created (i.e., tables and graphs). For example, while Carlos explained the patterns on his graphs in a *descriptive modeling way* (Maaß, 2010) as explaining or forecasting the real-life situation, Ahmad's explanations were solely focused on the generalized mathematical results and mathematical accuracy in a *normative modeling way* (Maaß, 2010). In the presentation, the excerpts will be shared under each reasoning pattern, and possible instructional implications will be discussed.

MAKING SENSE OF SENSELESS THINGS: AN ENACTIVIST ANALYSIS OF HARMONY AND DISSONANCE IN PROBLEM SOLVING

Operating from an enactivist theory of cognition, this work seeks to understand the emergent nature of mathematical activity mediated by manipulatives. Enactivism takes a biological approach and theorizes that perception consists in perceptually guided action enabled by cognitive structures that emerge from recurrent sensorimotor patterns (Proulx, 2013; Varela, Rosch, & Thompson, 1992). These processes are non-linear, unfolding, and ongoing events where meanings emerge and transform in interactions, not inside of minds and bodies (Malafouris, 2013; Proulx, 2019). Further, one's way of knowing is driven by an evolutionary imperative to act in an adequate, fitting, and harmonious way with one's environment (Maheux & Proulx, 2015). This search for harmony leads to a *structural coupling* between the individual and their environment with the individual's history of recursive interactions playing a crucial role in *structurally determining* this course of evolution (Proulx, 2013).

This work seeks to elucidate the nature of emergent mathematical activity mediated by manipulatives by addressing the question, *"What role might manipulatives play in the emergent processes of sense making?"* To do so, we analyzed the activity of "Dolly" and "Lyle" as they aimed to make sense of the flip-and-multiply algorithm for fraction division in a problem-solving interview using a manipulative Dolly created for engagement with fraction concepts. The data comes from a larger study that is exploring how an open-ended and iterative design experience centered in Making (Halverson & Sheridan, 2014) might inform prospective mathematics teachers' (PMTs') pedagogy. We took a revelatory case study approach to analyze and transcribe the video data (Yin, 2014), and focused our analysis on the particular interactions aiming to coordinate meanings of fraction division in the manipulative and in the algorithm that presumably substantiates those meanings (Malafouris, 2013).

Our analysis illuminates the role manipulatives can play in establishing a notion of sense making that is grounded in embodied understandings. For example, although Dolly and Lyle arrived at the correct answer with the manipulative early in their problem solving, they were dissatisfied because it did not seem to *fit* with the answer they derived from the algorithm. Eventually, this dissonance gave way as they established harmony between the two, thereby revealing the compelling power that embodied tool use can have for altering a space of possible actions and consequently on sense-making activity. Our analysis also reveals what might be problematic about a pedagogical practice where a procedure is adequate and *sense making* is not the criteria for fit. The enactment of the algorithm was disrupted through use of a tool, ultimately leading to an authentic understanding of what it means to *do* fraction division. These findings further substantiate extant arguments for engaging mathematics learners in embodied, tool-mediated problem-solving activity in conjunction with the learning of procedures.

TALKING IN MATHEMATICS – DO WE KNOW HOW?

Pauline Tiong
Simon Fraser University
pauline_tiong@sfu.ca

Keywords: Communication; Classroom Discourse; Teacher Education - Inservice / Professional Development; Mathematical Knowledge for Teaching

With communication being highlighted as a process standard in The Curriculum and Evaluation Standards for School Mathematics by the National Council of Teachers of Mathematics (NCTM) in 1989 (NCTM, n.d.), the notion of communicating mathematically (Pimm, 1991) has since become an increasing important yet demanding task both for students and for teachers. Moreover, the role of spoken communication and how it effectively helps in the development of mathematical thinking did not seem clear. On the one hand, it was often assumed that students know how and what to communicate in the mathematics classroom, i.e. mathematical communicative competence was assumed to be a given (Adler, 2002; Pimm, 1987; Sfard et al., 1998) when it is the exact opposite. On the other, teachers face the challenge of orchestrating and facilitating meaningful mathematical conversations with and for their students, as Sfard et al. (1998) argued that it is "an extremely demanding and intricate task" (p.51) for conversations (either orchestrated or spontaneous) to be meaningful or productive in the mathematics classroom.

As part of this poster presentation, the author has attempted to explore the value and process of spoken communication in the mathematics classroom; and surfaced some corresponding implications on the teaching (and learning) of mathematics. In particular, on the value of spoken communication in the mathematics classroom, Pimm (1991) has suggested how spoken communication can be considered as the pathway to written communication if used purposefully with the intent of acquiring the mathematics register with regard to the notion of communicating mathematically. As for the form of spoken communication in the mathematics classroom, Barnes' (1976) studies on classroom talk can be a possible source of reference in providing a frame to understand classroom talk which contributes to learning. Based on these ideas, a preliminary framework (Figure 1) is proposed with the intent of explaining why and how spoken communication (or mathematical talk) can contribute to the teaching (and thus learning) of mathematics. While it may not fully explicate the value and process of spoken communication in the mathematics classroom, this idea can be further explored and refined through future research, e.g. the use of the framework as a possible structure for teacher professional development activities, focusing on developing the necessary mathematical knowledge for teaching (Ball et al., 2008) to orchestrate and facilitate mathematics talk.

DEVELOPMENT OF THE MATHEMATIC MODELING PROCESS IN MATHEMATICS UNDERGRADUATE STUDENTS

DESARROLLO DEL PROCESO DE MODELACIÓN MATEMÁTICA EN ESTUDIANTES DE LICENCIATURA EN MATEMÁTICAS

Jesús David Berrio-Valbuena
Universidad del Atlántico
jberriovalbuena@mail.uniatlantico.edu.co

Zuriel Fitzgerald Peña-Ubarne
Universidad del Atlántico
zpena@mail.uniatlantico.edu.co

Maria de los Ángeles Torrenegra-Giraldo
Universidad del Atlántico
mdtorrenegra@mail.uniatlantico.edu.co

Posing of the Problem and Justification

In light of the distinct changes that modern society faces and the new "normal" it is necessary that individuals relate mathematics to their environment. Mathematical modeling is a process that allows one to determine a real-world problem, which is subsequently subject to observation and experimentation in order to obtain data and conclusions on said phenomenon (Villa-Ochoa y Ruiz, 2009). However, at the time of implementing the modeling in the classroom, it becomes evident that there are difficulties that do not permit its full development. Since modeling tends to be presented as a mathematical application (Villa-Ochoa et al., 2009) and therefore aspects such as observation and experimentation are left out of this process (Berrio, Peña y Torrenegra, 2018).

Methodology and Results

For this research an experimental activity was developed in the classroom, which consisted of rolling100 dice and removing those dice that landed on the number 5.

With the activity defined, we proposed an a priori analysis on how this process should have been developed (figure 1). The results obtained are shown in figure 2.

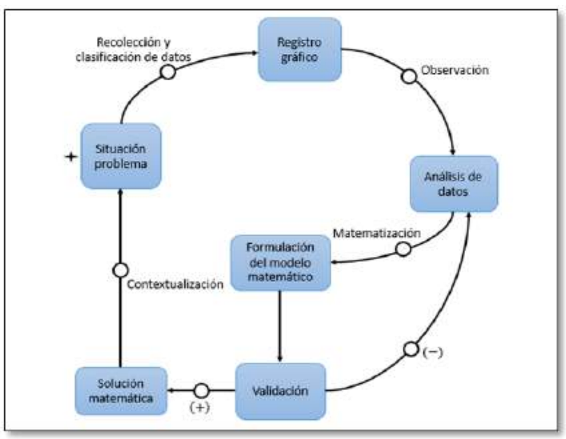

Figure 1: Berrio et al (2019)

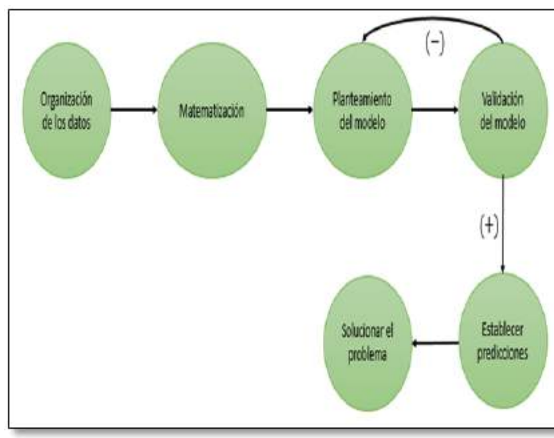

Figure 2: Berrio et al (2019)

Conclusions

- Experimental activities in the classroom give students a more concrete sense of reality, allowing inferences to be made outside the initial domain, which allows them to identify the limitations of the proposed model.

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

- There are difficulties in solving problems of mathematical modeling on the part of students, because the notion of mathematical modeling that they have consists of a mathematical application or problem.

Planteamiento del problema y justificación

Ante los distintos cambios que enfrenta la sociedad actual y la nueva “normalidad” se requiere de individuos que relacionen las matemáticas con su entorno. La modelación matemática es un proceso que permite determinar un problema de la realidad, que posteriormente es sometido a la observación, y a la experimentación con el fin de obtener datos y conclusiones sobre dicho fenómeno (Villa-Ochoa y Ruiz, 2009). Sin embargo, al momento de implementar la modelación en el aula, se evidencian dificultades que no permiten su completo desarrollo. Pues se tiende a presentar la modelación como una aplicación matemática (Villa-Ochoa et al., 2009) y por consiguiente aspectos como la observación y experimentación quedan por fuera de este proceso (Berrio, Peña y Torrenegra, 2018).

Metodología y resultados

Para esta investigación se desarrolló una actividad experimental en el aula que consistió en el lanzamiento de 100 dados y aquellos que quedaban con la cara superior en el número 5 se retiraban.

Con la actividad definida, planteamos un análisis a priori sobre cómo se debía desarrollar el proceso (figura 1) los resultados obtenidos se muestran en la figura 2.

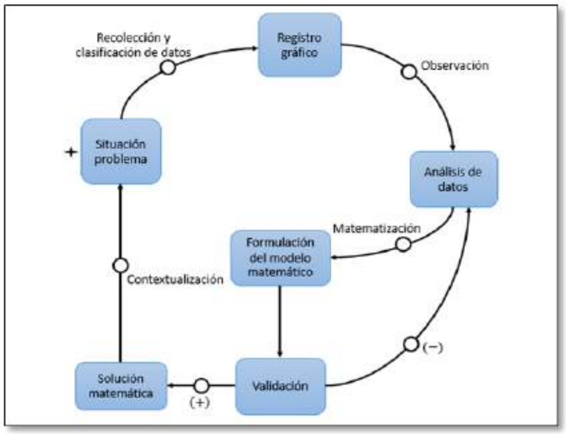

Figura 1: Berrio et al (2019)

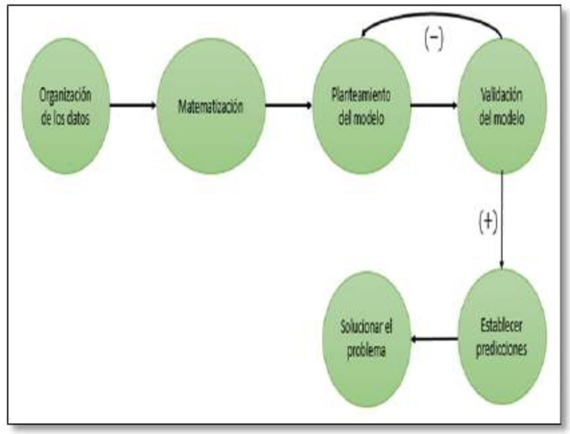

Figura 2: Berrio et al (2019)

Conclusiones

- Las actividades de experimentación en el aula, les da a los estudiantes una noción de realidad más concreta, lo que permite realizar inferencias fuera del dominio inicial, lo que les permite identificar las limitaciones del modelo planteado.
- Existen dificultades en la resolución de problemas de modelación matemática por parte de los estudiantes, pues la noción de modelación matemática que tienen consiste en una aplicación o problema matemático.

Theoretical Approach

In Schoenfeld's (1985) Mathematical Problem-Solving (MPS) theory it is key to illustrate ideas, reflections of the use of diagrams and representations, heuristic strategies, and discussion of all the possible and distinct solution methods. For Santos (2014), the learning process is categorized into resources, prior mathematical knowledge; heuristic strategies, methods to reach a solution; metacognitive strategies, monitoring and regulation of the process itself for decision making; and beliefs, ideas about mathematics and how to solve problems. To verify and evaluate this process, Polya's four-phases of his Problem-Solving theory (1945) consisting of comprehension of the problem, design of a plan, carrying out the plan, and looking back has been followed; these particular questions provide information on the learning process.

Research Questions and Design

It was necessary to analyze the effects of a didactic sequence based on MPS theory applied on first-semester students of *Teoría del Cálculo I* from the LIMA programme at UdeG, for the learning of resources, strategies, beliefs and competences in mathematical Problem Solving. In this course, students are expected, in particular, to model the volume function applying the concept of Relative Extrema in a realistic scenario. The sequence consisted of a non-routine problem and working sheets with questions relating to Polya's phases. A group of 12 students were asked to work in triads to design a prototype of a container in the shape of a trapezoid using a 50cm x 65cm cardboard sheet; it had to guarantee the maximum possible volume taking into consideration that the trapezoidal face must be an isosceles trapezium containing the assigned acute angles (University of Colorado, s.f.)

Data Collection and Analysis

Since this is a qualitative phenomenological research, focus groups' activities were monitored and recorded; additionally, the answers to demi-structured interviews were analyzed through worksheets provided to the students. Altogether, they were triangulated with a matrix of categories and indicators based on the analysis of the data and the dimensions of Schoenfeld's theory.

Summary

According to data triangulation, students were able to follow Polya's solving problem phases and showed a satisfactory performance according to MPS theory. The most relevant effect of the sequence was the fact that the contextualization of the problematic proved beneficial to the development of the metacognitive process by giving students guidance in the decision making of the procedure to follow in the operations to perform, and in the direction to reach a solution. In general,

Perspectiva Teórica

En la teoría de resolución de problemas matemáticos (RPM) de Schoenfeld (1985) es clave ilustrar ideas, reflexiones sobre el uso de diagramas y representaciones, estrategias heurísticas y discutir todos los métodos de solución posibles. Para Santos (2014), el proceso de aprendizaje se clasifica en recursos, conocimiento matemático previo; estrategias heurísticas, métodos para llegar a una solución; estrategias metacognitivas, monitoreo y regulación del proceso mismo para la toma de decisiones; y creencias, ideas sobre las matemáticas y sobre cómo resolver problemas. Para verificar y evaluar este proceso, se han seguido las cuatro fases de Polya de su teoría de Resolución de Problemas (1945) que consiste en la comprensión del problema, el diseño de un plan, la ejecución del plan y la visión retrospectiva; sus preguntas características proporcionan información sobre el proceso de aprendizaje.

Preguntas de Investigación y Diseño

Se requiere analizar los efectos de una secuencia didáctica basada en la teoría RPM aplicada en estudiantes de primer semestre de *Teoría del Cálculo I* del programa de la LIMA en UdeG, para el aprendizaje de recursos, estrategias, creencias y competencias en resolución matemática de problemas. En particular, se espera que los estudiantes modelen la función de volumen aplicando el concepto de Extremos Relativos en un escenario realista. La secuencia consistió en un problema no rutinario y hojas de trabajo con preguntas relacionadas con las fases de Polya. Se pidió a un grupo de 12 estudiantes que trabajaran en tríadas para diseñar un prototipo de un contenedor en forma de trapecio usando una lámina de cartón de 50 cm x 65 cm; tenía que garantizar el máximo volumen posible teniendo en cuenta que la cara trapezoidal debe ser un trapecio isósceles que contenga los ángulos agudos asignados (Universidad de Colorado).

Técnicas y Análisis de Recopilación de Datos

Al tratarse de una investigación cualitativa fenomenológica, se monitorearon y registraron las actividades de los grupos focales. Las respuestas a las entrevistas semiestructuradas se analizaron a través de las hojas de trabajo proporcionadas a los estudiantes. Además, la información recopilada se trianguló con una matriz de categorías e indicadores basados en el análisis de los datos y en las dimensiones de la teoría de Schoenfeld.

Resumen de Hallazgos

Según la triangulación de datos, los estudiantes lograron seguir las fases de resolución de problemas de Polya y mostraron un desempeño satisfactorio de acuerdo con la teoría RPM. El efecto más relevante de la secuencia fue que la contextualización de la problemática benefició el desarrollo del proceso metacognitivo al brindar orientación a los estudiantes en la toma de decisiones del procedimiento a seguir, operaciones a realizar y la dirección a la solución. En general, la secuencia de un problema matemático no monótono influyó positivamente en el aprendizaje del concepto de Extremos Relativos, en el desarrollo de estrategias metacognitivas y en las habilidades de modelado.

SECONDARY TEACHERS' PRACTICAL RATIONALITY OF MATHEMATICAL MODELING

Wenmin Zhao
University of Missouri
wenminzhao@mail.missouri.edu

Samuel Otten
University of Missouri
ottensa@missouri.edu

Keywords: Mathematical modeling, practical rationality, norms, obligations

Various policy leaders and educational scholars have advocated for teachers to implement mathematical modeling in their classrooms (e.g., Common Core State Standards in Mathematics, 2010). In spite of arguments in favor of modeling, the implementation of modeling is still relatively rare in teaching practice in most countries including the United States (Blum, 2015). What makes modeling not viable or desirable from the perspective of secondary mathematics teachers? In what ways do teachers' day-to-day routines or views of their professional responsibilities align or not with modeling? In this study, we employed *practical rationality* as a framework for examining how teacher decisions are rationalized at the level of the instructional situation and to further understand the potential challenges of enacting modeling in classrooms.

The *practical rationality* approach suggests that instructional norms and professional obligations come into play in teachers' instructional decisions (Herbst & Chazan, 2012). Teachers view their role as entwined with obligations to different stakeholders corresponding to four sources of obligations: *disciplinary obligation*, *institutional obligation*, *individual obligation*, and *interpersonal obligation*. This study presents an analysis of the norms that are perceived by secondary teachers in relation to modeling and the professional obligations that they use to justify their departure from or alignment to the associated norm through the use of a scenario-based survey.

Secondary mathematics teachers (n=176) from the Midwestern United States participated in the study, varying in terms of their experience of teaching different courses and experience of enacting modeling tasks. They were randomly assigned to one of two groups. Each group includes four narrative sets in the situation of modeling. Within each narrative set, teachers were asked to choose what they would do next, presenting three options that included a hypothesized normative instructional action (e.g., close off the opportunities for students to use their everyday life knowledge) and two less typical actions (e.g., encourage students to bring in their background experiences). These hypothesized actions are based on prior studies of the enactment of modeling tasks (e.g., Leiß, 2007), non-traditional tasks (e.g., Herbst, 2003), and word problems (e.g., Chazan, Sela, & Herbst, 2012), and classroom observations in the United States.

Our findings show that while 68.2% of teachers chose to give clear directions for factor selection for their students and 94.3% of teachers expected students to find a symbolic representation (e.g., functions) as their final product of modeling, these teachers felt strongly obligated to teach the underlying mathematical concepts and the properties. In addition, only 34.1% of teachers were amenable to emphasize the social justice aspect of the task. However, for those who chose not to attend to social justice issues, they felt strongly obligated to interpersonal obligations (e.g., maintain a classroom environment that is conceived to learning) and disciplinary obligations (e.g., teach a valid representation of the mathematical knowledge and practices). The findings imply that the environmental impacts (e.g., disciplinary obligations) on the instructional practice of mathematical modeling should be taken into account. In the poster session, we will further illustrate how practical rationality can be used to better understand how teacher decisions are rationalized in mathematical modeling.

NUMERICAL ESTIMATION SKILLS, EPISTEMIC COGNITION, AND CLIMATE CHANGE: MATHEMATICAL SKILLS AND DISPOSITIONS THAT CAN SUPPORT SCIENCE LEARNING

Ian Thacker
University of Texas at San Antonio
ian.thacker@utsa.edu

Texts presenting novel statistics can shift learners attitudes and conceptions about controversial science topics. However, not a lot is known about the mechanisms underlying this conceptual change. The purpose of this study was to investigate two potential mechanisms that underlie learning from novel statistics: numerical estimation skills and epistemic cognition. This research investigated two treatments—a numerical estimation and epistemic cognition intervention—that were expected to enhance people's ability to make sense of key numbers about climate change. Results indicated that undergraduate students (N = 516) who were given instruction on numerical estimation strategies before shown novel climate change statistics had fewer misconceptions when compared with people who did not. Findings provide emerging evidence that supporting mathematical reasoning skills can enhance conceptual change in science.

Keywords: Numerical Estimation, Epistemic Cognition, Conceptual Change, Plausibility Judgments, Mathematics For Sustainability

Now more than ever, people need to be skeptical of the information that they encounter online. Inaccurate, self-authored misinformation is being created and circulated at an alarming rate (see, e.g., Allcott, Gentzkow, & Yu, 2019; Kata, 2012). Internet searches for controversial science topics like climate change, genetically modified foods, and vaccinations reveal millions of articles, much of which include scientifically incorrect information (e.g., Kortum, Edwards, & Richard-Kortum, 2008; Scheufele, & Krause, 2019); and much of this misleading information relies on misleading data.

Numerical data (e.g., statistics) found in the news can be a powerful tool for conceptual change, whether that change is for better or for worse. On the one hand, prompting people to estimate just a handful of statistics about climate change and then presenting them with the actual value can shift their attitudes, beliefs, and misconceptions to be more aligned with scientists (Ranney & Clark, 2016). On the other hand, presenting people with misleading statistics can shift their scientifically correct conceptions and attitudes to be less aligned with those of scientists (Ranney & Clark, 2016). Taken as a whole, this research suggests that statistics can be used as a catalyst for conceptual change. However, the mechanisms that underlie this change process remain understudied.

The purpose of this study was to examine mechanisms that underlie the learning that occurs when people encounter novel statistical information. Namely, I draw from theory on conceptual change (Dole & Sinatra, 1998, Lombardi, Nussbaum, & Sinatra, 2016), and epistemic cognition (the active reflection on whether information is true or justified; Chinn, Rinehart, & Buckland, 2014) to examine the impact of two mechanisms of conceptual change when learning from real-world numbers—numerical estimation skills and epistemic cognition.

Theoretical Framework

Conceptual Change

When individuals encounter statistics in the news or online that conflict with their prior conceptions, conceptual change may occur. Conceptual change represents a particular kind of learning that occurs when new information conflicts with a learners' background knowledge, leading

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

to a restructuring of conceptual knowledge (Dole & Sinatra 1998; Murphy & Mason, 2006). Conceptual change researchers tend to describe concepts as either consistent or inconsistent with the understanding of experts and many define conceptual change as a correction of scientifically inaccurate conceptions, or *misconceptions*. For example, if a person holds the misconception that scientists believe that humans are not responsible for climate change and reads a statement that "97% of scientists agree that climate change is caused by humans," then there may be potential for the learner to question their idea and shift them to be more consistent with scientists. In this way, a single number has the potential to instigate conceptual change. Of course, there are many contributing factors and processes left unexplained in in this simplistic example, as conceptual change can be viewed as a process that is contingent upon people's motivation, emotion, and attitudes—factors that are often called *warm constructs* (see Dole & Sinatra, 1998; Pintrich, Marx, & Boyle, 1993; Sinatra, 2005; Sinatra & Seyranian, 2016). As such, the extent to which people engage with and learn from numerical data may be influenced by motivational factors such as their beliefs about their ability to succeed in mathematics (*self-efficacy*; e.g., Bandura, 1997), or emotional factors such as their trait-level anxiety associated with engaging in mathematics (*mathematics anxiety*; e.g., Ramirez, Shaw, & Maloney, 2018).

Plausibility judgments for conceptual change. When individuals encounter a novel statistic, they may implicitly or explicitly judge whether that information is plausible and then shift their conceptions accordingly. Research on plausibility judgments for conceptual change offers a useful frame for investigating these shifts in understanding. The Plausibility Judgments for Conceptual Change model (PJCC), posits that novel information (like novel statistics) can incite conceptual change because they prompt learners to appraise or reappraise the plausibility of their existing beliefs (Lombardi et al., 2016). When people encounter a novel explanation like a statistical figure, they first pre-process the information (e.g., by employing numerical estimation skills to judge the reasonableness of the number), and then make a judgment of the plausibility of the conception supported by the new information. Plausibility judgments can be either implicit or explicit. The extent to which people explicitly evaluate the plausibility of a conception depends, in part, on their views about knowledge (epistemic motives and dispositions); more explicit plausibility evaluations are thought to lead to greater potential for conceptual change—but only if the learner finds the new conception to be more plausible than their previous conception. That is, learners process statistical information and then appraise the plausibility of their initial conceptions based on this information; learners that find a novel conception more plausible than prior conceptions have higher potential for conceptual change.

Numerical Estimation

One way that learners process numbers is by estimating whether they are reasonable (e.g., Reys & Reys, 2004). Research on measurement estimation concerns the explicit estimation of real-world measures (Bright, 1976; Sowder & Wheeler, 1989) and is useful for understanding factors that help people judge whether real-world quantities are reasonable. Findings suggest that peoples' estimation accuracy and judgments of reasonableness improve when they use measurement estimation strategies, such as the benchmark strategy—the use of given standards and facts that can be applied by the learner through mental iteration and proportional reasoning to better estimate and judge the plausibility of real-world quantities (e.g., Brown & Siegler, 2001; Joram et al., 1998). For example, a person's estimate of the number of jellybeans in a container is likely to be more accurate and they will be a better judge of reasonableness of other peoples' guesses if they are first told the number of jellybeans in a different container. Measurement estimation strategies may therefore support people's comprehension and evaluation of given real-world quantities.

Epistemic Cognition

Epistemic cognition is the thinking that people do about knowledge and knowing (Chinn, et al., 2014; Sandoval, Greene, Braten, 2016) and is hypothesized to predict the extent to which learners evaluate the plausibility of a claim in light of new information (Lombardi et al., 2016). There are multiple models of epistemic cognition (for a review, see Sandoval et al., 2016), but for the purpose of this study, I draw from the AIR model of epistemic cognition (Chinn et al., 2014). According to this model, epistemic cognition is considered to be a situated process that relies on individuals' Aims (goals and associated values of goals), Ideals (espoused standards for achieving epistemic aims), and Reliable processes for knowing (schema for producing true, justified beliefs; Chinn et al., 2014).

An Existing Learning Intervention: EPIC

Prior classroom and laboratory studies have demonstrated the impact of presenting people with surprising numbers about controversial topics on their understanding of social issues (for reviews, see Ranney et al., 2019; Yarnall & Ranney, 2017). Many of these studies are grounded in a paradigm called "Numerically Driven Inferencing" (NDI, Ranney, Cheng, Garcia de Osuna & Nelson, 2001; Ranney & Thagard, 1988), which assumes that individuals' understanding of numerical information is connected to their knowledge, attitudes, and beliefs about larger issues. One of the central techniques from this perspective is called EPIC, an acronym for an intervention which introduces novel numerical information by prompting learners to Estimate quantities, state a Preference for what they would like the quantity to be, Incorporate the answer, and then Change their preferences afterward (e.g., Ranney & Clark, 2016; Rinne et al., 2006). Studies that use EPIC often operationalize conceptual change in terms of shifts in the preferences that individuals state for given numbers (i.e., differences between the "P" and the "C" in EPIC).

In sum, I contend that in order for learners to select high quality content from which to learn, they must develop skills to evaluate epistemic aspects of new information and also develop estimation skills necessary to accurately evaluate the statistics that they encounter along the way. That is, they must learn epistemic cognition and numerical estimation skills. Currently, there is little to no empirical research that investigates the role of estimation skills and epistemic cognition in conceptual change processes. My research is therefore guided by five questions:

1. To what extent does estimation of and exposure to novel statistics regarding climate change (i.e., an adapted EPIC intervention) shift learners' knowledge of climate change?
2. To what extent does enhancing this intervention with instruction on estimation strategies change learners' knowledge of climate change?
3. To what extent does enhancing this intervention with prompts to activate epistemic aims change learners' knowledge of climate change?
4. Is there an interaction between estimation skills and epistemic thinking on conceptual change?
5. To what extent do warm constructs (i.e., mathematics anxiety, mathematics self-efficacy, epistemic dispositions, and reported surprise from reading statistical information) mediate relations between pre- and post-intervention knowledge?

Methods

To answer my research questions, I formed a nationally representative Qualtrics panel of 516 undergraduate students to participate in an experimental online survey. Participants' median reported age was 20years, and 81% identified as Female, 64% White, 11% African American, 9% Asian, 9% Hispanic, and 43% as either Liberal or Very Liberal. All participants (a) completed a pretest to measure their misconceptions about climate change, mathematics self-efficacy and anxiety, and prior epistemic dispositions, (b) were randomly assigned to one of five conditions created by a control group and combinations of two interventions (see below), and (c) completed an identical post-test of knowledge and a demographics questionnaire.

Outcome Measure

Knowledge. Knowledge of human-induced climate change was a primary outcome in this study and was measured using seven items from the 28-item human induced climate change knowledge questionnaire (HICCK; Lombardi, Sinatra, & Nussbaum, 2013). Construct and content validity of the abbreviated scale was established through pilot studies and cognitive interviews (see Thacker, 2020). The knowledge questionnaire was given to participants just prior to and immediately after instruction and was intended to measure participants' conceptions about the consensus on human-induced climate change and were selected to align with information presented in the EPIC intervention. For example, participants rated their agreement with statements such as, "greenhouse gas levels are increasing in the atmosphere" on a scale from 1 (*strongly disagree*) to 5 (*strongly agree*). The measure at pre and posttest was reliable at conventional levels (Cronbach's alpha = .85 pre, .88 post).

Covariates

Mathematics Self-Efficacy and Anxiety Questionnaire (MSEAQ). Participants mathematics-specific self-efficacy and anxiety were measured using the Mathematics Self-Efficacy and Anxiety Questionnaire (MSEAQ; May, 2009). The MSEAQ consists of 28 items that can be divided into two subscales, mathematics self-efficacy (13 items) and mathematics anxiety (15 items). Construct validity was established in a prior study using factor analytic methods with an online sample and by establishing strong correlations with a classic measures of mathematics anxiety (s-MARS) and mathematics self-efficacy (see May, 2009). The instrument was shown to be reliable overall (Cronbach's Alpha = .96), as were the two subscales for mathematics self-efficacy (Cronbach's Alpha = .94) and mathematics anxiety (Cronbach's Alpha =.93). Average scores for the two subscales were computed and used in mediation analyses.

Epistemic dispositions. Baseline epistemic dispositions were measured using the Actively Open-Minded Thinking scale (AOT; Stanovich & West, 1997). The AOT is a measure of epistemic dispositions toward knowledge that consists of seven items. Participants reported their agreement with five statements (e.g., "Changing your mind is a sign of weakness") on a scale from 1 (*completely disagree*) to 7 (*completely agree*). The Chronbach's alpha was found to be .70 with the main analytic sample. The AOT was included in mediation analyses to observe whether epistemic dispositions mediate conceptual change outcomes, as inferred from the Plausibility Judgments for Conceptual Change model (Lombardi et al., 2016).

Surprise. Participants in the main analytic sample who were assigned to estimate quantities about climate change by way of the EPIC intervention were also prompted to report their sense of surprise after being shown the true values. Namely, participants were asked to "Rate how surprised you are by this number" on a scale from 1 (*not at all*) to 7 (*extremely surprised*). Surprise ratings had Cronbach's alpha = .82. Similar to prior research (e.g., Munnich et al., 2007), I expected that participants' sense of surprise from exposure to novel statistics would correspond with change in climate change beliefs. Participants in the control group did not estimate climate change numbers and therefore were not prompted to report surprise.

Interventions and Experimental Conditions

Participants were randomly assigned to one of five conditions: (1) a control group in which participants were presented with an 817 word expository text about the greenhouse effect (2) the EPIC task; (3) the EPIC task accompanied with an estimation skills modification that presents learners with strategies for using the given "hints," (4) an EPIC task accompanied with an epistemic cognition modification, or (5) an EPIC task accompanied by both estimation and epistemic cognition modifications. These interventions and modifications are described below.

The EPIC task required learners to estimate 12 climate change-related quantities before being presented with the scientifically accepted answer. Six of these items were taken from Ranney & Clark (2016) and asked participants to estimate unitless proportions. The remaining six were created by Thacker (2020) to be more mathematically challenging, requiring participants to estimate raw units of length, area, volume, mass, and temperature and included a "hint" that might be rescaled to better estimate the unknown quantity (see Table 1 for sample items).

The estimation skills modification consisted of a 132-word text that provided direct instruction on how to use the "hints" embedded in half of the EPIC items to more accurately estimate unknown numbers followed by two interactive examples (see Table 1 for an excerpt). The epistemic cognition modification was intended to activate epistemic aims and consisted of an open answer text-box that appeared after each of the twelve number estimates, prompting participants to "...reflect on the differences between your estimate and the true value. How does the true value change what you know about climate change or the way you think about climate change? Explain." This prompt was intended to activate epistemic aims.

Table 1. Sample Items from the EPIC Intervention and Modifications to the Intervention.

Sample EPIC Items			
Source	# of items	Sample item	Correct Answer
Ranney & Clark (2016)	6	What is the change in percentage of the world's ocean ice cover since the 1960s? (units in %)	40% Decrease
Thacker (2020)	6	What was the average Arctic Sea ice thickness in 2008? *Hint: Arctic ice thickness was 3.64 meters in 1980*	1.89 meters
Excerpt from Numerical Estimation Strategies Modification			
Numbers that you already know can help you estimate numbers that you do not know. For example, if you know that about 300 pennies fit in a small, 8oz milk carton, you can use this information to estimate the number of pennies that fit in a larger container… When using benchmarks, you may want to round values to make mental computation easier. For example...			
Excerpt from Epistemic Cognition Instruction Modification			
...Please reflect on the differences between your estimate and the true value. How does the true value change what you know about climate change or the way you think about climate change? Explain.			

Results

Preliminary analyses revealed no significant differences in pre-intervention knowledge between conditions (F = 1.54, p = .187). Skew ranged from -.78 to -.34 and kurtosis ranged from .01 to .36 for the revised knowledge measure though both failed the Shapiro-Wilk normality test (p < .001 for both pre- and post-knowledge), as such, both classic and robust analyses are presented. An initial omnibus test revealed significant differences between the five conditions when the seven-item knowledge score at post-test was used as the main outcome (F = 3.126, p = .0147). This finding was corroborated with nonparametric ANOVA analyses using a Kruskal-Wallis rank sum test (Kruskal-Wallis Chi-squared = 17.18, df = 4, p = .001). Raw means and standard deviations by condition and overall for all variables are shown in Table 2.

Table 2. Descriptives by Condition for the Main Analytic Sample of N = 516 Undergraduate Students.

Control versus all other conditions (RQ1). To address my first research question, I used contrasts to assess the knowledge of the control group compared with the combined average of the remaining four groups. A Welch's two sample t-test revealed significant differences in mean post-intervention knowledge between control (M = 3.88) and EPIC conditions (M = 4.12, t = 3.23, p = .001, Cohen's d = .33), as did Yuen's method of trimmed means, bootstrapped T, and bootstrapped medians (all $p <$ .009). In other words, students assigned to the EPIC conditions performed about one third of a standard deviation better on the seven-item knowledge posttest when compared with the control.

Estimation intervention versus no estimation intervention (RQ2). To address my second research question, I first dropped the control from analysis to consider only the four EPIC conditions, and then used planned contrasts to compare those who were given estimation instruction with those who were not. A Welch's two sample t-test revealed a marginally significant and positive impact of the estimation intervention on post-intervention knowledge (b = .09, SE = .05, p = .086). After adjusting for prior knowledge, nonparametric ANCOVA methods using a Thiel-Sen estimator revealed significant differences in post-intervention knowledge scores for those at the upper third (*Difference* = .31, *95% CI* = 0.04-0.58) and fourth (*Difference* = .17, *95% CI* = 0.08-0.27) of five evenly spaced points along the range of prior knowledge, a range that includes 67% of the analytic sample. In other words, the estimation intervention appeared to be effective in shifting knowledge for participants on the upper end of the prior knowledge range[1].

Epistemic cognition intervention versus no epistemic cognition intervention (RQ3). To answer my third research question, I again used contrasts to compare those who were given epistemic cognition prompts with those who were not after dropping the control from analysis. Contrasts

[1] Pairwise comparisons using the Benjimani-Hochberg method revealed significant differences between post-intervention knowledge scores when comparing the control and unmodified EPIC intervention (p = .022, Cohen's d = .46) and when comparing the control and EPIC supplemented with estimation strategy instruction (p = .026, Cohen's d = .46).

revealed no significant differences on the revised knowledge scale at post-test, even after adjusting for prior knowledge.

Tests for interactions (RQ4). To answer my fourth research question, I tested for main effects and interactions of the two modifications to the EPIC intervention. I first ran classic two-way ANOVAs followed by robust two-way ANOVAs using Johansen's heteroscedastic method for trimmed means (see Wilcox, 2017, Chapter 10). Both sets of tests revealed no significant main effects or interactions when post-intervention knowledge was the outcome.

Mediating role of warm constructs (RQ5). To explore relations between prior knowledge, warm constructs, and post-intervention knowledge, I tested a hypothesized model inferred from Lombardi and his colleagues (2016; presented in Figure 1a.) using maximum likelihood estimation with robust (Huber-White) standard errors and a scaled Yuan-Bentler test statistic in R using Lavaan 0.6-3 (Rosseel, 2012). The model resulted in acceptable fit at conventional levels (CFI = .99, TLI = .93, $RMSEA$ = .077; Hu & Bentler, 1999).

As expected, results revealed that warm constructs mediated relationships between prior- and post-intervention learning outcomes (see Figure 1b for all coefficients). Notably, I found indirect effects of prior knowledge on post-test knowledge through active open-minded thinking (*indirect effect* = .059, $p < .01$).

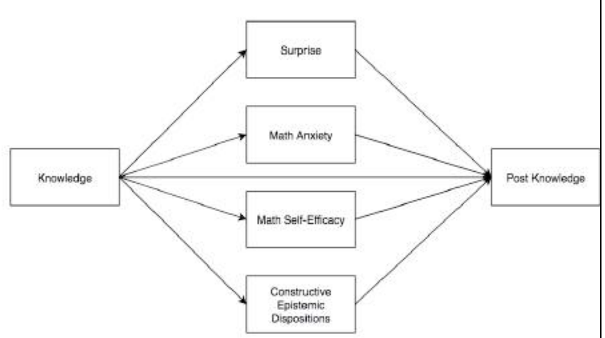

Figure 1a. Hypothesized model to address RQ5. Intercorrelations between warm constructs (surprise, mathematics anxiety, mathematics self-efficacy, and constructive epistemic dispositions) are included in the model but not shown in this figure.

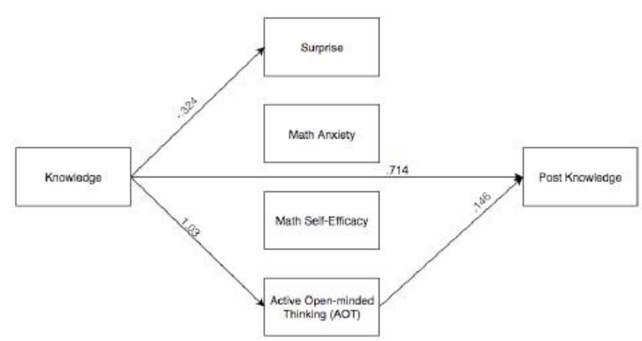

Figure 1b. Full path model. Only significant paths at the .05 level are shown. Intercorrelations between warm constructs were included in the model but not shown in this figure. Standard errors range between .010 and .132.

Significance

I sought to investigate whether the learning that occurs when people encounter novel statistics was enhanced with additional instruction on estimation strategies or prompts to activate epistemic aims. I found that students who learned from novel statistics performed about a third of a standard deviation better than a control group on a post-test of climate change knowledge, which is consistent with prior findings demonstrating the effectiveness of EPIC for climate change learning (e.g., Ranney & Clark, 2016; Ranney et al., 2019).

I also found that enhancing this intervention with numerical estimation instruction had a small but positive impact on students' science learning; an effect that was concentrated among students in the upper range of the prior knowledge distribution. These findings provide emerging evidence that numerical estimation skills can be leveraged for improved scientific learning. Future research support students' numerical estimation skills as applied to additional policy-relevant topics.

Findings also revealed that prompts to activate epistemic aims had no detectable effect on undergraduate students learning. To date, efforts to design micro-interventions intended to shift epistemic dispositions are only emerging. Only longer interventions spanning the duration of several weeks have yielded impacts on patterns of epistemic thinking (e.g., Lombardi et al., 2013; Chinn & Buckland, 2012). More research is needed to explore whether such an intervention is possible. Related to this, I found no significant interactions between intervention conditions, likely due to the very small and insignificant effects of the epistemic cognition intervention. With improved intervention design, future research might explore whether such an interaction might exist.

Though the brief online intervention created for this study was not found to *shift* learners' epistemic dispositions, learners' *baseline* epistemic dispositions were shown to be important mediators of conceptual change processes. Namely, a path model revealed that epistemic, motivational, and affective constructs were important predictors of conceptual change outcomes, as predicted by the Plausibility Judgments for Conceptual Change model (Lombardi et al., 2016), and that epistemic dispositions significantly mediated relationships between pre-intervention knowledge and post-intervention knowledge.

Conclusions

Findings from this study contribute to better understanding the extent to which individuals shift their conceptions about climate change based on just a handful of novel statistics and illuminate mechanisms that underlie such conceptual changes. Evidence that epistemic cognition, estimation skills, motivational, and emotional factors play a role in conceptual change provide empirical support for the Plausibility Judgments for Conceptual Change model (Lombardi et al., 2016). Findings also provide emerging evidence that mathematical knowledge can be leveraged for conceptual change regarding scientific topics. By creating and testing instructional interventions, this study also provides both mathematics and science instructors and those concerned with public understanding of science with a collection of strategies for better preparing people with skills to navigate the minefield of deceptive statistics found in today's online news landscape.

UTILIZING MATHEMATICS TO EXAMINE SEA LEVEL RISE AS AN ENVIRONMENTAL AND A SOCIAL ISSUE

Debasmita Basu
The New School

Nicole Panorkou
Montclair State University
panorkoun@montclair.edu

The phenomenon of the sea level rise is a pressing environmental and social issue of the present age. Starting with the assumption that mathematics can be utilized to help students explore this phenomenon, we designed a simulation in NetLogo, in which students investigated the relationships between the quantities of temperature rise, height of future sea level, and total land area. In this paper, we present the analysis of a whole-class design experiment in a sixth-grade classroom and discuss how our design helped students to examine sea level rise as both an environmental and a social issue.

Keywords: Social Justice, Interdisciplinary Studies, Technology, Mathematics for Sustainability

In 2001, The Intergovernmental Panel on Climate Change (IPCC) projected that the global sea level would rise up to .88 meters by 2100, which was only .09 meters in 1900 (Raleigh, Jordan, & Salehyan, 2008). Sea level rise would not only cause inundation and displacement of wetlands and lowlands, coastal erosion, and flooding (Nicholls & Mimura, 1998), it would also bear a severe impact on people residing in low-lying coastal areas (Rowley, Kostelnick, Braaten, Li, & Meisel, 2007) as these would be the first people to experience flooding. Further, damage of properties, loss of lives, and injuries caused due to increased sea level would disproportionately impact the poorer section of the society, who, despite being the least contributor to sea level rise, would be most vulnerable to its impact (Dodman & Satterthwaite, 2008). Lack of preparedness and financial limitation would make poor people more susceptible to the effects of sea level rise (Walker & Burningham, 2011). Hence, like any other climatic issue, sea level rise also qualifies as an issue of social injustice.

Climate Issues and School Curriculum

Research shows that the introduction of climatic issues in the school curriculum would help students as the future citizens to develop an awareness about and cultivate sensitivity towards the climate (Shepardson, Niyogi, Choi, & Charusombat, 2009). Mathematics education inarguably plays a significant role in the process. Mathematics literacy is not only necessary to identify the different traits that indicate climatic disruptions, but it also helps students to predict the future impacts of climate change (Barwell, 2013). Although school mathematics has traditionally modified itself and accommodated issues that marked the needs of the time, climatic phenomena have seldom been incorporated in mathematics textbooks or tasks (Renert, 2011). When Abtahi et. al. (2017) investigated Norwegian and Canadian mathematics teachers' opinion regarding inclusion of climatic issues in mathematics classroom, they found that even though the teachers acknowledge their moral obligation towards educating students about climate, they indicate that the complexity of climatic issues, the lack of students' mathematical and technical knowledge, and the lack of resources and time are some of the roadblocks towards implementation of climatic issues in mathematics classrooms. The study reported in this paper aimed to address those challenges by designing an interactive simulation and accompanying tasks and questioning that would help students explore the causes and consequences of sea level rise in a way that would make this complex phenomenon accessible to sixth grade students. Specifically, we report on how we assisted students to reason

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

covariationally about the quantities involved and how this reasoning helped students understand how their own city can be affected by the sea level rise.

Design and Methods

Most of the information about sea level rise in the news and public media is in the form of data and graphs. To support students' interpretation of data and graphs, this study focused on students' covariational reasoning about the quantities underlying the phenomenon. Covariational reasoning involves coordinating two quantities as the values of those quantities change (Confrey & Smith, 1994). A student reasons covariationally when she envisions two quantities varying simultaneously (Thompson & Carlson, 2017). For instance, as air temperature increases, the height of sea level also increases. To support students' understanding of the sea level rise, we designed an interactive simulation and a set of integrated activities that asked students to reason about the relationships of the quantities.

We designed the Sea Level Rise simulation using NetLogo (Wilensky, 1999), a multi-agent programmable modeling environment. We hoped that the dynamic environment of NetLogo, together with its animated outputs and result plots, would provide students with a self-exploratory space to change and reverse change the values of different quantities, which is not always practical with physical manipulations. Four cities familiar to the students were selected and arranged vertically according to their elevations from the sea level (Figure 1). The user can drag the temperature rise slider to the left and right, manipulate its value, and observe the impact of the change on the height of sea level and total land area. The simulation was accompanied by a set of activities and discussion questions that we hoped would prompt students to reason about different covarying quantities and identify the environmental and social aspects of sea level rise. For example, questions such as "What would happen to Manhattan if height of future sea level doubles?" not only required students to focus on the covariational relationship between height of future sea level and elevation of Manhattan, but also to identify the consequences of sea level rise on lives of people living at lower elevation, such as Manhattan.

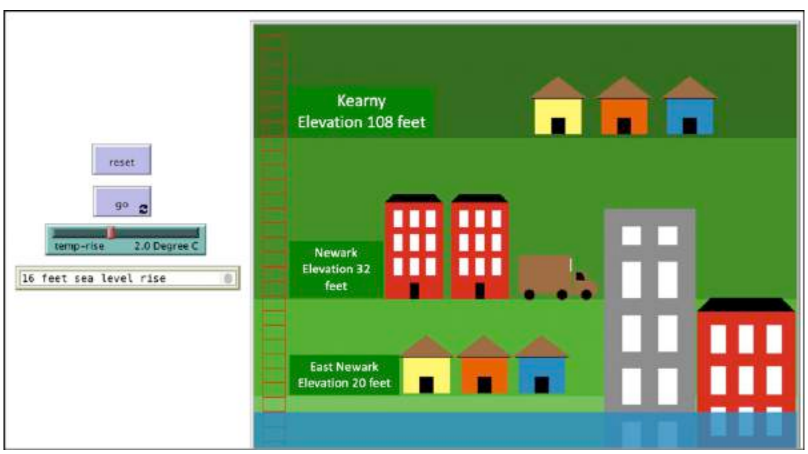

Figure 1: Sea level rise simulation

Our goal was to explore the ways that our design, which included engineering learning opportunities for students to reason covariationally, helped students to reason about sea level rise as an environmental and a social issue. More specifically, we examined the research question: *How did our design help students develop an understanding of sea level rise as an environmental and a social issue?*

This study took place in a public elementary school located in the North-Eastern part of the United States. We conducted a week-long design experiment (Cobb et. al., 2003) in a sixth-grade classroom containing 17 students. The teacher conducted the whole-class instruction and a research team member interacted with a small group of students. All the sessions were video recorded, transcribed, and coded using the software program Quirkos. In this paper, we focus on our interaction with a student named Ani to illustrate how our design helped students explore the phenomenon as an environmental and a social issue.

Findings

The Sea Level Rise simulation provided the students with a dynamic environment to drag the temperature rise slider and observe its impact on the height of sea level (Figure 2). For instance, when Ani was asked "What happens if I lower the temperature?," he dragged the temperature rise slider to the left and said, "the lower the height of sea level."

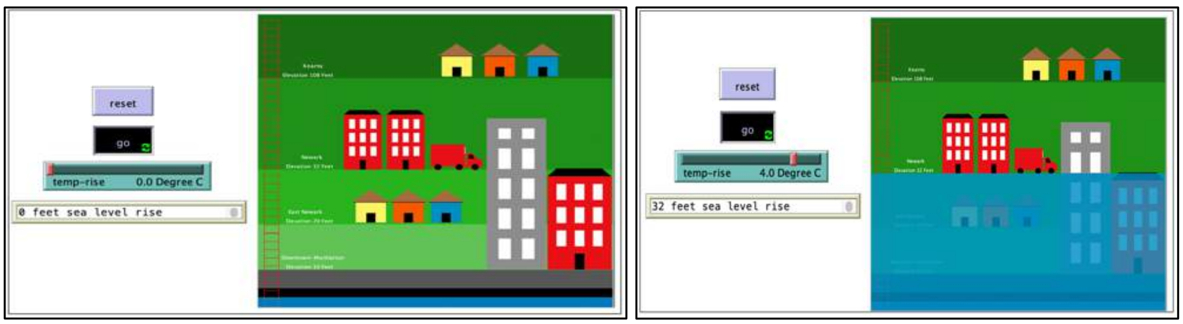

Figure 2: Temperature rise increases, height of sea level increases, total land area decreases

To prompt the students to reason numerically between the two covarying quantities, we asked them to graph the relationship between temperature rise and the height of future sea level. Students used the simulation to find the height of future sea level for different values of temperature rise and plotted the ordered pairs on a graph. When Ani was asked to explain the graph, he stated that the graph was "rising like super straight line" because "when temperature rises 0.5, it rises by 4 feet every time." From his response it seems that Ani attributed the "straight" shape of the graph to the constant increase of height of future sea level for a uniform change of temperature rise.

