Regardless of the techniques, model specifications, time periods, and data sets used, studies on the effects of unemployment insurance (UI) benefits on the duration of unemployment of individuals all indicate that UI prolongs spells of unemployment and lowers employment among its recipients. Unfortunately, the magnitudes of these estimated effects vary more than one would like. The single best estimate is that a 20 percent rise in weekly benefit amount for a UI claimant with a wage replacement ratio of 0.5 would increase the duration of his or her spell of unemployment by about a week. Another source of work disincentives is the maximum potential duration of UI benefits. Given the range of estimates in the literature, a best guess is that an additional week of duration increases a spell of unemployment by no more than 0.5 weeks. The evidence thus far shows that benefits extended beyond the exhaustion of regular UI benefits has very small negative effects on employment. One can find no compelling evidence in support of the proposition that UI increases wages by providing time for better job matches to be made and that, therefore, UI increases job stability. However, those effects may exist. They may simply have not been measured yet, due to significant data problems. Virtually all the studies on the effects of UI are limited in that they are not experimental. Future studies should include examination of the effects of UI on post-unemployment earnings, on the quality of post-unemployment job matches, and on job search intensity. This project was funded under Purchase Order No. 99-9-4766-75-019-04 from the U.S. Department of Labor, Commission on Workforce Quality and Labor Market Efficiency. Opinions stated in this document do not necessarily represent the official position or policy of the U.S. Department of Labor, Commission on Workforce Quality and Labor Market Efficiency.
This paper examines the relationship between Unemployment Insurance (UI) benefits and the duration of unemployment. Our focus is at the level of the individual worker and the effect of UI benefits on the duration of unemployment. We review extant empirical evidence on the question of whether the receipt of UI benefits leads unemployed workers to prolong their spells of unemployment. Our objective is to examine representative studies of UI and worker job search responses with an eye toward eliciting implications for public policy and future research.

A disconcerting feature of empirical analysis of UI data is the wide range of estimated effects of policies and programs that abound in the literature. The disparate results stem from, among other things, differences in data sets, model specifications, time periods, and estimation techniques. One common finding in the studies reviewed below, however, is a positive association between length of spells of unemployment and the receipt of UI benefits. Nevertheless, this still leaves open the question of how to characterize the underlying behavior of unemployed workers. Two competing hypotheses have been suggested in the past: (1) UI benefits constitute a subsidy to leisure; and (2) UI benefits constitute a subsidy to job search. These competing hypotheses have implications for labor market efficiency and public policy.
The basic static model of consumer choice of consumption and leisure (Moffitt and Nicholson, 1982) underlies the leisure subsidy argument. The income loss from a spell of unemployment overstates the value of the utility loss from reduced earnings. This is because of the value of the utility gain from the (forced) additional consumption of leisure. Hence, unemployment can have some value to workers because of the leisure consumption it makes possible. According to this view, UI benefits increase the attractiveness of unemployment by reducing the opportunity cost of unemployment (leisure). Empirically, one would expect to find a positive association between UI and unemployment duration, and a clustering of unemployment terminations around the week of UI benefit exhaustion. In this framework an increase in the potential maximum of UI benefit duration will have income and substitution effects for those who would have otherwise have exhausted their entitlements. If unemployment is a normal good, the extension of potential duration will unambiguously raise the duration of unemployment.

Job search theory holds that unemployed workers are searching for jobs in a manner that maximizes the present value of expected utility (expected income for a risk neutral worker) from search (Mortensen, 1986). UI benefits serve to reduce the opportunity costs of the search process and can lead unemployed workers to search longer and hold out for better job offers. This model would also imply a positive association between UI benefits and the duration of unemployment as well as some clustering of unemployment terminations around the week of UI benefit exhaustion. Also, an extension of maximum benefit duration would lead to a longer spell of unemployment. Empirically, the job search model is
distinguished from the leisure subsidy model by the prediction that UI benefits will produce better job matches including higher post unemployment wages. Our review will examine the available empirical evidence of the effects of UI on unemployment duration in light of these two alternative models.

The remainder of our paper is divided into three parts. Part I is a selective review and summary of what is known about the disincentive effects of UI from non experimental empirical studies. Part II reviews completed and ongoing laboratory and field experiments pertaining to the financial incentives of UI for job search behavior. Part III is a discussion of the research and program policy implications of what has been learned to date about the incentive effects of UI at the level of the individual worker.

Part I: Representative non experimental studies

The Ehrenberg and Oaxaca (E-0) (1976) study represents an early attempt to focus UI research on the effects of UI benefit payments on post unemployment wages as well as duration of unemployment and time spent out of the labor force. This study used data from the National Longitudinal Survey (NLS) on four gender/age cohorts: males 14-24 and 45-59, and females 14-24 and 30-44 over the period 1966-71. E-0 specified their UI variable as a wage replacement fraction, i.e., the ratio of weekly UI benefits to pre-unemployment weekly wages. Here we confine our summary to the E-0 results pertaining to workers who completed their spells of unemployment by changing employers.
E-0 calculated the effects of raising the wage replacement fraction by 10 percentage points, from 0.4 to 0.5. If one takes a base wage replacement fraction of 0.5, this represents a 20 percent increase in UI weekly benefits. Such an increase was estimated by E-0 to raise the duration of unemployment (in weeks) by 0.2, 1.5, 0.5, and 0.3 for males 14-24, males 45-59, females 14-24, and females 30-44. The wage gain effects of this increase in UI benefits were estimated to be 7 percent for males 45-59 and 1.5 percent for females 30-44. Among the 14-24 year olds, the wage replacement ratio had no statistically significant effects on wage gains. Finally, this increase in weekly UI benefits was estimated to reduce time spent out of the labor force by 0.8 weeks for females 14-24 and 0.7 weeks for females 30-44. This effect was not estimated for the older male group and was not statistically significant for young males.

