MODELS FOR PREDICTING GROSS ENROLLMENTS
AT THE UNIVERSITY OF CALIFORNIA

I. INTRODUCTION

1. Background

The purpose of this report is to discuss and compare two mathematical models for predicting student enrollments at the University of California. One has already been proposed in the scientific literature and we will refer to it as the Gani-Young-Almond model (GYA), while the second has been used by the State of California since 1963 to forecast student enrollments; we will refer to the latter as the Grade Progression Ratio method (GPR).

Enrollment forecasts are required for different purposes. At the departmental level, for example, they are used to predict faculty workloads and make faculty, classroom and advising assignments. At the statewide level forecasts are used for overall budget and planning purposes. In this report we are primarily concerned with forecasts of the latter type in the absence of quota restrictions on total enrollments. The effect of such quotas will be studied at a later time.

Forecasts differ not only in the degree of fineness to which they predict various categories of students, but they often refer to different periods of time. Predictions of gross enrollments may refer to an upper division enrollment during an academic year, while the forecasts of departmental majors may only be useful if they refer to class enrollments at the beginning of each quarter. Besides the usual statistical question
of the reliability of any forecast, an item of major importance is the degree to which numbers obtained by aggregating grades and time periods in one model is consistent with numbers obtained from a separate model that predicts gross enrollment figures in an unaggregated form.

A second item of importance is the clear distinction between the variables being predicted and those identified as policy variables. As we will point out in later sections of this report, this distinction is particularly important in periods where enrollment quotas are imposed and one attempts to find admission, redirection and student reclassification policies that maintain these quotas or other restrictions imposed by a university administration.

The specific problems that we address in this report are the prediction of gross enrollments, i.e., freshmen, sophomores, etc., for a particular campus or the University as a whole. Although we restrict our experimental data to undergraduates, the discussion and conclusions are probably appropriate to graduate levels as well.

Figure 1 is a plot of the actual numbers and forecasts of Berkeley campus enrollments in the period 1963-1967. The solid line refers to actual enrollments, the dashed lines to forecasts made before the beginning of Fall 1963 and Fall 1964 by the Department of Finance of the State of California.

- 1963 Forecasts
- 1964 Forecasts
II. ENROLLMENT FORECASTS

1. Two Mathematical Models

Denote by $X_i(t)$ the number of enrolled students in grade $i$ at the beginning of time period $t$. The subscript index might, for example, refer to sophomores, and the parameter $t$ might refer to the beginning of the fall quarter 1967. Denote by $Y_{ij}(t)$ the new admissions to grade $i$ during the $t$th time period. It is the purpose of enrollment forecast models to make a prediction or estimate of $X_i(t+1)$ on the basis of certain historical information and past trends on enrollment and admission data.

One model that has evoked considerable interest assumes that the fraction which leave grade $i$ and move to grade $j$ is a fraction $p_{ij}$ such that

$$X_j(t+1) = \sum_{i=1}^{m} X_i(t) p_{ij} + Y_j(t+1)$$

where it is understood that for some $i$, $\sum_{j=1}^{m} p_{ij} < 1$. The $p_{ij}$'s may themselves be time dependent.

Gani (1963) used such a model for predicting gross enrollments in the Australian university system. His statistical data seems to indicate that it is reasonable to assume that transitions between grades have a fixed probability over time for time periods of the order of five years. In 1965 Gani adopted a revised model for use at Michigan State University which also took into account (i) the number...
of credits completed by the student, and (ii) the possibility of transfers between majors.

The GYA model has the important feature that contributions to the enrollments in one grade are identified by their origins (prior grades, return to the same grade, new admissions, etc.) and are added to give a total enrollment figure. Secondly, it has the appealing feature that the fractions $p_{ij}$ can be interpreted as transition probabilities and thus allows one to adopt useful results from the theory of Markov Chains even though the process itself may not be Markovian. Thirdly, the conditional short-term forecasts given today's enrollments have an intuitively correct structure, and finally, the method has some experimental evidence to support it.