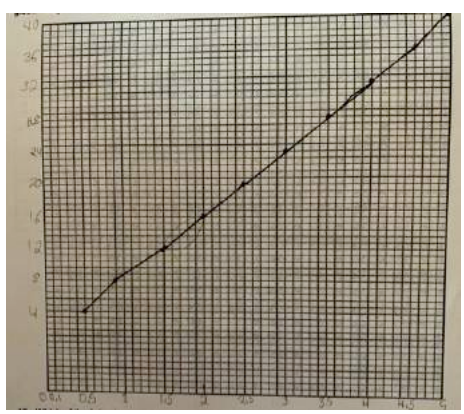

Figure 3: Ani's graph showing the relationship between global temperature (horizontal axis?) and height of future sea level (vertical axis)

To help students identify the consequences of sea level rise in their own lives, we encouraged them to think about the impact of sea level rise on total land area. When we asked Ani to state what would happen to the total land area if the sea level rises, he responded, "the less land, the total land area is going to be less." He further justified, "because the more higher the sea level is, it takes over land. So, instead of land over water, it will be under water." Through his reasoning, Ani identified the direction of change between the height of sea level and total land area. The graphics of the simulation (Figure 2) were powerful in helping Ani coordinate the direction of change of the two quantities. We further prompted Ani to think and explain why an increasing temperature results in a rise of sea level and a reduction of land area. Ani thought briefly and said, "The higher the global temperature, the higher the sea level. Rising the global temperature, the ice caps in the Antarctica will melt which makes more water to go into the water and sea level rises, which means less land area." Ani not only explicitly described the relationship between the three quantities but also identified melting ice caps in Antarctica as a consequence of increased temperature and a cause of the rising sea level.

In the Sea Level Rise simulation, the inclusion of the names of places familiar to the students helped them identify the consequences of sea level rise in connection to their own lives. Students were relieved to find themselves located at a higher sea level, compared to their neighboring towns of Newark and Manhattan. They identified that if sea level rises, then that will "cause places like…low elevation like Newark go under water." Students also expressed their anxiety about the lack of economic affluence of people to endure the impact of displacement caused by flooding. For example, during the small group conversation when we asked the students, "What is going to happen to our home (if sea level rises)?", Ani replied, "It is gonna be destroyed, and we cannot rebuild it." Further, he added that the situation would be different for rich people, since their homes would also be "Destroyed, but they can rebuild it." Ani resonated the argument of Dodman and Satterthwaite (2008) that climatic threats, such as sea level rise and flooding are issues of social injustice since they bear down a disproportionate impact on the people belonging to different socio-economic strata. The students' articulations "they can rebuild it" and "we cannot rebuild it" indicate that students recognized how low socioeconomic conditions of certain people limit their access to resources and opportunities to fight the impact of climatic disruption.

Conclusion

Consistent with Barwell's (2013) assertion, this study illustrates that students' mathematical reasoning provided them a platform to engage in a meaningful discussion around sea level rise. Students not only reasoned covariationally between rising air temperature, height of future sea level, and total land area, and examined the environmental aspect of sea level rise, they also explored the social aspect of the climatic phenomena. Students identified that economic disparity makes poor people more vulnerable to the risk associated with sea level rise (Dodman & Satterthwaite, 2008), while wealthy people possess both resources and financial stability to escape its impact. So, through this study we convey that incorporating climatic issues in mathematics classroom is complex, but it is high time that mathematics educators and researchers acknowledge their roles and responsibilities in empowering students mathematically and helping future citizens to become more sensitive towards the climate.

In a world that is in increasing demand for creativity, mathematics courses and programs need to shift from more routine and computational to more creative and problem-solving focused. We present preliminary results of a qualitative research study in which we examined students' perceptions of mathematical creativity in an introduction-to-proofs course. We conducted interviews with students as well as collected their reflection assignments at the end of the semester. Using a definition of creativity from a relativistic perspective, we analyzed interview data to describe how students' perspectives of mathematical creativity evolved throughout the semester and the sources of those shifts. Students shifted from previously not seeing themselves, others, or mathematics as creative, to believing they are creative. The sources found in the data are related to content and course design.

Keywords: University Mathematics, Creativity, Affect, Emotion, Beliefs, and Attitudes

Introduction

Curriculum-standard documents, both in the United States and internationally, mention creativity as an important skill when learning mathematics (Askew, 2013). Additionally, creativity has become one of the most sought-after skills for academia and industry employers (World Economic Forum, 2016). While the mathematical creativity literature at the K-12 level is well-developed, there remain few studies at the undergraduate level and fewer still that investigate students' beliefs about creativity and its role in mathematics. In this qualitative study, we explored students' perceptions of mathematical creativity and how they evolved over the semester of an introduction-to-proofs course. Furthermore, we examine the sources of these shifts as evidenced by the students' own words.

Theoretical Perspective

As with many of our research projects on mathematical creativity (Tang et al., 2015; Savic, Karakok, Tang, El Turkey, & Naccarato, 2017), this study uses a *developmental* perspective of creativity (Kozbelt, Beghetto & Runco, 2010). This theoretical lens contends that creativity develops over time and emphasizes the role of the environment in the development of creativity. Such an environment should provide students authentic mathematical tasks and opportunities to interact with others (Sriraman, 2005).

We operationalize mathematical creativity as "a process of offering new solutions or insights that are unexpected for the student, with respect to their mathematical background or the problems [they've] seen before" (Savić et al., 2017; p.1419). This definition focuses on the *process* (Pelczer & Rodriguez, 2011) of creation, rather than the *product* that is created at the end of a process (Runco & Jaeger, 2012).

Background Literature

Moore-Russo and Demler (2018) examined the perceptions of U.S. faculty and staff participants from gifted mathematics programs and found that, through counts of coding using several creativity frameworks, mathematical creativity in education was more of a process than "a subjective experience" (p.23). This particular orientation allows us to keep a dynamic view rather than a static one to capture nuances in the individual's thinking. Furthermore, our definition takes a *relativistic* perspective—creativity relative to the student—in contrast to absolute creativity for the field of mathematics (Leikin, 2009). For example, Levenson (2013), using a similar viewpoint, focused on the discussion of ideas put forth by individual students and how these ideas helped in developing a product of collective mathematical creativity in fifth- and sixth-grade mathematics classrooms. Levenson also emphasized the teachers' roles in facilitating these discussions.

While there is literature on mathematicians' and mathematics instructors' perceptions on mathematical creativity (Borwein, Liljedahl & Zhai, 2014; Sriraman, 2009), research on students' perceptions on mathematical creativity as well as classrooms that impact these perceptions has received less attention. In one of our earlier studies, we examined university students' and mathematicians' definitions of mathematical creativity using three process categories: taking risks, making connections, and creating ideas (Tang, El Turkey, Savić, & Karakok, 2015). We found that students rarely associated making connections using different mathematical content with creativity compared to mathematicians (9% of students' responses compared to 38% of mathematicians' responses). This study alerted us to think about explicitly valuing and discussing the processes that are deemed to be important in developing mathematical creativity (El Turkey et al., 2018). In this paper, we explore the following research question: In what ways do students' views on creativity evolve in an introduction-to-proofs course which explicitly valued mathematical creativity?

Methods

Data were collected in an introduction-to-proofs course at a small liberal arts college in the Southwestern United States. This course was taught using an inquiry-based learning (IBL) pedagogy (Laursen et al., 2014), where students often worked on proofs in small groups and gave presentations to the class on proofs constructed both in class and for homework. The instructor explicitly valued creativity by making use of the Creativity-in-Progress Rubric (CPR) on Proving (Savić et al., 2017; El Turkey et al., 2018), a formative assessment tool developed by the authors that students can use to persevere in proving and encourage creative processes. The rubric has two main categories: making connections and taking risks (see Author, 2017 for a more detailed discussion of the CPR on Proving). The instructor gave assignments and exam questions where students had to use the rubric to assess their own or other's work.

At the end of the semester, 4 female and 3 male students agreed to be interviewed and participated in 60 to 90-minute semi-structured interviews. During the interview, students were asked to describe the course, discuss their views on creativity, and discuss the use of the CPR in the course. As part of a larger study, interviews were coded using hypothesis coding (Saldaña, 2013) with five categories, one of which being creativity. This is the coding category we focus on for this report. Three of the seven participants' transcripts were coded separately by the first and second author with 97% agreement. Because of this high degree of inter-rater reliability, the remaining transcripts were coded by only the first author.

Results

From three of the students interviewed (all of whom identified as female), an explicit shift in the way they thought about creativity or how they viewed themselves as creative people was reported. The students that reported an evolution in perspective on creativity were able to ascribe this to one of two sources: mathematical content and course design. In what follows, we show a sampling of student quotes where they indicate a shift in perspective and ascribe a reason to this change.

For instance, Stephanie (all names reported are self-chosen pseudonyms) spoke about content with respect to *learning new tools* to work with. That is, she feels that having a larger mathematical toolbox allows one to be more creative when proving or problem solving.

> I think I started to look at creativity a little bit different through this course...Prior to this it's been all very applied mathematics...So before, just using the trig equations to solve geometry was creative for me. Whereas now, this has just opened up a whole new door of opportunities for it because I can solve a proof using a contradiction, while somebody else used a contrapositive and somebody else used a direct proof and somebody else used induction, and we all do it completely different.

Whereas, Olivia attributed her shift to the social structure of the course. As the course included collaboration and presentation, Olivia reported that the environment was conducive for growth and students were able to see each other's creativity and began to feel more creative as the semester progressed.

> We kind of all went in with kind of not really feeling confident in our abilities to be creative, so it was really interesting to see students that were quiet, reserved early on like show their work later in the semester and they had done something like totally cool and amazing...So, I feel you know their ability, like their confidence levels went up and I could say that's true of me as well. So, I wanna say that it's, you know it wasn't that like all the creative people took this course because I didn't consider myself creative and I took the course, and I would say that that's probably true of other students as well.

In a later part of her interview, Stephanie echoed Olivia's comment almost exactly with her assessment of the course culture and its contribution to everyone's creativity.

> At the beginning of the semester, I think a lot of people in that class were very shy and quiet, and so it was kind of hard to judge where their creativity was because they weren't sharing it as much. Um, by the end of the course you had everybody speaking, you had everybody giving their opinions and how to work on things together, and you saw everyone grow. You saw everyone coming up with their own tools and tricks. And everyone was posing questions, not just the few of us that were outspoken to begin with. So, you definitely saw growth in the class, um not only with the shyness but with the creativity and coming up with their own ideas to change things and make them better.

The IBL practices of the course required students to present their work to each other. The instructor also especially encouraged multiple presentations on the same problem if different students approached the problem using different methods. Two of the interviewees spoke directly to this aspect of the course design as contributing to their own creativity. That is, this shift seems to be a result of *seeing others' work as creative and reflecting it back on themselves*. For instance, Peyton said:

> I really, I really did not feel like I was being creative at all throughout the course. It really was just things in my head, it makes sense that led to a conclusion that made sense. But, considering that I thought other people were exceptionally creative, I kind of thought that maybe they though that about me too.

In fact, Peyton had perhaps the starkest change in her beliefs on mathematical creativity and in seeing herself as a creative person. The following excerpt shows that Peyton started the semester believing that mathematics was not a creative subject and ended with a completely opposite viewpoint.

Interviewer: And in your reflections you said…'I think I am on the spectrum that generally believes that, believes there is no need for creativity in mathematics. That's been a key reason why I enjoy math. I know, I know if I get the answer then I have done it correct. There is a set process and if I learn the process then…I'll be successful'. So, do you wanna comment on that part?

Peyton: I…should have made that more in the past tense, because I believed that prior to taking this course…There has been, you can figure out problems and it's creative in the sense that you can figure out how, where you wanna start with the problem. But I like being able to know that if I am doing it correctly, the process correctly, then I will get to the answer… I enjoy knowing when I'm gonna do something correctly as opposed to just spending a lot of time and then not even knowing if it's gonna yield good results. But this course changed that quite a bit, because there really was no assurance that anything would be correct, but it still… required me to use different thought processes to get to a result hoping for the best, which was stressful to say the least, but still, it was fun.

Discussion

These three females explicitly acknowledged that their previous perceptions of not seeing themselves, others or mathematics as creative shifted to thinking they or mathematics are creative. We found two main sources of these shifts a) *content* - having more mathematical tools to work with, b) *course design* - developing a mathematical community that allows students to see each other's creative work with opportunities to reflect and connect back to their own work. Thus, for these students, content and course design seem to be important sources in shifting students' perceptions of themselves, others, or mathematics as creative.

Furthermore, although Stephanie does not explicitly mention the CPR on Proving, she mentions two of the subcategories "Tools and Tricks" and "Posing Questions". By using the CPR on Proving, it is evident that this particular instructor's course design and teacher actions aimed to explicitly value and foster students' mathematical creativity. This facilitated the evolution of students' perspectives on mathematical creativity. The connection between course design, teachers' actions, and changing students' perspectives on mathematical creativity requires additional exploration and our future work aims to examine this connection in detail and catalog specific *creativity-fostering teacher actions*. In particular, we wish to determine not only which teacher actions are more fruitful to afford such changes, but also what other course design features can contribute to shifts in student appreciation of mathematical creativity and fostering of creative behavior in the classroom.

LEARNING TO POSE PROBLEMS WITHIN DYNAMIC GEOMETRY ENVIRONMENTS: A SELF STUDY INVOLVING VARIGNON'S PROBLEM

José N. Contreras
Ball State University
jncontrerasf@bsu.edu

This paper reports my second experience on my trajectory to learn how to pose mathematical problems within Dynamic Geometry Environments. I used The Geometer's Sketchpad and mathematical reasoning as tools to verify the plausibility and reasonability of each new problem situation. Using a problem-posing framework that I had developed during my first problem-posing experience within dynamic geometry environments, and subsequently refined and enriched with subsequent tasks, I was able to generate a diversity of problems by modifying the attributes of Varignon's problem. Among the problems generated were special problems, general problems, extended problems, further extended problems, converse problems, and proof problems. Examples of each of these types of problems are provided.

Keywords: Problem posing, problem solving, teacher educators, technology

Engaging in problem-posing tasks is recognized by mathematicians (e.g., Halmos, 1980; Polya, 1945/1973), mathematics educators (Brown & Walter, 1983, 1993; Kilpatrick, 1987; Silver, 1994, 2013), and professional organizations (Australian Education Council, 1991; National Council of Teacher of Mathematics [NCTM], 1989, 1991, 2000) as a worthwhile mathematical activity. According to Halmos (1980), the heart, the essence, of mathematics consists of problems. NCTM (1991), on the other hand, calls for all students to "be given opportunities to formulate problems from given situations and create new problems by modifying the conditions of a given problem" (p. 95).

Purpose of the Study

Problem posing continues to receive increased attention from curricular, pedagogical, and research perspectives as attested by the recent publications of two books: *Mathematical problem posing: From research to effective practice* (Singer, Ellerton, & Cai, 2015) and *Posing and solving mathematical problems: Advances and new perspectives* (Felmer, Pehkonen, & Kilpatrick (2016). Initially, most research focused on understanding and documenting students' abilities to pose mathematical problems (Ellerton, 1986a, 1986b, 1988; English, 1996, 1997, 1998, 2003; Silver & Cai, 1996). If teachers and prospective teachers are to engage their students in problem-posing activities, it is important that they have experiences in problem generation. To help students to enhance their problem-posing abilities, research also examined teachers' approaches to pose mathematical problems (Author, 1998; Crespo, 2003; Ellerton, 2013; Engström & Lingefjärd, 2007; Lavy & Shriki, 2010; Silver et al. 1996). However, as noticed by Beswick and Goos (2018) and Castro Superfine and Li (2014), mathematics teacher educator knowledge has received limited attention.

While numerous studies on problem posing have investigated both students and teachers' abilities to pose problems, little research has been done on mathematics teachers educators' abilities to pose mathematical problems. I extend this research on problem posing by focusing on myself as teacher educator, a teacher of teachers. As noted by Suazo-Flores et al. (2019), qualitative methodologies such as narrative inquiry, self-study, and autoethnography have increasingly becoming modes of inquiry in mathematics teacher education research.

The purpose of this paper is to describe the types of problem that I have generated by modifying the conditions of Varignon's problem. To understand how I came to pose the problems, I present a brief story of my experiences with a problem-posing framework and how it enhanced my abilities to pose mathematics problems with the support of The Geometer's Sketchpad (GSP).

Perspectives on Mathematical Problem Posing

Problem posing tasks involve both the generation of new problems aimed at exploring and examining a given situation, as well as the reformulation of given problems (Silver, 1994). As noted by Silver (1994), problem posing can occur before, during, and after solving a given problem.

When we are trying to solve a challenging problem, a strategy is to reformulate the problem into an equivalent problem to make it more accessible. For example, we could reformulate a geometric problem in terms of algebra. A second way to reformulate a problem is to "think of a related, more accessible problem" (Polya, 1945/1973).

Problem posing can also occur before and after problem solving. It can occur before problem solving when the goal of the task is not to solve a mathematical problem, but to simply create new mathematical problems. It can occur after solving a problem as we examine the problem and pose follow-up questions or problems, a stage in the problem-solving process coined "looking back" by Polya. Brown and Walter (1983, 1993, 2004) have reported extensively about this type of problem posing by applying what they call the "What-if?" and "What-if-not" strategies in which problem conditions and constrains are changed.

While solving problem is recognized almost universally as an important mathematical, curricular, and pedagogical activity, problem posing is not, as evidenced by research examining opportunities to pose problems afforded by textbooks (Cai & Jiang, 2016; Cai, Jiang, Hwang, Nie, & Hu, 2016).

Methods of Inquiry

As stated by Pinnegar (1998), self-study is a "methodology for studying professional practice settings" (p. 33). LaBoskey (2004) adds that 'the aim for teacher educators engaged in self-study is to better understand, facilitate, and articulate the teaching-learning process" (p. 857). To illuminate the process of learning to pose mathematical problems, I decided to conduct a self-study research of how I came to learn to pose mathematical problems within dynamic geometry environments.

My Background

I was a high school mathematics teacher for 7 years at a state University in Mexico. After completing a bachelor's degree in Mathematics with a minor in mathematics teaching, I came to the USA and completed a Master's degree and a Ph. D degree in mathematics education. I have about 24 years of teaching experience at the University level. Currently, I teach content and methods courses at the undergraduate and graduate levels, mostly for prospective and practicing teachers.

First encounter with the concept of mathematical problem as the essence of mathematics. As undergraduate, I did not realize the importance of problems for mathematics. I conceived mathematics mainly as a well-integrated body of knowledge involving concepts and procedures connected through theorems whose proofs revealed explicitly the connections. As part of an assignment in one on my methods courses, I read Halmos's (1980) article *The Heart of Mathematics* where he argues that "the heart of mathematics consists of problems". Halmos concludes his article with a call to all instructors that they should "train our students to be better problem-posers" (p. 524). However, I did not interiorize nor appreciate the importance of the idea of learning how to pose problems.

First explicit encounter with the concept of posing problems. As a graduate student, I was one day perusing some books at the library when I encountered by chance Brown & Walter's (1983) *The art of problem posing*. The title of the book intrigued and intimidated me. It intrigued me because it seemed like a book from which I could learn how to pose problems. It intimidated me because learning how to pose problems seemed more like an art, and I did not see myself as a creative person. I left the book where it was and I did not think for a longtime of learning how to enhance my abilities to pose mathematical problems.

First experience on posing problems within dynamic geometric environments. The first problem-posing experience within dynamic geometry environments that I had was with the following problem: Prove that the angle bisectors of the angles of a parallelogram form a rectangle (Landaverde, 1970, p. 85). As a result of this experience and other experiences posing problems without the use of technology, I developed the problem-posing framework displayed in Figure 1 (Contreras & Martínez-Cruz, 2003). Notice that the base problem is the initial given problem whose attributes are to be modified to pose new related problems.

The base problem. I used as base problem the well-known Varignon problem. Typically, the Varignon problem is stated as a theorem (The midpoints of a quadrilateral are the vertices of a parallelogram). I consider this theorem as a mathematical situation within an implicit problem that we can reformulate as a proof problem or as a more open-ended problem. My version of Varignon' problem is as follows: Let E, F, G, and H be the midpoints of the consecutive sides of a parallelogram ABCD. What type of quadrilateral is EFGH?

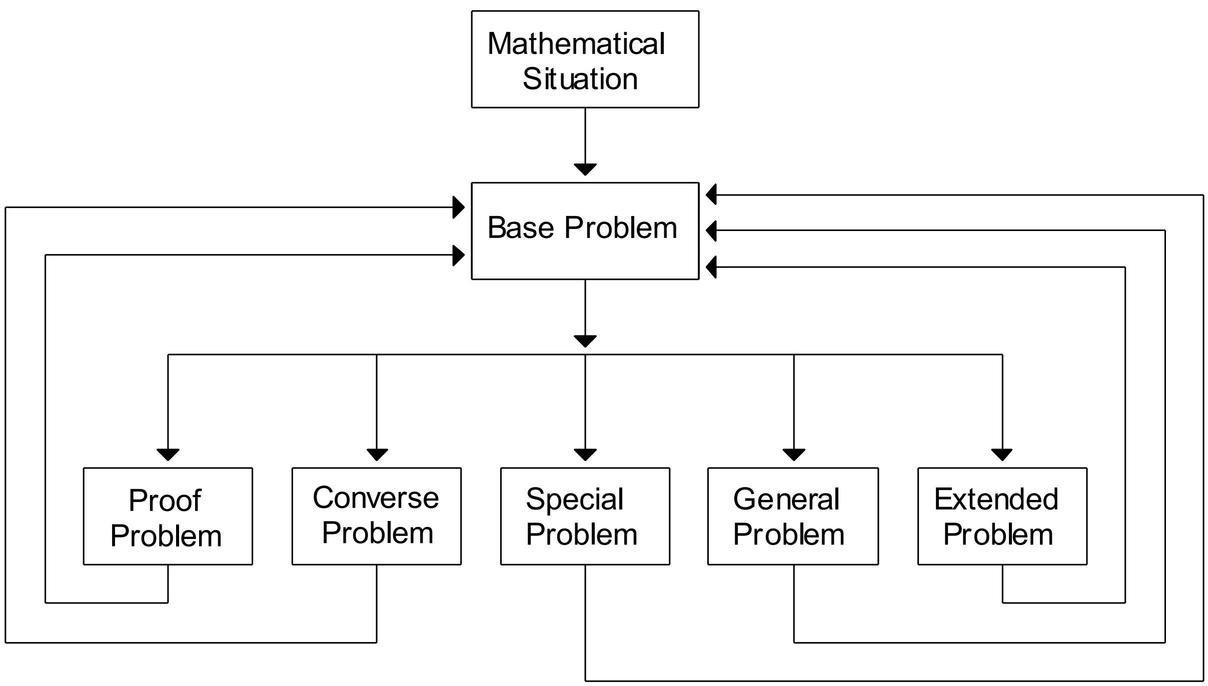

Figure 1: A Problem-Posing Framework

Analysis and Results

Using the problem-posing framework, I posed a diversity of problems that after analysis I classified as special problems, converse problems, extended problems, prove problems, and further extended problems. Typical problems of each of these types are displayed in Table 1.

Table 1: Examples of problems generated using the problem-posing framework

Type of problem	Problem
Special and proof problem	If E, F, G, and H are the midpoints of the consecutive sides of a rhombus ABCD, prove that EFGH is a rectangle.

Converse problem of a special problem	E, F, G, and H are the midpoints of the consecutive sides of a quadrilateral ABCD. If EFGH is a rectangle, what type of quadrilateral is ABCD?
Converse problem of a general problem	If E, F, G, and H are the midpoints of the consecutive sides of a quadrilateral ABCD. If EFGH is a parallelogram, what sort of quadrilateral is EFGH?
Extended problem	ABC is a triangle. Characterize quadrilateral BDEF where D, E, and F are the midpoints of the sides BC, CA, and AB, respectively. (Extended problem to a triangle, which is a degenerate case of a quadrilateral)
Extended and proof problem	Prove that the medial quadrilateral of a kite is a rectangle.
Further extended and proof problem	Prove that the points of intersection of the angle bisectors of the consecutive interior angles of a parallelogram ABCD are the vertices of a rectangle.
Further extended problem	I, J, K, and L are the points of intersection of the sides of a parallelogram ABCD with the interior angle bisectors. What sort of quadrilateral is IJKL?

Conclusion

Researchers (e.g., Crespo, 2003; Crespo & Sinclair, 2008; Nicol, 1999; Silver at al., 1996) report that students, teachers, and prospective teachers typically generate problems that are "predictable, undemanding, ill-formulated, and unsolvable" (Crespo & Sinclair, 2008). While there is some degree of predictability on the types of problems suggested by the problem-posing framework, I used a diversity of language to make them more interesting. I believe that I created a diversity of well-posed problems, each of which is a good and interesting problem because each one opens the mathematics involved or required by the problem (Crespo & Sinclair, 2008). In addition, I used mathematical reasoning and conceptual understanding to generate each problem. The plausibility of each problem was supported with GSP, but I went beyond exploring each problem with GSP and I provide a mathematical solution. In summary, I was actively engaged in the authentic process of doing mathematics. I have made public my second experience in posing mathematical problems within dynamic geometry environments to challenge other mathematics educators to test the problem-posing framework in other appropriate mathematical contexts.

A LARGE-SCALE STUDY ON TEACHER NOTICING

Yasemin Copur-Gencturk
University of Southern California
copurgen@usc.edu

Jessica Rodrigues
University of Missouri
rodriguesjm@missouri.edu

Teachers' noticing of key aspects of instruction is an important skill for learning from and improving their teaching because noticing enables the opportunity for change. We investigated what teachers notice in short video clips of a real classroom teacher's interaction with students around a mathematics problem by conducting the largest survey study on teacher noticing to date. According to our analysis of data collected from 496 fourth- and fifth-grade teachers from 48 states, the key issues that were vital to improving teaching and students' learning caught the attention of only 13.7% of teachers. However, 67.5% of the teachers focused on interpreting issues around content-specific teaching and learning, and 17.7% paid attention to general issues, such as the classroom climate.

Keywords: Mathematical Knowledge for Teaching, Teacher Knowledge

Teacher noticing, or the act of observing and interpreting classroom events (e.g., Sherin & van Es 2009), influences the likelihood for desirable teacher actions such as responding to student mistakes and making a variety of other pedagogical choices. Yet, the act of noticing classroom events that are pedagogically relevant for improving teaching and advancing students' thinking is not a simple skill. During any second of classroom instruction, teachers are inundated with numerous inputs (e.g., each individual student's attention, students' reaction to given tasks, or the impact of his/her choice of sequencing of activities on students' thinking), requiring teachers to be selective in their noticing. Research demonstrates that teachers' noticing of classroom events is widespread; aspects of the classroom that capture teachers' attention include classroom climate, students' math thinking, and the organization of the classroom (e.g., Sherin & van Es, 2009). Furthermore, when teachers attend to one particular classroom occurrence, they are consciously or unconsciously missing other events occurring in the classroom. Effective teaching thus relies in part on noticing and attending to the most pedagogically relevant aspects of the class and filtering out other aspects (Sherin, Russ, & Colestock, 2011).

Researchers acknowledge the importance of noticing for teaching expertise and have conducted explorations of teacher noticing skills that made significant contributions to the field. Yet studies on teacher noticing to date also have certain limitations, namely that they are conducted with limited numbers of teachers, with teachers who were attending a professional development program targeting their noticing skills, or with teachers from only certain school districts (e.g., Jacobs, Lamb, & Phillip, 2010; van Es, 2011). Our current understanding of mathematics teacher noticing is thus informed in large part by research settings that involved prompts and facilitators guiding teachers to attend to certain aspects of classroom events and samples that limit generalizability. We argue that an analysis investigating what teachers across the United States notice independent of a professional development setting or teacher education program seeking to improve their noticing skills is needed to better understand the overall trend in teachers' noticing skills. This analysis will advance not only our general understanding of teachers' noticing, but also our preparedness to help teachers improve their noticing skills to develop more effective teaching.

Objectives

The present study is the first large-scale analysis of mathematics teachers' noticing. Fourth- and fifth-grade teachers (N = 496) watched four short videos of classroom mathematics instruction that targeted fraction concepts. The instruction was aligned with the upper elementary mathematics standards (National Governors Association and Council of Chief School Officers, 2010). We consider certain types of noticing to be more beneficial for teachers to make changes to their content-specific pedagogical practices. As such, we intentionally selected videos that showed instructionally problematic teaching moments and/or students' confusion around the targeted mathematical content. Our aim was to investigate whether these key moments would attract teachers' attention compared with other generic issues. Although we did not direct teachers' attention to these specific particular issues, we specifically asked them to report what they noticed around the mathematical content. Again, our rationale was that teachers cannot make content-specific pedagogical decisions if they cannot notice these issues. Building on prior work on teachers' noticing (van Es & Sherin, 2008), we aimed to explore the following research questions:

1. What overall topics of the classroom instruction presented in the video clips caught the teachers' attention? What levels of analysis did teachers' noticing entail?
2. What subtopics of the classroom instruction at each level of analysis did teachers notice?

Methods

This study used data from 496 fourth- and fifth-grade teachers. The teachers completed an online mathematics teaching survey that included four videos of classroom instruction from Kersting and colleagues developed to capture teachers' useable knowledge (2008, 2010, 2012). For each of the four videos, teachers were asked, "Please list the three most significant things that you notice regarding how the teacher and the students in the clip interacted around the targeted mathematical content." The videos were presented in a random order for each participant. For our analysis, we include teachers who provided responses to at least one of the videos.

Analysis

We developed a 4-point rubric to evaluate the depth and topics of teachers' responses. Our goals were to differentiate between teachers' surface-level noticing and more sophisticated noticing, and also to identify responses focused on *content-specific teaching and learning-related issues* that limited students' understanding of the concepts in the videos. Thus, we created our rubric to distinguish among purely descriptive responses, analytical responses, and responses that focused on the problematic content-specific issues in each video. We also coded a subsample of responses to ensure that our rubric captured qualitative differences in teachers' responses. An important distinction between our rubric and those used in prior studies is that we consider both content and depth of analysis within single codes, whereas other rubrics use separate codes to capture content and stance of analysis (e.g., Sherin & van Es, 2009)

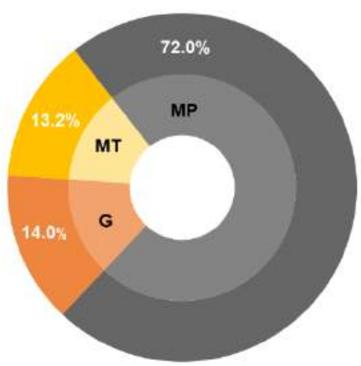
In our rubric, Level 1 responses did not include mathematics-specific events (e.g., describing seating arrangements, describing the teacher's tone of voice); Level 2 responses focused on content-specific aspects that were either purely descriptive or that contained a binary judgment (e.g., restating the problem, stating that the lesson was good); Level 3 responses analyzed some aspect of students' mathematical thinking or the teacher's mathematics pedagogy (e.g., noticing that the students were confused, interpreting why the teacher chose to use a strategy); Level 4 responses included responses that focused on the problematic issues related to students' mathematical understanding or teachers' mathematical instructional practices.

Our rubric also captured the topics of teachers' noticing responses. Adapting the methods of van Es and Sherin (2008), we differentiated among responses related to three topic categories: the mathematics pedagogy code identified responses that focused on teaching actions and strategies, such as the use of manipulatives or questioning techniques; the mathematical thinking code identified responses that focused on students' thinking and ideas; and the general code identified responses that were not related to the mathematical content.

After we finalized our rubric and gained confidence in using the rubric to reliably code responses, we coded the remaining responses by rotating the order and combination of the responses to the videos. Interrater reliability as measured by exact agreement was 95.3% for Noticing Levels and 95.9% for the Noticing topics. Furthermore, coefficient kappa was .927 and .909 for noticing levels and noticing topics. Teachers' responses were scored with a high degree of consistency.

Results

On the basis of our analysis of 5,382 responses, the vast majority of responses (72%) were related to pedagogical content, such as the actions, choices, or strategies the teacher used during the lesson (see Figure 1). 13.2% of the responses were focused on students' mathematical thinking, and 14% of the responses were about the general classroom climate and environment not specific to mathematics.[1] In terms of the depth of teachers' analysis of classroom events, we found that 14.8% of the responses had no focus on mathematics and 33% were purely descriptive (i.e., they did not indicate any analysis or interpretation; see Figure 2). Nearly half of all the responses (47.79%) included some level of analytical thinking about students' learning and teachers' pedagogical choices around the mathematics content but did not identify the key mathematical ideas related to the problematic mathematics content. Only about 6% of responses included an analysis of key mathematical issues around either the teachers' pedagogical choices, students' understanding, or both.



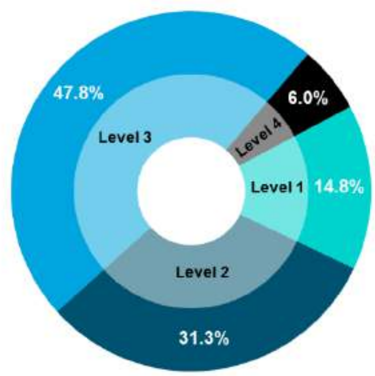


Figure 1. Percentages of overall noticing topics across 5,382 responses. MP = mathematics pedagogy; MT = mathematical thinking of students; G = general. Figure 2. Percentages of noticing depth levels across 5,382 teacher responses.

Aspects of Mathematics Classroom Events Teachers Noticed at Level 1 and Level 2

Level 1. Level 1 of our rubric contained responses that did mention mathematics but merely in a descriptive or evaluative way (e.g., "good" or "important" or "difficult"), without any analysis. The vast majority of Level 1 responses (91.4%) focused on teaching-related issues, such as the instructional tools and questioning strategies the teacher used. Among those responses focusing on content-specific pedagogical issues, almost one-third of the responses (30%) mentioned the use of manipulatives, visuals, or hands-on materials (e.g., "The students were working with manipulatives;" "I like that they used the pie fraction pieces").

Level 2. Level 2 responses included analytical or interpretive statements about the mathematics content in the video, but they did not identify the problematic mathematics content. At Level 2,

[1]Recall that teachers were asked to list three things they noticed. Some listed two and gave no answer for the third one. We assigned the "no answer" responses a score of 0, and we include these responses in the "general" noticing category.

79.8% of responses focused on content-specific pedagogical issues, whereas 20.2% focused on students' mathematical thinking.

Among the issues related to students' mathematical thinking, the majority of responses (74.6%) focused on what students seemed to understand or were struggling to understand ("Students are manipulating the pieces, but I can't tell if they are truly understanding the concept;" "The kids don't seem to have an understanding of parts to whole"). In relation to how students engaged with the problem ("The student used trial and error to find the correct fraction pieces to use;" "I noticed students were engaged in the lesson with the chips and did not seem to give up in understanding in solving the problem"), 8.5% of the responses focused on students' readiness to deal with the given concept or problem ("Her work with one student seemed effective, but I don't think the whole class was ready to tackle this problem;" "The students obviously had background knowledge on how to solve these problems").

Discussion

The concept of teacher noticing has important implications for student learning, research and teacher education because teachers do not address events that do not catch their attention. The majority of prior work on mathematics teacher noticing has been conducted with teachers in a program aiming to improve teachers' noticing skills; thus, the present study is unique by investigating trends in what a national sample of fourth- and fifth-grade mathematics teachers noticed independent of professional development or teacher education programs.

In alignment with prior work, our study indicated that pedagogical topics caught teachers' attention more often than any other topic (e.g., Sherin & van Es, 2009). In fact, more than two-thirds of teachers noticed content-specific pedagogical topics in each video; however, one-third of the teachers did not report anything on students' mathematical thinking.

Our study contributed to the current understanding of noticing in that teachers analyzed pedagogical strategies in greater depth, and their analyses targeted a wide range of pedagogical strategies. In contrast, teachers' analysis of students' mathematical thinking seemed limited. As scholars in several studies have noted, attending to and interpreting students' thinking is an important aspect of quality teaching (e.g., Ball & Cohen, 1999; Jacobs et al., 2010) and one that contributes to students' learning (Carpenter, Fennema, Peterson, Chiang, & Loef, 1989). Thus, teachers' lack of attention to students' mathematical thinking may indicate a lack of attention to their own students' thinking. Therefore, teachers may need more targeted interventions to learn to focus on students and how they analyze students' thinking.

REASONING ABOUT THE RATE OF CHANGE WHILE LINKING CO_2 POLLUTION TO GLOBAL WARMING

PENSANDO EN LA RAZÓN DE CAMBIO AL VINCULAR CONTAMINACIÓN POR CO_2 CON EL CALENTAMIENTO GLOBAL

Darío A. González
Center for Mathematical Modeling, Universidad de Chile
dario.gonzalez@fulbrightmail.org

This paper characterizes the way three preservice mathematics teachers (PSTs) understand and quantify the rate of change as they model the link between carbon dioxide (CO_2) pollution and global warming. I also discuss what PSTs learned about the concept of forcing by CO_2, a key metric of global warming. The PSTs completed a mathematical task during an individual, task-based interview. The study revealed three levels of understanding of the rate of change in relation to quantitative operations (comparison versus coordination), graphing activity (pointwise versus smooth and continuous), and concavity (discovering versus anticipating). Depending on their level of understanding, PSTs could imagine the rate of change changing discretely or continuously with respect to an independent variable. PSTs also learn four central ideas regarding the forcing by CO_2 as a result of working on the task.

Keywords: Cognition, Modeling, STEM/STEAM, Teacher Education - Preservice

Introduction

Climate change is a pressing issue for this century with potentially irreversible and disastrous consequences for social and natural systems (Intergovernmental Panel on Climate Change [IPCC], 2013). The *United Nations* has called for incorporating climate change education in schools (Anderson, 2012; Global Education Monitoring [GEM], 2016). Since students have different interests and learning abilities, teachers from all disciplines can contribute to climate change education (McKeown & Hopkins, 2010). Mathematics teachers can play a central role in this endeavor since mathematical modeling represents a promising approach for connecting mathematical learning and climate change education (González, 2018, 2019; Barwell & Suurtamm, 2011; Barwell, 2013a, 2013b). Teachers, however, need to be prepared for the challenge, which requires teacher education programs to prepare preservice mathematics teachers (PSTs) for incorporating climate change into their instruction.

Lambert and Bleicher (2013) have identified two key concepts from climate sciences that preservice science teachers need to learn about in order to understand climate change: (a) the Earth's energy balance, and (b) the link between carbon dioxide (CO_2) pollution and global warming. It is reasonable to extend this premise to PSTs since they are less familiar with concepts from climate science than preservice science teachers. Therefore, a starting point may involve studying the energy balance and the link between CO_2 and global warming as dynamic situations where two (or more) variables change together (covariation). In this paper, I characterize, from a covariational reasoning perspective, the way three PSTs think about the rate of change as they model the link between CO_2 pollution and global warming. I also discuss what PSTs learned about the concept of *Forcing by CO_2*, a key metric for assessing the impact of CO_2 pollution on global warming.

Conceptual Framework

Covariational reasoning refers to "the cognitive activities involved in coordinating two varying quantities while attending to the ways in which they change in relation to each other" (Carlson,

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

Jacobs, Coe, Larsen, & Hsu, 2002, p. 354). Johnson (2015) distinguished two categories of quantitative operations that students use when reasoning about covariation and rate of change: operations of *comparison* (QO-Comp) and operations of *coordination* (QO-Coord). *QO-Comp* involves conceiving a quantity's variation in chunks and produces associations of amounts of change between covarying quantities. The amounts of change in *y* are compared for (not necessarily equal) amounts of change in *x* in order to make viable claims about the rate of change. *QO-Coord* involved conceiving a quantity's variation smoothly and produces relationships between covarying quantities. The relationships are coordinated through division to create a new quantity measuring *degrees of change* that supports accurate claims about the rate of change. Carlson and colleagues' concept of covariational reasoning and Johnson's (2015) QO-Comp and QO-Coord informed the discussion about the ways PSTs understood and quantified the rate of change.

Methodology

This paper is part of a larger study that investigated how PSTs make sense of simple mathematical models of climate change. Three secondary PSTs —hereafter Jodi, Pam, and Kris— enrolled in a mathematics education program at a large Southeastern university in the United States participated in that larger study. Here, I focus on their responses to one task of the larger study: the *Forcing by* CO_2 *Task*.

The Forcing by CO_2 Task

The Erath's energy balance accounts for all heat flows (in Joules per second per square meters, or $Js^{-1}m^{-2}$) that there exit in the continuous heat exchange between the sun, the planet's surface, and the atmosphere (Figure 1a). The sun warms up the planet's surface at an approximately constant heat flow *S*. As the surface heats up, it radiates heat to the atmosphere (R). A small fraction of it escapes to space (L), but the majority (B) is absorbed by *greenhouse gases* (GHG) in the atmosphere. The atmosphere then re-radiates a fraction of the absorbed heat back to the surface (A), further increasing its temperature. The heat flow A represents the magnitude of the *greenhouse effect*, which enhances the planet's mean surface temperature. The energy balance shows that changes in the concentration of GHG result in changes in the planet's mean surface temperature. The Fording by CO_2 Task (Figure 1b) focuses on carbon dioxide (CO_2) because it is a key driver of global warming, as human activity produces large amounts of it by burning fossil fuels (IPCC, 2013).

The task defines the forcing by CO_2 as $F = (S + A) - R$, which is a measure of the warming effect over the planet's surface produced by an instantaneous increase in the atmospheric CO_2 concentration, C, (in parts per million, or ppm). If C increases, then the atmosphere can absorb more heat and, consequently, can radiate more heat towards the surface (A increases). Thus, as C increases, so does F, but $lim_{C\to\infty} F(C) = 45$ since S and R remain constant, which puts a cap on the growth of A and, consequently, on the growth of F. This suggests that F increases asymptotically towards 45 $Js^{-1}m^{-2}$ as C increases, producing an increasing, concave-downward graph.

Data Collection

Each PST completed the task during an 80-minute long, individual, task-based interview (Goldin, 2000). The interview followed a *semi-structured* format and was video recorded and transcribed for analysis. I started the interview by showing each PST a 7-minute long video introducing the concepts of energy balance and greenhouse effect. After the video, the PST and I had a Q&A session in which I summarized the central ideas regarding the energy balance and the greenhouse effect and clarified any questions they may have had about those ideas. The video and Q&A session were meant to provide PSTs with a basic knowledge regarding the energy balance and the greenhouse effect so that they could start working on the task.

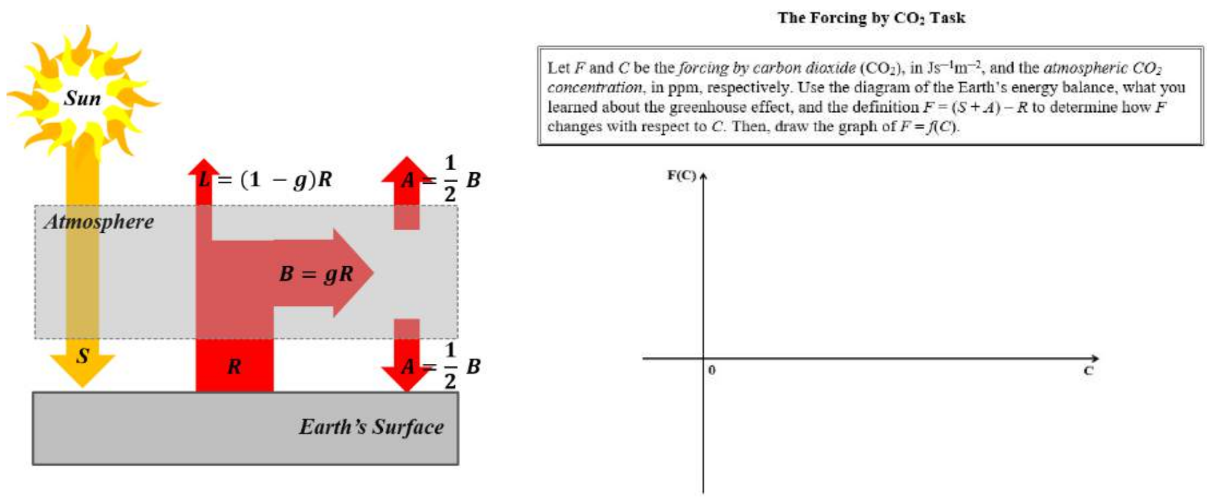

Figure 1. (a) the Earth Energy Balance (Left) and (b) the Forcing by CO_2 Task (Right).

Once the Q&A session ended, PSTs were given the Forcing by CO_2 Task along with a diagram of the energy balance (Figure 1a). The interview had four distinct parts. First, PSTs were asked to think about how F changes as C increases by examining the diagram of the energy balance. The diagram had no values for the heat flows to encourage PSTs to imagine changes happening dynamically. When PSTs experienced difficulties, I gave them initial values for the heat flows so that they could find F-values by using the given definition $F = (S + A) - R$. Second, PSTs had to think about two theoretical scenarios *Scenario 1* described a completely transparent atmosphere (an atmosphere that absorbs no surface heat) and was assumed to happen for $C = 0$ ppm. Scenario 1 corresponded to the minimum forcing (F-value) for the given initial values of the heat flows. *Scenario 2* described a completely opaque atmosphere (an atmosphere that absorbs all surface heat) and was assumed to happen for $C = 1{,}000{,}000$ ppm (highest concentration possible). Scenario 2 corresponded to the maximum forcing (F-value). The PSTs were expected to imagine how F increased from Scenario 1 to Scenario 2 and anticipate the graph's concavity. Third, I introduced the *Excel Simulation*, a spreadsheet that allowed PSTs to enter C-values and obtain the corresponding F-values. The Excel Simulation assisted PSTs in examining and quantifying changes in F for corresponding changes in C and evaluating the accuracy of their graphs. Finally, I asked PSTs to draw the graph of the *Sensitivity of F to C*, or the rate of change of F with respect to C. Here, I examined the PSTs' ability to conceive the rate of change as a measure of sensitivity and as a quantity in and of itself that covaried with C.

Data Analysis

Interview videos and transcripts were analyzed through the *Framework Analysis* (FA) method (Ward, Furber, Tierney, & Swallow, 2013). I watched all videos and divided them into smaller episodes. For each episode, I took notes regarding PSTs' views of forcing, covariational reasoning, and understandings of rate of change. I used the notes to develop an analytic framework, which included six codes about forcing, eight codes regarding covariation, and five codes about rate of change. The analytic framework was applied back to the data to code all episodes. Next, I looked for patterns across the participants' responses and categorized codes into themes. The patterns and themes helped me characterize the way PSTs understand the forcing and the rate of change.

Results

The Direction of Change of the Forcing

During the first part of the interview, PSTs looked at the diagram (Figure 1a) and identified the heat flows that changed when *C* increased and those that remained constant (i.e., unaffected by changes in *C*). In doing so, PSTs thought about how an increment in *C* influences the atmosphere's capacity to absorb and radiate heat (changes in *B* and *A*, respectively), which represents a foundational idea to understand the forcing by CO_2. PSTs inferred the direction in which *F* was changing by utilizing the given definition $F = (S + A) - R$. They noticed that an increase in *C* resulted in an increase in *A*, while the heat flows *S* and *R* remained constant, which meant that *F* increased when *C* increased. For instance, Kris stated "if *B* increases, then *A* is going to increase, and *S* and *R* stay the same [*pauses*]. So, [*F*] is going to be positive".

During the second part of the interview, PSTs thought about *Scenario 1* and *Scenario 2*. They realized that the scenarios represented the minimum and maximum forcing, respectively. For instance, Jodi described Scenario 2 as follows:

A would be 390 over 2, which is going to be [*uses calculator*]. So, A is 195, and we would need, we would want $_S$ to equal A [*writes S = A*]. But, since 240 is greater than 195, we would need to add [*F*] [*writes 240 = 195 + F*]. And, that would make F = 45. In the case we add more CO_2 to the atmosphere and L no longer is emitted

The PSTs assumed Scenario 1 occurred for $C = 0$ and found that $F = (240 + 0) - 390 = -150$ $Js^{-1}m^{-2}$. For Scenario 2, they assumed it occurred for $C = C_M$ and had $F = (240 + 195) - 390 = 45$ $Js^{-1}m^{-2}$. They represented these scenarios in the coordinate plane by the points $(0, -150)$ and $(C_M, 45)$, respectively. Then, Pam and Jodi drew a line incident to both points as the graph of *F* (Figure 2), while Kris could not decide whether the graph should be an increasing, concave-downward curve or an increasing line. She stated that a line "would imply that it is like a constant rate of change with *C* and [*F*]." Kris's understanding of rate of change appeared more advanced than Jodi and Pam's since it involved the realization that the shape of a graph is related to the variation in the rate of change.

The Rate of Change of the Forcing

During the third part of the interview, the *Excel Simulation* was introduced. Here, the PSTs also learned that *F* follows the rule "*F* increases by 4 $Js^{-1}m^{-2}$ every time *C* doubles[1]" which is widely accepted among the experts (Huang & Shahabadi, 2014; IPCC, 2013).

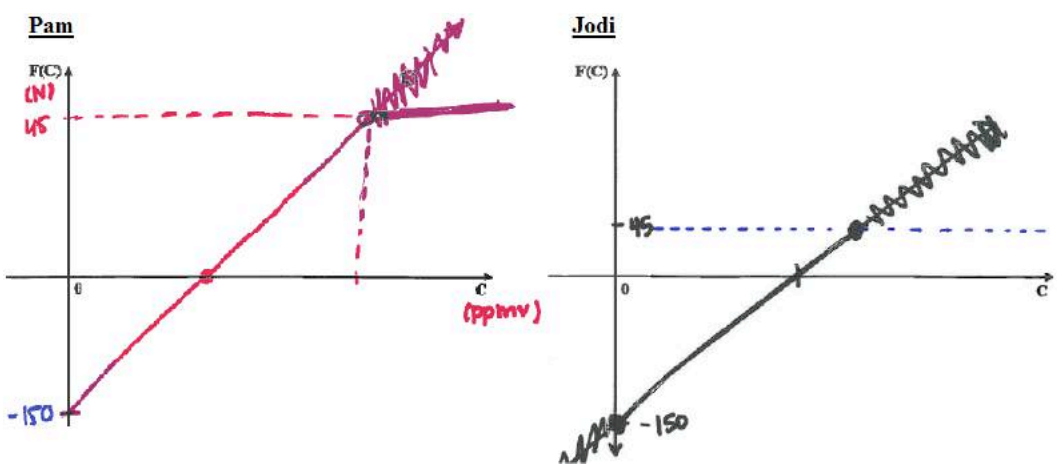

Figure 2. (a) Pam's linear graph of F (left) and (b) Jodi's linear graph of F (right).

