A study explored the effects of prequestions (questions provided prior to reading) and the influence of a prediction strategy upon the amount and types of information recalled by children in grades three through six. Subjects, 188 students in grades three through six who were reading at third grade level or above, read a 900-word expository article written at a third grade level. Subjects were randomly assigned to the following four groups: (1) only read the passage, (2) read 16 prequestions prior to reading the passage, (3) individually predicted answers to the prequestions in a group, and (4) predicted answers to the prequestions as a group. All subjects then completed a 32-item posttest, half of whose questions were identical to the prequestions. Results indicated that prequestions exercised no significant impact upon the total amount of recall of the children. Gains in cueing from prequestions seemed to be offset by a narrowing in focus of attention. Although predictions did not seem to overcome the narrowing influence of prequestions, prequestions with predictions did seem to increase recall on cued information without any additional narrowing of attention than was already caused by the use of questions. Although further study is needed, prediction seems a better strategy than prequestions for directing children's reading. (JL)
Prequestions and Predictions and Children's Reading Comprehension

ABSTRACT

This study attempted to determine whether prequestions or predictions contributed to the recall of young children (grades 3-6) as they do with adults, with regards to total amount of recall, and to recall of question-relevant and question-irrelevant information. 188 subjects reading at the third grade level or above were asked to read a 900-word expository article written at a third grade level. Subjects were randomly assigned to the following four groups: (1) only read the passage; (2) read 16 pre-questions prior to reading the passage; (3) individually predicted answers to the prequestions; (4) predicted answers to the prequestions in group. All subjects then completed a 32-item post-test (half of questions were identical to prequestions). With the effects of reading level controlled for, there were no differences in total recall between control subjects and pre-question subjects. As with adults, the control group was superior on question-irrelevant recall, while the prequestions groups were superior on question-relevant recall. The use of individual predictions, however, seem to have limited the narrowing influence of pre-questions.
Various purpose-setting procedures have been proposed for enhancing reading comprehension. The effects of these procedures have rarely been examined with elementary school age children, however. While this research approach has certain theoretical justifications, it has neglected the practical fact that these procedures are most commonly employed with children in that age group. This paper explores the specific effects of prequestions (questions provided prior to reading) upon the types of text information remembered by children in grades 3-6. This paper also attempts to explore the influence of a prediction strategy as an alternative to the use of prequestions alone as a purpose-setting device.

Background

Basal readers and reading textbooks often suggest that teachers should provide children with specific purposes for reading (Aukerman, 1981; Singer & Donlan, 1980). Three types of purpose-setting strategies seem to be recommended most frequently. These are: (1) the teacher makes a simple statement which tells the children what to find out from the text; (2) the teacher asks questions, and the children read to find answers to the questions; or (3) the teacher asks questions and the children predict or guess possible answers to these questions. The children then read to evaluate the accuracy of their
guesses. This paper will focus upon the effects upon comprehension of the latter two strategies, questioning and predicting.

Although both of these forms of purpose-setting are meant to enhance children's reading comprehension, they are based upon different philosophical and theoretical perspectives of learning. Questioning, as it is usually proposed, is teacher- or text-centered; that is, the teacher or text provides the rationale for reading. The use of such questions is intended to improve the reader's ability to access and to remember specific information from the text to be read (Betts, 1946).

Predicting, on the other hand, is more reader-centered and it is inductive in nature. Predicting activity involves learners in the generation of predictions and in the active testing or evaluation of these predictions or hypotheses (Posner, 1973). Stauffer (1969) has theorized that self-generated purposes in the form of predictions would have a different impact upon comprehension than would those purposes imposed by a teacher or text. Readers, for instance, could be expected to initiate more thorough schema activation because of the generative nature of prediction. Also, because readers must find out why their hypotheses are right or wrong, it is possible that predictions would require a more generalized or complete reading of the passage.

A sizeable body of research has demonstrated the complex nature of the impact upon recall of purpose-setting questions. Prequestions have usually been found to enhance the recall of question-relevant or cued information, to the detriment of the recall of question-irrelevant or non-cued information

Prequestion studies have usually focused upon the reading comprehension of older subjects. These studies have rarely examined the use of prequestions with students even as young as 10 or 11 years old (Memory, 1982). This omission is probably a result of the fact that children have usually been found to be less able than adults to employ selective attention strategies (Brown, 1981). For this reason, it is possible that prequestions would not have a positive impact upon the recall of children. It should be noted, however, that Memory (1982), in his recently published analysis of prequestion effects upon the reading recall of middle school children (ages 10-13), concluded that prequestions influence children in this age group in the same way that they influence adults. Also, although younger children are not as flexible as adults in the use of attentional strategies, this ability is already developing by second or third grade (Brown, 1980; Markman, 1977; Markman, 1979). It is theoretically plausible that prequestions would not influence younger children's recall, but it is with elementary grade level children that prequestions are so frequently used instructionally. Therefore, it seems reasonable to evaluate the implications of this rather widespread practice.