A second model that has been used by the State of California Department of Finance for predicting gross campus enrollments at the University of California is called the Grade Progression Ratio method. Although there are no published reports to document its mathematical structure, the method is based on defining progression ratios $a_{11}$ and $a_{j,j+1}$ for the $j$th grade and then using these ratios to predict enrollments $Z_j(t)$ for future periods by means of the system of first-order difference equations,

$$Z_1(t+1) = a_{11} Z_1(t) + Y_1(t)$$

$$Z_{j+1}(t+1) = a_{j,j+1} Z_j(t) + Y_{j+1}(t+1)$$

$a_{11} = p_{11}$ is the fraction of freshmen who return to that grade in the next period.
The ratio $a_{j,j+1}$ has the interpretation that it is the fraction of continuing students in grade $j+1$ (total minus new admissions) relative to total enrollments of a lower grade at the beginning of a previous period. In many of the applications that we have seen these coefficients also vary with time.

Throughout the remainder of this report we will make the further assumption that student flows between grades are only of three types: (i) to the same grade, (ii) to the next higher grade, or (iii) by departure from the university system. In this case Equation (1) can be specialized to yield the result

$$X_{j+1}(t+1) = X_j(t) p_{j,j+1} + X_{j+1}(t) p_{j+1,j+1} + Y_{j+1}(t+1)$$

(3)

In other words, enrollees in grade $(j+1)$ at the beginning of time period $(t+1)$ come from grade $j$ or grade $j+1$ in the previous period or represent new admissions. In the absence of quota restrictions on new admissions or total class size, Equation (3) is assumed to represent the underlying stochastic process and the problem is reduced to one of

(a) estimating $p_{j,j}$ and $p_{j,j+1}$ terms
(b) estimating $Y_j(t)$ terms
(c) recursively computing forecasts and estimates of fluctuations from Equation (3)
(d) establishing time periods which are natural to the forecasting process
and

(e) making experimental comparisons of forecast and real data.
2. One-Period Forecasts

In this section we consider the distribution of returning and new students given today's enrollments. Given the value \( X_j(t) \) for the enrollments in grade \( j \) at time \( t \), the number that return to the same grade, that advance to the next higher grade or that drop out in the succeeding time period are multinomially distributed. To illustrate, we denote by \( X_{j,j} \) the random number that do not advance, by \( X_{j,j+1} \) the number that advance from grade \( j \) to \( j+1 \) in one time period and by \( X_{j,0} \) the number that drop out. The probability that there are \( x \) returning to grade \( j \), \( y \) advancing and \( z \) leaving is

\[
\Pr\{X_{j,j} = x, X_{j,j+1} = y, X_{j,0} = z \mid X_j = n\}
\]

\[
= \frac{n!}{x!y!z!} (p_j)^x (q_j)^y (r_j)^z
\]

\[
p_j + q_j + r_j = 1
\]

\[
x + y + z = n
\]

where, to simplify notation, we have deleted the time parameter and substituted \( p_j \) for \( p_{j,j} \), \( q_j \) for \( p_{j,j+1} \) and \( r_j \) for the drop-out probability, \( 1 - p_{j,j} - p_{j,j+1} \).

The probability distribution for the total number of continuing students, i.e., those remaining in grade plus those advanced from a lower grade, given the actual enrollments in the previous period is
\[
\Pr(X_{j,j+1} + X_{j+1} = k \mid X_j = m, X_{j+1} = n) = \frac{k}{\sum_{i=0}^k \frac{m!}{i!(m-i)!} \frac{n!}{(k-i)!(n-k-i)!} \times [q_j^k(1 - q_j)^{m-i} (p_{j+1})^{k-i} (1 - p_{j+1})^{n-k-i}]} \tag{5}
\]

It follows from (5) or direct expectation arguments that the conditional one-period expectations are

\[
E[X_{j+1} \mid m, n] = mq_j + np_{j+1} + E[Y_{j+1}] \tag{6}
\]

where, once again, the time parameter is suppressed. With the further assumption that \(Y_j\)'s are statistically independent of previous \(X_j\)'s, the conditional variance of enrollments in the next period is

\[
\text{Var}[X_{j+1} \mid m, n] = mq_j(1 - q_j) + np_{j+1}(1 - p_{j+1}) + \text{Var}[Y_{j+1}] \tag{7}
\]

given \(m\) students in grade \(j\) and \(n\) students in grade \(j+1\).