[1] A more real estimate is about 3.7 $Js^{-1}m^{-2}$ (IPCC, 2013), but I rounded it to 4 $Js^{-1}m^{-2}$ for simplicity.

PSTs were asked to find out whether *F* was a linear or a nonlinear function of *C*. All three PSTs determined *F*-values corresponding to equally spaced *C*-values. Then, they compared the differences $\Delta_i F$ and noticed they were decreasing, discarding the linear model. After that, PSTs demonstrated three different ways of quantifying the rate of change and understanding its connection to the concavity of the graph of *F*, as they drew new versions of that graph. Pam did not anticipate the concavity of the graph from interpreting the decreasing increments $\Delta_i F$, suggesting she did not see them as an indicator of concavity or a measure of the variation in the *degree of change* of *F* with respect to *C*. Instead, Pam used the rule "*F* increases by 4 $Js^{-1}m^{-2}$ when *C* doubles" to coordinate *C*-values with *F*-values, creating a discrete collection of pairs (*C* , *F*) and drawing the graph of *F* using a pointwise approach (Figure 3a). When finished, Pam said "Oh! This looks like a logarithmic thing I hate", suggesting she did not anticipate the concavity of her graph as much as she *discovered* it.

In contrast, Jodi anticipated the concavity of *F* by interpreting the decreasing increments $\Delta_i F$ as indicating that *F* increased less and less as *C* increased.

So, the relationship is not linear because the change in $_y$ over the change in $_x$ is not equal between two points. But, I see that, as we increase [$_C$], the change in $_F$ is less. So, we may end up getting a function that looks like that *[draws a tiny, increasing, concave-down curve]*

Although Jodi anticipated the concavity, she still used the Excel Simulation to create a discrete collection of pairs (*C* , *F*). She then used a pointwise approach to draw her final version of the graph of *F*. This is an interesting behavior because it suggests that she did not have complete confidence on her interpretation of the differences $\Delta_i F$ in terms of concavity. A possible explanation is that her understanding of those differences as an indicator of concavity and a measure of the degree of change of *F* may have been still stabilizing in her mind.

Finally, Kris anticipated the concavity of *F* by interpreting the decreasing average rate of change of *F*. Her interpretation confirmed her previous suspicion that the graph was an increasing, concave-downward curve.

K: That is really weird, how like, if you look at the change from [*C* = 0] to [*C* = 1] [*pauses*]
I: There is a big jump
K: Yeah, like over a hundred (*F* increases more than 100 $Js^{-1}m^{-2}$). And then you get from [*C* = 10] to [*C* = 20] and it is only like four (*F* increases by approximately 4 $Js^{-1}m^{-2}$). So like, for every change [of] 2.5 [in *C*], [*F*] changes like one-ish. So that is what I was thinking about when I said that [the graph] may look like this [*draws an increasing, concave-downward curve*]

Kris's way of quantifying the average rate of change of *F* supported both anticipating concavity *and* drawing the graph of *F* in a smooth and continuous way (Figure 3b). Also, Kris's use of ratios represents a step forward in the formalization of the concept of rate of change in relation to the comparison of the differences $\Delta_i F$ for equal increments ΔC.

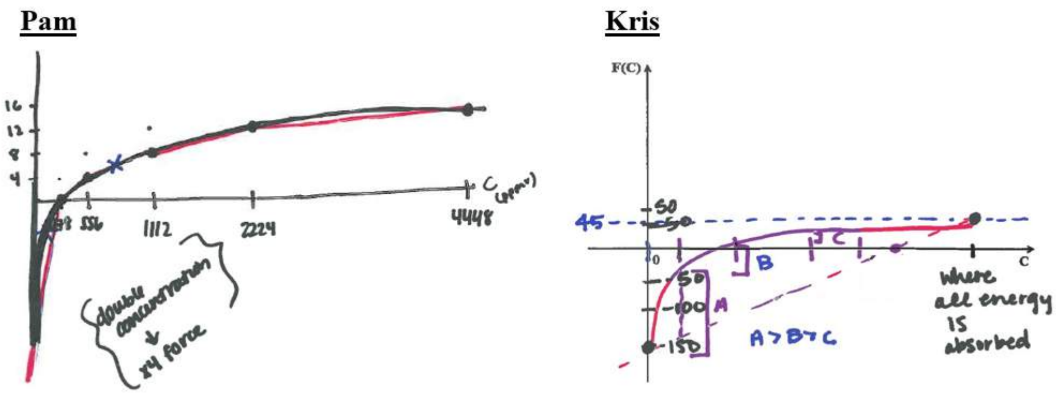

Figure 3. (a) Pam's final graph of F (Left) and (b) Kris's final graph of F (Right).

The Sensitivity of F to C

Pam and Kris participated in the fourth part of the interview involving the *Sensitivity of F to C* (i.e., the rate of change of *F* with respect to *C*). Unfortunately, Jodi did not have time to participate during that last part. The analysis of Pam and Kris's responses suggest two different ways of quantifying the *sensitivity* of *F* to *C* and two different ways of conceiving that sensitivity *covarying* with *C*.

Pam quantified the sensitivity by the *steepness* of the graph of *F* corresponding to unequally-spaced values of *C* (each interval was twice as long as the previous one). She then attended to the variation in the steepness as she moved from one interval of *C* to the next. She translated that variation into degrees of sensitivity (e.g., more or less sensitive).

P: So, it is not super sensitive here [*uses two fingers to indicate the steepness of the graph of F for* $2224 \leq C \leq 4448$]

I: Could you tell me a little bit more about how you figured that out by looking at this graph [*point at her graph of F*]?

P: Here [*points at the interval [0 , 278]*], [*C*] increased a little bit, and the force [*sic*] went crazy [*moves her index finger up quickly to indicate a large increase in F*], I mean compare to everything else, it went higher. Here [*points at the interval [278 , 556]*], [*C*] increased a little bit more, and the sensitivity didn't increase that much. So, [*F*] is not as sensitive when there is more concentration [*moves her fingers to the right to indicate the increase in C*]

The transcript above shows how Pam imagined the steepness decreasing as she moved from one interval of *C* to the next. This helped her identify the direction of change of the *sensitivity* (i.e., it decreases as *C* increases). However, she did not notice that the decline in steepness slowed down as *C* increased, hence she could not anticipate the concavity of the graph of the sensitivity. In order to draw the graph, Pam first found four values of the average rate of change of *F*: 4/278, 4/556, 4/1112, and 4/2224, corresponding to the intervals [278 , 556], [556 , 1112], [1112 , 2224], and [2224 , 4448], respectively. Then, Pam notice that "my concentration increases by double, and my sensitivity goes down by half [*writes 'concentration × 2, sensitivity ÷ 2'*]". She used that rule to create the discrete collection of pairs (278 , 1/2 *F'*(0)), (556 , 1/4 *F'*(0)), (1112 , 1/8 *F'*(0)), and (2224 , 1/16 *F'*(0)), where *F'* represents the sensitivity of *F* to *C*. Then, Pam drew the graph of the sensitivity with a pointwise approach (Figure 4a). This suggests she discovered the concavity of the graph of the sensitivity rather than anticipating it.

In contrast, Kris's ways of quantifying the sensitivity involved thinking in terms of *how resistant F* was to changes in *C*, as indicated by the graph of *F*. When I asked her how the sensitivity changes as *C* increases, Kris replied "sensitivity decreases because [*F*] is more resistant to a change in *C*". She then drew a decreasing, concave-upward graph of the sensitivity in a smooth and continuous way

(Figure 4b). Since she did not justify the concavity of her graph, I asked her to elaborate on how she figured the concavity out, to which she replied:

As we increase C by equal amounts each time *[uses two fingers to indicate equal increments in C], F is increasing by smaller, and smaller, and smaller amounts [uses two fingers to indicate decreasing increments in F]*. So, it is becoming less sensitive to the changes in C. Because it takes a bigger change in C to equal the equal change in F.

Because one must double *C* to create the same increment in *F*, she claimed that "the sensitivity decreases at a decreasing rate". Kris's quantification of the sensitivity allowed her to anticipate concavity, draw an accurate graph, *and* make viable claims about the rate of change of the sensitivity. This suggests that Kris not only reasoned about the rate of change of *F*, but also about the rate of change of the rate of change of *F*, which is foundational to understand second derivative in Calculus.

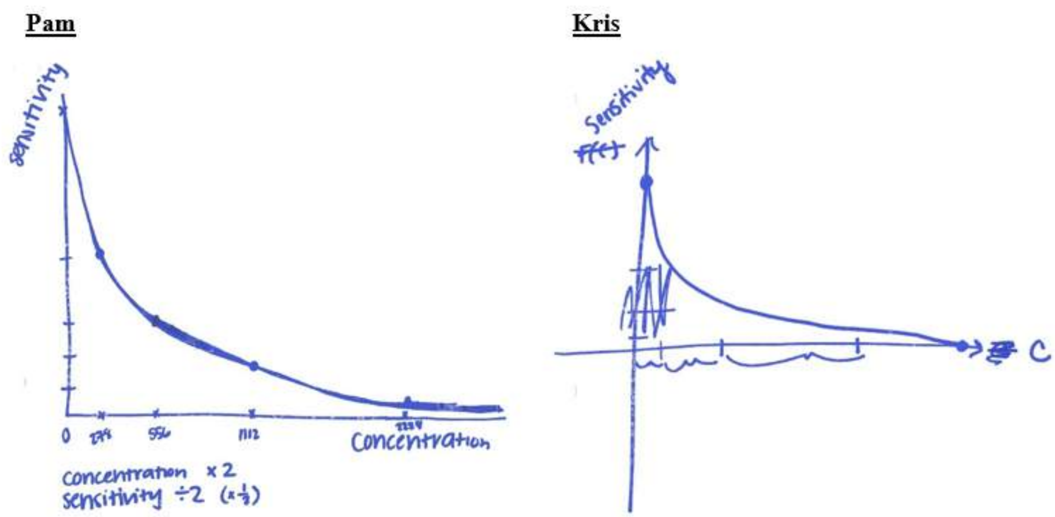

Figure 4. (a) Pam's graph of sensitivity (Left) and (b) Kris's graph of sensitivity (Right).

Finally, by thinking about the sensitivity of *F* to *C*, Pam and Kris learned that the forcing by CO_2 becomes less sensitive to changes in *C* as *C* increases. This is another characteristic of the forcing widely accepted among the experts (Huang & Shahabadi, 2014; IPCC, 2013).

Conclusions

The study revealed three different levels of understanding of the rate of change among the PSTs. *Level 1* is represented by Pam; she did not demonstrate quantitative operations related to reasoning about the rate of change *F*. She created a discrete collection of pairs (*C* , *F*) and used a pointwise approach to draw the graph of *F*. The concavity was discovered after finishing the graph and no viable claims about the rate of change were made. *Level 2* is represented by Jodi; she associated changes $\Delta_i F$ with equal changes ΔC and compared those associations (QO-Comp) to anticipate concavity and make viable claims about the rate of change. She, however, created a discrete collection of pairs (*C* , *F*) and used a pointwise approach to draw the graph of *F*. This suggests that her understanding of the relationship between a graph's shape and the rate of change was not completely stable in her mind. *Level 3* is represented by Kris; she coordinated changes $\Delta_i F$ with changes ΔC through division (QO-Coord) to create a single quantity that allowed her to anticipate concavity, make viable claims about the rate of change, and draw an accurate graph of *F*.

The analysis of Pam and Kris's responses suggest two different ways of quantifying the *sensitivity* of *F* to *C* and two different ways of conceiving covariation between the sensitivity and *C*. Pam quantified the sensitivity by the *steepness* of the graph of *F* corresponding to an interval of *C*. This allowed her to identify the direction of change of the sensitivity (i.e., it decreases when *C* increases). Then, she *compared* (QO-Comp) the values of the average rate of change of *F* for consecutive, unequally-long intervals of *C* (each interval was twice as long as the previous one) in order to define a correspondence rule between values of sensitivity and values of *C*: the sensitivity halves every time *C* doubles. Pam's QO-Comp allowed her to draw an accurate graph but did not support the ability to make claims about the rate of change of the sensitivity or anticipate concavity. In contrast, Kris quantified the sensitivity as the *resistance* of *F* to changes in *C*, as defined by the graph of *F*. This allowed her to identify the direction of change of the sensitivity (i.e., it decreases when *C* increases). Then, she *coordinated* (QO-Coord) changes in resistance with changes in *C* in order to draw an accurate graph of the sensitivity in a smooth and continuous way, make claims about the rate of change of the sensitivity, and anticipate concavity. Most interestingly, Kris's QO-Coord supported reasoning about the rate of change of the rate of change of *F*, a key idea to understand the second derivative in Calculus (Johnson, 2012).

Finally, the study also shows that PSTs learned four important aspects about the *forcing by* CO_2: (1) an increase in atmospheric CO_2 concentration enhances the atmosphere's capacity to absorb and radiate heat, which further warms the planet's surface; (2) the forcing has a theoretical minimum value, when the atmosphere absorbs no surface heat, and a theoretical maximum value, when the atmosphere absorbs all surface heat; (3) the doubling CO_2 rule for the forcing (*F* increases by 4 $Js^{-1}m^{-2}$ every time *C* doubles); and (4) the forcing by CO_2 becomes less sensitive to changes in *C* as *C* increases.

POSING PROBLEMS ABOUT GEOMETRIC SITUATIONS: A STUDY OF PROSPECTIVE SECONDARY MATHEMATICS TEACHERS

José N. Contreras
Ball State University
jncontrerasf@bsu.edu

Mathematics has developed into an extensive body of knowledge because there is, and has been, a continuous search for finding solutions to problems posed by someone. Therefore, problem posing is a fundamental activity of doing mathematics (Brown & Walter, 1983, 1993; Halmos, 1980; Contreras, 2019, 2020; Kilpatrick, 1987; Polya, 1973; Silver, 1994). Even though some researchers (Crespo, 2003; Crespo & Sinclair, 2008; Ellerton, 1986a, 1986b, 1988; English, 1996, 1997, 1998, 2003; Lavy & Shriki, 2010; Silver & Cai, 1996; Silver et al., 1996) have provided some insights about issues pertaining to this line of investigation, we do not know enough about the extent to which preservice teachers, who themselves are students, are able to pose problems by modifying the conditions of a given problem. In fact, the research community continues to investigate the different aspects of teaching and learning how to pose mathematical problems (Ellerton, 2013; Felmer, Pehkonen, & Kilpatrick, 2016; Silver, 2013; Singer, Ellerton, & Cai, 2013, 2015) including analysis of textbooks (Cai & Jiang, 2016; Cai et al., 2016).

From a mathematical point of view, generalizing, proving general statements, and generating problems by considering converse-type problems, are important mathematical activities. Generalizing mathematical patterns is one of the most important processes that contributes to the development of mathematics. According to Sawyer (1982), generalizing “is probably the easiest and most obvious way of enlarging mathematics knowledge” (p. 55). Proving these general statements is one of the central activities of doing mathematics. When creating or discovering a theorem, it is often worthwhile to investigate whether the converse of the theorem holds or what additional conditions or restrictions must be added for having a converse-type theorem.

In this study, 17 prospective secondary mathematics teachers were asked to pose problems related to each of four geometric situations. The four problem situations were chosen as to allow for posing general problems, problems about proving general formulas, and converse-type problems. The students generated a total of 225 responses (199 mathematical problems or questions, 4 nonmathematical problems or questions and 22 statements). The 199 mathematical problem were categorized as well-posed problems (168) and ill-posed problems (31). I used Author’s (1998) and Moses, Bjork, & Goldenberg’s (1990) frameworks for analyzing the strategies that the students used to pose the problems. The framework includes mainly the following seven strategies to pose the problems: variation of unknowns, variations of knowns or givens, variations of restrictions, reversing knows and unknowns (converse-type problems), generalizing, thinking of patterns, and proving (Contreras, 2003; Moses et al., 1990).

The most common strategies used by the students to pose the problems, and number of problems, were: generalization (38), variation of knowns (25), variation of unknowns (21), and a combination of strategies (12). Even though students generated a diversity of problems, only 10 students posed general problems and only two students posed at least one general problem for each geometric situation. In addition, the students rarely posed converse-type problems and proving problems. Given that most of the students were majoring in mathematics, the findings are not very encouraging. Thus, appears to be a need for prospective mathematics secondary mathematics teachers to learn how to pose these types of problems.

COMPREHENSION OF COMPLEX MATHEMATICAL TASKS WITHIN THE SCHOLARIZED CULTURAL ENVIRONMENT IN THIRD-GRADE

ENTENDIMIENTO DE TAREAS MATEMÁTICAS COMPLEJAS DENTRO DEL ENTORNO CULTURAL ESCOLARIZADO EN TERCER GRADO DE PRIMARIA

Uriel Escobar
Universidad Nacional Autónoma de México
urielescobar.unam@gmail.com

Felipe Tirado
Universidad Nacional Autónoma de México

Keywords: Cognition, Algebraic thinking, Order of operations, Problem solving

The understanding of complex quantitative relationships requires analyzing the cognitive processes of mathematical representations in students (Vygotsky, 1988), within school cultural environments. The development of concepts at an early age represents an opportunity in the forming of habits of abstract thinking for students of basic education (Carpenter et al, 2005; Carraher & Schliemann, 2007). The understanding of the quantitative relationships of mathematical concepts requires several areas: 1) the analysis of cognitive processes, through their mathematical representations and their discourse; 2) contemplate the school cultural environment in which children learn 3) the possibility of understanding complex concepts such as the order of operations or algebraic thinking.

For the present study, the understanding of quantitative relationships of 30 third-grade primary school students was analyzed, in complex mathematical tasks of the order of operations and algebraic thinking, in their schooled cultural environment (public primary). A teaching experiment was implemented based on tests of mathematical competence, concrete manipulative tasks based on part-whole relation (Davydov, 1962), and a content analysis of the students' discourse. The assessment of understanding was based on reactive tests of the order of operations and algebraic thinking. These tests were complementary with interviews with each participant. The tasks in the three stages of the teaching experiment were correlated with each other (RhO Spearman) to assess the internal consistency of the assessment.

The results indicate that 27% of the third-grade students expressed at least a potential understanding of the algebraic thinking tasks. The meaning of the variable and the unknown was linked to unknown or hidden quantities. 47% also expressed this understanding of the order of operations tasks. The justification for using the order of operations was the union between quantities that are multiplied compared to quantities that are added. The average scores of the children during the 10 sessions of the sequence had a high correlation with the average scores of the students in the tasks of algebraic thinking (0.733 ($p < 0.000$)) and the order of operations (0.769 ($p < 0.000$)). The results are compatible with the findings of multiple investigations of the order of operations or PEMDAS (Glidden, 2008; Gunnarsson et al., 2016; Linchevski & Livneh, 1999; Papadopoulos & Gunnarsson, 2020; Taff, 2017; Zorin & Carver, 2015).

It is possible, thanks to the potential of the formation of complex thinking habits, to understand algebraic thinking tasks and the order of operations schoolchildren at an early age, from concrete and significant experiences; When a child comes to understand and see the significance of mathematical tasks, he becomes enthusiastic about learning mathematics.

Keywords: Ethnomathematics, Geometry and spatial thinking, Secondary Education

A current of Ethnomathematics ("... set of knowledge produced or assimilated by an indigenous sociocultural group: counting, measuring, organizing space and time, designing, estimating and inferring, valid in their own context" (Villavicencio p.173 2001, cited by Avila p. 22 2014) is defined as the study of mathematics from other cultures, as indigenous peoples in various parts of the world (Suarez , Acevedo and Huerta s , 2009). Since each indigenous culture has its own language, representations of numbers, symbols, and number systems, so its instruments, units of measurement, and local forms of measurement make up a unique mosaic such as the O'dam culture that has a history ancestral in embroidery.

From the above, it is important then to prioritize meaningful learning in the classroom and support of learning strategies that enable students that are facing real problem situations, relevant and link with their environment, for this , the pedagogical approach that Challenge-Based Learning has meets the necessary conditions to achieve meaningful learning in students, discarding the idea that the teacher must teach a mathematical area or content so that learning can arise in students.

So, how to potentiate the learning of geometric concepts about transformations of figures in the plane, taking into account the cultural context of O'dam students? Thus, the challenge was proposed to the students to develop an embroidered backpack (bhai'mkar) or napkin, typical of their culture, with designs that included figure transformations such as translations, rotations and symmetries. The research was based on the ACODESA methodology: collaborative learning, scientific debate and self-reflection (Hitt and Cortés, 2009). Data was collected through observation, photographs, videos and products made by students (Figure 1). The proposed activities allowed students to explore different sources of available queries, interviews and search for information in textbooks. Through exhibitions, it was observed that the students were able to describe the type and characteristics of the transformations used to design their embroidery, thus helping to naturally identify movements in the plane in embroidery's in their community.

The O'dam indigenous cultural group uses a naturalistic and geometric cut in their handicrafts, so even though the students did not explicitly know the types of transformations used in their embroidery's; applied, demonstrated and communicated learning based on figure transformations.

Palabras clave: Etnomatemática, Geometría y pensamiento espacial, Educación Secundaria.

Una corriente de la Etnomatemática ("…conjunto de los saberes producidos o asimilados por un grupo sociocultural autóctono: contar, medir, organizar el espacio y el tiempo, diseñar, estimar e inferir, vigentes a su propio contexto" (Villavicencio, p. 173, 2001, citado por Ávila p. 22 2014,) está definida como el estudio de las matemáticas desde otras culturas, como pueblos indígenas de diversas partes del mundo (Suárez, Acevedo y Huertas, 2009). Dado que cada cultura indígena tiene su propio lenguaje, representaciones de números, símbolos, y sistemas numéricos, por lo que sus instrumentos, unidades de medida y formas de medición local conforman un mosaico único como lo es la cultura O'dam que tiene un historial ancestral en bordados.

A partir de lo anterior es importante priorizar el aprendizaje significativo en el aula, y apoyarse de estrategias de aprendizaje que permitan a los estudiantes se enfrenten a situaciones problemáticas reales, relevantes y de vinculación con su entorno, para esto el Aprendizaje Basado en Retos cumple con las condiciones necesarias para logar el aprendizaje significativo en los estudiantes para que pueda surgir el aprendizaje en los estudiantes con su propia vivencia.

Entonces, ¿Cómo potencializar el aprendizaje de conceptos geométricos sobre transformaciones de figuras en el plano, tomando en cuenta el contexto cultural de alumnos O'dam de educación secundaria? Así, se propuso el reto a los estudiantes de elaborar un morral bordado (*bhai´mkar)* o servilleta, propios de su cultura, con diseños que incluyeran transformaciones de figuras como traslaciones, rotaciones y simetrías. La investigación se apoyó en la metodología ACODESA: aprendizaje en colaboración, debate científico y auto reflexión (Hitt y Cortés, 2009). Se recolectaron datos a través de la observación, fotografías, videos y productos elaborados de los estudiantes (Figura 1). Las actividades propuestas permitieron a los estudiantes indagar en diferentes fuentes de consultas disponibles, entrevistas y búsqueda de información en libros de texto. Por medio de exposiciones se observó que los estudiantes lograban describir el tipo y características de las transformaciones utilizadas para el diseño de su bordado, ayudando así a identificar de forma natural los movimientos en el plano en tejidos elaborados en su comunidad.

El grupo cultural indígena O'dam usa en sus trabajos manuales un corte naturalista y geométrico, por lo que aun cuando los estudiantes explícitamente no sabían los tipos de transformaciones que se usan en sus bordados; aplicaron, demostraron y comunicaron el aprendizaje con base en las transformaciones de figuras.

Figura 1. Diseños de bordados O'dam basados en transformaciones de figuras.

Programmatic collaborations involving mathematicians and educators in the U.S. have been valuable but complex (e.g., Heaton & Lewis, 2011; Bass, 2005; Bass & Ball, 2014). Sultan & Artzt (2005) offer necessary conditions (p.53) including trust and helpfulness. Articles in Fried & Dreyfus (2014) and Bay-Williams (2012) describe outcomes from similarly collaborative efforts; however, there is a gap in the literature in attending to how race and gender intersect with issues of professional status, culture, and standards of practice. Arbaugh, McGraw and Peterson (2020) contend that "the fields of mathematics education and mathematics need to learn how to learn from each other - to come together to build a whole that is greater than the sum of its parts" (p. 155). Further, they posit that the two must "learn to honor and draw upon expertise related to both similarities and differences" across disciplines, or cultures. We argue that in order to do this, we must also take into account race, gender, language. For example, words like *trust* or *helpfulness* can read very differently when viewed from personal and professional culture, gender, or racial lenses.

This poster shares personal vignettes from the perspective of three collaborators – one black male mathematician, one white female mathematics educator, and one white woman who was trained as a mathematician but works as a mathematics educator - illustrating some of the complexity of collaboration. The title of the poster comes from a moment in conversation among the authors. One of the women, recalling a conversation with the mathematician, said, "oh, that conversation was brutal," without acknowledging or considering the history and potential painful ramifications of the word "brutal" when used about an interaction between a white woman and a black man - ramifications that could create barriers to collaboration. The mathematician returned with, "you say brutal, I say Thursday," meaning that the conversation was totally within the norms of a conversation between mathematicians. The vignettes in the poster serve as a contribution toward an eventual framework for studying and discussing intersectionality in collaborations in education.

We come to this work embodying a "humanistic perspective of mathematics as a discipline that drives and is driven by human endeavor" (PME-NA equity statement). Mathematics is deeply connected to the stories and histories of the people *doing* the mathematics. There has been a long history of positioning mathematics educators and mathematicians in problematic ways. Even more troubling is the way in which marginalized groups are positioned with respect to mathematics. Not attending to these critical identities falls short when we try to understand the goals, outcomes, and effects of collaborations between mathematicians and mathematics educators.

KINDERGARTEN STUDENTS' SPATIAL THINKING: PRACTICES ON DEBUGGING OF BUILDING BLOCKS

Keywords: Spatial Thinking, Kindergartener, Debugging, Computational Thinking

Spatial thinking is a process to mentally represent and transform objects and to interpret the relationship among these objects (Clement. 1998). Abstraction is a core component supporting faster and more effective spatial thinking by removing unnecessary details and producing a simpler representation (e.g., in mental rotation; Lovett & Schultheis, 2014). Computational thinking (CT) is a concept rooted in computer science, which refers to a set of problem-solving methods to solve complex problems (Wing, 2006). CT has suggested abstraction as one of the main concepts (Wing, 2006). Indeed, CT and spatial thinking interrelate with each other (Román-González, Pérez-González, & Jiménez-Fernández, 2017). This study focuses on the interrelation between spatial thinking and CT.

Giving more attention to abstraction as a concept of CT could support students' mathematics learning (Rich & Yadav, 2020). Likewise, spatial thinking is essential for students to develop some mathematical ideas (e.g., number sense) in early ages (Cheng & Mix, 2014; Geary & Burlingham-Dubree, 1989; Gunderson et al., 2012; Stieff & Uttal, 2015; Verdine et al., 2014). Further, some researchers argued that playing blocks is associated with improving children's spatial thinking (e.g., Caldera et al., 1999; Connor & Serbin, 1977; Verdine et al., 2014). Although many studies have concentrated on constructing blocks as an intervention to promote children's spatial thinking, far fewer have examined children's computational thinking in the constructing and deconstructing process. To help fill this knowledge gap, this study investigated the possible impact of debugging (finding and fixing mistakes) –an approach of CT (Angeli et al., 2016) – on kindergartener's spatial thinking. Further, debugging might also be helpful for their mathematics skills by enhancing spatial thinking.

The design of the study includes a paper guideline that serves as algorithms and an authentic model. The guideline is a series of solid figures showing detailed steps. Each step includes the shape of a building block being used and the outcome for this step while the model has mistakes when matching with the guideline (e.g., the incorrect orientation of piece on correct place, missing piece). The students need to deconstruct the given model by following the guidelines to detect the mistakes. Once they find and fix a mistake, they need to reconstruct the model with the guideline. In addition, pre- and post-tests will be used to measure students' spatial thinking and mathematics. We hypothesize that CT-inspired-heuristic such as debugging an authentic model of building blocks will have a positive impact on spatial thinking and mathematics in early ages. The findings will contribute to the theory and practice of developing students' spatial thinking in early ages. The study will also expand and enrich the discussion on the interplaying relations between computer science and mathematics.

TWO PROSPECTIVE MIDDLE SCHOOL TEACHERS REINVENT COMBINATORIAL FORMULAS: PERMUTATIONS AND ARRANGEMENTS

DOS FUTUROS MAESTROS DE ESCUELA INTERMEDIA REINVENTAN FÓRMULAS COMBINATORIAS: PERMUTACIONES Y ARREGLOS

We report on findings from two one-on-one teaching experiments with prospective middle school teachers (PTs). The focus of each teaching experiment was on identifying and explicating the mental processes and types of intermediate, supporting reasoning that each PT used in their development of combinatorial reasoning. The teaching experiments were designed and facilitated to guide each PT toward reinventing multiple combinatorial formulas. Drawing on a subset of this data, we describe the development of the PTs' mental processes and reasoning as they came to construct formulas for counting permutations and arrangements without repetition, and we analyze our findings through a psychological constructivist framework.

Keywords: Advanced Mathematical Thinking; Cognition; Teacher Education–Preservice

Enumerative combinatorics is a mathematical discipline concerned with the activity of *counting*. More specifically, by "counting," we mean finding the cardinality of particular set, either by exhaustive listing or by using a more sophisticated technique. Researchers have taken an increased look into students' combinatorial reasoning (e.g., Batanero et al., 1997; English, 1991; Fischbein & Gazit, 1988; Lockwood, 2011; Maher et al., 2010; Tillema, 2013), but relatively little research has investigated the combinatorial reasoning of *teachers*, either current or prospective (exceptions to this include McGalliard & Wilson, 2017, and Speiser et al., 2007). Research on teachers' development of combinatorial reasoning can be an important component of studying the development of the specialized mathematics content knowledge (Hill et al., 2008) needed by teachers.

The aim of the present study was to investigate the nature of prospective middle school teachers' (PTs') combinatorial reasoning. The study involved one-on-one teaching experiments with two PTs, DC and NK. In these teaching experiments, DC and NK were guided to develop increasingly sophisticated conceptualizations and ways of reasoning needed to solve increasingly complex tasks. Ultimately, both PTs constructed multiple generalized counting formulas and ways of making sense of those formulas. We present a subset of data in which the PTs developed formulas for counting permutations and in which DC developed a formula for counting arrangements without repetition. The two tasks outlined below, as well as numerous extensions to these tasks, were instrumental in guiding the PTs' development.

- *3-Cube Towers with 3 Colors.* Using three different colors of cubes, how many different towers 3-cubes-high can be made without repeating colors? [Answer: 3!, or 6]
- *3-Cube Towers with 5 Colors.* Using five different colors of cubes, how many different towers 3-cubes-high can be made without repeating colors? [Answer: $5\times4\times3$, or 60]

The following research question guided this study: How do two PTs' conceptualizations and forms of reasoning develop as they are given increasingly complex tasks pertaining to permutations and arrangements with repetition, particularly tasks within the context of constructing block towers?

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

Literature Review

Research on combinatorial thinking has consistently shown that students tend to struggle with solving counting problems. This includes, for instance, choosing an appropriate combinatorial operation for a given situation (e.g., Batanero et al., 1997; Fischbein & Gazit, 1988). Researchers have identified certain practices that help students develop in their combinatorial reasoning, such as productive listing (Lockwood & Gibson, 2016) and reflecting on the outcomes being counted (Lockwood, 2014). Tasks within the context of enumerating block towers have been shown to be particularly useful for developing combinatorial reasoning, both with children (Maher et al., 2010; Maher & Speiser, 1997) and with prospective elementary teachers (McGalliard & Wilson, 2017; Speiser et al., 2007).

One study investigated the processes by which two undergraduates (former integral calculus students) came to reinvent four combinatorial formulas (Lockwood et al., 2015), including those pertaining to this study. Framing their analysis using Lockwood's (2013) model of combinatorial thinking (sets of outcomes, counting processes, and formulas/expressions), the authors conjectured that a reinvention of counting formulas would require reasoning about counting processes—in particular, about the Multiplication Principle. Instead, the authors found their participants relied heavily on empirical patterning to reinvent certain formulas. We situate our study within the literature, guiding two PTs to construct generalized combinatorial formulas and develop in their combinatorial reasoning along the way.

Theoretical Perspectives

This study used a teaching experiment methodology (Steffe & Thompson, 2000) which was most appropriate given that the primary purpose of the study was to investigate the development of NK's and DC's conceptualizations and ways of reasoning as they were posed with increasingly complex combinatorial tasks. Ultimately, these tasks led to the construction of several combinatorial formulas and ways of using and making sense of those formulas; in this sense, our study is consistent with the principle of guided reinvention within the theory of Realistic Mathematics Education (Freudenthal, 1973; Gravemeijer, 1999). We view this work as contributing toward the overarching goal of developing a hypothetical learning trajectory (Simon, 1995) for permutations and arrangements without repetition, tracing the development of the PTs' conceptualizations and ways of reasoning as needed to make sense of increasingly complex tasks and—including the construction of generalized counting formulas.

Mathematically, we focus on the development of two combinatorial structures: permutations and arrangements without repetition. A *permutation* is a particular ordering of a set of n (distinct) objects. The number of permutations of n objects can be expressed as $n\times(n-1)\times(n-2)\times\ldots\times2\times1$, or $n!$. An *arrangement without repetition* is an ordering of a subset of k objects from a set of n distinct objects, the number of which can be expressed as $\frac{n!}{(n-k)!}$.

Reformulating the elaboration of Piaget's theory of abstraction by von Glasersfeld (1995) and Steffe (Steffe, 1998; Steffe & Cobb, 1988), Battista (1999, 2007) proposed *levels* of abstraction of sensory objects and motor activities (collectively called mental items). At the most basic *perceptual* level, a person has abstracted an item from their experiential flow and can perceive the item as a coherent unit. At this level, the item cannot be re-presented (visualized) without the presence of relevant sensory input. At the *internalized* level, a person can either re-present sensory objects in their mind in the absence of perceptual material or reenact a motor activity in the absence of kinesthetic signals from physical movement. However, the internalized level is limited in that a person cannot yet reflect upon an item's re-presentation or analyze an item's composition and structure. Only upon reaching the *interiorized* level of abstraction can a person reflect upon and analyze internalized items.

Interiorization "leads to the isolation of structure (form), pattern (coordination), and operations (actions)" (Steffe & Cobb, 1988, p. 337). Procedurally, a student's focus shifts from performing a sequence of actions to analyzing the meanings and results of those actions, treating the procedure as an object of reflection. Upon reaching the *second level of interiorization*, a person can perform *operations* on mental items without re-presenting or generating the material, and they can use symbols as "pointers" to the abstracted material, substituting the material with these symbols. Procedurally, second level interiorization allows a person to mentally operate on a procedure's components without actualizing the procedure using numbers. Symbols can refer to abstracted spatial components (e.g., "positions" in a generic 3-cube tower) or numerical components (e.g., a numerical procedure from reasoning about positions). At the *third level of interiorization*, a person can meaningfully represent the arithmetic/algebraic structuring of a generalized computational procedure with algebraic notation.

Findings and Analysis

In this section, we present, make inferences about, and analyze selected key events in the development of the PTs' conceptualizations and forms of reasoning.

Permutations

Episode 1. Both teaching experiments began with the 3-Cube Towers with 3 Colors task, and in both cases the PT was shown an example. NK constructed all six 3-cube towers using a single blue, green, and red cube, deconstructing the previous tower in order to make the next one.

> NK: The easiest way to think about it would be to start with a color. So, I would start with blue at the top. I always start at the top and go down. So like blue, green, red would be one, and then blue, red, green would be two.

NK then constructed the two 3-cube towers with a green top cube and the two towers with a red top cube. Notably, NK's count did not match her intuition (that there would be 3^2 towers), so she used the cubes to construct all towers in order to verify her count. Given the first follow-up task—counting 4-cube towers with 4 colors without repetition—NK responded,

> NK: OK, so same thing. Let's start with blue. So we have blue, black, green, red. I'm not gonna sit here and make all of these because, if you start with blue, you know that there's, if we have 3, then there's 6 combinations that can have blue at the top. … So blue times 6, 6 times 4, 24.

After asking for further elaboration, NK continued her explanation.

> NK: So, however many times you can arrange these three [bottom three cubes] is gonna be however many times you can arrange this whole thing, because blue will constantly be at the top. So you can just kind of omit it [the top cube] out of your thinking and see how many times this [bottom three cubes] can be combined, and then throw the blue at the top and that's the tower of four.
>
> NK then indicated the same number of towers could be made with each choice of top-cube color, motivating her multiplication of 6×4.

DC, on the 3-Cube Towers with 3 Colors task, constructed all six towers (so that all towers were present on the work-table) using a strategy similar to NK's, except his construction process was anchored by the color of the bottom cube (which he called the "base") instead of the color of the top cube. Given the 4-cube tower follow-up task (with black cubes added as the fourth color), DC deconstructed each of his original six towers; he then placed three green cubes in a line on the work table and was going to place three red cubes next to them, but he shifted his approach and instead constructed six 4-cube towers each with a green cube as base. He reasoned,

> DC: Each color has two possible towers if that color is the base [of a 3-cube tower]. But I *rose* it a level. So this is still the red base [*pointing to the two 4-cube towers with red cube second from the bottom*], but it's on top of the green base.

To clarify, DC had constructed six 4-cube towers, all with a green base and two with a red cube second-from-the-bottom. When he said he "rose it a level," he was referring to his action of taking six 3-cube towers and adding a green cube to each. After this, DC constructed all six 4-cube towers with a red base. He then predicted there would be the same number of towers with blue and black bases, concluding there would be $6 \times 4 = 24$ total 4-cube towers. Later, DC further explained, similar to NK, that 4-cube towers with green bases can be made by taking the composite of six 3-cube towers and appending a green cube to the bottom of each tower.

Inferences. We infer that NK conceptualized towers spatially as composites consisting of a single cube appended to an (n-1)-subtower, while DC had a similar spatial structuring but with the appending cube in the bottom position rather than the top. This spatial structuring led the PTs to organize their processes of tower construction by using the appended cube as an anchor, similar to what English (1993) calls a "major constant item." When transitioning to the 4-cube-tower follow-up task, both PTs used a recursive strategy, now reconceptualizing each 3-cube tower as a composite unit and operating on the composite of six 3-cube towers (mentally, in NK's case, or perceptually, in DC's case) by appending to each tower an additional cube. We also infer that, initially, DC planned to construct each 4-cube tower systematically, but he realized the composite of 4-cube towers could be constructed by building on the composite of 3-cube towers.

Analysis. Both NK and DC had interiorized the process of constructing 3-cube towers, indicated by the fact that their constructions were coordinated by a spatial structuring. Further, we interpret NK's reasoning on the 4-cube-towers task as reasoning about "symbolic" positions (of a generic 4-cube tower) rather than about specific instances of towers, indicating second level interiorization of the process of constructing 4-cube towers. DC's reasoning was also coordinated by a spatial structuring, but his reasoning relied on the perceptual material available on the worktable and did not appear to draw on the structure of a generic 4-cube tower. Thus, we interpret that DC interiorized the process of constructing 4-cube towers.

Episode 2. *NK.* Extending to counting 5-cube towers with 5 colors of cubes, and without constructing any towers perceptually, NK reasoned,

> NK: So you could do the same thing where you start with a different color, but how many different combinations you can make with 4 is going to be 24. …Let's pretend [the fifth color] is white. So you could start with white, and you would have 24 different combinations of these [gestured to other four colors of cubes] that would go under the white. So it would be 24 times 5, because each one of these colors would get their chance to be at the top.

Extending to counting 6-cube towers with 6 colors, NK described her strategy more generally.

> NK: So there's a pattern. So it's, whatever 5 is, which we found that 5 is 120, it would be 120 times 6. … Sorry, I keep thinking with the mindset of, just like, you can omit the top cube. So you can start with like a constant, your constant would be like whatever color [is at the top].

The next follow-up task jumped to counting 9-cube towers with 9 colors. She did not have an immediate answer, but she took colored pencils and paper and started reflecting on her previous enumerations, searching for a pattern.

> NK: Oh! Okay, okay. So, if you were to start with two colors, there are two combinations. Then you go to three, we found that there are six. Then you go to four, and find whatever 6 times 4 is, which is 24. Then you take 24 and multiply it by 5. 'Cause we have 5 things, so I multiplied it by 5 and got 120. And we came here, and we multiplied 120 by 6, which is… 720. And then you can

> take that and multiply it by 7… which is 5,040. And then you can do that and multiply it by 8, which is the number of combinations you get if you had 8 colors, which is 40,320. And then you can multiply it by 9 to finally find how many it would be, which would be 362,880.

Inferences. As with her spatial structuring of 4-cube towers from 3-cube towers, NK visualized appending a fifth-color cube to the top of each 4-cube subtower, then reasoning multiplicatively with the number of available colors. Similar to her reasoning in Episode 1, NK counted 5-cube towers by reasoning about positions—that is, her reasoning drew on an abstraction of the spatial structure of a generic 5-cube tower. With this spatial structuring guiding her reasoning, NK used a recursive strategy once more, multiplying the number of top-cube color possibilities by the number of ways to arrange the cubes in the (n-1)-cube subtower.

Analysis. NK used an interiorized spatial structuring to guide her reasoning about the number of towers of any height, although at this point her reasoning was recursive in the sense that she relied on knowing the number of (n-1)-cube-towers to compute the number of n-cube-towers. As with the previous episode, NK's reasoning is based on positions, indicating second level interiorization of her recursive scheme for counting n-cube towers.

Episode 2. *DC.* Counting 5-cube towers with 5 colors, DC searched for a pattern in the number of towers that are present with a given color base cube.

> DC: I'm going to take a guess. So, we went from two of each to six of each, which means we multiply by 3. So when we multiply by 3 again… oh no, I should multiply by 4. I'm gonna multiply that [pointed to the six constructed 4-cube towers, each with a green base] by 4 because there are four colors, excluding the new color. I don't know if that's right…. So, 6 times 4, 24 combinations. No, 24 is what we have now if we did just have the 4 of them.

He placed the six 4-cube towers with green bases in one group, and adjacent to those he placed the six 4-cube towers with red bases. He then lined up six blue cubes and six black cubes to symbolize the 4-cube towers with blue and black bases, respectively. With this, he could see there would be 24 4-cube towers in total. Although he still expressed uncertainty, DC predicted there would be 24×5 5-cube towers that could be made with 5 colors.

To help DC resolve his uncertainty, he was given five different colors of cubes arranged in a line on the table and was asked how many different ways the five cubes could be rearranged by interchanging cubes. DC exhaustively enumerated 24 of the possible 5-cube orderings, keeping the right-most cube (which he still called the "base") constant and multiplying, at the end, by 5. His enumeration was systematic although not a complete odometer pattern (English, 1991). Moving to counting 6-cube orderings in a row, DC reasoned,

> DC: I know that in the 5-color scheme, there are 120 combinations per base color. Now, with a *super-base* sixth color, there are six different options for the super-base, and 120 options for the regular base. And so 6 times 120 is… 720.

Of note, DC's verbal comments indicated he thought about constructing towers and enumerating orderings of cubes interchangeably. Extending to counting 9-color orderings in a row, DC said,

> DC: I would go through if we had seven colors and then eight colors first. All I would do is take that 720… multiply it by 7, to get 5,040. That's how many combinations we have for seven colors. Then multiply that by 8… 40,320. And then for nine, we would multiply that value by 9.

Inferences. DC had constructed 12 of the 24 4-cube towers with 4 colors, and he placed six blue and six black cubes on the table to represent the remaining 12 towers. With this visual aid, DC predicted there would be 24×5 5-cube towers, but he did not seem to visualize "raising" this 24 5-cube-tower composite with the added sixth color of cubes (as he did to construct 4-cube towers from

3-cube towers). After moving to counting 5-cube orderings, DC's counting was systematic, and he reflected on this process to enumerate orderings of larger numbers of cubes.

Analysis. At first, DC seemed to have internalized, but not interiorized, the process of constructing 5-cube towers. After perceptually finding all 5-cube orderings with a fixed right-most cube (and reflecting on those actions), DC reasoned about positions—specifically, multiplying the number of 5-cube orderings with a fixed right-most cube (24) by the number of possible right-most cubes (5)—which indicated second-level interiorization of the process of constructing 5-cube towers. With subsequent tasks, his reasoning extended to counting increasingly larger orderings, indicating second level interiorization for a more general (recursive) scheme for counting permutations, although it became less apparent that DC's reasoning was guided by his spatial structuring.

Episode 3. Extending to counting 20-cube towers with 20 colors, NK began to search for a function that would produce the number of towers of a given height (and number of colors), n. Thinking the function would be exponential, but unable to predict a specific formula, she reflected on her previous strategies.

> NK: So you would start at 20, so it would be 20 times 19 times 18 times 17 times 16 times 15 times 14 times 13, 12, 11, 10, 9, 8, 7, 6, 5, 4, 3, 2, 1. The whole time I've been multiplying *this* direction [motioned from left to right, indicating starting at 1 and ending with 20], but I just started multiplying by the number of colors we have.

On follow-up tasks, NK then predicted the number of 100-cube towers with 100 colors to be $100\times 99\times 98\times \ldots\times 1$, and she wrote a general expression for the number of n-cube towers with n colors to be $n\times(n-1)\times(n-2)\times(n-3)\times \ldots\times 1$.

DC predicted the number of 20-cube towers with 20 colors by multiplying the number of 9-cube towers, 362,880, by 10, then by 11, by 12, etc., and finally by 20. He searched for an "equation" that would calculate the number of towers, but he was not able to find one. Extending to counting 100-cube towers, DC described that he would continue multiplying the product found in the 20-cube-tower task by 21, by 22, by 23, etc., until finally multiplying by 100. After leading DC through a quick review of his work so far, DC said,

> DC: *Oh wait*! Would this work, where we have 2 there, and that's the 2 combinations we can get with 2 colors…. Then we multiply that by 3, because then we added a third color. And then we would multiply that by 4, because we added a fourth color. Then we multiplied that by 6, which is what I'm doing, but then you could just go up to 100.

He wrote the following to express what he had verbalized: $(((((2)3)4)5)6\ldots)100$. He initially kept the parentheses so as to maintain the order of multiplication, but he later cited the associative property of multiplication to reason that he could remove the parentheses. Finally, extending to counting n-cube towers with n colors, DC said there would be $2\times 3\times 4\times \ldots\times n$ different towers.

Inferences. NK's calculations, now reversed from their original order, no longer seem to be guided by a mental process of recursively operating on towers of height n-1 to form towers of height n. For DC, after guiding him through a review of his previous enumerations, he reconceptualized 362,880 as the product of consecutive integers $(2\times 3\times 4\times \ldots\times 9)$. He then extended and generalized this strategy, although at this point his reasoning still seemed recursive.

Analysis. Both NK and DC reached the third level of interiorization for counting permutations, indicated by both PTs' generalized algebraic expressions. Even still, NK's reasoning seemed more sophisticated than DC's as she realized she could reverse her multiplicative process and achieve the same result, which we suspect is important for counting and reasoning about arrangements.

Overall, both PTs exhibited remarkable progress in their conceptualizations and ways of reasoning about permutations. NK and DC were able to enumerate block tower composites successfully and efficiently with cubes, either mentally or with perceptual material, and use this to structure their numerical reasoning.

Arrangements—DC

Due to space constraints, only a subset of DC's progress toward thinking about arrangements without repetition is presented.

Episode 4. DC first considered the task of counting 3-cube towers with 4 possible colors of cubes. He systematically constructed the six 3-cube towers with a red base, then reasoned:

> DC: If we use red as our first bottom color, our first base, after red only 3 other colors can be the middle color in our tower of 3. Then, for each of those, there are only 2 colors remaining. And since it's a tower of 3, it's just those 2 colors on top. … So 6 total for red, times 4.

He clarified "times 4" was to account for the number of possible base-cube colors. Given the 3-Cube Towers with 5 Colors task, he constructed the remaining 3-cube towers with a red base, including those with the newly-added fifth color, culminating in 12 3-cube towers with a red base on the worktable.

> DC: So now there are 12 different combinations for each color as base, times 5—60. There are 60 possible combinations.

Given the next follow-up task, counting 3-cube towers with 6 colors, DC initially tried to find a pattern, first noticing a doubling pattern in which the number of towers "per base" went from 6 (using 4 different colors) to 12 (using 5 different colors). DC predicted there would be 24 towers per base in the 6-color task, but he was not certain. He resorted to systematically constructing all 3-cube towers with a red base using 6 colors, finding 20 towers in total. He reflected on the number of towers that were added when transitioning from towers with 5 colors to towers with 6 colors, but this did not lead to a new insight. We returned to the task of counting 3-cube towers with 4 colors, and it was in this task that DC made a new insight.

> Int: With the first problem with 4 colors making towers 3-cubes-high, I remember you saying in this original problem that you thought about it as 3 times 2…. So, you saw the 3 times 2 in that problem. Could we see something similar when we move up to 5 colors?
>
> DC: I mean, it's 4 times 3. 'Cause there are 4 possible options for the second tier, and then on top of each of those there are 3 possibilities for what can be left…. That's 12 per base, and then 12 times the possible 5 bases is 60 combinations. With 6 colors, if we look at it in the same way we just did, there are 5 combinations for what can come on top of each base, times 4 possibilities for what can come on top of that second tier… 5 times 4 is 20, times the possible 6 bases, which is 120 possible combinations. So, if we were dealing with 4 colors—*Oh!* Here it is, I think I might have just done it. We have n times $n-1$ times $n-2$ equals that value…. This gives us the number of possible combinations above each base, times the number of bases, gives us the total number.

Inferences. DC's reasoning was guided by a specific spatial structuring: He conceptualized composites of 3-cube towers by focusing on a subset with a particular base-cube color appended to 2-cube towers, then generated the entire composite of 3-cube towers by multiplying by the number of possible colors for the base. When the teacher-researcher led DC to revisit and reflect on his numerical procedures, he realized a numerical pattern connected to his spatial structuring: the number of color possibilities "on top of each base" multiplied by the number of color possibilities "on top of that second tier."

Analysis. DC's process of counting 3-cube towers reached second-level interiorization, indicated by his reasoning about positions within 3-cube towers, and quickly progressed to third-level interiorization as he generalized his numerical procedure to counting 3-cube towers with any number of colors.

Episode 5. DC was asked to count k-cube towers with n different colors, without repetition.