Despite the extensive research concerning prequestions, there have been very few studies, with subjects of any age level, of the effects of pre-
dictions upon reading recall. One such study (Peeck, 1971) found no differences in the "shape" of comprehension (i.e., differential impact on question-relevant and question-irrelevant information) for groups of college students who guessed or did not guess answers to multiple-choice prequestions.

However, multiple-choice questions have been found to operate differently in this paradigm than do answer-constructive questions (Anderson & Biddle, 1975).

Another study (Hammond, Note 1) found that predictions led to higher recall for cued information, with no significant negative impacts upon the recall of non-cued information, for fifth graders. This study is difficult to interpret, however. First, the youngsters were all quite experienced with the prediction technique, and because of this it is possible that the treatment was actually more than just the question provision described. Second, there was no control group. All subjects, in these two conditions, received prequestions. It seems possible that the prequestions might have had no real impact upon the comprehension of these children. Whether it did or not, it is impossible to discern whether the effect was due to differences in the difficulty of the two types of questions or to attentional shifting. Finally, because the predictions were given aloud in a reading group, it is difficult to determine whether the result was due to an increase in prior knowledge brought about by the shared information (schema sharing) or to an increased depth of processing (schema activation) caused by prediction.
Thus, it is unknown whether prequestions operate with children as they do with adults. It is also unknown whether alternative purpose-setting strategies, such as prediction, can prevent the negative influence of prequestions while continuing to maintain their positive outcomes.

Objectives

Given the limitations of the available research, it was concluded that an investigation of the impact of prequestions upon the reading recall of elementary age level children was needed. When prequestions are given to children, is there a differential impact upon question-relevant and question-irrelevant information, as there is with adults? This study also attempted to assess the possibility that prediction, might enhance comprehension without the "narrowing" problem engendered by prequestions. Finally, on the possibility that prediction might be found to be effective, experimental conditions were created which allowed the comparison of two explanations of their efficacy (schema sharing vs. schema activation).

The specific objectives of this research were:

1) to determine whether prequestions or predictions contribute to total amount of information recalled by young children (grades 3-6);
2) to determine whether prequestions enhance the recall of question-relevant and question-irrelevant text information for young children;
3) to determine whether prequestions combined with predictions enhance the recall of question-relevant and question-irrelevant text information;
4) to compare the effects of predictions on the reading recall of children who predict alone (schema activation) with the recall of those who predict in group (schema sharing).

**Method**

**Subjects.** The subjects were 188 students in grades 3-6, attending an elementary school in suburban Chicago. All subjects were reading at a "third grade level or above" according to their classroom teachers. Only subjects proficient in the English language were included in the sample. Subjects labelled as "learning disabled" by the school were included in the sample if they possessed the requisite reading level.

**Material.** The text used for this study was an article about kangaroos which was written in an expository style (taken from The Surprising Kangaroos by P. Lauber. New York: Random House, 1965). The text was approximately 900 words in length. It was selected because it was written at a third grade readability level (Harris & Sipay, 1980); it contained much information about kangaroos not commonly known; and, it was similar to the material which appears in many basal readers with regards to content, length, and treatment.

A set of 32 constructed-answer questions was developed for use with this material. The article was subjectively divided into eight topical zones. For each zone, four questions were written using the Pearson & Johnson taxonomy (1978). Two textually explicit and two textually implicit questions were written for each zone. This set of questions was used as the post-test measure for this study.
Pre-reading questions were selected directly from the post-test. Two questions, one of each question type, were randomly selected to represent each information zone on the pretest. In all, students answered 16 prequestions. Half of the post-test questions were cued (i.e., used as prequestions) and half were non-cued (i.e., not used as prequestions).

Procedure. Subjects were assigned, using stratified random sampling with respect to grade levels, to one of four treatment groups.

Group I: Control Group. Subjects in this group were provided with no specific reading purposes in the form of questions or predictions. These subjects were asked to read the article silently, and immediately after that they completed the post-test. (n = 47)

Group II: Pre-questions only. Subjects in this group were asked to read a massed list of prequestions silently while the investigator read them aloud. Then they were asked to read the passage and to complete the post-test. These subjects were told that the prequestions would give them an idea as to what information was important to remember. (n = 47)

Group III: Individual Predictions. Subjects in this group were asked to read the prequestion list, but they were also directed to write answers to each question, individually. They were asked to guess when they did not know an answer. After writing answers to the 16 prequestions, these subjects read the passage and completed the post-test. (n = 47)
Group IV: Group Prediction. Subjects in this group were asked to generate answers to each of the prequestions orally. Students shared their predictions aloud in group. Not every student shared a prediction for each question, but each student heard at least three predictions per question. No judgements as to the accuracy of the predictions were made, and there were no attempts to achieve consensus. Subjects then were asked to read the passage and to complete the post-test. (n = 47)

Analysis & Results

Number of questions answered on each section of the post-test (cued-explicit; cued-implicit; non-cued explicit; non-cued implicit) was used as the dependent variable. Reading level, as measured by the SRA Reading Achievement Tests, was used a covariate. Vector variables were created using effect coding (Kerlinger & Pedhazur, 1973) in order to represent planned orthogonal contrasts of treatment groups, and question types. These vector variables were used as independent measures in a multiple regression analysis. Two-way and three-way interactions among the experimental variables were tested also.