The variance to mean ratio for one-period forecasts of continuing students given that there are \(m\) students in grade \(j\), \(n\) in grade \(j+1\) is

\[
1 - \text{Max}(q_j, p_{j+1}) < \frac{mq_j(1 - q_j) + np_{j+1}(1 - p_{j+1})}{mq_j + np_{j+1}} < 1 - \text{Min}(q_j, p_{j+1}) \tag{8}
\]

with the GYA model. This variance to mean ratio may be reduced or increased by new admissions and transfer of students as is indicated.
by the ratio,

\[
\frac{mq_j (1 - q_j) + np_{j+1} (1 - p_{j+1}) + \text{Var} [Y_{j+1}]}{mq_j + np_{j+1} + E[Y_{j+1}]},
\]

(9)

for next period enrollments. When new admissions can be forecast exactly, \( \text{Var} [Y_{j+1}] = 0 \); the denominator of (9) is larger than (8) and the variance to mean ratio of enrollments is considerably smaller than the corresponding figure for continuing students. If the \( \{Y_j\} \) process is characterized by a sequence of independent Poisson variables, then the ratio of (9) is larger than the ratio in (8).

Consider, for example, the case of sophomore enrollments in the year 1961 at the Berkeley campus. When we assume that \( q_1 = p_{12} = 0.58 \), \( p_2 = p_{22} = 0.23 \), \( m = 3843 \), \( n = 3445 \), the variance to mean ratio for continuing students is 0.51. The number of new sophomore admissions in 1961 is 751 students. If this number were known with certainty, then the variance to mean ratio of the one-period enrollment forecast is reduced from 0.51 to 0.41. If, on the other hand, the new sophomore admissions for fall 1960 are Poisson with \( \text{Var} [Y_2] = E[Y_2] = 751 \), then the variance to mean ratio for the one-period forecast increases to the value of 0.61. The usual method for reporting forecasts is to give a figure for the mean plus or minus two standard deviations. In the first case we would predict a figure of 3772 ± 79 students enrolled in the sophomore class of 1961 while in the latter case we would obtain 3772 ± 96 students.
Since we are unable to find published accounts for the GPR model, it is difficult to guess what the underlying stochastic process might be for continuing students. It may be reasonable to assume that each undergraduate at grade \( j \geq 2 \) leads to \( k = 0, 1, 2, 3, \ldots \) continuing undergraduates at the next higher grade with probability distribution \( p_k \) having mean and variance

\[
\mu_j = \sum_k k p_k; \quad \sigma_j^2 = \sum_k (k - \mu)^2 p_k. \tag{10}
\]

Our data seems to suggest that for the transitions from grade \( j \) to grade \( j+1 \)

\[
\mu_j = a_{j,j+1}
\]

Using conditional expectation arguments and the assumption that each student acts independently of all others, we obtain

\[
E[ Y_{j+1}(t+1) \mid Y_j(t) = m ] = ma_{j,j+1} \tag{11}
\]

and

\[
\text{Var} [ Y_{j+1}(t+1) \mid Y_j(t) = m ] = \sum_1^m \sigma_j^2 = m \sigma_j^2. \tag{12}
\]

It is important to notice that with such a model the one-period expectations are unaffected by the number of enrollments, say \( n \), in grade \( j+1 \) at time period \( t \). Furthermore, the variance to mean ratio for continuing students is independent of \( m \) as distinct from the results of (8) which
depend on both \( n \) and \( m \). These are some of the reasons why one might be tempted to rely more heavily on the GYA than on the GPR model.
3. **Admissions, Enrollments and Long Term Forecasts**

If Equation (1) represents the underlying stochastic process, it is possible to recursively compute expectations and variances of enrollments in future periods. If we write (1) in matrix form,

$$ X(t+1) = P X(t) + Y(t+1) $$

(13)

we compute recursively on t to obtain

$$ X(t+1) = p^{t+1} X(0) + \sum_{j=0}^{t} p^j Y(t-j+1) $$

(14)