> DC: Let's just say k=5 in this instance. Then the equation would be $n(n-1)(n-2)(n-3)(n-4)$. And… the integer that you're subtracting is k minus—like, goes up to k-1, but doesn't quite get to k. And so, it's like the reverse factorial here. Like, this is k-1 [pointed to 4 in n-4], k-2 [pointed to 3 in n-3], k-3 [pointed to 2 in n-2], k-4 [pointed to 1 in n-1].

When asked to generalize from k=5 to a general k, DC used this same "reverse factorial" idea and wrote $n(n-k-(k-1))(n-k-(k-2))(n-k-(k-3))\ldots$. He was asked if $(n-k-(k-1))$ might be able to be simplified; after some algebraic manipulation, he realized that, for any value of k, the number of towers of height k with n colors of cubes is $n(n-1)(n-2)(n-3)\ldots(n-(k-1))$.

Inferences. DC thought that a generalized expression for counting k-cube towers with n colors would require an expression involving both n and k, leading to his conceptualization of the "reverse factorial."

Analysis. DC's process for counting arrangements had reached third-level interiorization.

Conclusions

The PTs' spatial structuring was instrumental toward guiding the development of their reasoning about permutations and arrangements. Both PTs developed recursive strategies but progressed past recursion through processes of action, reflection, and abstraction. This ultimately led their processes of enumerating permutations and arrangements to third-level interiorization.

REPORT OF A CLASSROOM EXPERIENCE FOR THE DEVELOPMENT OF DISTRIBUTION MODELS

EXPERIENCIA EN EL AULA PARA EL DESARROLLO DE MODELOS PARA EL REPARTO

María José Aviña González
Facultad de Ciencias Exactas UJED

Angelina Alvarado Monroy
Facultad de Ciencias Exactas UJED

This paper presents the design and analysis of a Model-Eliciting Activity (MEA), which aims to support the refinement of the conceptual system associated with directly proportional distribution problems (example: linear function, percentage, proportion, variation, etc.). The situation explores a context that is close to the student, encouraging the construction of a generalizable mathematical model that can be transferred to diverse contexts. For the design, the principles of the Models and Modeling perspective (Lesh and Doerr, 2003) were considered. The target population were students enrolled in the first semesters of a university degree in Accounting. For the analysis, we considered the construction of models (performed in teams); the mathematical representations within the process observed (such as diagrams and tabular organizations); as well as the individual solutions of the students.

Keywords: Model-Eliciting Activities, Models and modeling, Distribution problems

Objectives and purpose of the study

Distribution problems may represent an opportunity for college students to delve into mathematical notions related to the multiplicative conceptual system. Researchers such as Martínez-Juste, Muñoz-Escolano and Oller-Marcén (2019) consider that distribution problems have gained relevance in recent years because they can explore a diversity of contexts close to the reality of the students.

The multiplicative conceptual system associated with distribution problems elicit fundamental ideas of mathematics, that´s why it is present in the curricula from elementary education to high school. In Mexico, these kind of problems are introduced in the third grade of elementary school (SEP, 2017) and, in subsequent years, variants of these problems are developed where notions such as: proportionality (direct and inverse), linear function, percentage, ratio, linear equation, rational number, proportion, variation and arithmetic progressions. According to Sánchez-Ordoñez (2013), distribution problems allow on the one hand, to shape reason, proportion and proportionality as mathematical objects that contribute to the understanding and mastery of the multiplicative conceptual field by students, and on the other hand, to identify the way in which ratios, proportions and proportionality are recognized and manipulated by students in classroom situations (p. 71,72).

Based on this, the intention is to answer the question: Which are the cycles of understanding that emerge in undergraduate students when they are solving a distribution MEA? In order to develop a possible answer, we present the analysis of the solutions for a situation which was solved by a group of students enrolled in the first semester of a degree in Accounting at the School of Economics, Accounting and Administration of our institution (UJED), with the intention of eliciting the notion of proportionality and to develop integrated knowledge in order to connect and refine the associated conceptual system. It should be noted that the activity was led by the teacher who is also the author of this article.

The Models and Modeling perspective (Lesh and Doerr, 2003) was fundamental for the theoretical framework. The proposed activity was designed as a MEA. Thus, the proposed situation aims to promote the construction of a reusable and generalizable model that provokes mathematical understanding in students in order to achieve the objective of refining and eliciting concepts

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

associated with the multiplicative conceptual system; such as those associated with algebra (ratio, linear variation, function, etc.) as the ones associated with statistics (percentage, frequency tables, etc.). This activity is part of a sequence of activities which were aimed at achieving the course objectives, however, in this paper only the scope of the distribution MEA will be mentioned.

The analysis presented includes the solution interpretation of the student's productions that emerged during the problem solving process where the student used mathematical resources available in order to build a model that can be generalized to solve similar but varied situations.

The Models and Modeling Perspective (PMM) as a theoretical framework

This perspective was developed by Lesh and Doerr (2003) and proposes the resolution of problematic situations endowed with a real context, which can be approached from the particular, taking, as a starting point, the previous knowledge that each participant may have. Through the socialization of the solution proposals, the refinement of the solution model that satisfies the requirements of the approach is reached. The MMP considers learning as a process for developing conceptual systems (models), which emerge when students share and analyze situations that have more than one answer, so that the solution is not a number or word. The problems addressed should encourage students to describe, argue and explain the solution processes used. Doerr (2016) explains that learning mathematical content is a process of developing an adequate and productive model that could be used and reused in a certain range of contexts.

The MMP considers that learning mathematics is a process that includes progressive construction of understanding cycles, modification, extension and refinement of ways of thinking where the subjects manage to elicit a mathematical concept or construct at different levels by relating data, goals and the possible routes of solution they are exposed to when facing a problematic situation (Lesh and Doerr, 2003). Therefore, the product of learning is the process in which the fluidity of mathematical representations allows for the understanding of most of the mathematical constructions (Lesh and Doerr, 2003).

In MMP, the ADM or MEA are proposed as a way to generate products that go beyond short answers to specific questions. MEA allow students to get involved in an interactive and iterative process where they express, test and redefine their ways of thinking about significant problem situations (Doerr, 2016). Therefore,,the meaningfulness of the context provokes new mathematical understanding in the students, which allows them to express, in their procedures, their current knowledge that can come from their experience and/or their previous mathematical knowledge.

MEA must comply with the six design principles established by Lesh, Hoover, Hole, Kelly, and Post (2000) which are: reality or personal meaning, construction of the model, self-evaluation, model externalization or model documentation. simple prototype and model generalization.

The characterization of understanding cycles exposed by Vargas-Alejo, Reyes-Rodríguez and Cristóbal-Escalante (2016) was used for the analysis of the model construction process. The researchers propose a characterization based on their interpretation of the MMP in which they identify cycles (qualitative, quantitative and algebraic) that emerge when individuals approach contextualized situations. Understanding cycles is also associated with eliciting a mathematical construct or concept, which is why, for example, in a *qualitative understanding cycle* the individual gives meaning to the situation where the problem develops and can identify the variables involved, as well as the possible relationship between them. However, in order to express this relationship the individual only elaborates verbal descriptions, diagrams, analogies or metaphors. In contrast, in a *quantitative understanding cycle* the individual makes assumptions, discards useless information and may establish a quantitative meaning of linguistic expressions by making numerical comparisons, for this, the student may use tabular and graphical representations which leads to a more elaborate interpretation of the situation. When the individual seeks to describe and interpret a phenomenon through the construction, use, transit and coordination of different representations (tabular, graphic, verbal, etc.) where there is fluency between them and algebraic symbols can be manipulated to solve a situation, then he has reached the *algebraic understanding cycle*. Researchers agree that, in order to reach the last cycle, it is possible for the individual to pass through different interpretations of the situation and, previously, has managed to differentiate, integrate and refine different models.

Design studies

Within design research there are multiple methodologies and theoretical perspectives in education and other fields. Some researchers consider that process and tangible products (didactic sequences, associated conceptual systems, etc.) are involved in the design (Hjalmarson and Lesh, 2008). However, intangible products formed during the process are also relevant, since the objective of this methodology is to improve the design processes and, consequently, to obtain different results both within the process and the product.

The design of this experiment is composed of three phases: preparing for the experiment, experimenting in the classroom and conducting retrospective analyzes of the data generated during the implementation with the students (Cobb & Gravemeijer, 2008). This type of study aims to develop particular forms of learning while studying the learning obtained in the designed environments.

Investigation method

The target population, the context and the data collection techniques, as well as the theoretical and methodological tools for its analysis, are described below.

Study population

The activity presented was implemented in a group of 36 students enrolled in the first semester of studies for a degree in accounting and whose ages ranged between 18 and 20 years of age. In previous sessions, the members had solved a modeling activity, so they already had experience in dealing with this type of situation. The implementation of the activity required 4 sessions of one hour each.. During the implementation, data was collected through photographs, video, and student logs.

The participants were organized into nine teams made up of four members each. The activity was solved as a team and, later, the solution reached was socialized in a group discussion. In a final production, the students submitted an individual solution to the problem. The role of the teacher was key throughout the process, asking key questions to the students aimed at deepening the solution model reached.

Description of activities

The design and characterization of the models developed during the implementation were based on the MMP theoretical framework. To familiarize the students with the context of the situation, the "warm-up" activity is presented (Figure 1), which consisted of reading a newspaper article and a subsequent group discussion to clarify possible doubts regarding the understanding of the context. The MEA (Figure 2) was then presented, which addressed a problem related to the context of the reading. These activities are described below, accompanied by the image of the worksheets.

Warm-up activity (Figure 1). It had the aim of introducing the context from real and current data to sensitize students to the problem and motivate them to resolve the profit sharing situation in the ADM (Figure 2).

Model Eliciting Activity: Income Distribution. In this activity (Figure 2), the situation shows a sister and brother (Alondra and Paco) who decide to start a business together where the tasks they would perform are divided equally. However, the time that Alondra spends doing her tasks represents eight times more than what her brother Paco dedicated to his tasks. The situation also takes into consideration that Paco contributed a little more than half of the initial investment. This has given rise to the dilemma of how to distribute the income; therefore, the brother and sister have decided to ask for help so that the students have to propose solutions for the distribution of the profits.

Figure 1: Warm-up activity

PROBLEMA 3

Para comenzar su negocio de pasteles, Alondra y Paco habían invertido $800.00 pesos, de los cuales Paco había aportado $455.00 y Alondra $345.00 y, desde el principio, ambos hermanos habían comenzado trabajando tanto en la elaboración como en la venta. Sin embargo, negocio de pasteles había crecido, por lo que consideraron necesario dividir el trabajo, Paco se dedicó a calendarizar los pedidos, cobrar y entregar los pasteles, mientras que Alondra se encargó de comprar los ingredientes, hacer los pasteles y decorarlos. Paco tenía varios conocidos que habían probado los pasteles elaborados por Alondra, por lo que no tardó en comenzar a calendarizar los pedidos de pasteles y pastelitos. Los pedidos quedaron así:

Pedidos

- Para el Lunes debía entregar dos pasteles para el cumpleaños de Jorge
- Para el martes debía entregar seis pasteles para la cafetería "El encuentro"
- Para el miércoles debía entregar un pastel y una docena de pastelitos o cupcakes para el cumpleaños de Regina
- Para el jueves debía entregar 20 pastelitos o cupcakes para el babyshower de Sofi
- Para el viernes debía entregar 2 pasteles y 62 cupcakes para el cumpleaños del jefe de Raúl

Pedidos semanales

Al finalizar la semana, Alondra estaba muy cansada pues, por cada cuarto de hora que Paco había destinado a la venta, ella había dedicado 2 horas al proceso de preparación de los pasteles.

Ayuda a los hermanos a llegar a una forma de repartir las ganancias entre ambos. Puedes tomas como base la información que se te presenta y analizar las posibles maneras de dividir las ganancias entre ambos, también puedes buscar maneras alternativas de repartir las ganancias, sin embargo debes sugerir la que consideres mejor y justificar el por qué. Considera que Alondra y Paco continuarán con su negocio de pasteles, por lo que las condiciones pueden variar, por ejemplo, puede que haya veces que Paco trabaje más horas que Alondra o que Alondra decida invertir más dinero en la empresa.

Redacta una carta donde expliques cual es la manera que sugieres para la repartición de las ganancias, justifica las razones que te llevaron a concluir esto y realiza una comparación de los beneficios que conlleva esta repartición en comparación de las otras.

Figure 2: MEA income distribution

Results

In this section, students' productions are analyzed during the resolution of the proposed activities, first in a team and then in a group discussion. The characterization of the understanding cycles of Vargas-Alejo, Reyes-Rodríguez and Cristóbal-Escalante (2016) was used for the analysis of the construction process of a model that responds to the situation presented in the MEA exhibited by the students.

Understanding cycles

The warm-up activity (Figure 1) introduced the context. It was during the implementation of the MEA (Figure 2) were the students put into evidence the understanding cycles they went through, as well as the concepts and representations that emerged from their previous individual knowledge. The interaction with their teammates allowed to observe, in the written procedures, the solution model for income distribution. The observations made are briefly explained below.

Qualitative understanding cycle. This cycle took place after the students read the problem. In it, they selected the data that they considered important for the resolution of the ADM and discarded the information that they considered irrelevant. For example, within the data shown in student procedures is the division of labor. This data was part of the writing of the ADM; however, the information does not follow the arrangement in the document that allows for the visual comparison of the quantities. Therefore, the order where a visual comparison can be made of the data selected as relevant to the situation was notable in the students' productions. This allowed us to identify a qualitative approach to solving the problem.

Quantitative understanding cycle. After the students made a qualitative comparison of the selected information, they decided to make different mathematical representations in the construction of a solution model. Among the procedures exhibited, the following was observed:

Circular diagrams. The implicit use of percentages is shown to designate the proportion of the graph that corresponds to a category as a percentage of investment or time dedicated to a task.

Arithmetic representations. For the calculation of the fourth proportional, the students used the algorithm known as the “rule of three”. For example, this procedure allowed them to find the percentage proportion corresponding to the initial contribution of Paco and Alondra.

Tabular representation. The evidence shows the tabular organization where the linear variation was related, the arithmetic progression and the search for the unit value. This representation was used by teams 1 and 2. It shows the use of rational numbers and the designation of time units (hours); the teams used this to be able to identify and compare the time that each member dedicated to their tasks.

Algebraic understanding cycle. The evidence written by the members shows algebraic representations of linear functions.

Solution models formalization prior to group discussion

Students were asked to give a short presentation regarding their solution. All the teams presented their solutions. The solutions presented show: the distribution of the income taking into account each partner’s investment proportion; the time spent on their tasks; or a mix of both elements to decide the fairest distribution, taking into account some other characteristics such as the difficulty of the tasks.

Group discussion of solutions achieved by the teams

It was during the group discussion of the results by the team that a refinement of the model was observed. The group presentation and discussion allowed the students to appeal to mathematical representations that emerged during the understanding cycles and allowed, not only to support and argue about the solution model reacheds, but also to construct other representations that had not emerged in the models achieved by the teams.

Table 2 summarizes some of the procedures shown, the mathematical concepts that emerged, as well as their representations.

Table 1 Results of the implementation of the distribution activity

Cycles	Representation	Procedures	Mathematical concepts
Qualitative	Verbal		Comparison
Quantitative	Arithmetic	Fourth proportional calculation Use of the circular diagram to represent quantities (investment and time worked).	Fraction Reason Proportion Percentage Proportionality
	Diagrams	Arithmetical progression Frequency	
	Tabular	Use of algebraic symbolism	Constants and variables Value unit Dimensional Unit
Algebraic	Algebraic	Use of algebraic symbolism	Linear function

Source: Our own elaboration based on Vargas-Alejo, Reyes-Rodríguez and Cristóbal-Escalante (2016)

Discussion and conclusion

As a design study, a first conclusion is that the activity complies with the design of a MEA by verifying that it satisfies the design principles established by the researchers Lesh, Hoover, Hole, Kelly, and Post (2000). The topics addressed in the modeling tasks documented in this article have interested students who have been involved in developing a solution that contrasts with the situation raised to validate it and, later were able to refine it in more than one cycle of understanding. The transition between the qualitative, quantitative, as well as the algebraic cycles was observed in the procedures carried out by the participants during the implementation of the activity. However, the researchers Vargas-Alejo, Reyes-Rodríguez and Cristóbal-Escalante (2016) mention: "conceptual understanding or understanding is not achieved through a linear process [...] there may be intermediate understanding cycles between the previous cycles, which indicate a transition between cycles and involve an incomplete development of the differentiation, integration and refinement phases" (p. 70). Figure 3 shows an example regarding the transit between cycles of understanding, in this case, students are between the cycle of quantitative and algebraic understanding since they identify a "formula" to generalize the possible solutions for the distribution of profits, however, the expression used is not algebraic.

◦ Los 2 Recursos que en este caso se invierten en el negocio de la Repostería son: El Tiempo y El Dinero.

Como sabemos 800$ es la inversión total, Alondra invirtió 345$ ósea un 43.125% y Paco 455 un 56.875%

Cuando alondra trabaja 2 horas, Paco apenas trabaja 15 minutos, en términos de porcentajes

Alondra hace 87.5% del trabajo mientras que Paco un 12.5%

Y si se siguiera una de las 2 escalas, la repartición de la ganancia seria muy desigual, porque al pagarle según su inversión, Paco recibiría mas dinero solo por haber invertido mas y no trabajar casi nada en comparacion, mientras que si se hiciera la repartición en cuestión del tiempo invertido Alondra recibiría mucho mas que Paco e incluso Paco terminaría perdiendo dinero.

Por lo tanto la mejor opción es realizar un promedio entre ambos parámetros con la siguiente formula

(%de aportación + %de Tiempo)/ 2 Para así realizar una proporción Ideal

Figure 3: Evidence of transition from the quantitative to algebraic understanding cycle

EXPERIENCIA EN EL AULA PARA EL DESARROLLO DE MODELOS PARA EL REPARTO

REPORT OF A CLASSROOM EXPERIENCE FOR THE DEVELOPMENT OF DISTRIBUTION MODELS

María José Aviña González
Facultad de Ciencias Exactas UJED

Angelina Alvarado Monroy
Facultad de Ciencias Exactas UJED

Este escrito presenta el diseño y análisis de una Actividad Detonadora de Modelos (ADM), la cual pretende apoyar el refinamiento del sistema conceptual asociado a los problemas de reparto directamente proporcional (ejemplo: función lineal, porcentaje, proporción, variación, etc.). La situación explora un contexto cercano al estudiante alentando a la construcción de un modelo matemático generalizable y transferible a contextos diversos. Para el diseño se consideraron los principios de la perspectiva de Modelos y Modelación (Lesh y Doerr, 2003). La población objetivo fueron estudiantes inscritos en los primeros semestres de la carrera de Contador Público. En el análisis se consideraron la construcción de modelos (realizada en equipos); las representaciones matemáticas dentro del proceso observados (como diagramas y organizaciones tabulares); al igual que las soluciones individuales de los alumnos.

Objetivos y propósitos del estudio

Los problemas de reparto pueden representar una oportunidad para que los estudiantes universitarios profundicen en nociones matemáticas vinculadas con el sistema conceptual multiplicativo. Investigadores como Martínez-Juste, Muñoz-Escolano y Oller-Marcén (2019) consideran que los problemas que plantean una situación de reparto han tomado relevancia en los últimos años debido a que pueden explorar una diversidad de contextos cercanos a la realidad de los estudiantes.

El sistema conceptual multiplicativo asociado con los problemas de reparto vincula ideas fundamentales de las matemáticas, es por ello que está presente en la currícula desde la educación inicial hasta la educación media superior. En México, este tipo de problemas son introducidos a partir del tercer año de educación básica (SEP, 2017) y, en los años subsecuentes, se desarrollan variantes de dichos problemas donde se abordan nociones como: proporcionalidad (directa e inversa), función lineal, porcentaje, razón, ecuación lineal, número racional, proporción, variación y progresiones aritméticas, entre otros. Según Sánchez-Ordoñez (2013) los problemas de reparto permiten «por un lado, dar forma a la razón, la proporción y la proporcionalidad como objetos matemáticos que contribuyen al entendimiento y dominio del campo conceptual multiplicativo por parte de los estudiantes, y por el otro, identificar la manera como son reconocidas y manipuladas las razones, las proporciones y la proporcionalidad por los estudiantes en situaciones de aula» (p. 71,72).

Dado lo anterior, se pretende dar respuesta a la pregunta: ¿Cuáles son los ciclos de entendimientos que emergen en los estudiantes de nivel superior al resolver la ADM de reparto? En aras de elaborar una posible respuesta, se presentará el análisis de las soluciones para la situación planteada y, la cual, fue resuelta por un grupo de estudiantes inscritos en los primeros semestres de la carrera de Contador Público en la la UJED con la intención de profundizar en la noción de proporcionalidad y desarrollar conocimientos que se integren para conectar y refinar el sistema conceptual asociado. Cabe señalar que la actividad fue dirigida por el docente quien también es el autor de este artículo.

La perspectiva de Modelos y Modelización (Lesh y Doerr, 2003) fue fundamental para el marco teórico, dado que la actividad de reparto propuesta, fue diseñada como una ADM. Así, la situación planteada pretende promover la construcción de un modelo reusable y generalizable que, a su vez, provoque entendimiento matemático en los estudiantes para alcanzar el objetivo de refinar y profundizar en conceptos asociados al sistema conceptual multiplicativo; tanto aquellos asociados al álgebra (razón, variación lineal, función, etc.) como a la estadística (porcentaje, tablas de frecuencia, etc.). Esta actividad forma parte de una secuencia de actividades las cuales estaban encaminadas a lograr los objetivos del curso, sin embargo, en este escrito sólo se mencionarán los alcances de la ADM de reparto.

El análisis que se presentará comprende la interpretación de los procedimientos de solución que surgen entre los estudiantes durante la resolución del problema al hacer uso de los recursos matemáticos dispuestos a su alcance para construir un modelo que pueda generalizarse para resolver situaciones similares pero variadas.

La Perspectiva de Modelos y Modelación (PMM) como marco teórico

Esta perspectiva fue elaborada por Lesh y Doerr (2003) y propone la resolución de situaciones problemáticas dotadas de un contexto real, las cuales, pueden ser abordadas desde lo particular tomando, como punto de partida, los conocimientos previos que cada participante pueda tener. El refinamiento se lleva a cabo mediante la socialización de las propuestas de solución donde se alcanza un modelo de solución que satisfaga los requerimientos del planteamiento. La PMM considera al aprendizaje como un proceso de desarrollo de sistemas conceptuales (modelos), los cuales emergen cuando los estudiantes comparten y analizan situaciones que tienen más de una respuesta, por lo que la solución no es un número o palabra. Las problemáticas abordadas deben alentar a los estudiantes a describir, argumentar y explicar los procesos de solución empleados. Doerr (2016) explica que el aprendizaje de un contenido matemático surge durante el proceso de desarrollo de un modelo adecuado y productivo el cual puede ser usado y reusado en cierto rango de contextos.

La PMM considera que aprender matemáticas es un proceso que comprende ciclos progresivos de construcción de entendimiento, modificación, extensión y refinamiento de formas de pensar donde los sujetos logran profundizar en un concepto o constructo matemático a distintos niveles al relacionar datos, metas y posibles rutas de solución expuestos al enfrentar una situación problemática (Lesh y Doerr, 2003). Por lo tanto, el producto del aprendizaje es el proceso durante el cual la fluidez de las representaciones permite entender la mayoría de las construcciones matemáticas (Lesh y Doerr, 2003).

Dentro de la PMM se proponen a las ADM o MEA como una manera de generar productos que vayan más allá de respuestas cortas a preguntas específicas. Las ADM permiten a los estudiantes involucrarse en un proceso interactivo e iterativo donde expresan, prueban y redefinen sus maneras de pensar respecto a situaciones problemáticas significativas (Doerr, 2016), de esta manera, al estar en un contexto significativo, provocan entendimiento matemático nuevo en los estudiantes permitiéndoles expresar en sus procedimientos su conocimiento actual el cual puede provenir tanto de su experiencia como de su conocimiento matemático previo.

Las ADM deben cumplir con los seis principios del diseño establecidos por Lesh, Hoover, Hole, Kelly, y Post (2000) los cuales son: significado de la realidad o personal, construcción del modelo, auto-evaluación, externalización del modelo o de documentación del modelo. prototipo simple y generalización de modelos.

La caracterización de los ciclos de entendimiento expuesta por Vargas-Alejo, Reyes-Rodríguez y Cristóbal-Escalante (2016) fue utilizada para el análisis del proceso de construcción de modelos. Los investigadores proponen una caracterización a partir de su interpretación de la PMM en la cual identifican ciclos (cualitativo, cuantitativo y algebraico) que surgen cuando los individuos abordan situaciones contextualizadas. Los ciclos de entendimiento también están asociados con la profundización de un constructo matemático o concepto, es por ello que, por ejemplo, en un *ciclo de entendimiento cualitativo* el individuo da sentido a la situación donde se desarrolla el problema y puede llegar a identificar las variables involucradas, así como la posible relación entre ellas, sin embargo, para expresar dicha relación sólo elabora descripciones verbales, diagramas analogías o metáforas. En contraste, en un *ciclo de entendimiento cuantitativo* el individuo elabora supuestos, descarta información que considera inútil y puede llegar a establecer cuantitativamente el significado de expresiones lingüísticas haciendo comparaciones numéricas, para ello, puede llegar a utilizar representaciones tabulares y gráficas lo que conlleva a una interpretación más elaborada de la situación. Cuando el individuo busca describir e interpretar un fenómeno a través de la construcción, utilización, tránsito y coordinación de distintas representaciones (tabulares, gráficas, verbales, etc.) fluidez entre ellas y puede manipular símbolos algebraicos para resolver una situación, entonces ha alcanzado el *ciclo de entendimiento algebraico*. Los investigadores coinciden que, para poder alcanzar el último ciclo, es posible que el individuo haya pasado por diferentes interpretaciones de la situación y, previamente, haya logrado diferenciar, integrar y refinar distintos modelos.

Estudios de diseño

Dentro de la investigación del diseño se encuentran múltiples metodologías y perspectivas teóricas en la educación y otros campos. Algunos investigadores consideran que, tanto el proceso como los productos tangibles (secuencias didácticas, sistemas conceptuales asociados, etc) están involucrados en el diseño (Hjalmarson y Lesh, 2008). Sin embargo, también son relevantes los productos intangibles formados durante el proceso, puesto que el objetivo de esta metodología es mejorar los procesos de diseño y, en consecuencia, a resultados diferentes tanto dentro del proceso como en el producto.

Es importante considerar en el experimento de diseño las tres fases: prepararse para el experimento, experimentar en el aula y realizar análisis retrospectivos de los datos generados durante la implementación con los estudiantes (Cobb & Gravemeijer, 2008). Este tipo de estudios pretende desarrollar formas particulares de aprendizaje mientras se estudia el aprendizaje provocado en los ambientes diseñados.

Método de investigación

Enseguida se describe la población objetivo, el contexto y las técnicas de recolección de datos, así como las herramientas teórico metodológicas para su análisis.

Población de estudio

La actividad presentada fue implementada en un grupo de 36 estudiante inscritos en los primeros semestres en la carrera de Contador Público y cuyas edades oscilaban entre los 18 y 20 años de edad. En sesiones anteriores, los integrantes habían resuelto una actividad de modelación, por lo que ya contaban con experiencia para abordar este tipo de situaciones. La implementación de la actividad requirió de 4 sesiones con duración de una hora cada uno. Durante la implementación, los datos fueron recolectados mediante fotografías, video y bitácoras de los estudiantes.

Los participantes fueron organizados en nueve equipos compuestos por cuatro integrantes cada uno. La actividad fue resuelta en equipo y, posteriormente, la solución alcanzada se socializó en una discusión grupal. En una última producción, los estudiantes entregaron una solución individual al problema. El rol del docente fue clave durante todo el proceso realizando preguntas clave a los estudiantes encaminadas a profundizar en el modelo de solución alcanzado.

Descripción de las actividades

El diseño y la caracterización de los modelos desarrollados durante la implementación se sustentaron en el marco teórico de la PMM. Para familiarizar a los estudiantes con el contexto de la situación planteada se presenta la actividad calentamiento (Figura 1) que consistía en la lectura de un artículo de periódico y, su posterior discusión grupal para esclarecer posibles dudas respecto a la comprensión del contexto. Acto seguido se presentó la ADM (Figura 2) la cual abordaba una problemática relacionada con el contexto de la lectura. A continuación, se describen dichas actividades acompañadas de la imagen de las hojas de trabajo.

MÉXICO ES EL PAÍS DE LA OCDE QUE MÁS HORAS LABORA

Unas 2,255 horas al año es el promedio, mientras que Alemania es la nación con la cifra más baja entre los miembros de la organización, pero una de las más productivas.

La cultura laboral actual sostiene que cuántas más horas se trabaja, mejor será el sueldo percibido. Este no es el caso de México, uno de los países miembros de la OCDE donde los profesionales dedican más horas de trabajo semanales y reciben a cambio sueldos muy por debajo del promedio. Es por esto que cada día más trabajadores buscan mejorar sus condiciones salariales a través de nuevos empleos o emprendimientos propios.

Esta situación, sumada a la cantidad de trabajadores informales que existen en nuestro país (que alcanzan los 30 millones), genera inestabilidad y disconformidad en los profesionales mexicanos. Para cambiarlo, es necesario un control de la normativa laboral existente y la generación de nuevas políticas que alienten a las empresas y compañías a generar una mayor retribución por productividad y brindar beneficios de acuerdo a los intereses de cada trabajador.

Las estadísticas muestran que México es el país donde más horas se trabaja de la OCDE y el de peor sueldo promedio (los profesionales cobran, en promedio, 1 dólar por hora)

Mientras el ingreso salarial de una familia de cualquier otro país de la OCDE es más del doble

De acuerdo con el Foro Económico Mundial (WEF, por sus siglas en inglés), "las diferentes actitudes culturales y los factores socioeconómicos juegan un papel clave en la cantidad de horas que los empleadores esperan de los trabajadores".

Figura 1:Actividad de calentamiento

PROBLEMA 3

Para comenzar su negocio de pasteles, Alondra y Paco habían invertido $800.00 pesos, de los cuales Paco había aportado $455.00 y Alondra $345.00 y, desde el principio, ambos hermanos habían comenzado trabajando tanto en la elaboración como en la venta. Sin embargo, negocio de pasteles había crecido, por lo que consideraron necesario dividir el trabajo, Paco se dedicó a calendarizar los pedidos, cobrar y entregar los pasteles, mientras que Alondra se encargó de comprar los ingredientes, hacer los pasteles y decorarlos. Paco tenía varios conocidos que habían probado los pasteles elaborados por Alondra, por lo que no tardó en comenzar a calendarizar los pedidos de pasteles y pastelitos. Los pedidos quedaron así:

Pedidos

- Para el Lunes debía entregar dos pasteles para el cumpleaños de Jorge
- Para el martes debía entregar seis pasteles para la cafetería "El encuentro"
- Para el miércoles debía entregar un pastel y una docena de pastelitos o cupcakes para el cumpleaños de Regina
- Para el jueves debía entregar 20 pastelitos o cupcakes para el babyshower de Sofi
- Para el viernes debía entregar 2 pasteles y 62 cupcakes para el cumpleaños del jefe de Raúl

Pedidos semanales

Lunes, Martes, Miércoles, Jueves, Viernes, Sábado, Domingo, Notas

Al finalizar la semana, Alondra estaba muy cansada pues, por cada cuarto de hora que Paco había destinado a la venta, ella había dedicado 2 horas al proceso de preparación de los pasteles.

Ayuda a los hermanos a llegar a una forma de repartir las ganancias entre ambos. Puedes tomas como base la información que se te presenta y analizar las posibles maneras de dividir las ganancias entre ambos, también puedes buscar maneras alternativas de repartir las ganancias, sin embargo debes sugerir la que consideres mejor y justificar el por qué. Considera que Alondra y Paco continuarán con su negocio de pasteles, por lo que las condiciones pueden variar, por ejemplo, puede que haya veces que Paco trabaje más horas que Alondra o que Alondra decida invertir más dinero en la empresa.

Redacta una carta donde expliques cual es la manera que sugieres para la repartición de las ganancias, justifica las razones que te llevaron a concluir esto y realiza una comparación de los beneficios que conlleva esta repartición en comparación de las otras.

Figura 2: ADM Reparto de ganancias

Actividad de calentamiento. Expuesta en la Figura 1 con el objetivo de introducir el contexto desde datos reales y actuales para sensibilizar a los estudiantes respecto a la problemática y motivarlos a resolver la situación de reparto de ganancias en la ADM (Figura 2).

Actividad Detonadora de Modelos: Reparto de ganancias En esta actividad (Figura 2) se plantea una situación en la cual dos hermanos (Alondra y Paco) quienes deciden iniciar juntos un negocio donde las tareas que realizarían están dividas a la por igual, sin embargo, el tiempo que Alondra le dedicada a las tareas que realiza representa ocho veces más del dedicado por su hermano Paco. La situación también contempla que, al momento de realizar la inversión inicial, Paco aportó un poco más de la mitad de dicha inversión. Lo anterior ha dado pie a la disyuntiva de cómo repartir las ganancias, por ello, los hermanos han decidido pedir ayuda para que los estudiantes propongan soluciones de reparto de las ganancias.

Resultados

En este apartado se analizan las producciones de los estudiantes durante la resolución de las actividades propuestas, primero en equipo y, posteriormente, la discusión de las mismas de manera grupal. Para el análisis del proceso de construcción de un modelo que dé respuesta a la situación presentada en la ADM exhibido por los estudiantes, se utilizó la caracterización de los ciclos de entendimiento de Vargas-Alejo, Reyes-Rodríguez y Cristóbal-Escalante (2016)

Ciclos de entendimiento

La introducción del contexto se llevó a cabo con la actividad de calentamiento (Figura 1). Fue durante la implementación de la ADM (Figura 2) cuando los estudiantes pusieron en evidencia tanto los ciclos de entendimiento por los que atravesaron, como los conceptos y representaciones que surgieron desde su conocimiento individual previo. La interacción con sus compañeros de equipo permitió observar, en los procedimientos escritos, el modelo de solución para distribuir las ganancias. A continuación, se explican, brevemente, las observaciones realizadas.

Ciclo de entendimiento cualitativo. Este ciclo tuvo lugar después de que los estudiantes leyeron el problema. En él seleccionaron los datos que consideraron importantes para la resolución de la ADM y desecharon la información que consideraron irrelevante. Por ejemplo, dentro de los datos que muestran en los procedimientos de los estudiantes está la división de trabajo. Estos datos formaban parte de la redacción de la ADM, sin embargo, la información no sigue la disposición en el documento que permita la comparación visual de las cantidades, por ello, fue notable en las producciones de los estudiantes el orden donde puede hacerse una comparación visual de los datos seleccionados como relevantes en la situación. Lo anterior, permitió identificar una aproximación cualitativa a la solución del problema.

Ciclo de entendimiento cuantitativo. Después de que los estudiantes realizaron una comparación cualitativa de la información seleccionada, decidieron realizar distintas representaciones matemáticas en la construcción de un modelo de solución. Dentro de los procedimientos exhibidos se observaron:

Diagramas circulares. se exhibe el uso implícito de porcentajes para designar la proporción de la gráfica que corresponde a una categoría como porcentaje de inversión ó tiempo dedicado a una tarea.

Representaciones aritméticas. Para el cálculo del cuarto proporcional los estudiantes utilizaron el algoritmo conocido como “regla de tres”. Por ejemplo, este procedimiento les permitió encontrar la proporción porcentual correspondiente a la aportación inicial de Paco y Alondra.

Representación tabular. La evidencia muestra la organización tabular donde la variación lineal fue relacionada, la progresión aritmética y la búsqueda del valor unitario. Esta representación fue utilizada por los equipos 1 y 2. En ella se muestra el uso de números racionales y la designación de unidades de tiempo (horas), los equipos la utilizaron para poder identificar y comparar el tiempo que cada integrante le dedicaba a sus tareas.

Ciclo de entendimiento algebraico. Las evidencias escritas por los integrantes muestran representaciones algebraicas de funciones lineales.

Formalización de los modelos de solución previa a la socialización en grupo

Se les pidió a los estudiantes que realizaran una presentación corta respecto a su solución. Todos los equipos expusieron sus soluciones, entre ellas se encontraron: repartir la ganancia tomando en cuenta la proporción de la inversión entregada por cada socio; el tiempo dedicado a sus tareas; o bien, una mezcla entre ambos factores para decidir la repartición más justa tomando en cuenta algunas otras características como dificultad de las tareas.

Socialización de las soluciones alcanzadas por equipos

Fue durante la socialización de los resultados por equipo donde se observó un refinamiento del modelo. La exposición y discusión grupal permitió que los estudiantes recurrieran a representaciones matemáticas que surgieron durante los ciclos de entendimiento y permitieron, no sólo, sustentar y argumentar respecto el modelo de solución alcanzado en el equipo, también dio paso a la posibilidad de construir otras representaciones que no habían surgido en los modelos alcanzados por equipo.

En la Tabla 2 se resumen algunos de los procedimientos mostrados, los conceptos matemáticos que emergieron, así como las representaciones.

Tabla 2 Resultados de la implementación de la actividad de reparto

Ciclos	Representación	Procedimientos	Conceptos matemáticos
Cualitativo	Verbal		Comparación
	Aritmética	Cálculo del cuarto proporcional	Fracción
Cuantitativo	Diagramas	Uso del diagrama de circular para representar cantidades (inversión y tiempo laborado).	Razón Proporción Porcentaje Proporcionalidad
	Tabular	Progresión aritmética Frecuencial	Constante y Variables Valor unitario Unidad dimensional
Algebraico	Algebraica	Uso de simbolismo algebraico	Función lineal

Fuente: Elaboración propia con base en Vargas-Alejo, Reyes-Rodríguez y Cristóbal-Escalante (2016).

Discusión y conclusión

Al ser un estudio de diseño una primera conclusión es que la actividad cumple con el diseño de una ADM al verificarse que satisface los principios de diseño establecidos por los investigadores Lesh, Hoover, Hole, Kelly, y Post, (2000). La temática abordada en las tareas de modelación documentadas en este artículo han interesado a los estudiantes y se han involucrado para desarrollar una solución que contrastan con la situación planteada para validarla y, posteriormente, la retoman para refinarla en más de un ciclo de entendimiento. Se observó, en los procedimientos llevados a cabo por los participantes durante la implementación de la actividad, el tránsito entre los ciclos cualitativo, cuantitativo, así como algebraico. Sin embargo, aquí se encuentra también lo que Vargas-Alejo, Reyes-Rodríguez y Cristóbal-Escalante (2016) mencionan: «la comprensión o entendimiento conceptual no se logra por medio de un proceso lineal […] pueden existir ciclos de entendimiento intermedios entre los ciclos anteriores, los cuales señalan un tránsito entre ciclos e involucran un desarrollo incompleto de las fases de diferenciación, integración y refinamiento». (p. 70). La Figura 3 muestra un ejemplo respecto al tránsito entre ciclos de entendimiento, en este caso, los estudiantes se encuentran entre el ciclo de entendimiento cuantitativo y el algebraico puesto que identifican una "formula" para generalizar las posibles soluciones de reparto de ganancias, sin embargo, la expresión utilizada no es algebraica.

- Los 2 Recursos que en este caso se invierten en el negocio de la Repostería son: El Tiempo y El Dinero.

Como sabemos 800$ es la inversión total, Alondra invirtió 345$ ósea un 43.125% y Paco 455 un 56.875%

Cuando alondra trabaja 2 horas, Paco apenas trabaja 15 minutos, en términos de porcentajes

Alondra hace 87.5% del trabajo mientras que Paco un 12.5%

Y si se siguiera una de las 2 escalas, la repartición de la ganancia seria muy desigual, porque al pagarle según su inversión, Paco recibiría mas dinero solo por haber invertido mas y no trabajar casi nada en comparacion, mientras que si se hiciera la repartición en cuestión del tiempo invertido Alondra recibiría mucho mas que Paco e incluso Paco terminaría perdiendo dinero.

Por lo tanto la mejor opción es realizar un promedio entre ambos parámetros con la siguiente formula

(%de aportación + %de Tiempo)/ 2 Para así realizar una proporción Ideal

Figura 3: Evidencia de tránsito del ciclo de entendimiento cuantitativo al algebraico

CONSTRASTING SOCIAL AND SOCIOMATHEMATICAL NORMS OF TWO GROUPS OF STUDENTS IN A POSTSECONDARY PRECALCULUS CLASS

This paper characterizes the engagement of two groups of students in a Precalculus course at a four-year public university. A set of "Multiple Solutions Activities" was designed for the course to expose groups of students to alternative solution methods, allowing instructors to explicitly negotiate productive norms to foster students' flexible knowledge. Over the duration of the semester, the groups developed contrasting social and sociomathematical norms. One group's norms seem to be particularly influenced by students' experience taking the same course the prior semester in a more traditional format.

Keywords: Post-Secondary Education, Precalculus, Instructional Activities and Practices

Purpose

Many developmental mathematics courses, like College Algebra or Precalculus, tend to emphasize remedial content coverage and practicing procedures (Cox, 2015; Grubb, 2013; Mesa et al., 2011). This may not require students to change their mathematical practices and habits that contributed towards some students' need for further mathematical background development (Carlson et al., 2010; Goudas & Boylan, 2013). Consequently, some researchers have suggested focusing on developing students' argumentation skills and reasoning strategies (Chiaravalloti, 2009; Partanen & Kaasila, 2014).

One way to do this is to provide opportunities for students to compare, reflect, and discuss multiple solution methods (Rittle-Johnson & Star, 2007). This has been shown to help develop flexible knowledge, which Star and Rittle-Johnson (2008) characterize as the awareness of multiple problem-solving strategies and when to use them. However, students with underdeveloped mathematical skills often prefer a dependent learning style focused on mastering algorithms, making it necessary for instructors of developmental courses to negotiate productive norms, and promote mathematical practices that can help students develop flexible knowledge.

We conducted a teaching experiment in a Precalculus class at a four-year public university, in which the course instructor (first author of this paper) negotiated such productive norms and practices with the students. Specifically, the instructors attempted to aid the development of students' flexible knowledge by negotiating the social norm that it is important to understand others' work and the sociomathematical norm that an acceptable solution is one that follows any mathematically valid approach. In this paper, we analyze two groups' in-class engagement to answer the following research question: What social and sociomathematical norms developed in these groups over the semester?

Framework

Our study is framed within the emergent perspective, which views psychological and social factors as necessary to characterizing classroom activity. Continual student and teacher interactions formulate mutually established and regulated activity, which constitute norms (Cobb et al., 2001). Social norms portray the classroom participation structure, whereas sociomathematical norms are those specific to mathematical aspects of students' activity (Yackel & Cobb, 1996). Social constructs are reflexively related to psychological constructs (See Table 1). For example, as students develop sociomathematical norms they reorganize their mathematical values and beliefs, while productive social norms support students' positive perspectives of communal mathematical activity.

Table 1: Modified Interpretive Framework (Yackel & Cobb, 1996)

Social Perspective		Psychological Perspective
Classroom Social Norms	$\leftrightarrow$	Beliefs about one's own role, others' roles, and the general nature of mathematical activity in school
Sooicomathematical Norms	$\leftrightarrow$	Mathematical values and beliefs

Data Sources and Methods

The data were collected in a post-secondary Precalculus class of about eighty students at a four-year public university. This is the only developmental mathematics course offered by the university, and is largely populated by students who intend to major in engineering or the physical sciences, but who did not meet the pre-requisite for enrolling in Calculus. In the semester of our study, the majority of the students enrolled in the course were retaking it because they did not attain the necessary score to advance to Calculus. The instructor and teaching assistant for the course were Mathematics Education Ph.D. candidates, who previously taught this course multiple times, but not in the semester preceding this study.

Multiple Solutions Activities were designed to expose students to a variety of solution strategies, while creating opportunities for students to critique and analyze mathematical arguments. The activities were intended for groups of three or four students. Each activity had three phases. First, students solved a mathematics problem and cooperatively constructed a grading key for it. Second, students used their grading key to evaluate three fictitious students' solutions to the same problem. These solutions contained errors and/or used different approaches than those previously discussed in class (see Fig. 1-2). After analyzing these sample solutions, students were given reflection questions to compare and contrast the solutions. The last phase was a class discussion facilitated by the instructors, which helped them respond to students' concerns and bring attention to various aspects of the solutions. This allowed the instructors to model practices and explicitly negotiate norms such as: an acceptable mathematical solution may follow any mathematically valid approach and that solutions must contain explanations. Four such activities were implemented throughout the semester, and served as a key data source for the study.

Additionally, students participated in a pre- and post-course survey, which asked questions about their mathematical and role beliefs. Each item used a four point Likert scale to assess student's agreement with (1 – Disagree, to 4 – Agree) or importance of (1 – Not Important, to 4 – Very Important) given claims. For example: "The most valid ways of solving a problem are the ones discussed in class," and, "To receive full credit, my solutions must use the same methods used in class." These items aimed to assess students' openness towards other approaches, a theme the instructors advocated for to support the development of students' flexible knowledge.

Another data source was weekly writing prompts, in which students were asked to reflect on various topics such as their individual mathematical beliefs and practices. Several students were interviewed during and/or at the end of the semester to expound on their written responses.

Analysis

We analyzed video data by classifying students' utterances and activity into categories within the interpretive framework (Table 1) and coded videos in conjunction with students' written original solutions, grading keys, and evaluations of the sample solutions. Particular attention was given to characterizing the sociomathematical norm of what constitutes an acceptable mathematical solution and the social norm of interpreting others' solutions. Similarly, students' individual responses to writing prompts were partitioned into meaning units (Tesch, 1990) and classified into categories within the interpretive framework.

In this paper, we focus on the analysis of two groups of students. Group 1 included Albert, Dwayne, Gordon, and Harry, and Group 2 was composed of Molly, Steve, Peter, and Chad (all names are pseudonyms). One of the primary reasons for choosing these two groups was that three of four students in Group 1 were taking the course for the first time whereas all of the students in Group 2 were taking the course for the second time.

The survey data were analyzed by item, using a paired t-test (JMP refers to this as a Matched Pairs test). The pre- and post-survey were paired using a non-identifying code, which students created when completing the surveys. Pre-course surveys' that did not have a matching code in the post-course survey pool, and vice versa, were not included in the analysis. In total, we analyzed 42 students' surveys, of which 26 reported taking the course in a previous semester.

Results

The quantitative analysis revealed that over the duration of the semester, in general, students developed beliefs that were supportive of developing flexible knowledge. But the qualitative analysis revealed major variations in students' perceptions, which could be seen in the norms developed in various groups of students. This was particularly evident in Group 1 and Group 2's interactions with Multiple Solutions Activities, as we will show below.

Survey Results on Flexibility

Table 2 shows the results of two survey items that assessed students' beliefs associated with flexible knowledge, both of which demonstrate a statistically significant change.

Table 2: Flexibility Survey Items and Paired T-test Results, n = 42 (1- Disagree, 4-Agree)

Question	*Pre-Mean*	*Post-Mean*	*Prob < t*
The most valid ways of solving a problem are the ones discussed in class.	2.88095	2.54762	0.0058
To receive full credit, my solution must use the same methods used in class.	2.14634	1.8297	0.0178

The decrease in mean scores suggest that students came to assign less value to following specific procedures, and view it as having less influence on receiving full credit for their work. This suggests improved openness to learning about multiple solution approaches. This change was not homogenous across all students in the class, as the next sections show.

Norms developed in Group 1

Social Norms. One of the most evident social norms that developed within this group during the Multiple Solutions Activities, was the importance of interpreting and understanding others' solutions. As the semester progressed, the students spent increasing effort to analyze the provided solutions to understand and evaluate novel approaches and to find errors in them. Even when the group to initially criticized novel approaches, this did not detract from their efforts to interpret a new method.

Another social norm that developed in this group is the importance of all group members' participation in collaboratively discussing each solution and their evaluation of it. The group exhibited a shared responsibility group to explain what they understood about each solution and to help clarify confusion to each other when possible. When analyzing novel solutions, group members would verbally share their confusion with one another. Naturally, not all group members were uniformly vocal. To accommodate Albert's introverted demeanor, the group would often ask for his opinion on the solutions to integrate him into the group discussions. The group demonstrated that they valued each other's concerns, questions, and suggestions.

Sociomathematical Norms. We provide one vignette of Group 1's typical work that depicts the characterization of their sociomathematical norm of what constitutes an acceptable solution. During the last Multiple Solutions Activity of the semester, on the topic of inverse trigonometry, as Group 1 formed their grading rubric, they explicitly expressed awareness that there are different ways to solve the problem besides their chosen method. Harry described reluctance to form a rubric that would be limited to only one familiar way of solving:

Harry: I don't know if there is another way to solve it, so I don't want to write [grading] rules.

As they looked at the sample solutions, the group was initially dismissive of "Jennifer's" solution (Figure 2-b), which utilized right triangle trigonometry with the angle $u = sin^{-1}\left(\frac{1}{2}\right)$. This represented a novel approach that the group was unfamiliar with.

Gordon: This person is doing some weird math.
Dwayne: What did you do here? What kind of [stuff] is this? How the [heck] did you get to that?

Their lack of familiarity with her solution was obviously discomforting to them. But, despite these initial reactions, the group continued to investigate.

Gordon: [Jennifer] didn't find the inverse sine, so. They never even solved for u.
Harry: She's saying this is sine of u, this triangle, so then tangent would be opposite over adjacent, so one over one. That's what she's saying … she just didn't do it right.
Gordon: Right, because this should be one half, square root of three over two, and one (pointing to the triangle, and referring to a common right triangle).

Gordon's remark suggested that when using trigonometry, the triangle must have a hypotenuse of one. Gordon did not seem to understand how Jennifer formed her triangle. But, as Dwayne asked questions about Jennifer's approach, he was able to clarify Gordon's misconception.

Dwayne: "a" squared plus "b" squared" is "c" squared. How did [she] get two? (Pointing to the hypotenuse). Oh! [She] did one over two. That's correct though. That's just a different proportion. That is right.

This insight helped Gordon, who eventually located the exponent mistake in Jennifer's solution. After he explained the mistake to the group, he noted:

Gordon: If she did her math right, she actually would have got it, because "a" would have come out as square root of three.
Dwayne: So her process is right … but she just made one mistake. And technically her tangent work is correct for the work.