Reading level ($R = .31, F_{1,750} = 79.28, p < .01$) contributed significantly to post-test performance, and was thus, used as a covariate. With the effects of reading level accounted for, various orthogonal contrasts and interactions were entered into the regression. There was no difference in post-test performance between the control group and the combined purpose-setting groups with regards to total amount of recall ($R = .001, F_{1,748} = .29$). An examination of the means of the four groups suggests, however, that
the questions-only group and the group predictions group did not do as well as either the control group or the individual predictions group. Thus, subjects who had no questions on predictions did as well as those who did, but the combination of the purpose-setting groups might have obscured real differences.

No differences in test performance were found when the questions-only group was compared with the combined individual- and group-predictions groups ($R = .004, F_{1,747} = 2.27$). Again, it appears that the combination of treatment group outcomes might have obscured important differences, as the scores for the two predictions groups are quite different.

A final planned contrast between groups compared the performances of the two prediction groups. It was found that individual predictions were more effective in enhancing recall than were the group predictions ($R = .02, F_{1,749} = 10.94, p < .01$). Students who predicted individually did about 10% better on the test than did those who shared their predictions aloud.

Performance on cued and non-cued questions was compared, also. Non-cued questions were found to be easier than were cued questions ($R = .02, F_{1,745} = 20.90, p < .01$). However, this was probably due simply to sampling differences in the question distributions. For this reason, the interaction of groups with cued and non-cued question types was made. It was found that the groups did not perform equally well on these two question types ($R = .01, F_{12,739} = 10.61, p < .01$).

The interaction vectors indicated that the control group did better than the combined experimental groups on the non-cued questions, but that the
experimental groups were superior on the cued information ($R = .01; F_{1,741} = 7.26, p < .01$). It was also found that there was no significant difference between the questions-only group and the combined predictions groups with regard to the non-cued information, but the predictions groups were superior on the cued information ($R = .01, F_{1,740} = 3.26$). There was no significant interaction effect with regard to cued and non-cued recall for the two predictions groups ($R = .001, F_{1,739} = .09$).

Textually explicit questions were found to be easier than textually implicit questions ($R = .10, F_{1,746} = 68.73, p < .01$). There were no significant interactions, however, between question-types (textually explicit, implicit) and treatment groups, between question-types and cueing, or between question-types, cueing and groups.

**Discussion**

As in studies with adults, prequestions were found to exercise no significant impact upon the total amount of recall of children. The influence of prequestions in this study might have been limited in that they were massed at the beginning of the passage, rather than interspersed throughout. Massed questions have been found to be not very beneficial with children because of the great memory demands imposed by massed questions (Memory, 1982). As in the adult studies, any gains due to cueing seem to have been balanced by the narrowed focus of attention. That is, there was no difference between groups on total recall, but the prequestions groups did better on the cued information than did the control group. The control group did better on
non-cued information, however. Thus, even though children lack the attentional flexibility of adults, and massed questions may have limited effectiveness, prequestions seem to operate on children's recall in much the same way that they do on the recall of adults.

Not all purpose-setting activities were not found to be equivalent either. The predictions groups were superior to the questions-only group on cued information, while these groups performed equally well on the non-cued information. These findings are identical to Hammond's (Note 1), but the use of a control group in the comparison reveals that contrary to Hammond's interpretation, predictions do not seem to overcome the narrowing influence of pre-questions.

Nevertheless, prequestions with predictions did seem to increase recall on cued information, without any additional narrowing of attention than was already caused by the use of questions. The depth of processing of the predictions groups seems to have increased. Cued recall for prediction groups was better than the cued recall for the control group or the questions-only group. This depth of processing effect was also demonstrated by the fact that the individual predictions group did slightly better than the other three groups on total recall. This is probably due to the fact that predictions require a more thorough activation of schemata or depth of processing than do questions alone.

Future research needs to explore the influence of predictions in variety of experimental conditions. The effect of predictions needs to be tested with
massed and interspersed questions, and with questions better designed to tap the use of prior knowledge during reading (Pearson & Johnson's scriptally implicit questions). Finally, the impact training on the use and effectiveness of predictions over time should be examined in order to find out whether the influence of predictions changes over time. Until such studies are carried out, however, the use of prediction for purpose-setting seems to be a more reasonable strategy than the use of questions only for directing children's reading.