It is well known that elements of higher powers of $P$ decrease geometrically with $t$; hence the initial enrollments represented by $X(0)$ in the matrix equation of (14) have vanishingly small effect on distant enrollment forecasts. In the case of a university system and where few students jump grades, the typical lifetime of an undergraduate student is of the order of four or five years; thus the major contribution to $X(t+1)$ is due to new admissions in one, two or three years just prior to the forecast date. Notice, for example, that the second power of $P$ is

$$ p^2 = \begin{pmatrix}
  p_{11}^2 & 0 & 0 & 0 \\
p_{12}(p_{11}+p_{22}) & p_{22}^2 & 0 & 0 \\
p_{12}p_{23} & p_{23}(p_{22}+p_{33}) & p_{33}^2 & 0 \\
0 & p_{23}p_{34} & p_{34}(p_{33}+p_{44}) & p_{44}^2
\end{pmatrix} $$
Since the magnitude of the typical grade advance probability at the University of California lies between 1/2 and 3/5 while the return to grade probability is less than or equal to 1/10, terms on the diagonal of powers of $P$ tend to become small rapidly in comparison with non-zero terms below the diagonal and the advance of students through grades is rapid in comparison to a typical management hierarchy where the diagonal terms tend to be much larger.

The calculation of expected enrollments at the beginning of period $t$ is straightforward: we simply substitute $E[X(t)]$ for $X(t)$ and $E[Y(t)]$ for $Y(t)$ in (13) or (14). To get some idea of the fluctuations that we can expect, it is useful to compute the variances of $X(t)$. To do this we make use of the result that the unconditional variance of $X(t+1)$ is related to the conditional variance and expectation of $X(t)$ by means of the formula

$$\text{Var}[X(t+1)] = E[\text{Var} X(t+1) | X(t)] + \text{Var}[E[X(t+1) | X(t)]]$$  \hspace{1cm} (15)

Considering enrollments in the freshman class we have from (14)

$$E[X_1(1)] = p_{11} X_1(0) + E[Y_1(1)]$$

$$E[X_1(2)] = p_{11}^2 X_1(0) + p_{11} E[Y_1(1)] + E[Y_1(2)]$$  \hspace{1cm} (16)

$$E[X_1(3)] = p_{11}^3 X_1(0) + p_{11}^2 E[Y_1(1)] + p_{11} E[Y_1(2)] + E[Y_1(3)]$$

$\vdots$
where $X_1(0)$ is known and given. The variance of $X_1(1)$ is obtained from

$$\text{Var} [X_1(1) | X_1(0)] = p_{11}(1 - p_{11}) X_1(0) + \text{Var} [Y_1(1)]$$

$$\text{E} [X_1(1) | X_1(0)] = p_{11} X_1(0) + \text{E} [Y_1(1)]$$

Since $\text{E} [X_1(0)] = X_1(0)$ and $\text{Var} [X_1(0)] = \text{Var} [\text{E} [Y_1(1)]] = 0$, the unconditional variance of $X_1(1)$ is just equal to our earlier result in Equation (7)

$$\text{Var} [X_1(1)] = p_{11}(1 - p_{11}) X_1(0) + \text{Var} [Y_1(1)] . \quad (17a)$$

In the next period additional terms enter because

$$\text{Var} [X_1(2) | X_1(1)] = p_{11}(1 - p_{11}) X_1(1) + \text{Var} [Y_1(2)]$$

$$\text{E} [X_1(2) | X_1(1)] = p_{11} X_1(1) + \text{E} [Y_1(2)]$$

and the sum of the expected value of the former and the variance of the latter yields the result

$$\text{Var} [X_1(2)] = p_{11}^2(1 - p_{11}) X_1(0) + p_{11}^3(1 - p_{11}) X_1(0)$$

$$+ p_{11}(1 - p_{11}) \text{E} [Y_1(1)] + p_{11}^2 \text{Var} [Y_1(1)] \quad (17b)$$

$$+ \text{Var} [Y_1(2)]$$

In this way one can recursively compute $\text{Var} [X_j(t)]$; efficient matrix methods for computing them are described by Pollard (1967) and
Bartholomew (1967). For long term forecasts, the effect of fluctuations due to the initial enrollments becomes small and the dominant terms are due to variances in the new admissions of the immediately preceding years and the variances due to uncertainty of continuing students.

In making long term forecasts one of the two cases that usually interests us corresponds to the assumption that \( Y_j(t) \) are known exactly; with such an assumption, fluctuations in enrollments are entirely due to the random nature of attritions and uncertainty in a student's progress once he has enrolled. A second case corresponds to Poisson admissions; in this case enrollment fluctuations are due to the superposition of random admissions with the random behavior of students once they are in the system.