This particular example demonstrates how the social norm of collaborative analysis of an unknown solution mediated the development of sociomathematical norms within the group. This example demonstrates the group's openness to unfamiliar solutions and the sustainment of their sociomathematical norm of what constitutes an acceptable solution: a solution is acceptable if it follows any mathematically valid method. Conversely, this sociomathematical norm may have influenced the social norm of understanding other's solutions.

Norms developed in Group 2

Social Norms. All students in Group 2 had taken the course the semester prior. As the instructor tried to negotiate productive classroom social norms, this group of students developed their own set of norms that reflected a more traditional mathematics class. One social norm that quickly developed within this group was a rejection of engagement with alternative solutions. This norm was sustained throughout the semester, as the group tried to avoid analyzing others' arguments or investigating different solutions. Instead, the group members tried to finish the activities as soon as possible, did not seek input from or ignored quiet group members. Once finished responding to the reflection questions, the group would often disengage for the rest of the class-period, including whole class discussions, which may have been particularly detrimental to the instructors' efforts of promoting students' flexible knowledge (Rittle-Johnson & Star, 2007). Since student participation in these discussions was not included in the assessment structure of the course, this may have implicitly negotiated less importance or value than other aspects of the course.

Sociomathematical Norms. The instructors attempted to negotiate the sociomathematical norm that an acceptable solution is one that follows any mathematically valid approach, not just a familiar one. However, the group was conflicted with the instructors' negotiations, instead developing an alternative norm: An acceptable solution to a problem is one that uses a familiar approach or leads to the correct answer. The following illustrates this norm.

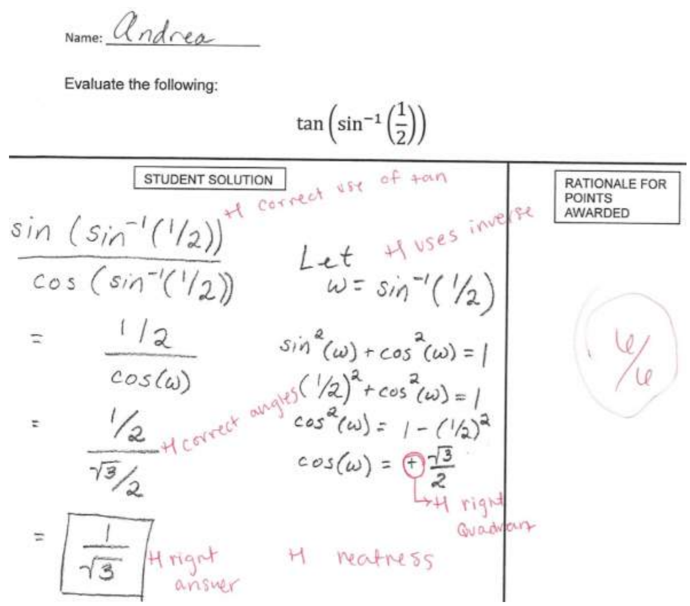

Figure 1: Molly's Grading of Andrea's Solution

During one activity, the group had to evaluate three sample solutions by the fictitious students "Andrea," "Dan," and "Jennifer," and then to compare and contrast these solutions. Andrea's solution used an unfamiliar approach but resulted in the correct answer, Dan's solution followed a method shown in class but had a wrong answer because of an intentionally included error, and Jennifer's solution was both unfamiliar and also yielded an incorrect answer.

The group favored Andrea's solution (Fig. 1), which yielded a correct answer, although it used an unfamiliar method. The group concluded that Andrea's solution was "interesting" and viable, since it "got them the right answer." The students relied on the authority of the answer to determine whether or not the approach was valid, but without thoughtful investigation.

The group was also receptive towards Dan's solution (Fig. 2-a), but for a different reason. Dan's solution resembled the approach the instructor modeled for similar problems. The approach was familiar to the group members, and eventually both Molly and Steve concluded that, "He has everything right except the answer." When students were familiar with a procedure, they were able to recognize patterns and locate errors, unlike in novel solutions like Jennifer's.

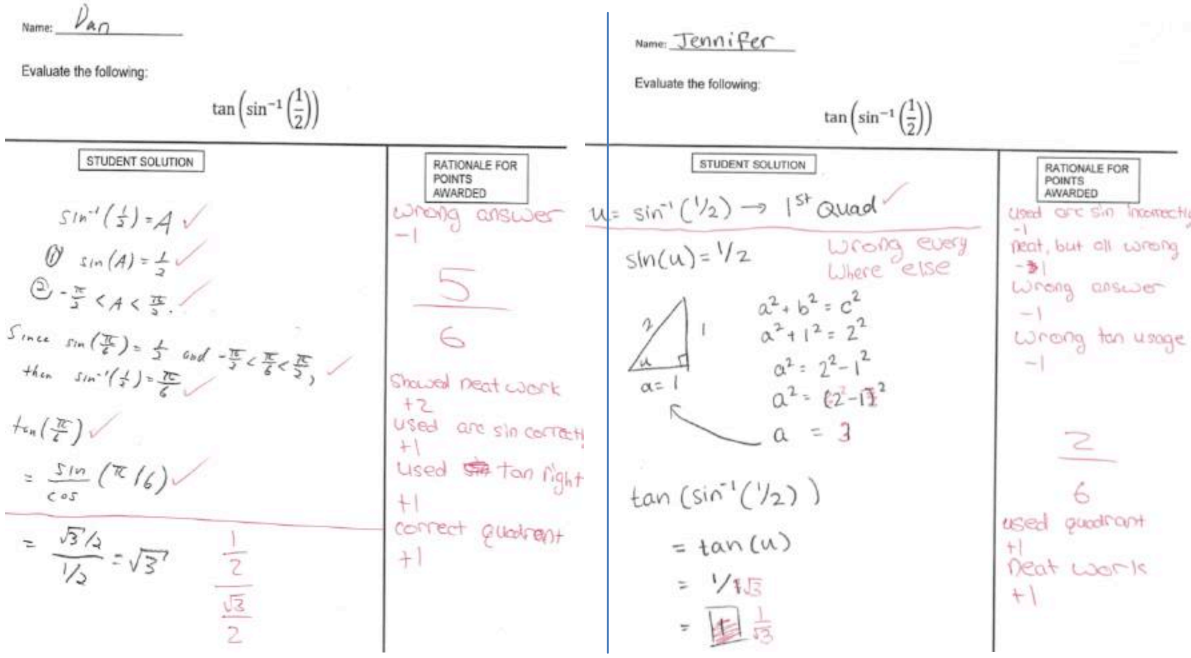

Figure 2 a & b: Steve's Grading of Dan (a) and Jennifer's (b) Solutions

Jennifer's solution (Fig. 2-b) used an unfamiliar approach and resulted in an incorrect answer. The group had a scathing first response towards the solution:

> Steve: Oh God, this already looks bad. Oh yeah, this is real bad. 0 out of 6 … I hope this is not a real student, I really hope.

The only discussion in the group was to determine if Jennifer should earn points for neatness or for "getting the quadrant right." The group did not notice the arithmetic mistakes until the instructor pointed it out to them.

In general, this group did not develop the sociomathematical norms that the instructors advocated and negotiated for. Instead, they chose to focus on the correct answer, as in Andrea's solution (Fig. 1), or a familiar procedure, as in Dan's solution (Fig. 2-a). The former is indicative of intellectual hegemony, relying on authority to determine that an approach is mathematically valid, which hinders the development of students' autonomy. The group's affinity towards familiar approaches coincides with their adopted social norm of aversion to exploring novel solutions. Consequently, they were eager to discredit novel solutions. Without a source of authority or the familiarity of an approach, the group was unable to determine its mathematical validity and vehemently rejected the solution, such as Jennifer's (Fig. 2-b).

Further Differences between the Groups

The two groups described above had varying perspectives, beliefs, and practices, which may help further explain some of the differences in the norms that developed amongst them. Below are some students' written responses to the question whether they found it helpful to learn about different approaches (asked near the end of the semester).

> Dwayne (Group 1):I think it is very helpful to me … I think multiple ways of solving a problem gives me an overall better [perspective] on the problem itself and gives me a better understanding of how it is broken down.
>
> Albert (Group 1): It is also pretty helpful to try different things to prove it in different ways, because this will increase understanding of different methods of proving things which you may find useful in other problems.

Harry (Group 1): I find it very helpful to learn about multiple ways of solving problems. Sometimes when I see a problem approached from a different mindset I can create a mental connection between various concepts or strengthen my knowledge of how a concept works. I also like seeing how you can use seemingly unrelated math concepts to find the solution to a problem.

Molly (Group 2): No, I like to learn one set way to do the problem. The more sets and procedures there are to a problem, the more confusing it can get.

Peter and Chad (group 2) expressed that they liked learning different methods but with the intention of finding a method that was easiest for them to replicate. In general, a common theme in Group 2's responses was their preference to learn and practice through repetition, as was evident in their responses to writing prompts:

Steve: When I am learning math, I heavily rely on seeing something done out in front of me and then having myself try the example myself and try and get the same answer as the example. I will then try more examples that relate towards that problem, I just need to know the answer in the end.

Peter: I also learn from observing, and repetition … I locked myself in a study lounge and kept doing complete the square problems until it came like second nature for me, just kept repeating the steps and applying them to different problems.

Molly: Given problems to do on our own with some way, either discussion or an answer key, we are given a way to check that we are doing it right. I personally like this way because it's repetitive and that's how I learn best in math.

The differences between the two groups manifested themselves in students' attitudes towards instructor's attempts to negotiate productive norms in the course, specifically, the importance of flexible knowledge of mathematics. Group 2 expressed their frustration with the instructor's approach towards teaching the class, which differed drastically from the previous semester:

Steve: Last semester they constantly drilled in our head that there was only one way to do it.
Molly: Yeah. So that's why I feel like a lot of us, or at least personally why I'm struggling.
Steve: It's a lot different.
Molly: I don't have a set rule to follow.

These comments may represent role beliefs that reflect the expectation that the instructor is responsible for abiding by the norms of a traditional mathematics class. Despite the instructor's efforts, most of the Group 2 members' beliefs and practices remained unaffected and staunchly sustained throughout the whole semester. At the end of the semester, Steve reflected:

Steve: Throughout the semester my studying habits have not changed, I have [continued] the same strategy that I used since the beginning, but my grade has started get worse and worse, but I do not believe that it due on my part.

This comment represented a deep-rooted conflict that may explain the nature of the norms that developed in Group 2 in contrast to the instructors' negotiations and expectations.

Discussion

This study examined student engagement in a post-secondary Precalculus course, in which an instructor implemented novel instructional activities and pedagogical strategies. The course and its activities aimed towards negotiating productive social and sociomathematical norms, which were intended to support students' flexible mathematical knowledge.

Our data analysis showed that the intervention produced mixed results. At a large scale, we saw some improvement in students' placing less emphasis on a single solution strategy, and possibly more openness towards multiple solutions (Table 2). Closer examination of student engagement revealed the variability between groups of students, which was evident in social and sociomathematical norms developed in different groups. Group 1 developed a social norm of interpreting and understanding others' solutions, which coincided with development of the sociomathematical norm that an acceptable solution may follow any mathematically valid approach. Meanwhile, Group 2's social norm of aversion to interpret or understand another's work developed concurrently with the sociomathematical norm that an acceptable solution is one with a correct answer or follows a familiar procedure. These data, along with the analysis of the differences between the two groups, suggest that there are several processes in place.

One is the interconnectedness and co-development of social and sociomathematical norms. The emergent perspective (Yackel & Cobb, 1996) emphasizes the reflexive relationships between psychological and social factors (see Table 1). In addition to these connections, our data suggest that social and sociomathematical norms may mutually influence the development of one another. For example, Group 2's sociomathematical norm of an acceptable solution as one following a familiar procedure may have influenced, and may be influenced by, the development of the social norm of avoiding engagement with non-familiar solutions. Thus, we assert that the interpretive framework can be enriched by incorporating this new dimension of reflexivity.

Second, our study demonstrates the lingering effects of detrimental classroom practices and norms. The emergent perspective describes a reflexive relationship between classroom norms and students' beliefs. Although classroom practices and norms dissolve after the conclusion of a course, the norms developed in one course affect students' individual beliefs and practices, which our study shows can persist and act as barriers to the negotiation of different norms and classroom practices in another course. This was particularly evident in Group 2's preference for repeated practice of a single procedure. Although there is value in developing procedural competences, unreflective repetitive practice may result in an illusion of competence. In our study, students seemed to hold onto inefficient practices that constrained their growth in the past, which continued to disservice them in the present. The case of Group 2 shows that changing these beliefs and negotiating productive norms, especially in developmental mathematics courses, is a gradual process. However, the case of Group 1 demonstrates the importance and positive effects of a constructive participation structure to the development of productive sociomathematical norms and improved learning outcomes.

STUDENTS' REASONING ABOUT MULTIVARIATIONAL STRUCTURES

Steven R. Jones

haleypras@gmail.com

Covariation and covariational reasoning are key themes in mathematics education research. Recently, these ideas have been expanded to include cases where more than two variables relate to each other, in what is termed multivariation. Building on the theoretical work that has identified different types of multivariation structures, this study explores students' reasoning about these structures. Our initial assumption that multivariational reasoning would be built on covariational reasoning appeared validated, and there were also several other aspects of reasoning employed in making sense of these structures. There were important similarities in reasoning about the different types of multivariation, as well as some nuances between them.

Keywords: Multivariation, Covariation, Student reasoning, Mental actions

Covariation and the cognitive activities involved in reasoning about it have become important themes in mathematics education research (e.g., Johnson, 2012; Moore, Paoletti, & Musgrave, 2013; Oehrtman, Carlson, & Thompson, 2008; Thompson, 1994; Thompson & Carlson, 2017). Yet, work on *co*-variational reasoning has essentially been limited to examining two variables changing in tandem with each other. Mathematical and scientific contexts often include more than two variables that are potentially related to each other. For example, the quantities pressure, volume, and temperature of a fix amount of gas inside of a flexible container are given by $PV = kT$, where P, V, and T could all be changing simultaneously. Mathematical functions of more than one variable, $z = f(x, y)$, also contain this feature. Note that we use "variable" in this paper to generically mean any potentially varying value, including values of real-world quantities as well as mathematical function inputs and outputs.

Recently, Jones (2018) used the term "multivariation" to theoretically describe situations where more than two variables relate to and change with one another. However, we do not yet have empirical data on the reasoning students might employ in making sense of these situations. This study was intended to explore, open-endedly, types of reasoning students might use when asked to think about multivariation structures. We went into this study with the assumption that multivariational reasoning would be related to covariational reasoning. Thus, our guiding research question was as follows: When analyzed through the lens of previous work on covariational reasoning, what reasoning mental actions are observed in students as they are asked to discuss different multivariational structures?

Background Research on Covariation

Because of our assumption that multivariational reasoning would be closely connected to covariational reasoning, we briefly review here some research work on covariation (see Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Castillo-Garsow, 2012; Johnson, 2015; Thompson & Carlson, 2017). The central theme to this work is that covariation consists of imagining "two quantities [i.e. variables] changing together" (Castillo-Garsow, 2012, p. 55) in which "they are changing simultaneously and interdependently" (Johnson, 2012, p. 315). The work of Carlson et al. (2002) provided the field with a framework of covariational reasoning mental actions, and then the more recent work of Thompson and Carlson (2017) heavily revised this into a new framework. For our purposes, we use the newer framework by Thompson and Carlson, though we draw on one major aspect of Carlson et al.'s original work. In particular, in Carlson et al.'s (2002) original framework,

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

the first mental action of covariational reasoning was (1) coordinating one variable with changes in another. We believe this to essentially mean that students *recognize the dependence* between two variables, in that they perceive a change in one to correspond to a change in another (see also Oehrtman et al., 2008). This first mental action did not find its way into the revised framework by Thompson and Carlson, but it is important to our study because of the connections it has to some of our results.

Beyond this first mental action, we then used the revised framework (Thompson & Carlson, 2017) for the remaining mental actions. These subsequent mental actions are: (2) imagining related, but asynchronous changes in variables (*precoordination*), (3) imagining generic increases/decreases between the variables (*gross coordination*), (4) coordinating the variables' values (*coordination of values*), (5) coordinating changes in variables' values in "chunks" (*chunky continuous*) and (6) imagining changes in the variables' values happening smoothly (*smooth continuous*). These six mental actions were used in our study as baseline codes to categorize and organize student statements, as described in the methods section. We also extended this work by identifying new mental actions pertinent to *multi*variational reasoning.

Multivariation

Multivariation consists of situations where more than two variables are related to and possibly changing in conjunction with each other (Jones, 2018). Conceptual analysis has revealed different possible types of multivariation, which we recap in this section.

Independent Multivariation

Jones (2018) described *independent multivariation* as situations where certain variables can be held constant while others vary. For example, in $F = GmM/r^2$, one can change the distance (*r*) to produce a different amount of force (*F*), while keeping mass (m) constant. Multivariable functions, $z = f(x, y)$, typically also behave in this way. Yet, in independent multivariation, what is held constant and what can change can be switched. In $F = GmM/r^2$ one can keep the distance (*r*) the same to see how *F* and *m* might covary with each other. It is critical to note, though, that independent multivariation is more than simply the covariation of two variables while holding the others constant. Rather, one can imagine *multiple* variables changing at the same time. For example, in $F = GmM/r^2$, r and m could both be changing simultaneously, each impacting how F changes. In $z = f(x, y)$, one could trace a path in $\mathbb{R}^2$ in which both *x* and *y* change at the same time, with *z* changing as one traces along that path (see also Martinez-Planell, Trigueros-Gaisman, & McGee, 2015). Finally, another aspect of this multivariation is that it can include as many variables as desired, such as $z = f(x_1, x_2, \ldots, x_n)$ having *n*+1 variables.

Dependent Mulvariation

Next, Jones (2018) described *dependent multivariation* as situations in which it is *not* possible to hold some variables constant while changing others. A change in any one variable in this situation will produce simultaneous changes in *all* other variables. Some real-world contexts exhibit this behavior (Bucy, Thompson, & Mountcastle, 2007; Roundy et al., 2015), such as $PV = kT$. If the gas inside the flexible container is heated up, the increase in temperature (*T*) would cause simultaneous changes in both the internal pressure (*P*) and volume (*V*). As another example, in free-market economics, if one changes the price of a commodity, both demand and supply will react simultaneously. It may not be realistic or even possible to hold "demand" constant to observe only changes in supply. Similarly, for parametric functions in mathematics, $\langle x(t), y(t)\rangle$, if one changes *t*, then *x* and *y* both change simultaneously.

Nested Multivariation

Third, Jones (2018) described *nested multivariation* as situations where the variables are related in a function composition structure. In the structure $z(y(x))$, as one imagines a change in x, there is a corresponding change in y. That change in y then automatically corresponds to a change in z. It may be necessary sometimes to *perceive* the intermediary variable if it is not explicitly labelled, such as $y = sin^2(x)$ consisting of the quantities x, sin(x), and y. As x changes, sin(x) changes, which in turn makes y change. Of course, it is possible to conceptualize two-variable covariation between x and y directly in this example. However, a complete understanding of their relationship would require interpreting the intermediary sin(x) value (see also Breidenbach, Dubinsky, Hawks, & Nichols, 1992). Otherwise, for instance, if x decreases into negatives, the values of y might not be accurately tracked. Real-world quantities can also have this nested structure. For example, in the theory of relativity, as an object's velocity changes, the object's mass changes, given by $= m_o/\sqrt{1 - v^2/c^2}$. As the velocity (v) changes, the ratio between it and the speed of light (v/c) changes, which in turn changes the Lorenz factor $1/\sqrt{1 - (ratio)^2}$, which in turn changes the mass (m) (see also Jones, 2015).

Study Methods

To document students' multivariational reasoning, we recruited 10 undergraduate students to participate in interviews, referred to as Students A–J. Students E, G, and J were female and the others male. Because our study was exploratory in terms of the types of reasoning students might use, we decided to recruit students who were more advanced in their mathematical studies, to better ensure that they had had exposure to and experience with multivariational contexts. Similar to how Carlson et al. (2002) recruited second-semester calculus students to investigate covariational reasoning, we recruited students in multivariable calculus (from two different classes) to investigate multivariational reasoning. In the interview, the students were given two contexts for each type of multivariation (Table 1). These contexts were chosen for their connection to the conceptual analysis that helped define multivariation (Jones, 2018). For each context, the students were allowed to clarify the context first, and then were asked, "What does this equation/formula mean? What does it say about the variables in it?" The students open-endedly discussed the context, but were also asked several scripted questions, including how the variables related to each other, how changes in one variable impacted the others, whether multiple variables could change at the same time or whether variables could remain unchanged, and what impact increases or decreases in certain variables might imply.

Table 1. Contexts Given to the Students in the Interviews

Multivariation	Context 1	Context 2
Independent	Let $z = x^2 - y^2$ be a function of two variables. [The function's graph was also given to the student.]	The formula $F = \frac{GMm}{r^2}$ relates gravitational force (F) with mass (m) and distance (r). M (Earth's mass) and G are constants.
Dependent	For a certain amount of gas in a flexible balloon, $PV = kT$ relates pressure (P), volume (V), and temperature (T).	The price (p) of a specific book is related to the number of books people want to buy (d for demand) and number of books the publisher is willing to print (s for supply).
Nested	Let $y = \sin(x)$ and $z = y^2$. In other words, $z = \sin^2(x)$.	$m = \frac{m_o}{\sqrt{1-(v^2/c^2)}}$ relates an object's mass (m) to its velocity (v). Note that m_o is the "resting mass" and c is the speed of light.

Our analysis was based on our assumption that multivariational reasoning would be related to covariational reasoning, though also extended beyond it as well. Thus, our initial analysis consisted of using the covariation mental actions described previously as starting codes. We marked any place in the data where a student exhibited reasoning behaviors similar to one of the covariational reasoning mental actions. While we did, we also used open coding to mark any reasoning instances that did not align with one of the covariational reasoning mental actions. After doing so, we examined these "other" reasoning instances in order to identify themes among them. This led to the emergence of new codes that were not a part of the covariational reasoning mental actions. Once we had our final set of codes, we recoded the entire data set again, using our completed coding scheme. Then, within each of independent, dependent, and nested multivariation contexts, we compared the reasoning used across the 10 students. We looked for trends in how the students tended to reason about each multivariation type. We also compared the reasoning used in one type of multivariation with reasoning used in another to identify if certain kinds of reasoning were distinctive to one type of multivariation or common across them.

Results

Our first main result was that the students did, in fact, employ much covariational reasoning within these multivariation contexts, supplying evidence for our assumption that multivariational reasoning is rooted in covariational reasoning. We observed all of the mental actions from Thompson and Carlson (2017) in our students. In fact, as seen subsequently, imagining only two variables at a time was a common and useful action that students did. Space constraints do not permit a full treatment of how each aspect of covariational reasoning was observed, and we instead focus the remainder of our results on reasoning mental actions specific to multivariation.

Students' Independent Multivariational Reasoning

In the independent multivariation contexts, all 10 of our students engaged in reasoning that was related to Carlson et al.'s (2002) first *recognize dependence* mental action. Yet, a slightly different aspect of that reasoning in these contexts was a similar mental action we call *recognize independence*. In this, the students decided which variable was to be treated as constant and which were to vary. For example, one of the first things Student B said when shown $z = x^2 - y^2$ was, "x and y are variables, independent variables. Which basically means as one changes the other doesn't necessarily have to change." In $F = GmM/r^2$, Student C stated, "As I am getting farther from the earth with a bowling ball, I'm not changing the mass of the bowling ball." Recognizing independence then permitted the students to use another new mental action that we call *decompose into isolated covariations*. For instance, when discussing $z = x^2 - y^2$, Student D early on stated, "Whether x is increasing or decreasing… it is going to be increasing the z either way." Then a few statements later, Student D described, "Let's just pretend that the x^2 doesn't exist and we're only playing with the y^2… We see the parabola for y, which is negative, it starts at the origin and then curves down in both directions." Here, Student D simplified the context to two variables at a time in order to understand the covariational relationships between x-z and y-z. After using this mental action to reduce the multivariation to covariation, covariational reasoning mental actions were then used to analyze that relationship between those two particular variables.

In conjunction with recognizing independence and decomposing into covariations, a third new mental action we observed was that students could *switch constants/variables*, in which they shifted their conceptualization of which variables were held as constant and which were allowed to vary. For example, a little after the previous excerpt, Student B explained, "If we follow this path $x = y$, our z stays constant." Similarly, Student C later stated, "Increasing the mass, getting a pebble compared to a rock and having them the same distance from the earth, I have increased the mass but the distance is still the same." These students demonstrated they were able to reason from different perspectives within the same context in terms of what changes or stays the same.

The students were also able to perform mental actions regarding the variables all changing at the same time. We call one such mental action *imagining simultaneous changes in inputs*. In this mental action, two variables were considered the "inputs" and their changes were imagined as linked together *before* then coordinating this with the variable considered to be the output. To illustrate, in discussing $z = x^2 - y^2$, Student H explained, "I could move simultaneously in both an x direction and a y direction. That's going to determine how my z direction is changing… If I'm changing my x and my y at the same time, then z can potentially change as well."

Building on imagining simultaneous changes, another mental action for independent multivariation was what we call *coordinate these multiple simultaneous changes*. For example, in the force context, after Student G had first decomposing into isolated covariations and then subsequently imagined simultaneous changes, she explained, "Say the mass is increasing and the distance is also, r is decreasing, then the force would definitely be increasing." This mental action consists of aligning the results of the isolated covariations together into an overall image of all the variables' changes. Student G also considered the possibility of m and r both increasing or both decreasing. She explained, "If the mass and the distance are both increasing or both decreasing, then it gets a little bit iffy. It depends on which one has a greater impact. [Pause] If m is increasing, at a rate that's greater than the rate at which r^2, the distance squared, is increasing, then the force will still increase." Here we can see Student G comparing the covariations between m and F and r and F. She decided that if m changes by more than r^2, then the positive covariation between m and F will overcompensate for the negative covariation between r and F.

In Student G's explanation, we also see another important mental action. Here, she did a mental action close to what Thompson and Carlson (2017) call *coordinating values*, but she did so without ever using specific numeric values. Thus, from our study, we decided that covariational and multivariational reasoning research would benefit from separating out what we call *qualitative amounts of change* versus *numeric amounts of change*. In other words, Student G was able to *qualitatively* image that the increase in F due to a large increase in m would be larger than the decrease in F due to a smaller increase in r^2. She could have done this by using specific numeric values, but her coordination at the qualitative level was productive for what she wanted to accomplish. We see this mental action as applying to both covariation and multivariation.

Lastly, another new mental action we saw was students attempting to *articulate the type of relationship* present between two or more variables. It appeared helpful for students to determine well-known relationships present between the variables. For example, for $z = x^2 - y^2$ Student I explained, "You maybe pick some value of x and keep it there and then you just basically have $z = c - y^2$. So it's just an upside parabola." Visualizing a parabola helped him think of how z and y would covary with each other. Students used other well-known relationships to assist imagining the situation, such as thinking of F and m as *proportional*, and F and r^2 as *inversely proportional*.

Students' Dependent Multivariational Reasoning

Recall it is not possible to hold some variables constant in dependent multivariation. Thus, an important mental action students used was, again, *recognize independence/dependence*. Yet, the way this mental action was carried out varied from student to student. For instance, in the $PV = kT$ context, Student H explained, "So, if my temperature were increasing… I can think of both my pressure and my volume increasing. The balloon is getting bigger and the pressure inside it is increasing." Here, Student H envisions a dependent relationship between all three variables simultaneously. However, when Student A was asked if T could change so that only P changes, without V changing, he explained, "If you just keep, I mean, is this according to the equation?

According to the equation, then I would say yeah [V can be kept constant], because if V is constant and P increases, then T would increase." Student A did accept that all three could be changing simultaneously, but also observed that in the mathematical equation, one can leave one as constant. These examples illustrate two things. First, whether a context is independent or dependent multivariation consists, at least in part, in how the person *conceptualizes* it. Regardless of how things behave in the "real world," if a student perceives that it is possible to hold some variables constant, then that is the type of situation they cognitively work with. Second, whether the students chose to conceptualize it as independent or dependent multivariation seemed connected with whether they believed they should operate mentally in a "math" world of the symbolic equations, or the way quantities behave in the "real" world.

When students determined that they were in a dependent multivariation situation, they also often decomposed into isolated covariations. But, then, the mental action *coordinate simultaneous changes* became important. For example, after decomposing $PV = kT$ into covariations, Student D stated, "If the balloon is being heated up, then its volume will greatly increase and its pressure will increase a little bit, depending on the capacity of the balloon to contract." He put the individual relationships together into a coherent whole. However, an important difference in dependent multivariation is that the simultaneous nature of the changes is *required*, where it is not required in independent multivariation. This excerpt again shows *qualitative amounts of change*, because Student D imagined relative changes without using exact numeric values. As another example, Student J stated, "If the increasing amount of T is greater than either [the change in] P or V, that means both would be increasing." She realized that if P and V both increase, they could not each increase relatively as much as T does by itself. Of course, students did engage in *quantitative amounts of change*, too, such as Student E examining what possibilities he could get for changes in P and V if temperature changed from "6 to 10."

Like for independent multivariation, in these contexts the students also spent time trying to *articulate the type of relationship* between the variables. For example, several students discussed "proportionality" between V and T, or "inverse proportionality" between P and V. In the supply and demand context, students also used ideas of proportionality and inverse proportionality. Some students tried to create a rough symbolic formula to relate them, which took the forms of $p \propto \frac{d}{s}$ (Student A), $p = k\frac{d}{s}$ (Student B), $p = d - s$ (Student F), and $d = \frac{p}{s}$ (Student H). Note that different relationships can be seen depending on which quantity was seen as changing first. For example, if price is seen to increase first, that might signal a decrease in demand. Alternatively, if demand increases first, that might signal an increase in price. Other students drew graphs of p versus d and p versus s that matched these equations. *Articulating these relationships* seemed to help students organize their thinking about relative changes between the variables. In particular, Student J drew the familiar supply and demand curves (Figure 1) and used them to help her organize her thinking of relative changes. She first imagined that where the decreasing demand curve intersected the increasing supply curve defined the price. An increase in demand was represented as a shift upward in the demand curve, which resulted in an intersection point at a higher supply and higher price (left image). Similarly, an increase in price (right image) resulted in a point lower along the demand curve but higher along the supply curve. This kind of reasoning seems to suggest another possible mental action, *identifying order of effect between variables*.

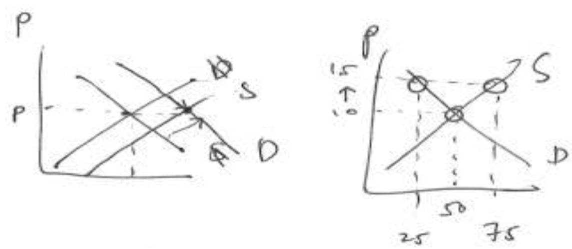

Figure 1: An example of *articulating relationships* helping students organize their thinking

Students' Nested Multivariational Reasoning

For this type of multivariation, as with the other types of multivariation, the students employed mental actions regarding *recognizing* relationships. In this case, the students attempted to *recognize a chain of influence* from one variable to the next. For example, with $z = sin^2(x)$, Student E imagined an intermediary quantity in the chain. She explained, "So, you put the *x* in, the *x* gets sine'd, and then that sine gets squared. So, it goes in like step one, it's turned into a sine, and then step two that sine is squared." Student E recognized that there was (a) the initial *x* value, (b) the sine of that *x* value, and (c) the square of that sine value. In the mass-velocity context, Student E similarly explained, "The velocity is never going to be more than the speed of light. So, this [points to v^2/c^2] is always going to be less than one, which means this [point to $1 - v^2/c^2$] will always be positive. But the more velocity increases, the closer this [points to v^2/c^2] is going to get to one, which means the smaller the denominator [e.g., $\sqrt{1 - v^2/c^2}$] is going to get, which means the larger the mass is going to be. So, the larger velocity gets, the larger mass gets." In this, Student E conceptualized explicitly the quantities (a) v, (b) v^2/c^2, (c) $\sqrt{1 - v^2/c^2}$, and (d) m. Several other students gave similar descriptions of these two contexts.

Once the chain of influence had been recognized, students again often used *decompose into isolated covariations*. To illustrate, as Student B thought about $z = sin^2(x)$ he described, "As x changes, we're going to end up with *y* having this oscillating pattern… between positive and negative one repeatedly. So, as you increase *x*, your *y* is going to be jumping between 1 and –1. If you decrease *x*, same thing… If *y* is positive, as we increase *y*, *z* will go up. If *y* is negative and we decrease *y*, *z* will also go up." Student B first examined *x* and *y* in isolation and then *y* and *z* in isolation. As before, these isolated covariations then needed to be *coordinated* into an overall image of the nested multivariation. Additionally, students also employed coordination of increases and decreases, including both *qualitative amounts* and *numeric amounts*.

Once students had completed mental actions of recognizing a chain of influence, decomposing into isolated covariations, and coordinating increase/decrease, these seemed to help students understand the direct relationship between the "initial input" variable (i.e. *x* and *v*) and the "final output" variable (i.e. *z* and *m*). They could take their new knowledge about the context and begin to work with direct covariation between the initial input and the final output. They did not necessarily need to work with the intermediary variables anymore. For example, after working through the nested reasoning, Student A summarized the velocity-mass context as follows, "As it's [v] changing, so if this gets bigger, then *m* would get bigger as well… So, if this [*v*] increases, *m* would increase and if this [*v*] decreases, *m* would decrease." Thus, one part of understanding nested multivariation structures might be to eventually conceptualize the direct two-variable covariation between the two most salient variables of interest.

As a last note, some students also attempted to circumvent the need for nested reasoning for $z = sin^2(x)$ by instead using visual reasoning on the graph of $\sin^2(x)$. They first took the graph of $\sin(x)$ and attempted to reason what the square of that graph looked like. Once they had a graph (whether correct or incorrect), the students then used that graph to vary x and report directly on its impact on the values of z.

Discussion

First, we observed that covariational reasoning was, in fact, an important part of these 10 students' reasoning. In all three multivariation types, students often *decomposed* the context to two-variable covariations at a time to organize their thinking. However, we note that this decomposition into covariations has connection to what Johnson (2015) termed simultaneous yet independent variation. In her work, she explained that students sometimes covaried two variables with *time* and then tried to coordinate the variables only through the intermediary of time. Johnson concluded that a full comprehension requires students to not need the intermediary of time, and to imagine the variables changing directly in relation to each other. Likewise in multivariation, it may be important for students to push past decomposition into covariations to imagining a single coherent image of the whole multivariational structure. Some of our students were able to compile the individual covariations to create a holistic image of the multivariation.

Next, our study extends covariational work by elaborating on *coordination of values* from the Thompson and Carlson (2017) framework. We suggest it be split into two types of coordination: *qualitative amounts of change* versus *numeric amounts of change*. Our students productively described "large" or "small" changes qualitatively to reason about a context. This mental action certainly goes beyond gross coordination. We even hypothesize that it may even be more complex than simply inserting numeric values into a formula and comparing resulting values (i.e. coordination of values), because it requires one to imagine relative sizes in changing values and coordinate them without the aid of specific numeric values. We perhaps even see chunky continuous coordination (Castillo-Garsow, 2012; Thompson & Carlson, 2017) as just adding intervals of a fixed size to *qualitative amounts of change*. Thus, we wonder if *qualitative change* may be between what is currently described as coordination of values and chunky continuous coordination. Of course, additional work would be required to examine if that is the case.

Third, another key idea from our study is that it requires cognitive work to *recognize dependence* and *independence* among the variables in multivariation. Students spent time imagining what variables could be held constant, which varied, which depended on which, and whether that dependence could be altered. In a recent paper, Kuster and Jones (2019) similarly noticed the importance of "recognize" in students using variational reasoning while discussing differential equations. They claimed that it may have been an oversight to drop "recognize" from the original covariational framework (Carlson et al., 2002) in the new framework (Thompson & Carlson, 2017). Our data concurs that it may be important to keep mental actions of "recognize" in variational reasoning frameworks, because of how important it is for more complicated variational structures. This suggests that in moving our students from covariation to multivariation, it may be useful to spend time engaging students in *recognizing* activities. It is possible we do not help students see, for example, the difference between independent and dependent contexts (see Bucy et al., 2007; Roundy et al., 2015).

Finally, we saw that there was much similarity in the types of reasoning across the different multivariation contexts. The good news is that it might not be necessary for students to learn about each type of multivariation separate from the others. By learning to reason about one type, they may simultaneously be developing reasoning abilities that transfers to other types. However, by being explicit about the different types, we as instructors might help students gain an appreciation for the nuances that exist between each type, enabling stronger reasoning.

"DYSLEXIA IS NATURALLY COMMUTATIVE": INSIDER ACCOUNTS OF DYSLEXIA FROM RESEARCH MATHEMATICIANS

Rachel Lambert
University of California Santa Barbara
rlambert@ucsb.edu

Edmund Harriss
University of Arkansas
eharriss@uark.edu

Using neurodiversity as our theoretical framework, rather than a deficit or medical model, we analyze the narratives of five dyslexic research mathematicians to find common strengths and challenges for dyslexic thinkers at the highest level of mathematics. We report on 3 themes: 1) highly visual and intuitive ways of mathematical thinking, 2) pronounced issues with memorization of mathematical facts and procedures, and 3) resilience as a strength of dyslexia that matters in mathematics. We introduce the idea of Neurodiversity for Mathematics, a research agenda to better understand the strengths (as well as challenges) of neurodiverse individuals and to use that knowledge to design better mathematical learning experiences for all.

Keywords: Equity and Diversity; Advanced Mathematical Thinking; Geometry and Geometrical and Spatial Thinking; Representations and Visualizations

The neurodiversity movement, developed from activism of people with autism, dyslexia, and other cognitive differences, demands that such individuals be understood not as deficient, but as different: part of the natural and beneficial cognitive diversity of society (Robertson & Ne'eman, 2008). Cognitive neuroscience demonstrates evidence of both strengths and challenges for individuals with dyslexia, the largest group of students in the special education system. While some individuals with dyslexia have been highly successful in mathematics, students with LD/Dyslexic score on average lower than their neurotypical peers on mathematics achievement tests, with gaps widening over time (Wei, Lenz, & Blackorby, 2013). However, educational research has focused almost exclusively on identifying and remediating deficits of individuals with dyslexia, with a pronounced silence on how related strengths might matter for learning mathematics. Rejecting a deficit lens on the mathematical thinking of students with dyslexia/LD, we propose Neurodiversity for Mathematics, a research agenda to better understand the strengths (as well as challenges) of neurodiverse individuals and to use that knowledge to design better mathematical learning experiences for this large group of learners.

Using interviews and narrative analysis, this project investigated this issue from the perspective of *neurodiverse insiders* who have experienced learning mathematics with success at the highest levels. Using neurodiversity as our theoretical framework, rather than a deficit or medical model, we analyze the narratives of five dyslexic research mathematicians to find common strengths and challenges for dyslexic thinkers at the highest level of mathematics. We report on three themes: 1) highly visual and intuitive ways of mathematical thinking, 2) pronounced issues with memorization of mathematical facts and procedures, and 3) resilience as a strength of dyslexia that matters in mathematics.

We ground the proposed research in the academic field of Disability Studies (DS), which recognizes that although individuals have natural biological variations, it is the social effects of difference that disable rather than the impairments themselves (Linton 1998). From the DS perspective, the medical model and behaviorist tradition depict disability as deficits located within individuals resulting in identifying, pathologizing, and stigmatizing difference; thus requiring specialized knowledge (e.g., special educators) for individualized instruction and remedy. Academia continually reinscribes difference between children with and without disabilities in an unconscious effort to maintain the status quo, in which children with disabilities are conceptualized as fundamentally different from

“normal children” (Linton 1998). In order to understand and improve the experiences of dyslexic students, we must ground our analysis in the perspectives of those with this difference. This study seeks to provide a new lens on the mathematical learning of neurodiverse individuals, grounded in the experiences of those with cognitive differences, rather than the perspectives of researchers who are often neurotypical. Our study is a collaboration between the first author, a cis white female former math teacher and special educator currently working in mathematics and disability studies at the university level, and the second author, a cis white male research mathematician with dyslexia.

Dyslexia is a hereditary neurobiological disability characterized by difficulties in reading, writing, and spelling, often unexpected in comparison to other academic skills (Lyons et al., 2003). While originally called dyslexia, these differences were reclassified “Learning Disabilities” when Specific Learning Disability became a category of special education services under US law. Learning Disabilities (LD) is a broader category that includes LD in the areas of reading (dyslexia), writing (dysgraphia), and mathematics (dyscalculia), as well as other variants of LD such as Auditory Processing. Individuals can experience LD in multiple areas. What tends to be consistent across LD is some form of processing and/or language difference that significant affects learning in school. A significant population of individuals with LD also have diagnoses of Attention Deficit Hyperactivity Disorder (ADHD). While LD is the term in US law, individuals often prefer the term “dyslexia.” Currently, laws in the US are shifting back towards dyslexia, specifically towards advocacy for multi-sensory, systematic reading instruction. Much of the research in LD and math is focused on students with dyscalculia, or significant difficulty learning mathematics. However, students with LD in general, which is most often most pronounced in reading, significantly underperform in mathematics (Wei et al., 2013).

Currently, there is little overlap between research in mathematics education and special education mathematics research (Lambert & Tan, 2020). These research traditions are largely separate because of pronounced theoretical and methodological differences over their history of development as fields (Woodward 2004). Based on a recent analysis of the literature on mathematics learning across the two fields (Lambert & Tan, 2020), we found that special education primarily understands mathematics learning through behavioral and information processing approaches, using quantitative methods that focus on large populations. In contrast, mathematics education is focused on constructivist and sociocultural approaches to understanding mathematics learning through a focus on individual thinking and classroom contexts. Research methodologies in mathematics education include both quantitative and qualitative methodologies. Special education research frames the achievement gap for students with learning disabilities as a problem of cognitive deficits in individuals and seeks interventions to remediate deficiencies. Recommended interventions are primarily explicit or direct instruction. In previous work, we have critiqued this focus on pedagogies as deficit-based and promoting narratives about students with learning disabilities being unable to learn through inquiry (Lambert 2018). These narratives, which we face continually in schools, are antithetical to the larger goal of increasing access to higher-level mathematics for students with learning disabilities.

There has long been speculation about the connection between dyslexia and visual-spatial talents, dating back to Orton in 1925 (Schneps, Rose, & Fischer, 2007). There is evidence that people with dyslexia have strengths in visual-spatial thinking, although not conclusively. Some of the differences in findings can be attributed to different ways to define and assess visual-spatial thinking (von Károlyi & Winner, 2004). One strength associated with dyslexia in several research studies is 3-D spatial thinking, connected to strengths in mechanics and complex visualization (Attree, Turner, & Cowell, 2009). Another strength is interconnected reasoning; many individuals with dyslexia tend to make unique associations between concepts, focused on the big picture (Everatt, Weeks, & Brooks, 2008). Individuals with dyslexia describe using this strength to analyze large data sets and recognize patterns. Dyslexic students scored higher than nondyslexics for original thinking (Akhavan Tafti, Hameedy, & Mohammadi Baghal, 2009) and creativity for tasks requiring novelty (Everatt, Steffert, & Smythe, 1999). There is evidence that these strengths are neurologically interconnected with the challenges of individuals with dyslexia (Eide & Eide, 2011). This research has been strongly supported by an increasing movement of adults with dyslexia to reject the medical, deficit model of dyslexia.

In studies on successful dyslexic adults (2007), Rosalie Fink has found that while the adults had several developmental pathways to becoming successful adult readers, a consistent thread was the importance of reading in areas that individuals were passionate about. Another pattern in Fink’s findings is that these successful adults continued to have significant early deficits in reading, difficulties with letter switching and decoding, yet were successful readers at a much higher level (both as self-reported and based on reading comprehension assessments). We know of only one study in the area of mathematics that is similar to our work; a collaboration between a mathematics education researcher and an individual with dyscalculia, investigating how the second author developed her own strategies to support learning in an undergraduate mathematics program (Lewis & Lynn, 2018). We believe that collaboration across difference is necessary to develop new understandings of the potential for dyslexic students in mathematics.

Research Questions

1. What have been the experiences and mathematical learning trajectory for individuals with dyslexia in higher mathematics?
2. How do individuals with dyslexia approach mathematics?

Methods

Participants

Participants were recruited using emails to professional organizations of research mathematicians by the second author. All participants were currently employed at universities in mathematics or related STEM departments. Four out of 5 participants reported being actively engaged in current mathematical research, with one participant focused on teaching. 3 out of the 5 participants were diagnosed with dyslexia and/or a reading learning disability during K-12 schooling. Another participant was given a diagnosis later in life related to the diagnosis of a child. Another participant had a diagnosis of a related disability (ADHD) but whose primary difficulty was reading and reading comprehension. Two out of the five participants reported a diagnosis of ADHD, one had significant speech and language delays as a child, and one participant self-identified as autistic. Two out of five participants identified as cis female, with 3 identifying as cis male, however we use the pronoun “they” throughout the document to avoid identification. Four out of 5 participants identified as white or Caucasian, with one Asian-American participant. We identify this lack of diversity as a significant limitation to our work and hope to expand the populations included in future studies. We report data on participants (P1-P5) in the aggregate to avoid identification, as not all participants were comfortable with disclosing their disabilities in the university setting. Thus, we purposefully report themes across the interviewees, rather than describing each individual as a case study. We also use the pronoun “they” to avoid identification of participants.

Data Collection

The first and second author together interviewed each participant for between 60 - 90 minutes. The interview was semi-structured with questions in the following categories: 1) description of current mathematical work, 2) school experiences in mathematics, 3) school experiences and diagnosis of dyslexia, 4) connections between dyslexia and mathematics. Interviews were video-recorded and then transcribed.

Data Analysis

We identified narratives within the interviews based on transcripts. We identified two kinds of narratives. The first was Life History Narratives, more typical retrospective narratives retelling a life event. We also identified a kind of narrative we called Narratives of Thinking, which we define as nontraditional narratives without a set sequence of events, with an experiential description of how it feels to think in a certain way, here related to mathematical thinking and problem solving (Lambert 2019). After identifying narratives, we coded thematically (Riessman 2007) with both apriori and emergent coding. All narratives were coded by the first author with discussion of coding categories with the second author.

There is a tension in our work between identifying commonalities between the participants and making diversity between them quite clear. When we report that 4 out of 5 interviewees noted their own strengths in visual thinking, we are not suggesting that 80% of people with dyslexia are visual thinkers. Our small set of studies is an opportunity to identify some common themes within a small, specific subgroup of the dyslexic population, dyslexic mathematicians. We would need different research to answer questions about how these preferences apply across people with dyslexia more broadly.

Findings

The research mathematicians were working in the following areas of mathematics with multiple participants in some categories: real analysis, three-dimensional geometry, topology, and algebraic topology. The life narratives of these research mathematicians describe a non-direct pathway to becoming a research mathematician. They describe barriers that could have limited their process, such as calculus focused on memorization, or classes such as organic chemistry focused on memorization. All participants noted that they moved forward in mathematics once they reached a place in which they were fascinated by the problems, most often, a visual-spatial set of problems to solve.

All participants described dyslexia as a set of strengths and challenges, although the specifics of those strengths and challenges varied between participants. P4 notes, “the dyslexia... I explain to people, it's sort of like you're strong in one thing, but it makes you weak in others.” Of course, our study attracted individuals who were interested in talking about their dyslexia, which possibly created a group that was more positive about dyslexia than a randomly constructed group. In this paper, we report on three themes: 1) highly visual and intuitive ways of mathematical thinking, 2) issues with memorization of mathematical facts and procedures, and 3) the development of resiliency as a strength.

Theme 1: Highly Visual and Intuitive Ways of Mathematical Thinking

Flexible, creative thinking. All participants noted that they had a history of unusual ways of solving mathematical problems. 4 out of 5 participants described visual thinking quite specifically. 4 out of 5 participants also noted that they were known for flexible, creative, “out of the box” solutions to complex problems. P3 shared that one of their collaborators once described them, saying,

> I talk in ghosts and mists. My brain seems to be really, really comfortable with just throwing out ideas. It just really is very flexible. It doesn't like boxes. It's just very, very flexible. And so, I get a sense that something is true, or something that I want, I need, is there. And then my brain really doesn't get bothered by the fact that some ideas don't work, it just will throw out lots and lots of ideas and sort of wander. And that drives co-authors nuts, because they'll say, "Oh, I see? That idea doesn't work." And it doesn't slow me down one bit. My brain just

> has like five other weird ideas, two of which you can throw out immediately, and the three others you have to spend time on. And it just sort of keeps working that way. (P3)

P1 noted their personal strengths in mathematics as:

> Coming out with the idea that pushes you beyond the routine. So thinking about things, especially a visual or spatial ideas. Questioning and poking at the routine to say how do we express this idea? So sort of coming up with ideas that are not in the routine, especially things that are related to images. (P1)

Visualization. Four out of 5 participants repeatedly brought up visualization as a personal strength in their own mathematical thinking. In multiple interviews, participants described a duality such as "verbal" vs. "visual", or "algebraic" vs. "geometric." Four out of 5 participants identified as visual and/or geometric mathematical thinkers, with P1 noting that they learn through "geometry first, thinking through space" and "I can do immensely technical work in images that others can do in language."

P4 describes a strong predilection for thinking visually, not just in mathematics but across topics; "Well my entire memory is sort of visual, it's like playing back little snippets of film." They became interested in "three-dimensional geometry and topology. Anything that I can draw or sculpt or anything that's like three dimensional and sort of visual-based." Once when struggling in a physics class, they saw a particular image in the text, of vector fields on a surface, and suddenly, the "pictures made it make sense." P4 prefers to not only think with visuals, but to write with them as well, noting a strong preference for storyboarding mathematical papers using a series of images. Another participant also indicated that they chose their mathematical topic based on their preference for visual thinking, specifically "picture drawing and the topology of it" and "I liked the fact that I could pin it down and think about it as something real" (P2). Another participant identified as both:

> A details kind of thinker and like a visual thinker. I can't get interested in the details unless I have the picture that I think I'm working out the details for. But, once I have a picture of what I think should be going on, then the details become interesting . . . It's not the other way around. (P5)

Symmetries and the commutative property. Three out of 5 participants at some point in their interviews suggested their dyslexia may have been connected to a way of seeing mirror images and/or symmetries in geometric shapes and algebraic equations, "Well I think I saw symmetries, I saw equations easily because of it. Because my brain would flip things around very easily. I understood equations quickly and easily because of my dyslexia" (P2). One participant wondered aloud if, "Somehow dyslexic thinking is naturally commutative?" (P1).

All participants noted difficulties with language in relationship to mathematics, each slightly differently. Some discussed primarily issues with communicating visual thinking through language, or through the more linear pathway of writing. One participant described how it was difficult for them to visualize symbols/mathematics when the only modality that is being used is talk.

> P5: This even happens when I'm with mathematician friends and they'll be vocalizing an argument. There's no white board and they'll say, you do this and then you ... Yeah, I'm not necessarily going to follow the point. But, I'll go back to my room later and I'll remember enough of the points that they were trying to make that I'll get it. And, I'm okay with that, I don't have to be as quick witted as some of my colleagues are in mathematics, and I don't mind that.
>
> A: So, it's really different for you if there's paper, or there's a white board?
>
> P5: Yeah, if I can visualize things I'm much better off. Well, is that true? ... I'm pretty good at visualizing, but what I'm not good is transcribing spoken language into notation . . . If someone were to read out loud the definition of continuity for all blah, blah, blah. I would say, "Yeah, that might be right. That might be wrong. I have no idea." So, it's this translation between spoken

> language, and it's kind of linear notation that mathematicians tend to use. I'm not good at that part. I'm good at visualizing geometric things, but not visualizing notation (P5)

This suggests that strengths in visualization may be connected to challenges around translating across different forms of language and/or modalities, particularly from visual thinking into verbal language, or vice versa.

Issues with Memorization of Mathematical Facts and Procedures

None of the participants noted significant difficulties with mathematics in elementary school, with one consistent exception across participants: difficulty with the times tables and/or memorizing mathematical procedures. Some brought this up spontaneously, and for others, they clearly did not connect memorization of facts to mathematics. In this exchange with P2, the first author is asking whether or not they had any difficulties with math in K-12.

> A: Was there any part of math, like in elementary school, middle school, or high school that was challenging for you?
>
> P2: No.
>
> A: So memorization of facts was not challenging for you?
>
> P2: Oh I never could memorize anything. I had to derive everything . . . Yeah, I've never been good at memorizing things, just like I couldn't memorize how to spell words, I couldn't memorize facts in math. So I paid attention in class, and I had good enough teachers that they derived everything. And I figured out how to derive everything I needed to know, and I just derived everything I needed to know. You take a trig class, for instance, okay ... I know the trig identity for sin of alpha plus beta. From that trig identity, I can derive all the other ones. And then if I needed any of them, I would just do that. But I never actually like memorized them. I still don't memorize them.

Similarly, P1 noted that their mother taught the multiplication tables through a smaller set of memorized facts, specifically the squares, and then encouraging P1 to build equations through the distributive property from known facts.

In addition to the multiplication tables, participants noted the difficulty of any kind of memorization “without structure.” P1 notes,

That is one of the reasons I'm slower. I have really good memory for connected facts. I can't remember phone numbers at all. Learning foreign languages was the one bit of school that I hated because you have this long list of words that had no connection to anything. So memorization without structure. So I memorized the structure. (P1)

Another participant noted that they had a history understanding “concepts” in mathematics and struggling with “the details.” When we asked what they meant by details, they told a story about being negatively judged for their lack of memorization of the multiplication tables in elementary school:

> I could've explained to you with a picture why nine times five was 45, and my friends could tell you that it was 45 but they couldn't tell you why. And it struck me as really upsetting that someone that, just memorizing that number, was valued more than me understanding why that was the right answer. And it's always been a problem. But it just seems to me that why something is true is much more important than knowing that it is true. (P3)

Several participants noted that their difficulties with memorization were connected to the expectation of speed connected to memorization. Not only was memorization without structure very challenging, participants were asked to do this task under time pressure, which made it feel impossible.

Theme 3: Developing Strengths Through Struggle

Four out of 5 participants specifically mentioned resilience as a strength of dyslexia. More specifically, participants noted that working through challenges made them more resilient and perseverant, which became a considerable strength for them in higher mathematics. When asked what a strength of dyslexia is, P2 said, “Resiliency, I guess. Just being able to kind of overcome things that are not necessarily the easiest for you.” P5 described their “coping mechanisms”:

> Basically being comfortable with the fact that I'm not going to be fast at a lot of things. And, being okay with not being fast, that's really pretty important because I think that this kind of reading comprehension and fluency stuff. The fluency tests really make you think that speed is the whole deal. And, it was really important for me to sort of realize that no, that's not what matters. (P5)

Success in mathematics, participants noted, comes with hard work. Because math gets hard for almost everyone, understanding what to do when that happens is a gift for a mathematician. As P1 notes,

> Sort of actually everyone is facing struggles. Calculus is hard for most people. And so what we can understand about how people get through it when they have greater struggles is really useful for the people who are having smaller versions of those same struggles. And that notion of motivation ... The point that people who want to do this material but it's really hard for them can do it then surely that's a principle for all education. (P1)

Discussion

This research contributes by challenging the deficit-based approach typically used in educational research with students with dyslexia, thus potentially opening new avenues of educational research that move beyond the medical model of disability which locates LD/dyslexia solely in individual students. While this paper focused on only 3 themes, these findings suggest ways in which we can make math classrooms more accessible for students with dyslexia. We describe these as initial tenets of *Neurodiversity for Mathematics*, and plan future research to both explore insider perspectives further and to test these ideas in the classroom.

1. Offer opportunities for visual thinkers to learn new concepts through visual thinking. Not only provide multiple modalities for learning mathematics, but explicitly connect different kinds of representations. For example, one participant explained how their own mathematics teaching relies on visuals, but also with explicit connections to algebraic representations for those who preferred to think that way.
2. Remove the focus on memorization and procedural learning for students with dyslexia. As P1, who attended school outside of the US, noted;
   The high school calculus in the U.S., I think I wouldn't be a mathematician if I'd taken that because it's so emphasized it's fast, technical things ... And I make a lot of errors when doing calculation, and when you have a test which is multiple choice which is designed to map you into all your errors, I would have got very poor scores (P1).

When mathematics focuses on speed and memorization “without structure,” the potential of those with dyslexia will not be realized in our schools.

WHAT IS A FUNCTION?

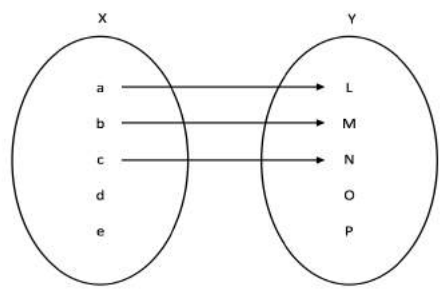
Alison Mirin — Arizona State University — amirin@asu.edu
Keith Weber — Rutgers University — keith.weber@gse.rutgers.edu
Nicholas Wasserman — Columbia University — wasserman@tc.columbia.edu

In the mathematical community, two notions of "function" are used: the set-theoretic definition as a univalent set of ordered pairs, and the Bourbaki triple. These definitions entail different interpretations and answers to mathematical questions that even a secondary student might be prompted to answer. However, mathematicians and mathematics educators are often not explicit about which definition they are using. This paper discusses these parallel usages and the related implications for the field of mathematics education.

Keywords: Curriculum, University Mathematics, High School Education

To frame the discussion of this paper, we invite the reader to answer the following questions that a secondary student might be asked about functions.

1. Does the following diagram represent a function?



2. Is the following set of ordered pairs a function? If so, what is its domain? $\{(-1,4),(0,7),(2,3),(3,3),(4,-2)\}$
3. Is $y = \sqrt{x}$ a function? If so, what is its domain?
4. Is $g(x) = \ln x$ the inverse function of $f(x) = e^x$?
5. Does $g(x) = \ln x$ have an inverse function? If so, what is it?
6. True or false: A function is invertible if and only if it is injective.

Two Definitions Of "Function"

Function is an important concept in mathematics, and students' understanding of function has been the subject of extensive research in mathematics education (Breidenbach et al., 1992; Leinhardt et al., 1990; Vinner & Dreyfus, 1989). Researchers have noted the mathematical definition of function has evolved: Initially, functions were characterized as explicit rules that assigned numbers to other numbers. Over time, the notion of function became more general— a function could take any type of object as its inputs or outputs (e.g., differentiation can be understood as a function that maps differential real-valued functions to other functions)— and *any* correspondence can be a function, regardless of whether the rule for the function can be explicitly stated or not. Finally, the modern treatment of function is usually provided in set theoretic terms (Kleiner, 1989). Research on students' understanding of function often shows that students hold varied conceptions of function that do not align with the formal theory, even when they can state the formal definition of function (Bardini et

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

al., 2014; Leinhardt et al., 1990; Mirin, 2018; Sfard, 1992; Thompson, 1994; Vinner & Dreyfus, 1989).

It is unsurprising that the meaning of function has evolved. The definitions of many mathematical concepts have become more precise and more abstract over time, and several concepts are now defined in structural or set theoretic terms although they were not originally conceived of in this way (Sfard, 1992). Likewise, students often hold different understandings of the same mathematical concept, with their understandings being internally inconsistent or at variance with the formal theory. We might expect there to be an agreed upon modern definition of function - or, absent a uniform definition, that the different definitions that mathematicians use are logically equivalent. Surprisingly, this is not the case. In fact, the different definitions in use do not even yield the same answers on questions that a secondary student might be asked. In this paper, we describe two commonly used definitions of functions in high school and university mathematics. We show that these definitions actually lead to different answers to the six questions that we posed in the beginning of the paper.

One Definition Of Function: The Bourbaki Triple

One treatment of function is that of Bourbaki (1968), which defines a function as a triple (f, A, B), where A and B are sets and f is a univalent and total subset of $A \times B$. That is, for *all* x in A (*total*), there exists a *unique* y in B (*univalent*) such that (x, y) is a member of f. The set A is called the *domain* of the function, B is the *codomain,* and f is the *graph.* We refer to this as the *Bourbaki Triple* function definition, objects of this type as *Bourbaki Triple functions,* and people who use this definition as *Bourbaki Triple people.*

Another Definition Of Function: The Ordered Pairs

Forster (2003) notes, "some mathematical cultures… [say] a function is an ordered triple of domain, range, and a set of ordered pairs. This notation has the advantage of clarity, but it has not yet won the day" (pp. 10-11). Forster then refers to the alternative definition of a function as *any set of ordered pairs f* that satisfies the following criterion: if (x, y_1) and (x, y_2) are in f, then y_1 and y_2 are equal. In this case, the *domain* of f is the set of all numbers x such that there exists some y where (x,y) is a member of f. There is no unique *codomain;* **a** (rather than **the)** *codomain* is any superset of the range of f. We refer to this as the *Ordered Pairs* function definition, objects of this type as *Ordered Pairs functions,* and people who use this definition as *Ordered Pairs people*.

Comparing and Contrasting Definitions

It's worth emphasizing that a Bourbaki Triple function is a different sort of object than an Ordered Pairs function; a Bourbaki Triple function is an ordered triple, whereas an Ordered Pairs function is a set of ordered pairs. Hence, when a Bourbaki Triple person mentions a function, they are referring to a different type of object than that of an Ordered Pairs person. The way someone understands questions or statements about functions will be related to what type of object they understand a function to be – a triple, or a set of ordered pairs.

Dumas and McCarthy (2015), Bourbaki Triple people, assert the following:

> When you write $f: X \to Y$, you are explicitly naming the intended codomain, and this makes the codomain a crucial part of the definition of the function. You are indicating to the reader that your definition includes more than just the graph of the function. The definition of a function includes three pieces: the domain, the codomain, and the graph. (Dumas & McCarthy, 2015, p. 25)

Dumas and McCarthy are correct *if* one is using the convention of a function as a Bourbaki Triple. In this case, "$f: X \to Y$" names the function (f, X, Y) with domain X, codomain Y, and graph f. However, a look at works by authors who use the Ordered Pair notion of function suggests that adopting such notation does not necessitate endorsing the view that a function is an ordered triple (Devlin & Devlin, 1993; Goldrei, 1998; Halmos, 1960; Stoll, 1979). Using the Ordered Pair interpretation, these authors write "$f: X \to Y$" to mean that f is a function with domain X where $f(x)$ is a member of Y for all x in X (that is, Y is **a** codomain of f). Rather than X and Y being *part* of the function itself, they are *attributes* of the function.

We can see how the differences in the notion of function manifest themselves in interpreting a function definition. Consider the following sentence: "Let $f: N \to Z, f(n) = n + 1$". Under the Ordered Pairs definition, the function is the set f=$\{(n, n + 1): n \in N\}$, and this set (function) has the *property* that N is its domain and Z is **a** codomain. Under the Bourbaki Triple definition, the function actually at hand *is* the entire triple (f, N, Z), where f is still the set $\{(n, n + 1): n \in N\}$, the domain is N, and **the** codomain is Z. The important thing here is that in one interpretation, the function is just the set $\{(n, n + 1): n \in N\}$, while in the other interpretation, the function is the entire triple $(\{(n, n + 1): n \in Z\},\ N, Z)$. Now consider the notation "Let $g: N \to N, g(n) = n + 1$." Under the Ordered Pairs definition, the function g is the same as the function f. Under the Bourbaki Triple definition, the function at hand is the entire triple (g, N, N), which is a different triple than (f, N, Z) (as Z is a different set than N).

Notice that the domain of an Ordered Pairs function is not necessarily stipulated; it is derived as a consequence of the graph itself. If f is a function, x is in the domain of f exactly when there exists a y such that (x, y) is in f. For this reason, the only criterion a set of ordered pairs needs to satisfy is being univalent. It does not make sense to ask whether a relation f is "total" in the abstract; one would need to ask if f was total on a specified set. Similarly, it does not make sense to ask if f is "surjective"; one would need to specify a set (codomain) that f might be surjective upon. The notation "$f: X \to Y$" might be used to stipulate such sets, but this notation is not always used.

A sharp difference between the Bourbaki Triple definition and the Ordered Pairs definition relates to invertibility. With the Ordered Pairs definition, the inverse for a function f, denoted by f^{-1}, is the set $\{(y, x): (x, y)\ \in f\}$. This set f^{-1} is a function if and only if f is one-to-one, i.e., f is invertible as a function if and only if it is injective. With the Bourbaki Triple definition, if (f, A, B) is a function, we consider the inverse of the triple to be (f^{-1}, B, A) where f^{-1} is defined as above. In this case, for (f, A, B) to be invertible as a function, more than injectivity is required; the triple (f^{-1}, B, A) must also be a function. This means that f^{-1}must be total on B, requiring that f be surjective onto B. We will revisit this difference later.

How Are Functions Treated In The Literature?

In the mathematics literature, both definitions of function are common. The Bourbaki Triple definition appears in some introductory proof books (e.g., Dumas & McCarthy, 2015) and other domain-specific textbooks, such as Abbott's (2012) textbook on real analysis. On the other hand, the Ordered Pairs definition also appears in some introductory proof textbooks (e.g., Forster, 2003) and in set theory textbooks (e.g., Enderton, 1977; Halmos, 1960; Jech, 2003). Still, other textbooks offer both definitions (e.g. Eccles, 1997). Finally, we will illustrate how others (e.g. Stewart, 2003) are ambiguous.

In the mathematics education literature, we find the Bourbaki Triple definition to be more common. For instance, in their influential review of students' understanding of functions, Leinhardt et al. (1990) refer to the Bourbaki Triple as the modern definition of function that mathematics educators would like their students to master. Other studies have used this definition as their backdrop for what is normatively correct, but they use the *word* "Bourbaki" only, without referring to the internal structure of the triple itself (e.g. Breidenbach et al., 1992; Vinner & Dreyfus, 1989). These authors tend to focus on the arbitrariness of a function as a correspondence rather than as a rule or an equation. Nonetheless, there is variation, and other mathematics educators have adopted the set of ordered pairs definition as their background theory (e.g. Sajka, 2003). Also, it is noteworthy that mathematics educators often describe $g(x) = \ln x$ as the inverse function of $f(x) = e^x$ (e.g. Even, 1990; Mayes, 1994), which seems to suggest the Ordered Pairs definition (discussed below).

In algebra and precalculus texts, we have again found both definitions used. For instance, Hungerford and Shaw (2009) define a function explicitly consisting "of three parts— a set of inputs (called the domain); a rule by which each input determines exactly one output; a set of outputs (called the range)" (p. 155). However, there are also books that define functions as a set of ordered pairs; for instance, Marecek (2017) wrote:

> A relation is any set of ordered pairs (x, y). All the x-values in the ordered pairs together make up the domain. All the y-values in the ordered pairs together make up the range [...] A function is a relation that assigns to each element in its domain exactly one element in the range. (Marecek, 2017, pp. 314-317)

Consistent with the Ordered Pairs definition, Marecek (2017) notes that the domain and range are not specified but derived from the set of ordered pairs, and there is no notion of codomain.

What is especially interesting to us is that some definitions stated in textbooks, and in the education literature, define function in such a way that it is ambiguous as to whether they are using the Bourbaki Triple definition or the Ordered Pairs definition. For instance, consider the way that Stewart (2003) defines functions in his widely used calculus textbook: "A function f is a rule that assigns to each element x in a set D exactly one element, called $f(x)$, in a set E" (Stewart, 2003, p.12).

Stewart's (2003) definition contains an ambiguity. We can either (i) view D and E as part of the meaning of function and/or claim they need to be specified in advance, or (ii) view the statement as an existential statement where f is a function if there exist sets D and E that fit the definition. That is, the definition allows for similar interpretation as the notation "$f: D \rightarrow E$", under both types of function definition (Bourbaki Triple and Ordered Pairs). In the remainder of Stewart's (2003) text, he appears to treat a function as equivalent to its graph (p. 14) and claims all injective functions are invertible (p. 64). He always treats the range and image of a function equivalently and never concerns himself with codomains. He thus appears to be using the Ordered Pairs definition of function.

Not only is there ambiguity in what an author might mean by "function," but there is also ambiguity in what definition the "Bourbaki approach" to functions implies. Selden and Selden (1992) take a function to be a set of ordered pairs: "the formal *ordered pair definition* of function, first introduced in 1939, is often referred to as the *Bourbaki* approach" (p. 2). Based on the preceding discussion, one might think that a "Bourbaki function" is a Bourbaki Triple. However, the above quote illustrates that this interpretation is not so straightforward.

Our main point thus far is as follows: There are two different definitions of function that are not logically equivalent: (i) both definitions are used in advanced mathematics, secondary mathematics, and the writing of mathematicians; and (ii) even when an author defines functions in their text, it can sometimes still be ambiguous as to which definition they are using. In the next section, we discuss how the different definitions entail different interpretations of mathematical questions that a secondary student might encounter.

Revisiting Questions

We address each of the six previously posed questions using the most straightforward interpretation of the two definitions of function above:

1. Consider the diagram in the first question at the start of this paper. A Bourbaki Triple person might interpret the question to be asking if the triple $(\{(a, L), (b, M), (c, N)\}, X, Y)$ is a

function. The answer is "no"; there are members of X that are not assigned a value in Y (the structure is not total). We believe this is regarded as the normatively desired response. However, an Ordered Pairs person might interpret the question to be asking if the set $\{(a, L), (b, M), (c, N)\}$ is a function. Of course the answer is "yes", because it is a univalent set of ordered pairs (assuming *a, b,* and *c* are distinct).

2. This question was taken from Redden (2012), p. 249, Example 2. According to the Ordered Pairs definition, $\{(-1,4), (0,7), (2,3), (3,3), (4, -2)\}$ is a function because it is univalent. Its domain is $\{-1, 0, 2, 3, 4\}$. We believe this is regarded by most as the normatively desired response (as in Redden, 2012; Even, 1990). According to the literal Bourbaki definition, we would say this set is *not* a function, for the simple reason that functions are triples and not ordered pairs; that is, no domain and codomain are stipulated here. If we were less literal, this question would be undefined; we would need to know what domain and codomain were stipulated. It is possible to interpret the question to be asking if there *exists* a domain *D* and codomain *E* such that (f, D, E) is a function, where f is the given set of ordered pairs above. However, we would not expect this interpretation from a secondary student.
   A Bourbaki Triple person can adopt conventions so that their answer to this question agrees with that of an Ordered Pairs person. If a domain is not specified, the domain of a real-valued relation is stipulated to be the largest set of real numbers to which the relation can apply, and if the codomain is not specified, it is assumed to be *R* (in the context of secondary algebra, calculus, or real analysis).
3. According to the set of ordered pairs definition, $y = \sqrt{x}$ is a function. That is, we interpret the function at hand to be the set $\{(x, y) \in R{\times}R \colon y = \sqrt{x}\}$. As this set is univalent, it is a function. We believe this is regarded by most as the normatively desired response. However, interpreting the question using the Bourbaki Triple definition is less straightforward. What object are we asking is a function? If we are stipulating that the domain and codomain are both R, which is arguably a convention in the context of a calculus or real analysis course, then our question is "is $(\{(x, y) \in R{\times}R \colon y = \sqrt{x}\}, R, R)$ a function?" and the answer is a clear "no", since this triple is not total on R. On the other hand, we can interpret the domain to be $[0, \infty)$, the largest domain on which it can be defined. In this case, the answer is "yes", as the triple $(\{(x, y) \in R{\times}R \colon y = \sqrt{x}\}, [0, \infty), R)$ is a function.
4. Using the Ordered Pairs definition, $g(x) = \ln x$ is the inverse of $f(x) = e^x$. That is, the set $\{(x, y) \in R{\times}R \colon y = e^x\}$ has the inverse $\{(x, y) \in R{\times}R \colon y = \ln x\}$, which is a function. We believe this is regarded as the normatively desired response; see, for instance, Stewart (2003, p.67), who defines logarithmic functions as the inverses to exponential functions. However, a Bourbaki Triple person who assumed the convention that the codomain of a real-valued function is *R* unless otherwise stated would assume that the question is asking if $(\{(x, y) \in R{\times}R \colon y = e^x\}, R, R)$ has an inverse function, and such a structure is not invertible as a function because it is not surjective onto R.
5. For similar reasons as in the previous example, an Ordered Pairs person would straightforwardly believe that $g(x) = \ln x$ has an inverse function (it is injective) and its inverse is $f(x) = e^x$, which, as we noted above, we believe is the normatively desired response.
   The Bourbaki Triple person would have a less straightforward answer. If they accept that $g(x) = \ln x$ is a function, then they would interpret it as a function from R^+ to R to ensure that it were total. Now, since *g* is bijective between R^+ to R, *g* must have an inverse. In this case, they would be interpreting "$g(x) = ln\, x$" to name the triple $(\{(x, y) \in R{\times}R \colon y = ln\, x\}, R^+, R)$. However, the inverse is not $f(x) = e^x$ because they would interpret "$f(x) = e^x$" to name the triple $(\{(x, y) \in R{\times}R \colon y = e^x\}, R, R)$, and this function's

codomain (R) is not the domain of $(\{(x,y) \in R{\times}R: y = ln\, x\}, R^+, R)$. The inverse would be the function $h: R \to R^+$defined by $h(x) = e^x$, which is the triple $(\{(x,y) \in R{\times}R: y = e^x\}, R, R^+)$. There is nothing contradictory about this; the Bourbaki Triple definition implies that functions with the same graphs but different codomains are different functions. We only observe that we ordinarily would not expect a student to distinguish between the differing codomains to receive credit for identifying the inverse of $g(x) = ln\, x$.

6. As we noted in the previous section, the Ordered Pairs person agrees that a function is invertible whenever it is injective. The Bourbaki Triple person disagrees, claiming a function needs to be surjective as well. It appears there is no consensus in textbooks or amongst mathematics educators for whether injective functions are necessarily invertible. Some, like Abbott (2012, p. 155) and Stewart (2003, p. 64) assert that all injective functions are invertible. Others, like Mattuck (1999) and Friedberg et al. (1989), claim that injectivity and surjectivity are both necessary.

Two Approaches For Coping With Difference In Mathematics Education

Functions and their inverses are fundamental concepts. Naturally, mathematics educators would like students to develop productive and normatively correct understandings of functions and inverses. However, there are two different ways of defining functions that lead to divergent answers to basic questions from secondary mathematics. For instance, one would hope that there is a straightforward consensus answer as to whether $f(x) = e^x$ is invertible, at least in the context of secondary mathematics, but this is not the case. How, then, is an educator to teach students or evaluate the quality of a student's understanding of functions and their inverses?

There are at least two positions that an educator may adopt: *dogmatism* or *contextualism*. With dogmatism, we can insist that one of the two definitions is *the right definition,* argue that textbook writers and other researchers should use this definition, and regard those who do not act in accordance with this definition as being mathematically sloppy or incorrect. For instance, a Bourbaki Triple dogmatist might insist on using the Bourbaki Triple definition; the Bourbaki Triple dogmatist might call for textbooks to clarify Questions like 2 and 3 in the beginning of the paper to be mathematically accurate. This would involve rewrites such as "is there a set *D* (domain) and a set *E* (codomain) such that $(\{(-1,4),(0,7),(2,3),(3,3),(4,-2)\}, D, E)$ is a function?" If $f(x) = \sqrt{x}$ defines a graph of a function, what could its domain be?"). The Bourbaki Triple dogmatist acknowledges that some textbooks and even some mathematics educators use the ordered pairs definition of function, but that does not mean mathematics educators *should* be flexible with their definition of function. Indeed, it would be unwise policy to draw conclusions about the nature of mathematics based on errors that textbook writers and mathematics educators sometimes make. Similar dogmatism could be recommended by an advocate for the Ordered Pairs definition. We admit that a dogmatist approach has several advantages. For one, it would unify the differential treatment of functions in textbooks and mathematics education literature. Further, it would provide clear normative guidelines for how functions and inverses should be discussed and how students' understanding of these functions should be evaluated.

The alternative approach, *contextualism,* is to declare that there is no universal definition of function, but rather that the definition of function depends on context. Consider the following passage from Dumas and McCarthy's (2015) text in which they justify adopting the Bourbaki Triple definition:

> If you identified the function with its graph, then every function would have many possible codomains (take any superset of the original codomain). Set theorists think of functions this way, and if functions are considered as sets, extensionality requires that functions with the

> same graph are identical. However, this convention would make a discussion of surjections clumsy, so we shall not adopt it. (p. 25)

We highlight three ideas here. First, Dumas and McCarthy acknowledge that there was more than one definition of function that they could have used in their textbook. In particular, they do not say set theorists are wrong for defining a function as a univalent set of ordered pairs. Second, they view the decision on which definition to adopt as their choice. Third, they do not view their choice as arbitrary; they provide a reason justifying their choice; they adopted the Bourbaki triple definition because it made it easier to discuss and reason about surjective functions, which was one of their goals in the textbook.

Similarly, Joel David Hamkins, a mathematician and philosopher from Oxford University, justifies why set theorists like himself prefer to think of functions as ordered pairs for mathematically practical reasons. For instance, Hamkins explains why it is difficult to speak of sequences of ordinals in set theoretic terms using the Bourbaki Triple definition. Responding to a challenge that the concept of function is "imprecise", Hamkins responds:

> Many words lack meaning out of context, while becoming precise in a context. Why should you expect that there is a meaning for this word [function] outside of any context? [...] The function concept *has* been made absolutely precise. In fact, it has been made fully precise twice, in two different ways. Each group prefers to use their own precise definition, for sound reasons. (Hamkins, 2010)

The contextual position, for which we advocate, synthesizes the comments above. The contextualist acknowledges that for mathematicians, everything else being equal, it would be best for the same concept to be defined in the same way across all mathematical contexts and communities. This adds clarity and facilitates communication between different mathematical communities. However, mathematicians consider other factors to consider when choosing a concept's definition. In particular, mathematicians desire that their definitions should facilitate their communication, problem posing, and problem solving. Because the needs with respect to function vary by mathematical community, it is not surprising that different mathematical communities would define the function concept in different ways. The value of uniformity in these cases is not necessarily worth more than the value of utility.

In the case of *function* in secondary mathematics, functions are usually used for purposes of modeling and equation solving. In these cases, the totality of a function tends not to matter. The functions $f(x) = 1/(x^2 + 1)$ and $g(x) = 1/x^2$ are, for the most part, interpreted and acted upon in the same way, even though the former is total while the latter is not. It would be detrimental to the theory to exclude partial functions on R like $g(x) = 1/x^2$ or $h(x) = tan\,x$, and it would be cumbersome to constantly stipulate domains. For these reasons, we think it is prudent for textbooks to ignore the totality of functions in this context, except in the cases where the lack of totality matters. Similarly, inverse functions are generally used to assist in equation solving, graphing, and differentiation. In most cases, the use of inverses does not depend on whether the inverse is total on the codomain of the original function. It would be detrimental to the theory to eliminate inverse functions for functions that are not surjective, and it would be cumbersome to complicate the reasoning by introducing and changing codomains. Textbooks are justified in treating injective functions as always having inverses in this context. However, in other contexts in which non-total functions are not the object of consideration or would needlessly complicate the theory (e.g., group homomorphisms), it makes sense to adopt the Bourbaki Triple definition. Likewise, in contexts in which surjectivity or function composition play a central role, it might make sense to adopt the Bourbaki Triple definition.

We conclude by offering some recommendations to the mathematics education community for their investigations of functions and inverses:

- Be aware that there are two definitions of functions in mathematical practice and that these definitions entail different answers to questions that a secondary student might be asked.
- In research reports, state which conception you have in mind and justify your choice. How did your conception of function allow you to achieve your pedagogical or research goals? If your definition of function was not germane to the study (e.g., you were only focusing on univalence and issues of totality and inverses did not arise), explain that too.
- Avoid being a dogmatist when evaluating research papers. Just because a scholar used a different definition of function than you would prefer does not mean that they are mathematically incorrect. On the contrary, regardless of whether they adopted the Bourbaki Triple definition or the Ordered Pairs definition, they are in good company with many prestigious mathematicians.
- Avoid being a dogmatist when evaluating students. Regardless of whether a student asserted that "every injective function is invertible" or its negation, it would be a mistake to evaluate this comment as mathematically incorrect. It would be more appropriate to look at the reasonings and understandings that the student used to justify their assertion.
- In instruction, it is misleading to assert that mathematical definitions are always universal. There are multiple definitions for mathematical concepts that are not logically equivalent, even in secondary mathematics. Other examples besides functions include natural numbers (does this set include 0?) and trapezoids (is a parallelogram a trapezoid?). Rather than speak in absolutes, we suggest acknowledging that some mathematical concepts are defined in different ways, and to highlight the benefit of the definitional choice in the particular classroom context in question.

UNDERSTANDING THE ROLES OF PROOF THROUGH EXPLORATION OF UNSOLVED CONJECTURES

Jeffrey Pair
California State University Long Beach
Jeffrey.pair@csulb.edu

Gabe Calva
California State University Long Beach
Gabriel.calva@student.csulb.edu

Mathematics majors, including future secondary teachers, should understand the work of pure mathematicians and the crucial role proof plays for the discipline of mathematics. Beyond the textbook proofs seen in most transition-to-proof courses, we conjectured that students might develop a deeper understanding of the discipline of mathematics and proof if they had the opportunity to do mathematical research—to try and prove an unsolved conjecture. As an added component of our transition-to-proof course, we designed an intervention so that students researched the Twin Primes conjecture or the Collatz conjecture. Students wrote reflections about their research and described how their perceptions of mathematics were influenced by the research. We analyzed the reflections and sought to understand how the students' views of mathematics and proof were enriched, if at all, through research on unsolved conjectures.

Keywords: Reasoning and Proof; University Mathematics; Problem Solving; Affect, Emotions, Beliefs, and Attitudes

Mathematics teachers should have a rich understanding of the discipline of mathematics. When a teacher possesses a healthy and informed conception of the discipline, she is well-positioned to pass on productive beliefs about mathematics to her students. Teachers and students benefit from understanding the important thought processes and practices that make mathematics the unique and enjoyable field that it is. But many mathematics majors and school teachers have naïve views of the discipline of mathematics (Pair, 2017; Thompson, 1992). Pair (2017) found that students in a transition-to-proof course were not familiar with conjectures in general and generally unaware of well-known conjectures such as the Twin Primes conjecture.

Students' Understanding of the Function of Proof

Research has shown that many students, even mathematics majors, struggle learning to prove (Bleiler, Thompson, & Krajčevski, 2014). This may be due in part to the fact that students do not experience the functionality of proof in the same way that mathematicians do (de Villiers, 1990). For instance, proof for a mathematician can a be a means to convince other mathematicians that a claim is true. Students may not experience proof in this way if they are only asked to prove textbook exercises which are assumed true from the get go.

De Villiers (1990) described five roles of proof for mathematicians that he conjectured would be productive for students to understand and experience: 1) Verification: Proof serves as a means of knowledge justification that enables mathematicians to obtain conviction that a claim is true; 2) Explanation: Proof provides insight into why a mathematical claim is true; 3) Systematization: Proofs serve to organize the deductive system of axioms, definitions, and theorems; 4) Discovery: Mathematicians make new discoveries through proof; and 5) Communication: A proof is a means by which mathematicians communicate mathematical knowledge.

We believe that a deeper understanding of the roles of proof corresponds to a deeper understanding of the discipline of mathematics. Some researchers have documented the types of course activities (e.g. critiquing classmates' proofs) that may engage students in these roles of proof (Bleiler-Baxter & Pair, 2017; Cilli-Turner, 2017). We conjectured that exploring unsolved conjectures may also provide students an opportunity to deepen their understanding of the discipline of mathematics and experience the functionality of proof as mathematicians do.

Transition-to-Proof Intervention Research Study

We conducted a research study in a transition-to-proof course at a university in Southern California. The course was required for students majoring in either pure mathematics or secondary mathematics education. There were thirty-three students enrolled in this class. Twenty-five of the students agreed to participate in the research project which was approved by our University's Institutional Review Board. Our University is a Hispanic-Serving Institution, and a diversity of races and genders are present in our sample.

As an added component of the course, students explored and invented their own methods to navigate one of two famous mathematical conjectures: either the Twin Primes conjecture or the Collatz Conjecture. Typically attributed to Euclid, the Twin Primes conjecture states that there are an infinite number of twin primes (Rezgui, 2017). Two prime numbers $x < y$ are twin primes provided $y = x + 2$. For instance, 3 and 5 is the smallest twin prime pair. The Collatz conjecture, named for the German mathematician Lothar Collatz, is also known as the $3n + 1$ problem (Bairrington & Okano, 2019). The conjecture concerns an iterative process on natural numbers. Given any natural number n, if n is odd multiply by 3 and add 1; or if n is even, then divide by 2; repeat the process on the resulting natural number; repeat again. The conjecture is that for any natural number, this iterative process will eventually reach 1. For instance, if we take n=3 the corresponding Collatz sequence is 3, 16, 8, 4, 2, 1 (if continued the sequence would cycle 4,2,1, 4,2,1…). These two conjectures have remained unsolved to the present day.

Students in the transition-to-proof course explored these conjectures for an entire semester, documenting their work and reflections in what was called their *mathematicians' notebooks*. Their work in the mathematicians' notebooks accounted for 5% of their course grades. In the first notebook assignment, students were tasked with exploring both the Twin Primes conjecture and the Collatz conjecture. For subsequent assignments, students chose which conjecture they would like to explore. Students were assigned to research teams with other members of the class based on their conjecture preferences.

About half of the students worked on the Collatz Conjecture[1] and half on the Twin Primes conjecture, with some students exploring both. Midway through the semester the students shared their findings with other members of the class. Students drew inspiration from each other and adopted their classmates' approaches in subsequent assignments. Twice during the semester, the instructor collected students' notebooks and provided feedback and direction to guide students in their explorations. One assignment also required the students to watch and reflect on videos of mathematicians addressing their own work on the conjectures.

See Figure 1 for an example of student exploration on the Collatz conjecture from a student's notebook. This student, a Hispanic male, was working backwards from 1, trying to show that all numbers will eventually cycle to 1. His first line shows powers of 2, which obviously will reach 1. For each power of 2, he considered if it was of the form 3n+1 by subtracting 1 from the number and dividing by 3. When he found such a number, he would find the value of n and use it to start a new number line—which started with n and increased by a factor of 2. He wrote "[the pink] represents how a new line in the form of $n \cdot 2^{x}$, where $x \geq 0$ and n is an odd integer, is made by subtracting by 1 and then dividing by 3 by another line in the same form. [The green line] represents the set of natural numbers in order starting from 1." This student recognized that if he could successfully show

[1] Slightly more students worked on the Collatz conjecture than the Twin Primes conjecture.

that every natural number appears in one of the number lines, then he could prove the Collatz conjecture.

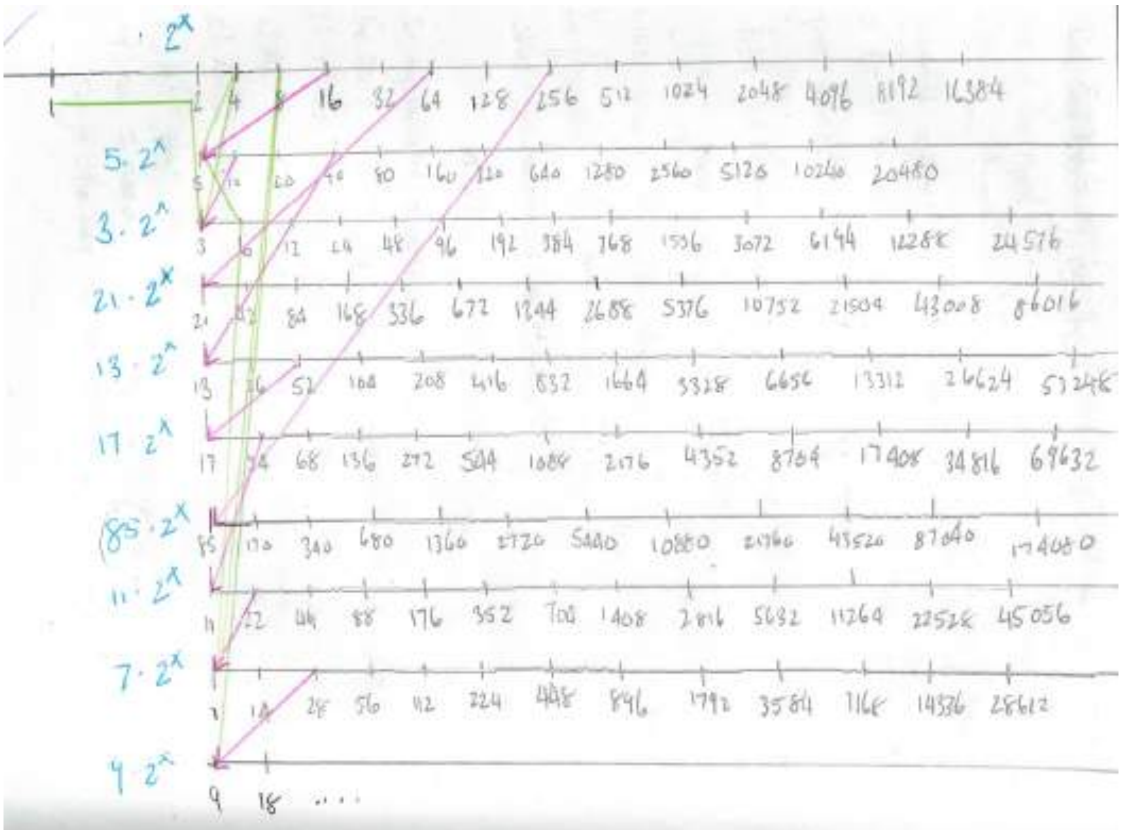

Figure 1: Example of Student Exploration of the Collatz Conjecture

We conjectured that through work on unsolved conjectures, mathematics majors would have novel opportunities to enrich their understanding of the nature of mathematics and the roles of proof. The first author (instructor of the course) designed the notebook assignments so that they would be a source of data useful for providing insight into what the students were learning about the nature of mathematics and proof as they explored the conjectures. Students had several reflective prompts they were required to address in their notebooks. For instance, at the beginning of the semester, students responded to the prompts *What is mathematics all about?* and *What is a mathematical proof, and how is it used by mathematicians?* The students responded to these prompts again at the end of the semester; they also responded to two additional prompts: (1) *How has your thinking regarding mathematics and mathematical proof developed and changed during this semester? Which changes were the result of engagement in the standard course activities (e.g. homework, tests, lectures) and which changes were the result of your experience conducting mathematical research (working on the unsolved conjectures)?* and (2) *What were the challenges and successes of your experience with mathematical research this semester?* The researchers analyzed student reflections to understand students' experiences working on the conjectures. In particular, we analyzed the notebook data to discern what students learned about the nature of mathematics and the roles of proof through their research.

Data Analysis

The data for the research study consisted of 25 student notebooks. The instructor (first author) and an undergraduate student from the course (second author) analyzed the data. First, each researcher individually read and examined a particular students' notebook. As we individually read through each student's notebook we took note of 1) Instances where students reflected about the nature of mathematics; 2) Possible evidence for changes in student's perceptions of the nature of mathematics (especially in regards to the five roles of proof); 3) Interesting mathematical ideas and approaches the student generated in working on the conjectures; and 4) Other interesting ideas expressed by the students. Each researcher then wrote a summary of his individual findings for the particular student's notebook.

After reading and analyzing a notebook, the researchers then shared their thoughts and findings with each other. We made notes on insights gained from the others' analysis and made note when a student demonstrated an understanding of any of the five roles of proof. We then repeated the process for the next student notebook.

Once we had analyzed all of the individual notebooks, the next step was for each researcher to create a holistic summary of the data that included broad themes in the students' responses as well as evidence (from the data) to back up our claims. The creation of these holistic summaries involved sorting student quotations into categories or themes (Ryan & Bernard, 2003), providing evidence that students' understandings of the nature of mathematics seemed to be enriched through the notebook project, and tallying how many students expressed certain ideas regarding the nature of mathematics in regards to the Roles of Proof framework. We also identified other recurring themes in the data related to students' experiences. We then shared our findings with each other, challenging each other to provide evidence for claims, which led to further refinement of the findings. We now present the results.

Results

We found that students alluded to four of de Villiers' (1990) five roles of proof while participating in this study: verification, explanation, systematization, and discovery.

Verification

Early in the semester, eight students' descriptions of the purpose of proof alluded to the notion of verification. For instance, a student wrote "A mathematical proof is a tool mathematicians use in order to determine if their statement is true or false." But by the end of the semester, seven additional students described the role of verification. These students wrote either about the role of proof in convincing others that a theorem is true, or the importance of proof in justifying and validating mathematical claims. For instance, one student wrote "Ideally, [a proof] should have no errors (holes) and must convince other mathematicians that it is correct and true for its purpose." Students were well aware of their inability to find a convincing proof for either the Twin Primes conjecture or the Collatz conjecture.

Explanation

Only two students alluded to the role of explanation in their initial descriptions about the purpose of proof, but by the end of the semester nine additional students alluded to this role of proof in their reflections. These students used language that emphasized proof's role in providing insight into why a mathematical claim is true. For instance, at the end of the semester a student wrote "At first, I feel like mathematics was more of just applying formulas and theorems to solve problems, but over the course I learned that it is more important to know why theorems work and how they work." Other students described how proof was needed to understand mathematics deeply. At the end of the semester a student wrote, "A mathematical proof is a way to understand how and why certain mathematical concepts exist. In math, there is always a reason for everything and math proofs help explain those reasons further. It is used by mathematicians to understand problems further and on a deeper level." Students recognized the surface level simplicity of the two conjectures (some students described how even an elementary student could understand them) but also recognized the complexity of what was required to understand *why* the conjectures were true.

Systematization

Four students alluded to the systematization role of proof at the beginning of the semester, and three additional students alluded to systematization at the end. These students described a building up of mathematics—results serve as the foundation for future results. A student wrote, "Proofs are facts so they have a crucial part to play in the development of other proofs where progression in the proof has more difficulty than normal." And another student, referencing a video she watched related to the twin primes, wrote, "Mathematicians use these proofs to help prove other conjectures. As Maynard's proof was influenced by Zhang's proof. Eventually, Maynard's proof will be used to help prove other conjectures." These students came to see that mathematicians work on conjectures; and proofs are used to build the body of mathematical knowledge.

Discovery

Four students alluded to the discovery role of proof, all at the end of the semester. These students seemed to better understand the mathematician's quest to discover new results. One student wrote, "Proofs are used by mathematicians to assist them in creating other proofs to eventually have a breakthrough that is groundbreaking in mathematics as well as the world." Another student wrote, "Mathematics is all about solving the world's greatest mysteries. Just from taking this class I have learned that mathematicians discover new problems and then spend their life trying to prove/understand it." See Figure 2 for a display of how many students alluded to a role of proof in their reflections.

Role of Proof	Alluded to at the Beginning of the Semester	Alluded to by the End of the Semester (but not at the Beginning)
Verification	8	7
Explanation	2	9
Systematization	4	3
Discovery	0	4
Communication	0	1

Figure 2: Number of Student Reflections on the Role of Proof

Other Results

We believe that most of the students had naïve views about pure mathematics and what it entails for mathematicians as they began the course. The notebook assignments provided students the opportunity to try their hand at proving conjectures that even famous mathematicians have not yet proven. This gave many of the students the opportunity to develop new ideas about what the discipline of mathematics and proof is all about, as many of them were dealing with a type of mathematics problem that they had never even conceived.

The notion of an unsolved conjecture provoked some of the students to start thinking more deeply about the topic, which in-turn led to creative and outside-the-box ideas. Eight of the students either showed a creative process in solving the conjectures, or stated they learned they could be more creative/look at conjectures from different angles and perspectives. Some forms of this creativity included working backwards on the Collatz conjecture, creating code to help find patterns and links within the Collatz conjecture, as well as finding a formula for the distance between twin prime pairs.

One student stated in their last reflection that "I learned we can look at an idea from many different angles." This student learned that some mathematical problems, such as conjectures, are not always a one-way road.

Another common trend amongst the students was that in the reflections, a number of the students took a step back and reflected from a broader point-of-view, and said they developed a deeper understanding of the nature of mathematics. Some students stated that they get the "bigger picture," or that they understand what happens "behind the scenes of mathematics." Of the 25 students, 10 of them had reflections in this vein. A few of those students were also ones that had a narrow idea of what mathematics was about in the beginning of the semester. These students originally had a concrete perception of mathematics being about calculations. For instance, a student wrote, "to me, mathematics is mainly about obtaining problem-solving skills through various mathematical problems," and, "mathematics is all about using formulas to solve problems." Working on an unsolved conjecture may have had an effect on their idea of mathematics and showed them that there is more to mathematics and it is not always about performing algebra with numbers. The same student, in their last reflection, wrote that "mathematics is all about solving the world's greatest mysteries."

The students' approaches and their perceptions of mathematics were not the only things they reflected about. Some of the students described a variety of emotions in their reflections. Eight of the 25 students expressed enjoyment in regards to the notebook. One student expressed how "math is getting more and more creative." Another student even stated that they were reassured and glad to be a mathematics major after completing the notebook, writing "I made the right choice in majoring in math since I love proofs so much."

Challenges

One of the most commonly noted student challenges was the struggle with finding where to begin proving the conjectures. Some of the students seemed overwhelmed at the prospect of exploring an unsolved conjecture that many mathematicians have tried and failed to solve. Some even expressed misconceptions, believing that they were being asked to prove something "impossible." Others were confused how they were supposed to go about proving something "unprovable." One student wrote, "I think the main challenge is just the fact that it's a conjecture. I could not find a way to write any proof because I did not understand or recognize the pattern behind it. I'm not sure if I'm doing the assignment correctly." Other students had a defeatist attitude, not believing that they would have anything positive to contribute: "Working on the conjecture was more irritating than exciting because I can't prove it. It took away all the satisfaction because it is a famously unproven conjecture and I couldn't solve it." Another student wrote, "Although it was intriguing, I gave up preemptively because I knew that I would not do anything that would help come to any conclusion." Although these students had trouble making progress, most were able to engage with the conjectures in some way. In subsequent semesters when implementing this project, the first author has incorporated more in-class discussion time for the conjectures. This has allowed the students more opportunities to get ideas from their peers for how to approach the conjectures.

Conclusions

Overall, we are encouraged that exploration of the unsolved conjectures was a productive experience for most students, and helped them to understand the role of proof and the discipline of mathematics in novel ways. We found that students had the opportunity to learn about what Hersh (1991) referred to as "the back of mathematics"—the messy informal work involved in proving conjectures. We believe that some students experienced and understood proof's role as verification, explanation, discovery, and systematization. Of the five roles of proof, explanation was most reflected on, with 9 students alluding to this role in their reflections (beyond the 4 that alluded to it at the beginning of the semester). We believe that working on unsolved conjectures provided students a special opportunity to understand this role of proof, as they were forced to come to the terms with the fact that even when they believe a conjecture to be true, it is not always easy to understand why it is true. We note that of the five roles of proof, communication was the only one we could not find addressed in the student reflections.[2] Other researchers have found that small-group work in inquiry-based classrooms brings to the forefront the communication role for students (Bleiler-Baxter & Pair, 2017; Cilli-Turner, 2017). Perhaps communication was not discussed by the students in our study as only one classroom day was devoted to student discussions of their work on the conjectures. We believe allotting more time for classroom discussion of conjectures may help students better understand the communication role of proof.

This paper presents the results of a large documentary study, the purpose of which is to promote a research and teaching program for the didactic reconceptualization of Calculus, through detailed argumentation that makes visible the problems surrounding the profound influence of the organization of Mathematical Analysis on the teaching of Calculus, which makes it difficult for students to understand and use the central ideas of Calculus. The study was conducted using theoretical notions of the onto-semiotic approach (OSA) to mathematical knowledge and instruction. An inquiry on the objects of study of each mathematical discipline will be presented, situating the different problem-situations that each one addresses and the procedures, languages, properties, arguments, and concepts that differentiate them. Finally, these differences are illustrated in relation to the notion of variable.

Keywords: Calculus, Curriculum, Instructional Vision.

Introduction and problem

At the center of Calculus teaching lies a problem deeply close to the historical development of this discipline and to Mathematics itself. Authors such as Moreno-Armella (2014) have described that problem as a tension between intuition and formalism, related to the tendency to present the intuitive ideas of Calculus from the perspective of Mathematical Analysis (Ímaz & Moreno, 2010). Calculus textbooks, that materialize this teaching approach, usually organize mathematical content around the notions of function and limit, considered the basis for studying the derivative and the integral of a function. The same textbooks emphasize mathematical practices such as defining, arguing, and demonstrating, and not the foundational intuitive ideas of Calculus about variation and accumulation.