Pollard (1967) has shown that if the number of new admissions are sequences of independent Poisson variables, then the students remaining in grade \( k \) at the beginning of the next time period are also Poisson distributed. Since the total enrollments in any grade are the sum over all students who have entered in prior years plus new admissions, the total number of enrollments in each grade are also Poisson distributed. The usefulness of this result lies in the fact that the variance and mean value of the Poisson distribution are equal and that it probably represents a realistic estimate of the magnitude of fluctuations in new admissions.
4. The Grade Progression Ratio Method

To illustrate the mathematical structure of the GPR forecasting model we consider forecast of the four undergraduate grades as obtained from Equation (2):

\[
\begin{align*}
Z_1(t+1) &= a_{11} Z_1(t) + Y_1(t+1) \\
Z_2(t+1) &= a_{12} Z_2(t) + Y_2(t+1) \\
Z_3(t+1) &= a_{23} Z_3(t) + Y_3(t+1) \\
Z_4(t+1) &= a_{34} Z_4(t) + Y_4(t+1)
\end{align*}
\]

In matrix notation,

\[
Z(t+1) = AZ(t) + Y(t+1)
\]  \hspace{1cm} (18)

The coefficient \(a_{11} = p_{11}\) is the fraction of returning freshmen. All other non-zero entries lie below the main diagonal and may be less than, equal to or greater than one. By iteration one obtains the \((t+1)^{st}\) forecast in terms of the new admissions in prior periods and powers of \(A\)

\[
Z(t+1) = A^{t+1} Z(0) + \sum_{j=0}^{t} A^j Y(t-j+1).
\]  \hspace{1cm} (19)

Since \(a_{11} = p_{11} < 1\), it is possible to discuss the asymptotic character of powers of \(A\) even though values for \(a_{j,j+1}\) may be greater than one. In fact, Equation (19) is identical to the development of forecasts of \(X_j(t)\) in powers of \(P\) except that \(A\) is substituted for \(P\) and \(Z\) for \(X\).
The difference lies in the structure of A, its rank, and the fact that it may not be possible to neglect high powers of A. For example, the second and third powers of A are given by:

\[
A^2 = \begin{bmatrix}
a_{11}^2 & 0 & 0 & 0 \\
a_{12}a_{11} & 0 & 0 & 0 \\
a_{23}a_{12} & 0 & 0 & 0 \\
0 & a_{23}a_{24} & 0 & 0
\end{bmatrix}
\]

\[
A^3 = \begin{bmatrix}
a_{11}^3 & 0 & 0 & 0 \\
a_{12}a_{11}^2 & 0 & 0 & 0 \\
a_{23}a_{12}^2a_{11} & 0 & 0 & 0 \\
a_{23}a_{34}a_{12} & 0 & 0 & 0
\end{bmatrix}
\]

and it is likely that the product \(a_{23}a_{34}a_{12}\) is large enough so that new freshman admissions of earlier years may dominate all other terms in the forecasts for seniors. For large \(t\) the first column entries of \(A^t\) are

\[
a_{11}^t \\
a_{12}a_{11}^{t-1} \\
a_{23}a_{12}a_{11}^{t-2} \\
a_{23}a_{34}a_{12}a_{11}^{t-3}
\]

while all other entries are zero. Hence for large \(t\) the typical contribution to the forecast of grade \(j\) is due to a fraction of earlier freshman enrollments.
Although we do not make any attempt to discuss the statistical problem of estimating $p_{ij}$ or $a_{j,j+1}$ terms, it has been common practice by the State of California to estimate values for $a_{j,j+1}$ on the basis of recent observations of the random enrollment data, namely, to define a time-dependent ratio

$$a_{j,j+1}(t+1) = \frac{X_{j+1}(t+1) - Y_{j+1}(t+1)}{X_j(t)}$$

where $X$ and $Y$ now refer to actual realizations of the enrollments. Suppose that Equation (3) represents the underlying stochastic process; then the enrollment in grade $j+1$ at time period $t+2$ is

$$X_{j+1}(t+2) = X_j(t+1) p_{j,j+1} + X_{j+1}(t+1) p_{j+1,j+1} + Y_{j+1}(t+2).$$

If, in making forecasts, we were to use Grade Progression Ratios generated by (3) and (20), then

$$a_{j,j+1}(t+1) = \frac{X_j(t) p_{j,j+1} + X_{j+1}(t) p_{j+1,j+1}}{X_j(t)}$$

$$= p_{j,j+1} + \frac{X_{j+1}(t)}{X_j(t)} p_{j+1,j+1}.$$ 

Generating the sequence of numbers obtained by substituting (22) into

$$Z_{j+1}(t+2) = Z_j(t+1) a_{j,j+1}(t+1) + Y_{j+1}(t+2),$$
yields the result

\[ Z_{j+1}(t+2) = X_j(t+1) p_{j,j+1} + \left( \frac{X_j(t+1)}{X_j(t)} \right) X_{j+1}(t) p_{j+1,j+1} + Y_{j+1}(t+2) \]  