This work is part of the research of Jiménez, Grijalva, Milner, Dávila-Araiza and Romero, (in press), which continues the line drawn by the study of Ímaz and Moreno (2010) to make a clear distinction, with didactic purposes, between Calculus and Mathematical Analysis. The study of Jiménez et al. it is a documentary research. It presents, in a critical way, historical and epistemological facts and arguments found in books and research articles that help explain the current state of Calculus teaching, drawing a path for its necessary transformation. The current didactic route, implicit in the textbooks, constitutes a path full of difficulties for students, associated with the formalized notion of limit (Cory & Garofalo, 2011; Roh, 2008 & Nagle, 2013) and other mathematical notions, such as real numbers and functions (Artigue, 1998). These notions are presented in classrooms from a perspective that seeks to establish a basis for the study of Mathematical Analysis and not the understanding of the key aspects of Calculus.

As one of the results of this documentary research, this paper will present, without pretenses of exhaustiveness, a distinction of the contents of Calculus and Mathematical Analysis, which serves to show the strong influence of Analysis on the teaching of Calculus. Later, with respect to the notion of variable, a distinction will also be made from the perspective of Calculus and Analysis. These distinctions will be made using theoretical tools of the onto-semiotic approach (OSA) to mathematical knowledge and instruction (Godino, Batanero & Font, 2007), which allows a detailed analysis of mathematical content and the establishment of categories that facilitate their contrast.

Theoretical Elements

In OSA a pragmatic position is assumed to study the mathematical objects that intervene and emerge when solving problems, putting the focus on the notion of *mathematical practice* to refer to any practical or discursive performance that is carried out when solving problems or communicating the obtained results. Rather than hinting at isolated practices, OSA is concerned with the *systems of practices* that are carried out to deal with problem situations. With this idea, *mathematical objects* are characterized as emerging from systems of practice, allowing the following six types of *primary* mathematical objects to be distinguished, some of which are ostensive in nature and others non-ostensive: *Problem-situations* (more or less open problems, exercises, extra or intra mathematical applications, etc.); *language* (specific mathematical terms, algebraic expressions, number tables, graphs, diagrams, gestures, etc.); *procedures* (techniques, algorithms, etc., undertaken or executed by the subject faced with mathematical tasks); *properties and propositions* (attributes of the mentioned objects); *arguments* (which are used to validate and explain the propositions) and *concepts* (mathematical objects recognized as part of the mathematical structure, characterized by their essential properties, which allow them to be distinguished from others and are usually expressed through descriptions or definitions).

Contrast of the primary mathematical objects of Calculus and Analysis

Below is an analysis of four of the six types of primary mathematical objects, corresponding to Calculus and Mathematical Analysis, from which it is possible to show that the current approach to teaching Calculus does not fully consider the initial ideas of this discipline, but rather presents a version more in line with the purposes of Mathematical Analysis.

Table 1. Contrast of primary mathematical objects of Calculus and Analysis

Calculus	Analysis
Concepts: Variable magnitude, variation and covariation, instantaneous rate of change, infinitely small magnitude, differential, accumulation, evanescent quantity, infinite sum, derivative, integral, function.	*Concepts:* Real number, function (increasing, decreasing, bijective, continuous, differentiable, bounded, integrable), derivative of a function, definite integral of a function in an interval, limit of a function, succession, convergence.
Problem-situations (usually linked to physical or geometric contexts): To determine how much there is of a magnitude at all times, knowing the rate of change of such magnitude at all times, and inversely determine its rate of change at all times knowing how much there is of that magnitude in any given moment. To determine the quadrature of a figure formed by a curve and the slope of the tangent line to that curve at each point of it.	*Problem-situations*: To define the mentioned concepts and establish their properties. From their definitions, to determine when a relationship is a function, when a function is injective, bijective, increasing, decreasing, continuous, differentiable or integrable. To determine the limit of a function. To establish when the limit of a function exists, when a function is continuous, if a discontinuity is removable, when a function is differentiable or integrable.
Properties (they tend to be implicitly assumed): variable magnitudes vary continuously. Differential magnitudes are non-Archimedean in nature. Differential quantities depend on the phenomenon.	*Properties* (presented in isolation from their contexts of extra-mathematical use): Theorems of the mean value and the intermediate value. Properties of the limits of functions and differentiable functions. Conditions of

Language: Combination of the natural language with specific languages from the application areas. Algebraic, numeric and geometric representations. Algebraic treatment of differential magnitudes, such as $\boldsymbol{dx, dy, dz, dt}$, and of infinite sums represented as $\int \boldsymbol{x^2 dx}, \int \boldsymbol{senx\ dx}$, among others.	integrability of a function, fundamental theorem of calculus, etc. *Language*: Predominant use of analytical language of a formal nature and little use of numerical and graphic representations. The center of the language of analysis is that associated to functions and, linked to it, the criteria of convergence and continuity, representing the proximity between representative values by means of the absolute value of the difference of two magnitudes of interest.

The notion of variable from the Calculus perspective

The study of variable begins in high school, where two main meanings are promoted, one associated with the study and resolution of equations of two or more variables, and the other as *a generalized number* associated with the problems of numerical and figurative patterns. Subsequently, in the Calculus university courses, the concept of variable is not usually discussed (Biehler & Kempen, 2013). Only when defining function is it mentioned that *x* is an element in a set called *domain*, while *y* is an element in the set called *range*. Consequently, the variable is considered as “something” that takes all the values in a certain set of numbers or “something” that represents all the elements of a given set. This concept of variable corresponds to Set theory, a typical approach from Mathematical Analysis (see Apostol, 1979, p. 40), more importantly, a *decontextualized and static meaning*.

Favoring an static and decontextualized meaning of the variable generates difficulties for students in the modeling of physical phenomena with the tools of Calculus (López-Gay, Martínez Sáez & Martínez-Torregrosa, 2015), since for the students a variable is a letter that represents replaceable constants, that is, the variables *do not vary* in the students' thinking, as documented by Jacobs and Trigueros (cited in Thompson, Byerley & Hatfield, 2013). Thompson, Byerley and Hatfield (2013) affirm that to develop a variational meaning of the variable characteristic of Calculus, it is not enough to think of the variation as the simple substitution of one number for another; it is important to understand that this change in value is not arbitrary, but it occurs under a certain progression or sequence that is usually dependent on time. This sheds light on an important distinction: time is a central notion in Calculus; however, in Analysis it is not, as Bolzano expressed: “the concept of time, and even more that of motion, is as external to general mathematics as that of space” (quoted in Bottazzini, 1986, p. 98).

In Calculus, the variable is a dynamic notion that is intimately linked to time and physical contexts, since it emerges from the study of variable magnitudes and the relationships that can be established between them when trying to understand, and mathematize processes and variation phenomena that are present in the physical and social environment, in which a measurable changing property is manifested. In Calculus, the verb *to vary* refers to a change in progress (Thompson, Ashbrook & Milner, 2016), whether it is actually happening, or one can imagine that it is. In this sense, a variable quantity can be described as a *quantifiable property* of an object, process, or phenomenon of variation. In other words, “the variable magnitude that is measured or calculated takes progressively different values at different times, as the phenomenon or process in which it intervenes develops” (Jiménez et al., In press). It is important to highlight that the quantifiable quality not only takes each and every one of the numerical values in a set, but it does so sequentially, as time passes.

Consequently, the variable magnitudes in the Calculus, due to all the characteristics that they possess, particularly those described above, do not have the same meaning as the variable from the perspective of Mathematical Analysis, where the variables have no link to physical reality, nor with time or motion, as Bolzano explained it. In Mathematical analysis the variables are timeless, dimensionless, static (they do not involve motion). The way in which the analysis variable "takes" the values of a set needs to be completely arbitrary, it does not obey a temporal sequence.

Conclusions

The analysis of primary mathematical objects allowed us to identify that the systems of mathematical practices of Calculus and Mathematical Analysis are essentially different. Broadly speaking, the mathematical practices of Calculus are oriented to the study of the phenomena of variation by establishing relationships between variable magnitudes, while the mathematical practices of Analysis focus on the definition and study of functions, derivatives, integrals, and its properties, through the notions of real number and limit.

Regarding the notion of variable, it is important to highlight that Calculus students hardly have an approach to it from a variational perspective, which would allow them to develop the variational thinking necessary for understanding the fundamental ideas of this discipline that will become mathematical tools necessary for the prediction and control of change processes; the field of application of the Calculus.

The presented arguments aim to outline, for didactic purposes, some essential differences between Calculus and Analysis, taking as a particular case the notion of variable, to shed light on how Calculus teaching neglects aspects that are central to the understanding of its foundational ideas, by privileging a formal treatment of the mathematical content more attached to the perspective of Mathematical Analysis. These reflections remind us that the discussion on how to reorient the teaching of Calculus, as well as didactic research, towards understanding the central ideas of Calculus that would allow students to be efficient users of the mathematics of change is still pending.

HACIA UNA DISTINCIÓN DIDÁCTICA ENTRE EL CÁLCULO Y EL ANÁLISIS. EL CASO DE LA NOCIÓN DE VARIABLE

TOWARDS A DIDACTIC DISTINCTION BETWEEN CALCULUS AND ANALYSIS. THE CASE OF THE NOTION OF VARIABLE

María Teresa Dávila Araiza
Universidad de Sonora
maría.davila@unison.mx

Agustín Grijalva Monteverde
Universidad de Sonora
agustin.grijalva@unison.mx

Se presentan resultados de un estudio amplio, de carácter documental, cuya finalidad es el impulso a un programa de investigación y docencia para la reconceptualización didáctica del cálculo, a través de una argumentación detallada que visibiliza la problemática en torno a la influencia profunda de la organización del Análisis Matemático sobre la enseñanza del Cálculo, que dificulta a los estudiantes la comprensión y uso de las ideas centrales del Cálculo. El estudio se realizó usando nociones teóricas del Enfoque Ontosemiótico del conocimiento y la instrucción matemáticos (EOS). Se presentará una indagación sobre los objetos de estudio de cada disciplina matemática señalada, ubicando las diferentes situaciones problema que aborda cada una de ellas y los procedimientos, lenguajes, propiedades, argumentos y conceptos que las diferencian. Por último, se ilustran estas diferencias con relación a la noción de variable.

Palabras clave: Cálculo, currículo, visión de enseñanza.

Introducción

En el centro de la enseñanza del Cálculo yace una problemática profundamente ligada al desarrollo histórico de esta disciplina y de las matemáticas mismas, que autores como Moreno-Armella (2014) han relacionado con una tensión entre lo intuitivo y lo formal, y una tendencia a presentar el Cálculo desde la perspectiva del Análisis Matemático (Ímaz & Moreno, 2010). En los textos de Cálculo, que materializan el enfoque de su enseñanza, se suele organizar el contenido en torno a las nociones de función y límite, para llegar al estudio de la derivada y la integral, enfatizando prácticas matemáticas como fundamentar, definir y demostrar, y no en torno a las ideas intuitivas fundacionales del Cálculo sobre variación y acumulación.

Este trabajo se enmarca en la investigación de Jiménez, Grijalva, Milner, Dávila-Araiza y Romero, (en prensa), que da continuidad a la línea trazada por la investigación de Ímaz y Moreno (2010) para realizar una distinción clara, con fines didácticos, entre el Cálculo y el Análisis Matemático como disciplinas en la enseñanza. La investigación de Jiménez et al. es de tipo documental; recopila hechos y argumentos de corte histórico y epistemológico en libros y artículos de investigación que permiten explicar el estado actual de la enseñanza del Cálculo y esbozar una línea para su necesaria transformación; considerando que la ruta didáctica actual, implícita en los libros de texto, constituye para los estudiantes un camino plagado de dificultades asociadas a la noción formalizada de límite (Cory & Garofalo, 2011; Roh, 2008 y Nagle, 2013) y otras nociones matemáticas, como los números reales y la función (Artigue, 1998), que son presentados desde una perspectiva que busca a sentar bases para el estudio del Análisis Matemático y no la comprensión de las nociones centrales del Cálculo.

Como uno de los resultados de esta investigación documental, en este escrito se presentará, primeramente, de manera general (y sin pretensiones de exhaustividad) una distinción de contenidos matemáticos del Cálculo y del Análisis Matemático, que permiten mostrar la fuerte influencia del Análisis sobre la enseñanza del Cálculo. Posteriormente, con respecto a la noción de variable, también se realizará una distinción desde la perspectiva del Cálculo y del Análisis. Estas distinciones se realizarán mediante herramientas teóricas del Enfoque Ontosemiótico, EOS, (Godino, Batanero & Font, 2007), las cuales permiten analizar detalladamente contenidos matemáticos y establecer categorías que faciliten su contraste.

Elementos teóricos

En el EOS se asume una posición pragmática para estudiar los objetos matemáticos que intervienen y emergen al resolver problemas, poniendo el enfoque en la noción de *práctica matemática* para referirse a cualquier actuación práctica o discursiva que se realiza al resolver problemas o comunicar los resultados obtenidos. Pero, más que hacer alusión a prácticas aisladas, el EOS se preocupa por los sistemas de prácticas que se realizan para enfrentar las situaciones problema. Con esta idea, se caracteriza a los objetos matemáticos como los emergentes de los sistemas de prácticas, permitiendo distinguir los seis siguientes tipos de *objetos matemáticos primarios*, algunos de los cuales son de naturaleza ostensiva y otros son no ostensivos: *Situaciones problema* (problemas más o menos abiertos, ejercicios, aplicaciones extramatemáticas o intramatemáticas, etc.); *lenguaje* (términos específicos de matemáticas, expresiones algebraicas, tablas numéricas, gráficas, diagramas, gestos, etc.); *procedimientos* (técnicas, algoritmos, etc., emprendidos o ejecutados por el sujeto ante las tareas matemáticas); *propiedades* (atributos de los objetos mencionados); *argumentos* (que se usan para validar y explicar las proposiciones) y *conceptos* (objetos matemáticos reconocidos como parte de la estructura matemática, caracterizados por sus propiedades esenciales, las que permiten distinguirlos de otros y suelen expresarse por medio de descripciones o definiciones).

Contraste de objetos matemáticos primaros del Cálculo y del Análisis

A continuación, se presenta de manera general un análisis de cuatro de los seis tipos de objetos matemáticos primarios, sin pretender ser exhaustivos, correspondientes al Cálculo y al Análisis Matemático, a partir del cual es posible poner de manifiesto que el enfoque actual de la enseñanza del Cálculo no considera plenamente las ideas iniciales de esta disciplina, sino que presenta una versión del Cálculo mas acorde a los propósitos del Análisis Matemático.

Tabla 1. Contrastación de objetos matemáticos primarios del Cálculo y del Análisis

Cálculo	Análisis
Conceptos: Magnitud variable, (co)variación, razón instantánea de cambio, magnitud infinitamente pequeña, diferencial, acumulación, cantidad evanescente, suma infinita, derivada, integral, función.	*Conceptos:*Número real, función (creciente, decreciente, biyectiva, continua, diferenciable, acotada, integrable), derivada de una función, integral de una función en un intervalo, límite de una función, sucesión, convergencia, entre otras.
Situaciones problema (normalmente vinculadas a contextos físicos o geométricos): Determinar	*Situaciones problema*: Definir los conceptos mencionados y establecer propiedades de estos. A

cuánto hay de una magnitud en todo momento, conociendo la razón de cambio de esa magnitud en todo momento, e inversamente determinar su razón de cambio en todo momento conociendo en todo momento cuánto hay de esa magnitud. Determinar la cuadratura de una figura formada por una curva y, determinar la pendiente de la recta tangente a dicha curva en cada punto de ella.	partir de dichas definiciones, determinar cuándo una relación es función, cuándo una función es inyectiva, suprayectiva, biyectiva, creciente, decreciente, continua, diferenciable o integrable. Determinar el límite de una función. Establecer cuándo existe el límite de una función, cuándo es continua una función, si es removible una discontinuidad, cuándo una función es diferenciable o integrable.
Propiedades (tienden a ser asumidas de forma implícita): Por ejemplo, las magnitudes variables varían de manera continua, las magnitudes diferenciales tienen una naturaleza no Arquimediana, las cantidades diferenciales son propias de cada fenómeno.	*Propiedades* (se presentan aisladas de sus contextos de uso extramatemático): Teoremas del valor medio y del valor intermedio. Propiedades de los límites de funciones y de las funciones diferenciables. Condiciones de integrabilidad de una función, teorema fundamental del cálculo, etc..
Lenguaje: combinación de la lengua materna con lenguajes específicos de las áreas de aplicación. Expresiones numéricas geométricas y algebraicas. que representan magnitudes diferenciales como $\boldsymbol{dx}, \boldsymbol{dy}, \boldsymbol{dz}$, d$\boldsymbol{t}$ y de las sumas finitas, representadas por expresiones como $\int \boldsymbol{x^2\,dx}$, $\int \boldsymbol{senx\,dx}$ y otras.	*Lenguaje*: preponderantemente analítico, de carácter formal y poco empleo de las representaciones numéricas y gráficas. El centro del lenguaje del análisis es el de función y, ligado a ésta, los criterios de convergencia y de continuidad, representando la proximidad entre valores representativos mediante el valor absoluto de la diferencia de dos magnitudes de interés.

La noción de variable desde la perspectiva del Cálculo

El estudio de la variable inicia en la escuela secundaria, donde se promueven dos significados principales, uno asociado al estudio y resolución de ecuaciones de dos o más variables, y otro como número generalizado asociado a los problemas de patrones numéricos y figurales. Posteriormente, en los cursos universitarios de Cálculo no se suele discutir el concepto de variable (Biehler & Kempen, 2013). Únicamente, al definir la función, se menciona que *x* es un elemento en un conjunto llamado dominio, mientras que *y* es un elemento del conjunto llamado rango. Como consecuencia, la variable es considerada como "algo" que toma todos los valores en cierto conjunto de números o "algo" que representa a los elementos de un conjunto. Este concepto de variable corresponde a un significado conjuntista, propio del Análisis Matemático (ver Apostol, 1979, p. 40), un significado descontextualizado y estático.

Favorecer un significado estático y descontextualizado de la variable produce dificultades en los estudiantes para la modelación de fenómenos físicos con las herramientas del Cálculo (López-Gay, Martínez Sáez & Martínez-Torregrosa, 2015), pues para los estudiantes una variable es una letra que representa constantes reemplazables, es decir, las variables no varían en el pensamiento de los estudiantes, como lo documentaron Jacobs y Trigueros (citados en Thompson, Byerley & Hatfield, 2013). Thompson, Byerley y Hatfield (2013) afirman que para desarrollar un significado variacional de la variable propio del cálculo no es suficiente pensar en la variación como el cambio de un número por otro; es importante comprender que ese cambio de valor no es arbitrario, sino que ocurre bajo cierta progresión o secuencia normalmente temporal. Esto arroja luz sobre un aspecto importante: el tiempo es una noción central en el Cálculo; sin embargo, en el Análisis no lo es, como lo expresó Bolzano: "el concepto de tiempo, y más aún aquel de movimiento, es tan externo a las matemáticas generales como aquel de espacio" (citado en Bottazzini, 1986, p. 98).

En el Cálculo, la variable es una noción dinámica que está íntimamente ligada al tiempo y a los contextos físicos, pues ésta emerge del estudio de las magnitudes variables y de las relaciones que se pueden establecer entre ellas al tratar de comprender, y matematizar, procesos y fenómenos de variación que están presentes en el entorno físico y social, en los cuales se manifiesta una propiedad cambiante que puede ser medible. En el Cálculo, el verbo variar se refiere a un cambio en progreso (Thompson, Ashbrook & Milner, 2016), ya sea efectivamente está sucediendo o bien que se puede imaginar que lo hace. En este sentido, una magnitud variable se puede describir como una propiedad de un objeto, proceso o fenómeno de variación, la cual es cuantificable. Es decir, "la magnitud variable que se mide o calcula toma progresivamente distintos valores en distintos momentos, a medida que va desarrollándose el fenómeno o proceso en que ella interviene" (Jiménez et al., en prensa). Es importante resaltar que la cualidad cuantificable no solamente toma todos y cada uno de los valores numéricos en un conjunto, sino que lo hace de manera secuencial, a la par que transcurre el tiempo.

En consecuencia, las magnitudes variables en el Cálculo, por todas las características que poseen y que se describieron líneas arriba, no tienen el mismo significado que la variable desde la perspectiva propia del Análisis Matemático, donde las variables no tienen vínculo alguno con la realidad física ni con el tiempo o el movimiento, como lo expresó Bolzano. En el análisis Matemático las variables son atemporales, adimensionales, estáticas (no involucran el movimiento). La manera como la variable del análisis "toma" los valores de un conjunto es completamente arbitraria, no obedece necesariamente una secuencia temporal.

Conclusiones

El análisis de objetos matemáticos primarios permitió identificar que los sistemas de prácticas matemáticas del Cálculo y del Análisis Matemático son esencialmente distintos. A grandes rasgos, las prácticas matemáticas del Cálculo se orientan al estudio de los fenómenos de variación mediante el establecimiento de relaciones entre magnitudes variables, mientras que las prácticas matemáticas del Análisis se centran en la definición y estudio de la función, la derivada, la integral y sus propiedades, a través de las nociones de número real y límite.

Con respecto a la noción de variable, es importante resaltar que difícilmente los estudiantes de Cálculo tienen un acercamiento a ésta desde una perspectiva variacional, que les permitiría desarrollar un pensamiento variacional necesario para la comprensión de las ideas fundamentales de esta disciplina que son en herramientas matemáticas necesarias para la predicción y control de procesos de cambio; el campo de aplicación del Cálculo.

Los argumentos presentados brevemente pretenden esbozar, con propósitos didácticos, algunas diferencias esenciales entre el Cálculo y el Análisis, tomando como caso particular la noción de variable, para arrojar luz sobre cómo la enseñanza del Cálculo desatiende aspectos que son centrales para la comprensión de sus ideas fundacionales, al privilegiar un tratamiento formal del contenido matemático más apegado a la perspectiva del Análisis Matemático. Estas reflexiones nos recuerdan que sigue pendiente la discusión sobre cómo reorientar la enseñanza del Cálculo, así como la investigación didáctica, hacia la comprensión de las ideas centrales del Cálculo que permita a los estudiantes ser usuarios eficientes de las matemáticas del cambio.

CONSTRUCTING RATES OF CHANGE THROUGH A UNITS COORDINATING LENS: THE STORY OF RICK

Jeffrey A. Grabhorn
Portland State University

Steven Boyce
Portland State University
sboyce@pdx.edu

In this research report, we describe the results of a paired-student constructivist teaching experiment with introductory calculus students focused on supporting their understanding of the derivative as rate of change. We focus on one student, Rick. We connect analyses of Rick's ways of assimilating and operating with numerical units with analyses of ways of conceptualizing rates. The results are conjectures about the relationships between levels of units students coordinate and their ways of quantifying rates.

Keywords: Cognition, Number Concepts and Operations, Rational Numbers, University Mathematics

Background

This report builds a connection between Johnson's (2015) work investigating the quantitative operations involved in constructing rates and research investigating the constraints and affordances of student's units coordinating activity as they develop understandings of calculus concepts (Boyce, Byerley, Darling, Grabhorn, & Tyburski, 2019; Boyce, Grabhorn, & Byerley, 2020). The goal of the current study is to identify connections between calculus students' units coordination and their understanding of rate of change.

Units Coordinating

Units coordination can be thought of as students' mental activity building and maintaining relationships of nested *levels* of units (Norton et al., 2015; Steffe, 1992). Some students bring a three-level units coordinating structure to bear when first encountering a task, what we call *assimilating* with three levels of units. Such students would be able to quickly reason through the Bar Task below (Figure 1) by recognizing that the orange bar is equivalent to nine ¼'s of a purple bar, thus 9/4 of a purple bar fits into the orange bar. Students that assimilate with two levels of units may construct an ephemeral third level of units in the midst of reasoning (what we call coordinating three levels of units *in activity*) by coordinating across two two-level units coordinating structures. Such activity requires perceptual reflecting on the outcomes of actions on physical or mental representations, often resulting in conflating or dropping units. For example, a student who assimilates with two levels of units may state 2 1/9 as an answer to the Bar Task by claiming that two full purple bars and one green bar (1/9 of an orange bar) fit into the orange bar.

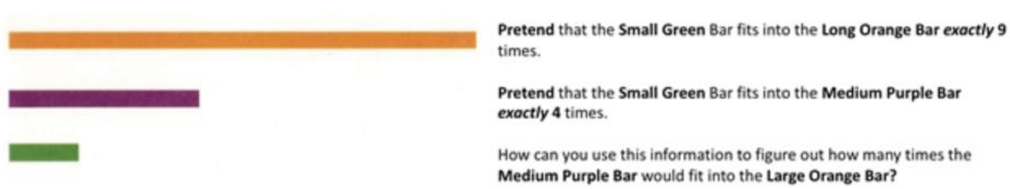

Figure 1: Units Coordinating Bar Task (Norton et al., 2015)

Rate of Change as a Ratio

Johnson (2015) investigated the affordances and constraints of secondary students' quantification of ratios in regard to their quantification of rate. The resulting Change in Covarying Quantities Framework distinguishes between quantitative operations involved in students' quantification of rate:

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

comparison refers to a quantification of rate as associations of changes of quantities (i.e., 12 miles per hour means associating a distance of 12 mile with an elapsed time of 1 hour), while *coordination* refers to quantification of rate as involving at least one continuously changing quantity (i.e. 12 miles per hour means as time increases, the distance traveled is 12 times as large). Johnson argued that "students' quantification of rate could help to explicate differences in students' conceptions of rate" (p. 86-87) and that the nature of how students might develop either operation of *comparison* and *coordination* is unanswered. We hypothesize that students' units coordinating activity may be helpful for understanding the nature of such operations.

Methods and Results

We conducted a paired-student teaching experiment (Steffe & Thompson, 2000) in summer 2019 at a large public university in the U.S. with the goal of producing models of introductory calculus students' developing understandings of rate of change. Our results and analysis will focus on one participant, Rick. Rick participated in five weekly one-hour teaching episodes concurrent with his enrollment in a differential calculus course. The first author served as teacher-researcher for each episode while the second author served as a witness. Each episode was video recorded and all written work was collected and scanned for analysis. Analysis methods included both ongoing (between session) and retrospective modeling of Rick's ways of coordinating units and Rick's ways of reasoning about rates of change (Steffe & Thompson, 2000). Rick was assessed as assimilating with two levels of units at the beginning of the teaching experiment. The following analysis details our attempt to support Rick in quantifying a rate via the *coordination* operation of Johnson's (2015) Change in Covarying Quantities Framework.

12 Meters In 3 Seconds

During the third teaching episode we focused on supporting Rick in quantifying a rate with the *coordination* operation. Rick's conception of a rate as the amount of change in a dependent quantity for a unit increase in an independent quantity was persistent. Rick was presented with the task displayed in Figure 2.

Compare and contrast the following statements.

A. I travel 12 meters in 3 seconds.
B. I travel at a constant rate of 12 meters per 3 seconds.
C. I travel at a constant rate of 12/3 meters per second.
D. It takes me ¼ seconds to travel 1 meter.

Figure 2: Comparing Rates Task

Rick first noted that statements B and C are similar because they were "a constant rate… over a certain interval of time", but that those statements are different from statements A and D because the latter pair did not reference a constant rate. When pushed to describe other similarities or differences, Rick claimed that "throughout the board… each second they would have traveled 4 meters". Even though Rick attended to the absence or inclusion of the phrase *constant rate*, he still compared statements by considering the amount of distance covered in 1 second (as if each statement referred to a constant rate of change between distance and time). Rick then stared at option A and claimed "actually, I don't know that". He then explained that each statement described traveling 12 meters in 3 seconds. The teacher-researcher then asked Rick to give an example where statement A is true, but does not describe traveling 4 meters in 1 second.

> Rick: Potentially within the first second maybe you're, uh… stopped the entire time. And then, so zero to one [seconds] you travel zero [meters]. Then one to two seconds you travel six [meters]. Then two to three [seconds] you travel another six [meters]. So, in one second it's not guaranteed to be four [meters] in that particular situation.

Rick was able to give several additional examples by considering individual changes in distance across three successive elapsed seconds, where the sum of changes in distance was 12 meters. Additionally, some of his examples included traveling four meters in one of the elapsed seconds but not all (e.g., 0 meters in the first second, 8 meters in the next second, 4 meters in the final second). According to Rick, "it could be any mixture of numbers leading to twelve".

We interpret Rick's response as indicating that, to him, a constant rate of 4 meters per second means that distance must change by four meters for *every* second he can consider throughout the trip. Additionally, Rick interprets any constant rate described with a non-unit change in independent quantity (in this case, time) by finding the associated change in dependent quantity per increase of one unit of the independent quantity that would maintain the originally stated ratio.

This explains why Rick singled out choice A as different than choices B and C but not D; For choice D, distance must change by four meters if we consider iterating ¼ second four times to let one second elapse. Even though Rick had an awareness that amounts of changes in distance can vary as time elapses for both statements A and D, Rick's image of that variation necessitated considering unit increases in time. Rick did not consider the variation of distance for individual ¼ second intervals of time, and thus statement D is consistent with statements B and C (in these three cases, for Rick, distance *must* increase by four meters for any increase of one second).

12 Meters In 0.8 Seconds

The previous task revealed that Rick could reason about rate of change by considering amounts of change in a dependent quantity constrained by an associated increase of the independent quantity by one unit. The following excerpt describes Rick attempt to reason about a rate with a non-unit change in the independent quantity. Specifically, we ask Rick to compare a statement similar to the previous task with a statement about instantaneous rate of change.

> Teacher-Researcher: Jim travels 12 meters in 0.8 seconds. Is it possible Jim traveled 12 meters per second at any point during his trip?
>
> Rick: Potentially… I don't want to say… Because I was thinking potentially Jim could go… travel 15 meters per second but stop at, you know, 0.8 seconds. And then Jim would be traveling… no… If you travel 15 [meters]… if Jim would stop at 0.8 [seconds] exactly after having traveled that, then 12 [meters] is eighty percent of 15 [meters].

Rick's activity is focused on relating a change in distance of 12 meters to a unit rate that describes traveling 12 meters in 0.8 seconds. One interpretation of his response is that Rick interprets "12 meters per second" as traveling 12 meters *within* one second, and thus it is possible to travel 12 meters per second during the trip.

Rick constructs (at least) three rates as he attempts to solve this task: 12 meters per 0.8 seconds (Figure 3a), 15 meters per second (Figure 3b), and 12 meters per second (Figure 3c). In each case, Rick can reason about a rate as a comparison of changes in distance and changes in time and appears to prefer reasoning about such rates over a unit interval (one second) of time. This may be due to Rick having not interiorized a conceptual structure for non-unit rates, thus necessitating activity to construct a unit rate with which to reason.

Rick can compare two speeds by constructing unit rates for speed and comparing the two changes in distance associated with a common unit increase in time. In doing so, Rick does not attend to time as a quantity that is necessary for his goal of comparing two speeds. This may explain his initial response that Jim could potentially travel 12 meters per second by traveling "15 meters per second but stop at, you know, point-eight seconds". Rick's suggestion links a unit rate with a change in distance of 12 meters.

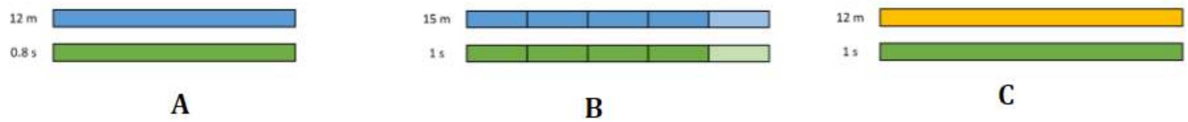

Figure 3: Author illustrations of rates that Rick constructs and compares

Ultimately Rick decided that it was not possible that Jim traveled 12 meters per second at any point during his trip because, "if we're going that specific interval [one second], that'd be fifteen meters per second. Not twelve".

Discussion

The goal of our research was to investigate how Rick, who we assessed as assimilating with two levels of units, reasoned about rate of change. We have focused analysis on two particular tasks to exemplify the powerful ways that Rick was able to reason about unit rates and able to coordinate three levels of units in activity involving known quantities. Still, throughout the teaching experiment, Rick did not exhibit behavior indicating that he constructed rates by engaging in the quantitative operation of *coordination*. Instead Rick was persistent in constructing rates through the *comparison* operation.

Rick is not an anomaly in that university students that assimilate with fewer than three levels of units exist in introductory calculus courses and appear to be at a higher risk of not finding success in such courses (Boyce, Grabhorn, & Byerley, 2020; Byerley 2019). Specific to our report, Johnson (2015) conjectured that sole reliance on the *comparison* operation could explain students' struggles with rates. This report builds a connection between Johnson's (2015) work investigating the quantitative operations involved in constructing rates and our previous research investigating the constraints and affordances of students' units coordinating activity as they develop understandings of calculus concepts. Further, Johnson left as an open question how students develop the *comparison* and *coordination* operations. We conjecture that engaging in the *coordination* operation (constructing a rate so that at least one of the quantities involved is continuously changing) requires assimilating with three levels of units.

Keywords: Precalculus Teacher Education - Preservice Design Experiments Problem Solving

Introduction

The concept of variable is of utmost importance since covariation, function, derivative and integral are built on it. However, as has been reported for decades (Rosnik, 1980), most textbooks tend to approach the concept of variable in an ambiguous and confusing way, due to the wide diversity of meanings that implies, causing difficulties in teaching (Díaz and Morales, 2005).

In this research is important to study in a particular way the difficulties that arise when working with a teaching model consisting of activities that involve the treatment of change and variation in situations of diverse contexts. Change is understood as the modification of states of the qualities involved in a phenomenon, and variation as the quantification of change; therefore, when carrying out these quantifications we are in the possibility of introducing the concept of variable.

The research central problem is related to reading / transformation of the textual spaces that involve the notions of change and variation, to give meaning to the arithmetic and algebraic variables.

We intend to characterize the way in which a group of future middle school math teachers give meaning to the notions of variation, function, variable and through experimentation with a Model of Teaching that incorporates work with dynamic phenomena and problem solving.

Based on these purposes, the following research questions were asked. What are the students' actions when solving problems related to variation and use of variables in different fields? How does the level of abstraction of the idea of change evolve, in order to give meaning to the notion of variable? And what are the main difficulties that arise when working iterative processes and solving problems related to variation and the concept of function?

Theoretical framework

The theoretical-methodological framework that guides this work is of the Local Theoretical Models (MTL) (Filloy, 1999), which allows to analyze the phenomena that occur during teaching / learning. Special attention is given to meanings of mathematical concepts thanks to its use more than its meaning in the abstract.

During the development of the teaching-learning processes of a mathematical content, four interrelated elements are presented: the person who teaches, the person who learns, the mathematical content to teach / learn and communication that is established between the participants in the process. Therefore, an MTL that contemplates the characterization of the phenomena and relationships between the aforementioned elements, is made up of the designed Teaching Model, the Model of cognitive processes under which the actions of the students will be characterized, the corresponding formal Model to the mathematical content and the Communication Model which analyzes the exchange of information between the participants (Filloy, Rojano, Puig, 2008).

In this research, the model of formal competence is supported in part by the ideas of Hans Freudenthal, exposed in his book Phenomenology Didactics of Mathematical Structures, specifically in the analysis he makes in the chapters "Algebraic Language" and "Functions" (Freudenthal, 1983). We also consider the formal study of the concept of iteration, which plays a prominent role in this work.

According to Freudenthal (1983), the concept of function is based on the concept of variable and the idea of dependency. The precision in which it is possible to describe the dependency between variables can be different, ranging from the use of notions of order (the more of this, the more of that), to relating one to the other more or less precisely, possibly numerically.

An idea that theoretically supports the notion of iteration, since it is considered to have the potential to contribute in the endowment of meaning to the concepts of variation and variable, highlighting its dynamic quality, from an approach with a low degree of abstraction (Choate, Devaney and Foster, 1999; Peitgen et al., 2004).

The formal model is an element that helps us to observe the students' productions, in addition to these references, we characterize the actions based on the categories: type of approach used by students when solving problematic situations, either qualitative or quantitative. We identify if they are productions of a dynamic or static type and we classify the uses of the variable, either arithmetic or algebraic.

Filloy (1999) states that there are theoretical bases that confirm that a first semantic approach to algebra is more convenient for the meaning endowment of concepts than a merely syntactic approach. In this research project, where the notions of change, variation, variable and function are worked on, it has been chosen to carry out a specific type approach based on a critical historical analysis of the concept of function, with the objectives to detect epistemological obstacles generated during its development (Cuevas and Díaz, 2014), and that students could present it during their learning process (Godino, 2003).

Methodology

The experimentation was carried out with 23 students (21-22 years old), who are currently studying the eighth semester of a Bachelor's Degree in Secondary Education with a specialty in Mathematics at Benemérita and Centennial Normal School of the State of Durango, located in Durango, Mexico.

The development of experimentation is based on the methodology defined in the Local Theoretical Models (Filloy, 1999), which establishes six stages: selection of the study population; design and application of a diagnosis; population classification, which was carried out based on the analysis of the level of syntactic, semantic competence and intuitive use of the population (Rojano, 1985); election of a representative sample of the population; case study through clinical interviews and elaboration of an observation report.

Experimentation results

Next, a representative problematic situation of the teaching model is presented, describing the students' productions during their resolution.

After the future teachers worked on a phenomenon of bank movements with simple interest, a similar problem was posed to them, but with a compound interest, since it is interesting to observe the way they treat phenomena where behaviors other than linear or quadratic are presented; in this case, exponential type. The situation raised was as follows.

> When in a loan the percentage is added to the capital and becomes part of the debt, the interest on this new capital is called compound interest.
>
> 1. Suppose we have a capital of 200 pesos at 20% compound interest for 5 months. Complete the following table to find out how much will be due at the end of each month

One of the main difficulties presented in this situation was detecting the type of variation involved. To achieve this, some students tried to help themselves with the graphical representation, first obtaining a tabular representation of the situation, and then graphing the values as ordered pairs. They proceeded by placing the corresponding points and then drew a line that passes through each of these. Thanks to this, linear variation began to be discarded as corresponding to the phenomenon worked.

Not being able to define the type of variation involved, some students carried out a different process, which consisted of calculating the differences between the consecutive terms and then calculating the differences of the differences, but when calculating the first and second differences they do not obtain constant values, which causes even more confusion. They even decide to make the calculation of the third differences without obtaining a result that makes it possible to make sense of the phenomenon. It can be seen that the method is rescued as a mechanized process.

There was another group of students who also used the method of differences and also did not allow them to determine the type of variation present in the phenomenon, but it was useful to discard the quadratic variation as a possibility, since they obtained the second difference, they did not have constant values.

The Numerical processing of the situation allowed two students to observe that, as the independent variable increases, the differences in the dependent variable become increasingly. It seems clear in their reasoning since they express in a qualitative way the characteristics that the graph would have if it were prolonged.

Conclusions

During the implementation of the teaching model, the students performed different productions in order to make sense of the change in dynamic phenomena, by observing and characterizing them, we can answer the questions posed initially.

Regarding the process of abstraction of notions of change, the following was identified. Generally, at first, a qualitative analysis is carried out in which the characteristics of the phenomenon that is modified is identified, which are expressed in the form of non-measurable qualities. By deepening in the analysis of the experiments, the need to measure these characteristics emerges. The qualities identified above are refined, to make way for the approach of magnitudes (variables) that can be measured.

After determining the magnitudes involved, those that change and those that remain constant are identified and, in turn, a class relationship approximation is carried out that maintains and the direction of said relationship (dependency).

By means of a quantitative analysis, consisting of operating arithmetically with the identified data, specific states of the variables are determined (use of the arithmetic variable) (regularly the initial state and one more).

By organizing the information obtained, it is possible to carry out a dynamic reading of it, which helps to determine the relationships between the variables.

By generalizing the arithmetic processes used, it is possible to produce an algebraic text that represent relationships (use of the algebraic variable), in other words: the statement of a function.

In some cases, the verification of the correspondence of the algebraic text with the set of states of the magnitudes were carried out, performing the substitution of data and observing if indeed the function represents the phenomenon.

Regarding the most frequent actions, there is a tendency to linearity: when the type of treatment that should be given to the phenomenon is not understood, a linear treatment was chosen. Students generate different strategies to define the kind of variation in phenomena, however, the most used resource is production is the production of Cartesian graphic texts. By observing the characteristics of these, they try to determine the type of function worked. When performing geometric text production with a low curvature, the variation tends to be defined as linear. However, when it is evident that the geometric text has a certain curvature, it tends to be defined as quadratic.

And finally, the most frequent difficulty arises when defining the type of behavior of the phenomena, resort to arithmetic text, generally in the form of tables of values. The frequent use of the method of differences was detected to define the variable dependent on the phenomena, Generally mechanically applied; the lack of meaning is evident when working with situations of exponential growth, where students state that they do not understand why they never obtain a constant value, despite making a large number of differences.

En esta investigación experimental, observamos y caracterizamos el desempeño de un grupo de futuros docentes que cursan la licenciatura en educación secundaria con especialidad en matemáticas (20-21 años). Adoptamos la propuesta de los Modelos Teóricos Locales como marco teórico-metodológico. El objetivo es caracterizar los procesos de producción de significado de las nociones de variación y variable mediante la aplicación de un Modelo de Enseñanza que implica el trabajo con fenómenos de cambio.

Palabras clave: Modelo de enseñanza, cambio, variación exponencial, sucesiones, dificultades

Introducción

El concepto de variable es de suma importancia ya que sobre él se construyen ideas como la covariación, función, derivada e integral. Sin embargo, como se ha reportado desde hace décadas (Rosnik, 1980), la mayoría de los libros de texto suelen abordar el concepto de variable de forma ambigua y confusa, debido a la amplia diversidad de significados que implica, causando dificultades en su enseñanza (Díaz y Morales, 2005).

En esta investigación interesa estudiar, de forma particular, las dificultades que emergen al trabajar con un modelo de enseñanza constituido por actividades que implican el tratamiento del cambio y la variación en situaciones y contextos diversos. Entiéndase el cambio como la modificación de estados de las cualidades implicadas en un fenómeno, y la variación como la cuantificación del cambio; por lo tanto, al llevar a cabo dichas cuantificaciones estamos en la posibilidad de introducir el concepto de variable.

El problema central de la investigación está relacionado con la lectura/transformación de espacios textuales que involucran las nociones de cambio y variación, para dotar de significado a las variables aritméticas y algebraicas.

Nos proponemos caracterizar la forma en que un grupo de futuros docentes de matemáticas de nivel secundaria dan significado a las nociones de variación, variable y función, mediante la experimentación con un Modelo de Enseñanza que incorpora el trabajo con fenómenos dinámicos y la resolución de problemas.

Con base en dichos propósitos se plantearon las siguientes preguntas de investigación. ¿Cuáles son las actuaciones de los estudiantes al resolver problemas relacionados con la variación y el uso de variables en diversos ámbitos?, ¿de qué forma evoluciona el grado de abstracción de la idea de cambio, para lograr dar significado a la noción de variable? y ¿cuáles son las principales dificultades que se presentan al trabajar procesos iterativos y resolver problemas relacionados con la variación y el concepto de función?

Marco teórico

El marco teórico-metodológico que guía este trabajo es el de los Modelos Teóricos Locales (MTL) (Filloy, 1999), el cual permite analizar los fenómenos que se presentan durante los procesos de enseñanza/aprendizaje. Se otorga una especial atención a la dotación de significados de los conceptos matemáticos gracias a su uso, más que por su significado en abstracto.

Durante el desarrollo de los procesos de enseñanza aprendizaje de un contenido matemático se presentan cuatro elementos interrelacionados: el sujeto que enseña, el sujeto que aprende, el contenido matemático a enseñar/aprender y la comunicación que se establece entre los participantes en el proceso. Por lo tanto, un MTL que contempla la caracterización de los fenómenos y relaciones entre los elementos mencionados, se compone por el Modelo de enseñanza diseñado, el Modelo de procesos cognitivos bajo el cual se caracterizarán la actuaciones de los estudiantes, el Modelo formal correspondiente al contenido matemático y el Modelo de comunicación, con base en el cual se analiza el intercambio de información entre los participantes (Filloy, Rojano, Puig, 2008).

En esta investigación, el modelo de competencia formal está sustentado en parte en las ideas de Hans Freudenthal expuestas en su libro *Fenomenología Didáctica de las Estructuras Matemáticas*, de forma específica en el análisis que hace en los capítulos “Lenguaje Algebraico” y “Funciones” (Freudenthal, 1983). También se considera el estudio formal del concepto de iteración, que juega un rol destacado en este trabajo.

Según Freudenthal (1983), el concepto de función se constituye sobre el concepto de variable y la idea de dependencia. La precisión con que es posible describir la dependencia entre variables puede ser distinta, yendo desde el uso de nociones de orden (cuanto más esto, tanto más eso), hasta relacionar una con otra de forma más o menos precisa, posiblemente numérica.

Una idea más que sustenta teóricamente la investigación es la noción de iteración, ya que se considera que tiene potencial para contribuir en la dotación de significado a los conceptos de variación y variable, resaltando su cualidad dinámica, desde una aproximación con un grado de abstracción bajo (Choate, Devaney y Foster, 1999; Peitgen et al., 2004).

El modelo formal es un elemento que nos sirve para observar las producciones de los estudiantes, además de estos referentes, caracterizamos las actuaciones con base en las categorías: tipo de aproximación empleada por los estudiantes al resolver situaciones problemáticas, ya sea de tipo cualitativa o cuantitativa. Identificamos si son producciones de tipo dinámica o estática y clasificamos los usos de la variable, ya sea aritmética o algebraica.

Filloy (1999) afirma que existen bases teóricas que confirman que un primer acercamiento semántico al álgebra es más conveniente para la dotación de significado de los conceptos que un acercamiento meramente sintáctico. En este proyecto de investigación, en donde se trabajan las nociones de cambio, variación, variable y función, se ha optado por llevar a cabo un acercamiento de tipo concreto con base en un análisis histórico crítico del concepto de función, con el objetivo de detectar obstáculos epistemológicos generados durante su desarrollo (Cuevas y Díaz, 2014), y que podrían presentar los estudiantes durante su proceso de aprendizaje (Godino, 2003).

Metodología

La experimentación se realizó con 23 estudiantes (21-22 años), que actualmente cursan el octavo semestre de la Licenciatura en Educación Secundaria con especialidad en Matemáticas en la Benemérita y Centenaria Escuela Normal del Estado de Durango, ubicada en Durango, México.

El desarrollo de la experimentación se basa en la metodología definida en los Modelos Teóricos Locales (Filloy, 1999), la cual establece seis etapas: selección de la población de estudio; diseño y aplicación de un diagnóstico; clasificación de la población, la cual fue realizada con base en el análisis del nivel de competencia sintáctica, semántica y de usos intuitivos de la población (Rojano, 1985); elección de una muestra representativa de la población; estudio de casos mediante entrevistas clínicas y elaboración de un reporte de observaciones.

Resultados de la experimentación

A continuación, se presenta una situación problemática representativa del modelo de enseñanza, describiendo las producciones de los estudiantes durante su resolución.

Luego de que los futuros docentes trabajaron un fenómeno de movimientos bancarios con interés simple, se les planteó un problema más del mismo estilo, pero con un interés compuesto, puesto que resulta de interés observar la forma en que hacen el tratamiento de fenómenos donde se presentan comportamientos distintos al lineal o cuadrático; en este caso, de tipo exponencial. La situación planteada fue la siguiente.

> Cuando en un préstamo el porcentaje es añadido al capital y pasa a formar parte de la deuda, el interés de este nuevo capital se llama interés compuesto.
>
> 1. Supongamos que tenemos un capital de 200 pesos al 20% de interés compuesto durante 5 meses. Completa la siguiente tabla para averiguar cuánto se deberá al finalizar cada mes

Una de las principales dificultades presentadas en esta situación fue detectar el tipo de variación implicada. Para lograrlo algunos estudiantes trataron de auxiliarse de la representación gráfica, obteniendo primero una representación tabular de la situación, y en seguida graficando los valores como pares ordenados. Procedieron colocando los puntos correspondientes y luego trazaron una línea que pasa por cada uno de éstos. Gracias a esto se comenzaba a descartar la variación lineal como correspondiente al fenómeno trabajado.

Al no conseguir definir el tipo de variación implicada, algunos estudiantes realizaron un proceso distinto, que consistió en calcular las diferencias entre los términos consecutivos y luego calcular las diferencias de las diferencias, pero al calcular la primera y segunda diferencias no obtienen valores constantes, lo cual causa aún más confusión. Incluso deciden hacer el cálculo de las terceras diferencias sin obtener un resultado que permita dotar de sentido al fenómeno. Se puede apreciar que el método se rescata como un proceso mecanizado.

Hubo otro grupo de estudiantes que también usó el método de las diferencias y tampoco les permitió determinar el tipo de variación presente en el fenómeno, pero sí fue útil para descartar la variación cuadrática como posibilidad, ya que al obtener la segunda diferencias no obtuvieron valores constantes.

El procesamiento numérico de la situación le permitió observar a dos estudiantes que, a medida que la variable independiente aumenta, las diferencias en la variable dependiente se hacen cada vez mayor. Se observa claridad en su razonamiento ya que expresan de forma cualitativa las características que tendría el gráfico si este fuera prolongado.

Conclusiones

Durante la implementación del modelo de enseñanza los estudiantes realizaron distintas producciones con el objetivo de dar sentido al cambio en los fenómenos dinámicos, mediante la observación y la caracterización de éstas podemos responder a las preguntas planteadas en un inicio.

Respecto al proceso de abstracción de las nociones de cambio se identificó lo siguiente. Generalmente en un primer momento, se realiza un análisis cualitativo con el cual se identifican características del fenómeno que se modifican, las cuales son expresadas en forma de cualidades no medibles. Al profundizar en el análisis de los experimentos emerge la necesidad de medir dichas características. Las cualidades antes identificadas se refinan, para dar paso al planteamiento de magnitudes (variables) que pueden ser medidas.

Luego de determinar las magnitudes implicadas, se identifican las que cambian y las que se mantienen constantes y, a su vez, se realiza una aproximación a la clase de relación que mantienen y la dirección de dichas relaciones (dependencia).

Mediante un análisis cuantitativo, consistente en operar de forma aritmética con los datos identificados, se determinan estados específicos de las variables (uso de la variable aritmética) (regularmente el estado inicial y uno más). Al organizar la información obtenida, es posible llevar a cabo una lectura dinámica de ésta, que ayude a determinar las relaciones entre las variables.

Mediante la generalización de los procesos aritméticos empleados, es posible producir un texto algebraico que represente las relaciones (uso de la variable algebraica), dicho de otra forma: el planteamiento de una función. En algunos casos, se llevó a cabo la comprobación de la correspondencia del texto algebraico con el conjunto de estados de las magnitudes, realizando la sustitución de datos y observando si efectivamente la función representa el fenómeno.

Respecto a las actuaciones más frecuentes, se presenta una tendencia a la linealidad: cuando no se comprende el tipo de tratamiento que se debe dar al fenómeno, se optaba por un tratamiento lineal. Los estudiantes generan distintas estrategias para definir la clase de variación en los fenómenos, sin embargo, el recurso más utilizado es la producción de textos gráficos cartesianos. Mediante la observación de las características de éstos, tratan de determinar el tipo de función trabajada. Cuando se realiza la producción de un texto geométrico con poca curvatura, se tiende a definir la variación como lineal. Sin embargo, cuando es evidente que el texto geométrico presenta cierta curvatura, se tiende a definir como de tipo cuadrática.

Y por último, la dificultad más frecuente se presenta al definir el tipo de comportamiento de los fenómenos, recurren a textos aritméticos, generalmente en forma de tablas de valores. Se detectó la utilización frecuente del método de las diferencias para definir el comportamiento de la variable dependiente en los fenómenos. Aplicado de forma mecánica generalmente; la falta de sentido es evidente al trabajar con situaciones de crecimiento exponencial, donde los estudiantes manifiestan no comprender por qué nunca obtienen un valor constante, a pesar de realizar una gran cantidad de diferencias.

FUNCTION IDENTITY AND THE FUNDAMENTAL THEOREM OF CALCULUS

Alison Mirin
Arizona State University
amirin@asu.edu

By analyzing the responses of 100 introductory calculus students to two questions, this study addresses how students understand the fundamental theorem of calculus as it relates to function identity. One question involves students' understandings of the fundamental theorem of calculus, and the other involves their concept definitions of function sameness. This analysis aims to better understand students' concept images of function sameness, both in the context of the fundamental theorem of calculus and in general.

Keywords: University Mathematics, Calculus

The fundamental theorem of calculus (hereafter "the FTC" or "the fundamental theorem") is an important aspect of mathematics that we would like calculus students to understand. The FTC provides a relatively fast way of calculating integrals, which are used in various quantitative situations. One way to view an integral is as a function, say $\int_a^x f(t)dt$, where x is a variable. This is, arguably, the manner in which Newton conceived it (Thompson & Silverman, 2008). In this light, the FTC is actually a statement of function identity: the function g defined by $g(x) = \int_a^x f'(t)dt$ is the same function as h defined by $h(x) = f(x) - f(a)$. This paper addresses student understanding of this concept; specifically, I investigate the following: how do students understand the fundamental theorem in relation to their conceptions of function sameness?

There are three broad topics that apply to this investigation: student understanding of *function*, *function identity*, and the FTC. Research suggests that secondary and university students often do not have a mathematically normative understanding of function (Bardini et al., 2014; Leinhardt et al., 1990; Mirin, 2017; Sfard, 1992; Thompson, 1994; Vinner & Dreyfus, 1989). Function and function identity are intertwined; how a student understands function identity is closely tied to how they understand function (Mirin, 2017). A student's concept of what a function is will be closely tied to how they understand when two functions are identical. For example, if a student thinks of a function as a process, then it would make sense for that student to think of functions as identical whenever they represent the same process. Relatedly, if a student thinks of a function as an equation, then they might therefore think of different but equivalent equations as necessarily representing different functions. Relatedly, some university students struggle with the notion of function identity, classifying functions represented differently as different functions (Mirin, 2017; Mirin, 2018; Mulhuish & Fagan, 2017).

There is little literature on how students understand the fundamental theorem. Thompson (1994) finds that students' issues grasping the FTC are grounded in underdeveloped understandings of rate of change and covariation. Orton (1983) reports the types of mistakes students make in doing problems with definite integrals. He focuses on how students understand definite integrals as limits. However, his study does not address integrals in the context of the fundamental theorem or as functions. Thompson and Silverman (2008) make the point that an integral *as a function* is conceptually different from a definite integral as a number. That is, conceptualizing $g(x) = \int_a^x f'(t)dt$ as a function is different than conceptualizing $\int_a^b f'(t)dt$ for a particular number *b,* in the same way that conceptualizing the squaring function is different from conceptualizing a particular number being squared. In this manuscript, I situate the FTC as a statement about function identity, and hence also as a statement about functions.

I adopt the constructs described in Tall and Vinner (1981): A student's *concept image* is "the total cognitive structure that is associated with the concept, which includes all the mental attributes and associated properties and processes" (p.152). One component of a student's concept image is their *concept definition,* which is their stated definition of a concept. This study involves investigating student concept definitions for function sameness, while acknowledging that there is likely more to a student's concept image than their stated concept definition.

The overarching epistemology guiding this study is radical constructivism, as described in Thompson (2000). This epistemology takes the perspective that students construct their own mathematical realities. A guiding aspect of my research is to not assume that what is a representation of an abstract mathematical object to us is also viewed as an abstract mathematical object by a student (Thompson & Sfard, 1994). Similarly, what is the same to us (e.g. different representations of the same function) might not be the same to students. This mathematical reality of the students is not directly accessible to us as researchers – the best we can do is create models (explanations) that account for students' responses (Clement, 2000).

Task Design, Subjects, and Data Collection

This is part of a larger study, the first portion of which can be found in Mirin (2018). A quiz was administered by the instructor to 102 students during the last week of an introductory calculus course at Anonymous State University (ASU). The course followed the Stewart (2013) text, and students had, within the week prior, learned about the FTC and practiced textbook problems applying it. The tasks discussed here are in Figure 1 (below).

1. Let p be the function defined on all real numbers by

$$p(x) = \int_2^x 3t^2 dt$$

and let q be the function defined on all real numbers by

$$q(x) = x^3 - 8$$

(a) How are p and q related? (Select option i. or ii.).

i. p and q are the same function.

ii. p and q are not the same function.

(b) Provide an explanation for your answer for 1a

2. Suppose g is a function and h is a function. What does it mean for g and h to be the same function? Explain.

Figure 1: The FTC Question (1) and the Function Sameness Question (2)

The first part of the quiz involved questions regarding derivative at a point of a single function represented in two different ways. The results of that portion indicated that students might have a mathematically non-normative concept image of function sameness. Here, I address student responses to the tasks in the second part of the quiz, which are relabeled as "Question 1", the FTC question, and "Question 2", the function sameness question (Figure 1, above). Notice that Question 1 is an instance of the FTC. The normatively correct response to this question is that p and q are the same function. Question 2 asks the student to give their concept definition of *function sameness.* Note that there are at least two different normatively correct responses to this question; the first is that g and h are the same if and only if g and h share a graph (set of ordered pairs) and also share a codomain, and the second only requires that they share a graph (Mirin et et al., in review). However, codomain was not once mentioned by students.

Analysis and Results

Due to the multiple choice nature of the question, coding the results of the Fundamental Theorem question was straightforward. Two students did not answer the question, nor did they answer 1b or 2. For this reason, they are excluded from the remainder of this analysis, leaving us with a convenient sample size of 100. Of the remaining 100, 61 chose option (i) (that p and q are the same function), and 39 chose option (ii) (that p and q are not the same function). One thing to note is that the students were not asked to "evaluate" the integral, that is, put it in closed form (e.g. as a polynomial, in this case). This means that there is a possibility that some students might have evaluated the integral as something different and have assessed p and q as different for that reason. Of the 100 students, 46 attempted to evaluate the integral, and 29 did so correctly. Unsurprisingly, there is a strong correlation between those who evaluated the integral correctly and those who answered that p and q are the same function, with 27 out of 29 (93%) who evaluated the integral correctly also claiming that p and q are the same function, and 8 out of 17 (47%) who evaluated the integral incorrectly claiming that p and q are not the same function (χ^2=12.4883, $p<.05$).

The nature of students' incorrect integral evaluations was illuminating and not due to any sort of minor computational errors. In fact, only two students who incorrectly evaluated the integral did so in such a way that it was a function of x (e.g. writing $p(x)=x^3+12$). Instead, 14 out of 17 (82%) included a "+C" in their evaluation of the integral. Students' explanations in 1b have not yet been analyzed to their full potential, but a preliminary reading provides insight to student thinking. Their explanations seem to suggest that some students might have viewed the integral as representing a string of symbols. This is consistent with Musgrave and Thompson's (2014) and Sfard's (1992) findings suggesting that some students think of a function as a string of symbols. To many of the students who evaluated the integral as involving a C (e.g. x^3+C), it would make sense that these students would not think of x^3+C as being the same as x^3-8, as these are different strings of symbols. For example, one student explains "when you derive p(x) it becomes the generalized formula $3x^2+C$. This is not equal to q(x)." Similarly, the students who evaluated the integral correctly tended to find that the resulting string of symbols (x^3-8) was identical to that in the definition of q, and therefore q and p are identical: "once calculated, the integral in p(x) becomes the same expression as q(x)".

There's a sense in which 36 out of 46 gave consistent responses; they either (1) evaluated the integral correctly and wrote that p and q are the same function, or (2) evaluated the integral incorrectly and wrote that p and q are different functions. This is consistent with thinking of a function as a string of symbols; if a student evaluates the integral correctly, then they observe that the resulting string of symbols is the same as x^3-8, and if they evaluate it incorrectly then they observe that the resulting string of symbols is different from x^3-8 (discussed above). The remaining 10 students had mixed responses. Those students' explanations in 1b provide some insight into their understanding of function identity. For example, some students included a +C for the integral yet assessed p and q as the same on the grounds that they share a derivative. Relatedly, some students wrote that p and q are the same function while also stating that they had a different constant. For these students, sameness of derivative was sufficient for sameness of function, and this was reflected in their concept definitions (discussed below).

Coding Question 2 results involved partitioning student answers into "extensional" and "not extensional". "Extensional" includes the characterization of function identity as same graph, same ordered pairs, or same output for every input. Statements such as "g and h are the same when g(x)=h(x)" were not coded as "extensional"; this is because in the absence of a universal quantifier, students could view "g(x)=h(x)" to mean that g(x) and h(x) are identical as equations (strings of symbols) or that g(x) transforms to h(x) under certain rules (Mirin, 2017; Sfard, 1988). Additionally, students might not view g(x) as representing a number or value of a dependent variable and instead view it as a name of a function (Musgrave & Thompson, 2014; Thompson, 1994, 2013b). Thirty-five students' concept definitions were coded as "extensional". Coding the remaining concept definitions is an ongoing project, but it bears mentioning that, consistent with the previous paragraph, 11 students included sameness of derivative in their criteria for function sameness.

I had originally hypothesized that there would be a correlation between students who give extensional function sameness concept definitions and those who answer that p and q are the same function. This is because I expected students with other, non-normative understandings of function identity to claim that p and q are different. This was indeed the case with at least two students, who asserted that p and q differ because one represents an area under a curve, and the other does not. However, a chi square analysis revealed no such correlation. It seems that because p could be expressed in closed form, students' assessment of sameness of p and q was primarily about how they calculated the integral. This allowed for students to assess that p and q are the same on the grounds that they are expressed by the same equation, rather than requiring a robust understanding of function sameness. This resulted in the possibility that students who understand functions as strings of symbols answered that p and q are the same function.

That so many students evaluated the integral with a "+C" is especially revealing. This might suggest that, despite the function notation *p*(x) being used and the quiz explicitly telling them that *p* is a function, these students might not have viewed *p* as a function (perhaps, as one student above put it, "a formula"). This leaves open the possibility that, when these students were asked if *p* and *q* are the same function, they were not viewing *p* as a function at all. This is consistent with the results of the first part of the quiz, in which students appeared to not think of a particular piecewise function as a function (Mirin, 2018).

Conclusions and Future Directions

This preliminary report provides valuable data on students' concept images of function sameness. It is notable that only 61% of these calculus students identified a straightforward instance of the fundamental theorem of calculus as asserting function identity. However, it seems that for several of those students, their assessment was mostly about their calculation of an integral. Perhaps, for the reasons discussed above, we could investigate whether students understand an integral (such as in 1a) to even be a function. It might also be productive to provide a similar function sameness question as in 1a, but instead using the notation f '(x) rather than providing a specific derivative that the student can anti-differentiate procedurally. It might additionally be wise to see how students use and understand the notation "+C".

This study also gives insight into students' concept definitions of function sameness, with 35% providing an extensional (mathematically normative) answer. Interestingly, 11% included sameness of derivative in their criteria for function sameness. I hypothesize that the FTC question might have influenced students' function sameness concept definitions. Future research can address this hypothesis by providing the concept definition question in a different context.

The transition to proof has been a heavily researched area in undergraduate mathematics research. As proof construction involved both formal-rhetorical and problem-solving aspects, this study investigated how undergraduate mathematics majors who recently completed a transition to proofs class engage with two different problems: one with formal rhetorical knowledge and one without. Overall, students exhibited behavior indicating that formal-rhetorical knowledge could continue to act as a barrier to approaching and solving problems. The study highlighted the importance of sense-making strategies and familiarity not only with mathematical content knowledge but also with the logical structure of mathematical arguments.

Keywords: Problem Solving, Reasoning and Proof, University Mathematics, Advanced Mathematical Thinking

Introduction

For much of schooling, mathematics education has often had computation and applications of theorems or formulas at the center. However, the academic discipline of mathematics is more concentrated on generalizations and abstractions; coming up with rigorous and correct proofs of previously unproved statements was the goal for most research mathematicians. This transition to formal proof usually took place during undergraduate studies, with many scholars having examined the cognitive difficulties in learning to do formal mathematical proofs (e.g., Brown, 2007; Moore, 1994; Thoma & Nardi, 2017). As a stark deviation from prior math experiences, this transition is abrupt and difficult (Moore, 1994). Despite the difficulty in learning proofs, research has recognized how proving and problem solving are closely related: It takes problem-solving in order to translate an informal argument into a valid formal proof (Mamona-Downs & Downs, 2009), and the proofs themselves can be divided into formal-rhetorical and problem centered parts (Selden & Selden, 2013). This translation is not an easy task, in that it requires both knowledge and instruction. Students often do not learn the necessary tools explicitly or rigorously until students are asked to construct formal proofs. In this study, we researched undergraduate mathematics students who recently completed their university's proof introductory course. Our research question was: How did these students engage with formal-rhetorical and problem-centered aspects of mathematical tasks?

Framing

The conceptual framework for this study drew from the following main areas: aspects of proof construction (Selden & Selden, 2013; Weber, 2005) and mathematical problem solving (Schoenfeld, 1985) to guide our data collection and analysis.

Aspects of Proof Construction

Though mathematical proofs have been studied for many years prior to their formulation, two considerations of proof construction procedures are particularly useful to this study. One delineates parts of a mathematical proof, whereas the other categorizes different types of proof constructions. Selden and Selden (2013) developed a framework of understanding proofs to be composed of two parts: the formal-rhetorical part and the problem-centered part. Between different statements and

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. Cinvestav / AMIUTEM / PME-NA. https:/doi.org/10.51272/pmena.42.2020

even different proofs of the same statement, there are different compositions when broken down into these constituent parts. Selden and Selden's idea of these two components of a proof will be the guiding main framework for this study.

Furthermore, Weber (2005) categorized three types of proof construction procedures demonstrated by undergraduate math students – procedural, syntactic, and semantic. Weber argued that learning opportunities are largely dependent on what type of construction students utilized. Together, the formal-rhetorical and problem-centered parts of proof and proof construction procedures provide a framework of understanding students' problem-solving pathways.

Mathematical Problem Solving

Schoenfeld (1985) developed a framework of understanding mathematical problem solving. He delineated four types of knowledge students draw from when engaging in mathematical problem solving: resources, heuristics, control, and beliefs. Others shortly categorized similar ideas in different ways. Considering related research together in a more cognition focused formulation, Schoenfeld (1992) recognized that "there appears to be general agreement on the importance of these five aspects of cognition: the knowledge base, problem solving strategies, monitoring and control, beliefs and affects, and practices" (p. 42). This framework has frequently been applied to college-level mathematics (e.g. Selden & Selden, 2003; Selden & Selden, 2013; Weber, 2005) and is useful for analyzing student problem-solving.

Methods

Ten undergraduate mathematics students, six females and four males, from a Hispanic-serving four-year research university in California participated in this study. All of the students completed a transition to higher mathematics course in the previous quarter. This course, as a prerequisite for many mathematics courses that follow, was described as an introduction to the elements of propositional logic, techniques of mathematical proof, and fundamental mathematical structures, including sets, functions, relations, and other topics.

We conducted and video-recorded task-based, think aloud interviews (Charters, 2003). The participants worked through two problems: a non-routine problem taken from the 2017 American Invitational Mathematics Examination II and a problem that asked students to construct an alternative proof of a well-known result given the argument's outline. The second was developed in consultation with a mathematics professor from the study's university, who taught a number of the participants in the quarter prior to data collection. For the rest of the paper, we will refer to these problems as P1 and P2 respectively. Students chose which problems to attempt first, but they worked through both tasks. The difference between the two tasks was that P1 was a "real-world" problem that needed no formal-rhetorical knowledge, and P2 required substantial formal-rhetorical knowledge (but concluded with the problem-centered part). After the tasks, we collected student work and finished with a quick debrief aimed at understanding the students' feelings about the problems (e.g., their ease and enjoyment) and clarifying the students' strategies. In relation to our research question: the student work informed and documented students' strategies and video data contributed both to our understanding of strategies as well as our understanding of students' feelings of working through the tasks.

To analyze the data, we did an initial round of focused coding (Maxwell, 2005), looking for students' feelings and strategies through the tasks while keeping track whether it related to formal-rhetorical or problem-centered aspects. After the initial coding, we developed another set of codes within strategies: sense-making, argumentation, and generality.

Findings

In general, students exhibited high levels of engagement with and interest in the tasks – every participant requested information about the solutions after the interview. Despite differences in students' feelings about the two tasks, we found similarities about what made the mathematics enjoyable for participants. Regarding strategies, we found that the presence and absence of formal-rhetorical aspects related to how students' sense-making and argumentation.

Students' Feelings: Familiarity, Fun, and Frustration

Familiarity played a role from the start in how students approached the problems. Excluding students whose decisions on which problem to attempt first was semi-arbitrary (i.e., left vs. right, top vs. bottom, etc.), the remaining students were split half and half. Notably, students chose P1 because of an expected enjoyment, whereas others began with P2 because it was more familiar. These reasons were consistent among P1-starters and P2-starters. Isaac, who began with P2, explained that he was, "more comfortable with this kind of thing … there were aspects of everything that [he] could relate to." Conversely, students who started with P1 did so because it seemed more puzzle-like and fun. Henry explained, he "[doesn't] know if [he] considers proof-writing fun," contrasting it with how P1 was "completely uncharted … never seen it before." While the task of constructing a proof felt familiar to students, only some were drawn to this comfort. Although there was certainly a problem-centered aspect to P2, and to proofs generally, the presence of formal-rhetorical aspects seemed to detract from it being seen as fun P1, even when they recognized the proof's puzzle-like aspect afterwards.

There was an interesting interplay between familiarity, fun, and frustration. A common theme among the students was that they enjoyed feeling productive without feeling as though they were doing tedious work. Esther considered P1, "not as much of a math problem." She expressed that sometimes she hard time motivating herself when she could think of how to code a computer program to compute it for her. Furthermore, students had a hard time engaging with the problem-centered part of P2 when they did not know how to approach it. That said, it should be highlighted that frustration was not inherently a bad feeling. Talia found P1 to be no only more frustrating but also more fun. Students found enjoyment when they had tools to approach the task and there was some familiarity, some frustration, and a feeling of progressing in the task without having it feeling immediately solvable by brute force.

Students' Strategies

Generality as a tool and obstacle. As a counting problem, P1 required thinking generally. All of the students recognized this: the students noticed that symmetry and choices were important aspects of the problem. For instance, Madison explained while solving, "If I can figure out how it works for one town, I can just apply that reasoning to other towns." Moreover, all of the students realized that the existence of a five-town loop would satisfy the conditions and attempted to count those configurations. However, though they all recognized it as a sufficient condition, not all of the students investigated whether the existence of a five-town loop was a necessary condition. In fact, Caleb was the only student to substantively explore this.

P2 had two major instances of generality in the desired proof. First, because the proof was a statement holding for every natural number, it sufficed to prove the result using a fixed but arbitrary natural number, maintaining its generality throughout the proof. Second, students had to represent two arbitrary elements of a set when proving that something was closed under multiplication. These uses of generality are routine in proof-writing. The students generally did not have an issue with the navigating the second instance, but there were instances where students reverted to considering all natural numbers simultaneously (as opposed to a fixed arbitrary natural number), which altered the argument's viability. Though students seemed aware of this generality's role, maintaining the correct level generality and applying it to sound argumentation proved to be an obstacle in both problems.

Sense-making to argumentation. Throughout the process, students employed different sense-making strategies. At the lowest level, every participant asked questions, reread the problems, and thought about the tasks to make sure that they understood the problems. However, the process of understanding and solving the problems were manifested differently between P1 and P2.

One of the most frequently used sense-making strategy was thinking of examples. Though this might have been due to the problems' context, every participant's primary approach to P1 entailed drawing examples. These examples then informed their understanding, helping students consider strategies as they constructed systematically. There were fewer instances of student example construction in P2: Isaiah and Gianna listed elements of the sets involved, and Megan drew a number line to explore parts of the problem. That said, the remaining students used symbol manipulation and, at most, tried thinking about the sets in their head. As another sense-making strategy in P1, two students considered a similar, yet simpler, problem (considering a system where there are fewer than the five towns). Additionally, Daniella calculated the total number of road configurations to provide an upper bound to the desired answer. Such a strategy not only provided a means towards an alternate solution path, namely subtracting the invalid configurations from the total to obtain the desired answer, but also provided a measure of reasonableness for future answers. Without this strategy, Henry and Esther got overwhelmed with the sheer number of possibilities and offered infinity as their initial proposed answer.

Largely due to the real-world context of P1, students used intuition to form their strategies. Half of the students clearly made and explored the realization of a working condition. As Talia said, "every town needs a way in and a way out." However, similar to student thinking of five-town loops, there was limited substantive work to show whether this was a sufficient and/or necessary condition. Isaac and Megan both recalled a puzzle that entailed drawing a certain figure without picking up their pencil. Because it seemed related enough, they took it as a potential solution strategy, taking time to realize that they had made an illogical jump to translate P1 into a nonequivalent problem. Conversely, many students explicitly unpacked the logical structure of the statement of P2 and how the argument outlined addressed the logical structure. Some went beyond doing this mentally or verbally, writing the statements translated into symbolic logic. Overall, students generally attended more to sense-making in P1 with sound argumentation taking a backseat, while the opposite was true for P2.

Discussion & Conclusions

The transition to proofs and higher mathematics in general is a complex process that deviates from what many students' previous mathematical experience. While they may not be strangers to mathematical problem solving and non-routine problems, students are asked to integrate formal-rhetorical knowledge when constructing proofs. The presence of this knowledge in problems may overpower the problem-solving that underlie mathematics' appeal. Making explicit connections between formal-rhetorical fluency to sound argumentation and problem-solving generally in instruction may aid understanding and value given to proofs.

TEACHERS-IN-TRAINING'S REFLECTIONS ON THE TEACHING OF CALCULUS TO PEOPLE WITH DISTINCT CHARACTERISTICS

PROFESORES EN FORMACIÓN QUE REFLEXIONAN SOBRE LA ENSEÑANZA DEL CÁLCULO A PERSONAS CON CARACTERÍSTICAS DIFERENCIADAS

Parada Rico, Sandra Evely
Universidad Industrial de Santander
sanevepa@uis.edu.co

Echeverría Ballesteros, Cristian Leonardo
Universidad Industrial de Santander
cristian2198157@correo.uis.edu.co

We present the progress of a study that seeks to answer: What learning do teachers in training consolidate that reflect on the teaching of Calculus to people with distinct characteristics in higher education? We expect to answer this using the model of reflection and action of Parada (2011) as a theoretical-methodological guide. The study follows an action research methodology, planned in six phases; here the results of the first four are reported. The learning constructed by future teachers will be described in terms of the three components of reflective thinking established by the model. A meaning so far reached by future teachers is the need to approach the context of students to pose problems tailored to their distinct characteristics.

Keywords: Teacher Preparation in Training, Special Education, Calculus.

Colombian educational policies have promoted inclusion in the country's Higher Education Institutions (HEIs). One of them is the Universidad Industrial de Santander (UIS) context of the study reported here, in which there is an agreement for special admissions, which has been implemented since the first period of 2014. In addition, the UIS within its strategies to face the problems of desertion and permanence has created a policy of Academic Excellence (Agreement No. 018 of 2014) that is executed through accompaniment and monitoring programs for students. One of the programs, called SEA-ASAE, is led by the Mathematics School and is focused on serving and accompanying students who take math courses through peer tutoring and academic monitoring. The tutors who offer the accompaniment are mathematics teachers in training, who are studying a Bachelor's degree in mathematics from the institution.

The SEA-ASAE program has been developing since 2012 and has allowed the constitution of a Community of Practice (CoP), made up of teacher educators, professors of the mathematics subjects, practicing tutors and auxiliary tutors (graduates of the didactics of calculus course). Within the course, students who have practiced as Differential Calculus tutors with students from Science and Engineering programs have reported cases of students who: have Asperger, have a mild cognitive disability, are from indigenous communities, among others. The tutors show difficulty in attending to this population because they have not received the didactic training to do so; hence the need to promote reflection among mathematics teachers in training on teaching calculus to people with distinct characteristics.

The aforementioned, offers us two problems that can be articulated in favor of educational inclusion in HEIs: i) mathematics teachers in training require instruction around inclusion and, ii) people with distinct characteristics need support and attention from people that understand their condition and have mathematical knowledge. For this reason, in the research reported here, we focus our attention on the practitioners of the CoP, who begin their participation in it as practicing tutors who, in turn, develop the Calculus Didactics course. Course, in which a conceptual and methodological structure will be developed that allows reflection on the teaching of calculus and attention to distinct characteristics, an experience with which we hope to achieve the research objective: describe the

learning built by training teachers reflecting on the teaching of calculus to people with distinct characteristics in higher education.

Background

According to Camargo (2018), since 1960 organizations such as UNESCO have pursued guiding principles with a view to promote inclusive education. As a result of these principles, policies have emerged in different countries, including Colombia.

The Colombian political constitution of 1991 and the General Law of Education of 1994 are the main policies that speak of inclusion in Colombia, establishing that education is a right for all and that Colombians should feel included, without differentiation of race, sex, religion, political beliefs, and other constituent elements of Colombian multiculturalism. These policies have been gradually implemented, in recent decades, at various levels of education, starting with basic and secondary education, and to a lesser extent in Higher Education Institutions (HEIs).

Because the inclusion policies for HEIs were not very precise, the Ministry of National Education (MEN), and the Higher Council for Higher Education (CESU, 2013), in the agreement for the upper 2034, establish a regulatory framework, in where it is stated that in order to achieve a quality education, the entrance, permanence and graduation of students with certain distinct characteristics must be guaranteed, which may be people: i) With Special Educational Needs (SEN), that is, they have some disability status or exceptional talents; ii) from indigenous communities or reservations; iii) from Afro-Colombian, *Palenquera* and *Raizal* populations; iv) from departments where HEIs do not exist; v) coming from municipalities with difficult access or with public order problems; vi) victims of the Colombian internal armed conflict; and viii) demobilized from the peace processes.

According to a study carried out by CESU (2013) in collaboration with the Development Research Center (CID) of the Universidad Nacional de Colombia (UNAL), it is established that students with distinct characteristics are the most likely to drop out of HEIs. Furthermore, it has been shown that these students have difficulties in understanding the mathematical objects of differential calculus. Moreover, according to MEN (2016), students with SEN present certain difficulties associated with their condition.

One of the strategies offered by the MEN to guarantee the permanence and therefore the graduation of the students with distinct characteristics is to have inclusive teachers in the HEI: to have a suitable training both in its disciplinary, didactic, as well as in inclusive education.

Silverman and Thompson 2008) mention that teachers must have a deep knowledge of mathematics; Ponte (2011) states that he must also have knowledge in the didactic; Llinares (2007), Flores (2009) establish that the teacher must be reflective; and Aké (2015) mentions the need to promote reflection among mathematics teachers about inclusive education.

Parada (2011) based on the reflection processes within the communities of practice, proposes the RyA reflection and action model, which aims to guide theoretically and methodologically the actions carried out by mathematics teachers before, during and after class, in order to increase the capacity of its members to reflect critically on their professional practices.

Theoretical and Conceptual Aspects

The research of which the first results are reported here, is based on the R-y-A model, whose main objective is to promote reflection processes in communities of practice (CoP) and whose main elements are: participation (which may be peripheral or full), reflection and action. The fundamental resource that is reflected on is action, understood as the performance of the mathematics teacher in her or his own professional practices.

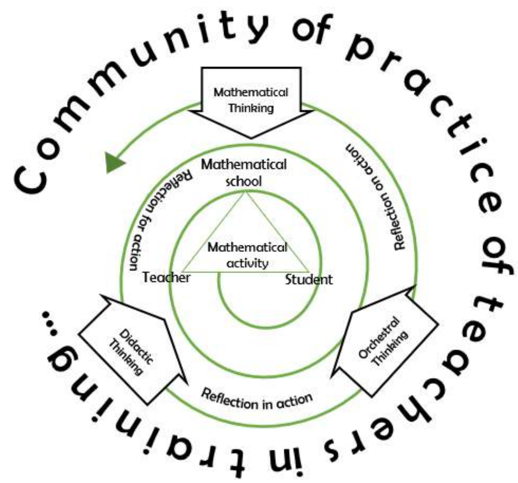

Figure 3. Adaptation to the R-y-A model of Parada (2011)

At the center of the Model is the **mathematical activity,** which is where professional development efforts are focused. Mathematical activity is found within the Saint-Onge pedagogical triangle (1997, cited by Parada, 2011),where there is a relationship between the student, the teacher and the mathematics school.

These relationships make the student's mathematical activity during class and the teacher's mathematical activity before, during and after class possible.

Following Dewey's ideas (1989), Parada (2011) understands **Reflection** as a process of resolving doubts, conflicts, and willingness to review one's performance; that is why it seeks to promote the **reflection processes** of mathematics teachers, which is a continuous process that favors professional development. It is broken down into three processes: **Reflection-for-action** (reflection made by the teacher before the class), **Reflection-in-action** (reflection made by the teacher during the class), **Reflection-on-action** (reflection made by the teacher after the class).

The three arrows around the spiral represent the three thoughts into which the **reflective thinking** of the mathematics teacher is broken down: **mathematical thinking** (the mathematical knowledge that the teacher uses to develop mathematical activity in the classroom), **didactic thinking** (arises when the teacher asks about the different ways of approaching the mathematical content to their students) and **orchestral thinking** (it is characterized around the conduct of the class and the way the teacher uses resources to promote mathematical activity in the classroom).

Research Methodology

The study reported here is of an action-research type, in the light of Kemmis and McTaggart (1988). It is carried out in six phases, which are briefly described below:

1) Phase 0 (preliminary study): study of national and international policies around inclusion in Higher Education, collection and analysis of data related to the number of students with distinct characteristics admitted to the UIS; 2) Phase 1: characterization of the community of practice (study context). Design of the intervention and participation plan with the CoP. Delimitation of the participants of the CoP on which the intervention will be carried out; 3) Phase 2: first approach to the CoP. Reflection and action processes with seven teachers in training who were developing the calculus teaching course in the first semester of 2019; 4) Phase 3: analysis of the results of the first approach; 5) Phase 4: second approach to the CoP, at the time of the writing this document. This phase is being developed with fifteen students who are ahead in the Calculus Didactics course; and 6) Phase 5: Data analysis and characterization of reflective thinking, which will answer the research

question taking into account the three dimensions of reflective thinking (variational thinking, didactic thinking and Orchestral thinking) of the mathematics teacher that the R-y-A model offers.

Some Results

The analysis of the institutional policies (Agreement No. 282 of November 7, 2017) and the data of the admissions of the University allowed us to know that between 2014 and 2019, the UIS has registered a total of 347 students who entered through special admissions, of which 220 (63%) students entered careers such as engineering, science and others, which have mathematics-related subjects, in particular differential calculus, in their study plan. Of these students: 81 come from municipalities with difficult access or problems of public order, 100 victims of the armed conflict, 15 from the Afro-Colombian, Palenquera and Raizal populations, 22 from indigenous communities and 2 from departments where there are no HEIs.

Regarding the first approach, through the negotiation of meanings that were made possible within the activities of the course, four projects were objectified, the purpose of which was to prepare a didactic design around an object of study of calculus aimed at a person with differentiated characteristics. It is from this first approach that the projects were made.

An interesting result was the one achieved by the teacher who carried out the design aimed at a student from the Misak indigenous community, with whom he worked on optimization based on problems contextualized to the needs and characteristics of his community. For this, the teacher in training initially made a documentary study of the community, then interviewed the student and later implemented its design. With the implementation of the design, it was found that from the contextualized problems the student managed to appropriate and get involved in the problem situations that were presented to him, thus favoring his learning regarding optimization.

First Reflections

Until now, some learning negotiated by teachers in terms of their reflective thinking have been evidenced: a) in mathematical thinking, they experienced confusion in their conceptual domains about the mathematical objects of differential calculus such as: function, variation, limit and derivative; which were resignified through reflection and discussion in CoP; b) in didactic thinking, they valued the need to make curricular adaptations, related to the use of language and the approach of contextualizingproblems adjusted to meet their student's needs and; c) in orchestral thinking, they managed to articulate different resources adjusted to the characteristics of the student and the mathematical objects of study.

PROFESORES EN FORMACIÓN QUE REFLEXIONAN SOBRE LA ENSEÑANZA DEL CÁLCULO A PERSONAS CON CARACTERÍSTICAS DIFERENCIADAS

TEACHERS-IN-TRAINING'S REFLECTIONS ON THE TEACHING OF CALCULUS TO PEOPLE WITH DISTINCT CHARACTERISTICS

Parada Rico Sandra Evely
Universidad Industrial de Santander
sanevepa@uis.edu.co

Echeverría Ballesteros Cristian Leonardo
Universidad Industrial de Santander
cristian2198157@correo.uis.edu.co

Presentamos avances de una investigación que busca responder a: ¿Qué aprendizajes consolidan en sus prácticas profesores en formación que reflexionan sobre la enseñanza del cálculo a personas con características diferenciadas en la educación superior? La que se espera responder usando como guía teórico-metodológica el modelo de reflexión y acción de Parada (2011). El estudio sigue una metodología de investigación-acción, planificada en seis fases, aquí se reportan resultados de las primeras cuatro. Los aprendizajes construidos por los futuros profesores se describirán en términos de los tres componentes del pensamiento reflexivo establecidos por el modelo. Un significado hasta ahora alcanzado por los futuros profesores es la necesidad de acercamiento al contexto de los estudiantes para plantear problemas ajustados a sus características diferenciadas.

Palabras clave: Preparación de Maestros en Formación, Educación especial, Cálculo.

Las políticas educativas colombianas, han promovido la inclusión en las Instituciones de Educación Superior (IES) del país. Una de ellas es la Universidad Industrial de Santander (UIS) contexto del estudio que aquí se reporta, en la que se cuenta con un acuerdo para las admisiones especiales, que se viene implementando desde el primer periodo de 2014, Además, la UIS dentro de sus estrategias para afrontar las problemáticas de deserción y permanencia ha creado una política de Excelencia Académica (Acuerdo No. 018 de 2014) que se ejecuta por medio de programas de acompañamiento y seguimiento a estudiantes. Uno de los programas, denominado SEA-ASAE, es liderado por la Escuela de Matemáticas y está centrado en atender y acompañar a los estudiantes que cursan las asignaturas de matemáticas mediante tutorías entre pares y monitorias académicas. Los tutores que ofrecen el acompañamiento son profesores de matemáticas en formación, que cursan Licenciatura en Matemáticas de la institución.

El programa SEA-ASAE se viene desarrollando desde el año 2012 y ha permitido la constitución de una Comunidad de Práctica (CoP), conformada por formadores de profesores, profesores titulares de las asignaturas de matemáticas, tutores practicantes y tutores auxiliares (egresados del curso de didáctica del cálculo). Al interior del curso los estudiantes que han realizado la práctica como tutores de Cálculo Diferencial con estudiantes de programas de Ciencia e ingenierías han reportado casos de estudiantes que presentan: Asperger, discapacidad cognitiva leve, son provenientes de comunidades indígenas, entre otros. Los tutores manifiestan dificultad para atender a esta población pues no han recibido la formación didáctica para hacerlo, de allí la necesidad de promover la reflexión en los profesores de matemáticas en formación sobre la enseñanza del cálculo a personas con características diferenciadas.

Lo antes descrito, nos ofrece dos problemáticas que pueden articularse a favor de la inclusión educativa en las IES: i) los profesores de matemáticas en formación requieren instrucción alrededor de la inclusión y, ii) las personas con características diferenciadas necesitan apoyo y atención de personas que comprendan su condición y tengan conocimiento matemático. Por ello en la investigación que aquí se reporta centramos la mirada en los practicantes de la CoP, que inician su participación en ella como tutores practicantes que a su vez desarrollan el curso de Didáctica del Cálculo. Curso, en el que se desarrollará una estructura conceptual y metodológica que permita la reflexión sobre la enseñanza del cálculo y la atención a las características diferenciadas, experiencia con la que esperamos alcanzar al objetivo de investigación: describir los aprendizajes construidos por profesores en formación que reflexionan sobre la enseñanza del cálculo a personas con características diferenciadas en la educación superior.

Antecedentes

Según Camargo (2018) desde 1960, organizaciones como la UNESCO han procurado principios orientadores con miras a favorecer una educación inclusiva. Producto de estos principios han surgido políticas en diferentes países, entre ellos Colombia.

La constitución política de Colombia de 1991 y la Ley General de Educación de 1994 son las principales políticas en donde se habla de inclusión en Colombia, estableciendo que la educación es un derecho para todos y que los colombianos se deben sentirse incluidos desde la diversidad, sin diferenciación de raza, sexo, religión, creencias políticas, y demás elementos constitutivos del multiculturalismo colombiano. Estas políticas se han venido implementando de manera paulatina, durante las últimas décadas, en varios niveles de la educación, iniciando por la educación básica y media, y en menor medida en las Instituciones de Educación Superior (IES).

Debido a que las políticas de inclusión para las IES no eran muy precisas el Ministerio de Educación Nacional (MEN), y el Consejo Superior de Educación Superior (CESU, 2013), en el acuerdo por lo superior 2034, establecen un marco normativo, en donde se afirma que para lograr una educación de calidad se debe garantizar el ingreso, la permanencia y la graduación de los estudiantes con ciertas características diferenciadas, que pueden ser personas: i) Con Necesidades Educativas Especiales (NEE), es decir, que presentan alguna condición de discapacidad hasta las que presentan talentos excepcionales; ii) procedentes de comunidades o resguardos indígenas; iii) procedentes de población afrocolombiana, palenquera y raizal; iv) procedentes de departamentos donde no existen IES; v)procedentes de municipios de difícil acceso o con problemas de orden público; vi) víctimas del conflicto armado interno colombiano; y viii)desmovilizadas de los procesos de paz.

Según un estudio realizado por el CESU (2013) en colaboración con el Centro de Investigación de Desarrollo (CID) de la Universidad Nacional de Colombia (UNAL), se establece que los estudiantes con características diferenciadas son los más propensos a desertar de las IES. Además, se ha evidenciado, que estos estudiantes tienen dificultades para comprender los objetos matemáticos del cálculo diferencial. Además, según el MEN (2016) los estudiantes con NEE presentan ciertas dificultades asociadas a su condición.

Una de las estrategias ofrecidas por el MEN para garantizar la permanencia y por tanto la graduación de los estudiantes con características diferenciadas, es la de contar con docentes inclusivos en la IES: poseer una formación idónea tanto en su ámbito disciplinar, didáctico, así como en educación inclusiva.

Silverman y Thompson 2008) mencionan que los profesores deben tener un conocimiento profundo en las matemáticas; Ponte (2011) expone que además debe contar con conocimiento en lo didáctico; Llinares (2007), Flores (2009) establecen que el profesor debe ser reflexivo; y Aké (2015) menciona la necesidad de promover la reflexión en los profesores de matemáticas acerca de una educación inclusiva.

Parada (2011) basada en los procesos de reflexión al interior de las comunidades de práctica, plantea el modelo de reflexión y acción R-y-A, el cual pretende guiar teórica y metodológicamente las acciones llevadas a cabo por los profesores de matemáticas *antes, durante y después* de clase, con el fin de aumentar la capacidad de sus miembros para reflexionar críticamente sobre sus prácticas profesionales.

Aspectos Teóricos y Conceptuales

La investigación de la que aquí se reportan los primeros resultados, se apoya en el modelo R-y-A, que tiene como objetivo principal promover los procesos de reflexión en comunidades de práctica (CoP) y cuyos elementos principales son: la participación (que puede ser periférica o plena), la reflexión y la acción. El recurso fundamental sobre el cual se reflexiona es la acción, entendida como la actuación del profesor de matemáticas en sus propias prácticas profesionales.

Ilustración 1. Adaptación modelo R-y-A de Parada (2011)

En el centro del Modelo se encuentra la **actividad matemática**. Que es donde se centran los esfuerzos de desarrollo profesional. La actividad matemática se encuentra al interior del triángulo pedagógico de Saint-Onge (1997, citado por Parada, 2011). En donde existen relaciones entre el alumno, el profesor y la matemática escolar.

Estas relaciones posibilitan la actividad matemática del estudiante *durante* la clase y la actividad matemática del profesor *antes, durante y después* de la clase.

Siguiendo las ideas de Dewey (1989), Parada (2011) entiende la **Reflexión** como un proceso de resolución de dudas, de conflictos, y de disposición para revisar su actuación; es por ello que se busca promover los **procesos de reflexión** de los profesores de matemáticas, siendo este un proceso continuo que favorece el desarrollo profesional, y se descompone en tres procesos: **Reflexión-para-la acción** (reflexión que hace el profesor antes de la clase), **Reflexión-en-la acción** (reflexión que hace el profesor durante de la clase), **Reflexión-sobre-la acción** (reflexión que hace el profesor después de la clase).

Las tres flechas que se encuentran alrededor de la espiral representan los tres pensamientos en los que se descompone el **pensamiento reflexivo** del profesor de matemáticas: el **pensamiento matemático** (los conocimientos matemáticos que el profesor emplea para desarrollar la actividad matemática en el aula), el **pensamiento didáctico** (surge cuando el profesor se cuestiona sobre las diferentes maneras de acercar los contenidos matemáticos a sus estudiantes) y el **pensamiento orquestal** (se caracteriza alrededor de la conducción de la clase y la forma como el profesor usa los recursos para la favorecer la actividad matemática en el aula).

Metodología de la Investigación

El estudio que aquí se reporta, es de tipo investigación-acción, a la luz de Kemmis y McTaggart (1988). Se lleva a cabo en seis fases, que se describen brevemente a continuación:

1) Fase 0 (estudio preliminar): estudio de políticas nacionales e internacionales alrededor de la inclusión en la Educación Superior, recolección y análisis de datos relacionados con el número de estudiantes con características diferenciadas admitidos en la UIS; 2) Fase 1: caracterización de la comunidad de práctica (contexto de estudio). Diseño de el plan de intervención y participación con la CoP. Delimitación de los participantes de la CoP sobre los que se hará la intervención;3) Fase 2: primer acercamiento a la CoP. Procesos de reflexión y acción con siete profesores en formación que desarrollaban el curso Didáctica del Cálculo en el primer semestre del 2019; 4) Fase 3: análisis de resultados del primer acercamiento; 5) Fase 4: segundo acercamiento a la CoP, en el momento en que se escribe este documento, se está desarrollando esta fase con quince estudiantes que se encuentran adelantado el curso de Didáctica del Cálculo; y 6) Fase 5: Análisis de los datos y caracterización del pensamiento reflexivo. Se espera responder a la pregunta de investigación teniendo en cuenta las tres dimensiones del pensamiento reflexivo (pensamiento variacional, el pensamiento didáctico y el pensamiento Orquestal) del profesor de matemáticas que ofrece el modelo R-y-A.

Algunos Resultados

El análisis de las políticas instituciones (Acuerdo No. 282 del 7 de noviembre del 2017) y los datos de las admisiones de la Universidad permitieron saber que entre el 2014 y el 2019, la UIS ha registrado un total de 347 estudiantes que ingresaron por medio de las admisiones especiales, de los cuales 220 (63%) estudiantes ingresaron a carreras como ingenierías, ciencias y otras, las cuales tienen en su plan de estudio materias relacionadas con matemáticas, en particular cálculo diferencial. De estos estudiantes: 81 provienen de municipios de difícil acceso o problemas de orden público, 100 víctimas del conflicto armado, 15 provenientes de población afrocolombiana, palenquera y raizal, 22 pertenecientes a comunidades indígenas y 2 provenientes de departamentos donde no existen IES.

Respecto al primer acercamiento, a través de la negociación de significados que se posibilitaron al interior de las actividades del curso, se cosificaron cuatro proyectos los cuales tenían como finalidad elaborar un diseño didáctico alrededor de un objeto de estudio del cálculo dirigido a una persona con característica diferenciada. De ese primer acercamiento, que proyectos se hicieron.

Un resultado interesante, fue el logrado por el profesor que realizó el diseño dirigido a un estudiante de la comunidad indígena Misak, con quién trabajó la optimización a partir de problemas contextualizados a las necesidades y características de su comunidad. Para ello, el profesor en formación hizo inicialmente un estudio documental de la comunidad, luego entrevistó al estudiante y posteriormente implementó su diseño. Con la implementación del diseño se pudo encontrar que a partir de los problemas contextualizados el estudiante logró apropiarse e involucrarse en las situaciones problema que se le planteaban, favoreciendo así su aprendizaje respecto a la optimización.

Primeras Reflexiones

Hasta el momento se han podido evidenciar algunos aprendizajes negociados por los profesores en términos de su pensamiento reflexivo: a) en el pensamiento matemático, ellos experimentaron confusión en sus dominios conceptuales sobre los objetos matemáticos del cálculo diferencial como: función, variación, límite y derivada; los cuales resignificaron mediante la reflexión y discusión en CoP; b) en el pensamiento didáctico, valoraron la necesidad de hacer adaptaciones curriculares, relacionadas con el uso del lenguaje y el acercamiento al contexto para el planteamiento de problemas ajustados a sus necesidades y; c) en el pensamiento orquestal, ellos lograron articular diferentes recursos ajustados a las características del estudiante y a los objetos matemáticos de estudio.

In this study we describe the generalization and justification practices of students in a highly selective summer mathematics program as they explore a sequence of problems from combinatorial game theory. We find that while study participants readily generate examples and reason recursively when analyzing Nim-like two-player combinatorial games and are able to reach valid conclusions about winning strategies in these games, they do not readily formalize their justifications into proofs using mathematical induction. We describe some obstacles that we observe in the transition between recursive reasoning and proof by induction.

Keywords: Advanced Mathematical Thinking, Problem Solving, Reasoning and Proof

Research in undergraduate mathematics education has identified obstacles to students' acquisition and understanding of mathematical induction as a proof strategy (*e.g.*, Brown, 2008; Dubinsky, 1989; Harel & Brown, 2008; Movshovitz-Hadar, 1993) and described the understandings that undergraduate students, including preservice teachers, have of induction (*e.g.*, Stylianides, Stylianides, & Philippou, 2007). Harel and Brown (2008) point out that in many standard instructional treatments of proof by mathematical induction (PMI), problems that exemplify the utility of the proof strategy can be categorized into *recursion* and *non-recursion* problems based on whether they involve recursive representations of functions or processes. The authors note that insistence on the use of PMI to solve non-recursion problems, in the absence of genuine intellectual necessity (Harel, 2013), can reinforce students' authoritative proof schemes.

One genre of problems that receives little attention in introduction-to-proof courses in the U.S. deals with *combinatorial games*, deterministic two-player games with perfect information (nothing concealed from either player). In a two-player combinatorial game with a finite set of possible game states that must terminate after a finite number of moves with one player winning, each game position can be characterized as affording a winning strategy to the next player to move (a *winning position*) or not (a *losing position*). The process of classifying positions in a game as winning or losing often involves *recursive reasoning* (Lannin, Barker, & Townsend, 2006), reasoning about cases of a problem by referencing previously established cases. This recursive reasoning can then be generalized to describe the set of all winning or losing positions for the game, and this reasoning can be distilled into a proof by mathematical induction that formally verifies and explains this description. We hypothesize that the genre of problems about combinatorial games offers a potential setting in which PMI can fulfill the explanation function of proof (De Villiers, 1990; Hanna, 2000). While problems involving combinatorial games have some complexity not associated with typical "textbook" problems, such as requiring complex induction hypotheses (incorporating assumptions about both winning and losing positions), we view them as possessing the exploratory nature and recursive structure needed to create intellectual necessity for inductive proof.

In analyzing students' work on problems that invite recursive reasoning about examples and eventually call for generalization of this reasoning, we categorize students' generalization activities into *result pattern generalization*, in which a general insight is obtained by observing regularity in results of calculations, or as *process pattern generalization*, in which this insight is backed by an understanding of regularity in the processes by which these results occur (Harel, 2001). We view

In: Sacristán, A.I., Cortés-Zavala, J.C. & Ruiz-Arias, P.M. (Eds.). (2020). *Mathematics Education Across Cultures: Proceedings of the 42nd Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*, Mexico. process pattern generalization as a potential way of transitioning from recursive reasoning about specific cases of a problem to the development of a general inductive argument.

Guided by this framework, we address the following question: In what ways do students engage in recursive reasoning and generalization as they work on problems involving two-player combinatorial games, and to what extent do they formalize their justifications using PMI?

Method of Study

We report results of a case study (Yin, 2017) of students' collaborative work on a sequence of problems involving combinatorial games, with each case consisting of the mathematical discussion, arguments, and written and visual representations of a group of four students. The study took place in an informal summer mathematics program for students ages 13-18.

We selected sixteen students in the program who reported low levels of prior familiarity with puzzles about Nim-like games (based on an initial questionnaire), and assigned them to four groups of four students each. Each group then participated in a video-recorded task-based interview lasting approximately an hour and a half. Each group worked collaboratively on a sequence of five tasks, each of which asked participants to analyze a Nim-like two-player combinatorial game. The first three tasks are shown in Figure 1. At the conclusion of each problem, a researcher asked the students to summarize and justify their conclusions orally, and asked questions as needed to clarify our understanding of students' reasoning.

Problem 1
Player A and Player B are playing a game where there is one pile of 10 marbles. Each player is allowed to take 1, 2, or 3 marbles from the pile on each turn. A player wins if they take the last marble. If Player A goes first and both players play as well as possible, which player will win, and how? **Justify your answer.**

Problem 2