(24)

which, though similar to Equation (21), leads to substantially different values when enrollments \( X_j(t) \) are time-dependent.

There are two obvious cases where the sequences generated by (24) and (21) do, in fact, agree. If \( p_{j+1,j+1} \) terms vanish, then the only contribution to \( Z_{j+1}(t+2) \) is due to continuing students from a lower grade and new admissions. In this case the sequence \( \{X_j(t)\} \) and \( \{Z_j(t)\} \) are identical.

Furthermore, if an equilibrium has been reached in the sense that

\[ Y_j(t) \rightarrow Y_j; \quad X_j(t) \rightarrow X_j \quad \text{independently of } t \]

then the ratio in square brackets in (24) is one and we obtain the simpler time-independent recursion

\[ Z_{j+1} = X_j p_{j,j+1} + X_{j+1} p_{j+1,j+1} + Y_{j+1} \]  

(25)

which agrees with (21) upon deletion of the time parameter \( t \) and substitution of \( Z_{j+1} \) for \( X_{j+1} \).
III. NUMERICAL EXAMPLES AND COMPARISON OF FORECASTS

Table I lists two forecasts and the actual observed enrollments of undergraduate students on the Berkeley campus for the period 1962-1966. The top entry in each cell is computed by the GYA model with the new admission data shown in Table II. It was assumed that the transition probabilities for Fall to Spring and Spring to Fall semesters were those given by the $P_1$ (Fall to Spring) and $P_2$ (Spring to Fall) matrices below:

$$P_1 = \begin{bmatrix}
0.9277 & 0 & 0 & 0 \\
0.0005 & 0.8612 & 0 & 0 \\
0 & 0.0313 & 0.9089 & 0 \\
0 & 0 & 0.0047 & 0.7937
\end{bmatrix}$$

$$P_2 = \begin{bmatrix}
0.0964 & 0 & 0 & 0 \\
0.6990 & 0.1001 & 0 & 0 \\
0 & 0.7924 & 0.1393 & 0 \\
0 & 0 & 0.7493 & 0.2917
\end{bmatrix}$$

Entries in both of these matrices were estimated from Berkeley campus student performance and attrition data that has been collected and summarized by the Office of Institutional Research for the academic
year 1961. The second entry in each cell is calculated by the GPR method using the ratios

\[
\begin{align*}
a_{11} &= 0.0970 \\
a_{12} &= 0.7877 \\
a_{23} &= 0.8766 \\
a_{34} &= 0.9944
\end{align*}
\]

published by the State Department of Finance for the year 1960-1961. Initial enrollment and admission data for the forecast period are the same as those used in the GYA model. The third entry in each cell is the actual observed student enrollment. In Table I an italicized entry denotes which forecast is closer to the actual enrollment count.

We should point out that the interval between GPR forecasts was one year (Fall semester to Fall semester), while the forecast period for the GYA model was one semester; in Table I we only list the values appropriate to the beginning of the Fall semester. This fact in combination with the intrinsically larger forecast variances of the GPR model for \(a_{j,j+1} > 1\) would seem to account for the discrepancies in the junior year.

In applying data to these models we have used the following convention: a new student is one coming to the U.C. Berkeley campus for the first time; in other words, he has not been registered before. A continuing student is one who has, with the exception of the summer sessions, a record of continuous registrations. For example, a student

* A new student is defined as one who has never before registered at the Berkeley campus.
registered in the Spring semester of 1963 is a continuing student if he registers in Fall 1963. A returning student is a student who was once registered at the campus but has left for one or more semesters.

In calculating the diagonal entries of $P_1$ and $P_2$ we divided the number of continuing and returning students in one semester by enrollments of the previous semester. Clearly, from the definitions given above it would be better to relate returning students to enrollments of a semester two or more periods in the past.