As far as the job search interpretation is concerned, the E-0 results are somewhat mixed. The lack of UI induced wage gains for young workers is consistent with any of the following explanations: (a) job search among young people is simply unproductive; (b) young people use their subsidized spells of unemployment to search for jobs with better on-the-job training opportunities at the cost of initially lower post-unemployment wages; and (c) UI is serving as a subsidy to leisure for young people. The E-0 study does not shed much light on which (if any) of these alternative explanations is correct. They do observe, however, that the apparent substitution of unemployment for time out of the labor force for the young women is consistent with the leisure subsidy argument. In the two cases for older workers in which UI benefits were
associated with wage gains, the magnitudes of these effects are implausibly large. The wage gain effects imply that an additional week of search induced by UI is associated with a 5 percent wage gain. One factor underlying these anomalous results could be that the NLS data used by E-O did not permit any control for the effect of UI on search intensity.

Burgess and Kingston (B-K) in their 1976 study estimated the impact of the weekly benefit amount (WBA) on the duration of compensated employment. The data base for the B-K study was the Service to Claimants (STC) experiment over the period 1969-70. The STC experiment was conducted in five cities - Boston, Minneapolis-St. Paul, Phoenix, San Francisco, and Seattle. The sample consisted of UI claimants who were deemed "job ready" (available for work without requiring retraining) but not "job attached" (no job promised within 30 days of the time UI benefits were filed for). The sample was restricted to those claimants who did not exhaust their benefits. Because a change in the UI law in Washington State created ambiguities in calculating WBA, B-K omitted the Seattle data from their study. Also omitted from the sample were those whose post unemployment Social Security wages exceeded the maximum taxable base ($7800 in 1969-70 dollars).

Since the design of the STC experiment was intended to test the effects of special job search assistance to UI claimants and not to test the effects of UI itself on search outcomes, we discuss the B-K results here rather than in Part II. The B-K estimates imply that an additional $10 of WBA raises subsequent annual earnings by $250. A problem here is that the duration of compensated weeks of unemployment was included as a
control variable by B-K in their wage gain equations. According to search theory, wage gain and duration of search are jointly determined. Consequently, Welch (1977) applied a rough correction to the B-K estimates and came up with estimates that implied that the total effect of an additional $10 in WBA raises subsequent annual earnings by $180 to $200.

Another study by B-K (1981) concentrated on estimating the effects of WBA on compensated weeks of unemployment after controlling for a worker's maximum duration of benefits. The STC data base was again used. This study found that an additional $10 of WBA raises the duration of compensated unemployment by 0.15 weeks. Combining this effect with the B-K earlier wage gain estimates implies that an additional week of compensated unemployment raises annual earnings between $1200 and $1300. B-K estimated that an additional week of potential benefit duration raises compensated unemployment by 0.61 weeks. Some differences by demographic characteristics were evident from the B-K 1981 study. WBA effects on compensated unemployment tended to decrease with age while the potential duration effects on compensated unemployment tended to increase with age. Both the WBA and potential duration effects tended to be larger among nonwhites.

The Classen study (1977) sought to determine the effects of UI benefits on unemployment duration and earnings by taking advantage of the fact that legislated increases in maximum UI benefits took place in 1968. Classen used the Continuous Wage and Benefit History (CWBH) administrative data on UI recipients in Pennsylvania and Arizona for the period 1967-70. The duration variable was measured as weeks of UI
benefits collected per successful claim, the UI variable was the WBA, and the earnings variable was high quarter earnings in the year following a completed spell of unemployment.

Classen found that the WBA had a virtually identical effect on benefit duration in Pennsylvania and Arizona, but it had no statistically significant effect on earnings in either state. Classen's results implied that a $10 (1968 dollars) increase in WBA was associated with an increase in benefit duration of 1.1 weeks. This $10 increase in WBA represented a 10 percentage point rise in the WBA/average weekly wage ratio (a 20 percent rise in the WBA for a worker with a replacement ratio of 0.5). Although Classen's study differs in many respects from the E-0 study, the estimated overall effects of UI on duration is quite consistent with the estimates from the E-0 study. In addition to the lack of an earnings effect from UI, Classen's study cast further doubt on the productivity enhancing aspects of UI benefits by failing to find any UI effect on the number of employers a worker had in the 2 year period following a spell of unemployment. It was expected that if UI promoted better job matches, workers would have fewer employers following spells of insured unemployment.

In a study by Holen (1977), the effects of UI benefits and the maximum potential weeks of UI eligibility on unemployment duration and subsequent wages were estimated. The data base for the Holen study was the Service to Claimants (STC) experiment. Holen included Seattle in her data base.

Holen specified the duration variable as compensated weeks of unemployment. The earnings variable was specified as earnings per
quarter for those with earnings that had not exceeded the maximum FICA taxable limit. Holen's results imply that a $10 (1969.70 dollars) rise in WBA would raise compensated unemployment by about 1 week and quarterly earnings by $90. In other words, each additional week of UI induced search raises quarterly earnings by $90. Holen conjectured that the wage gain effect reflected some combination of an extra week of search and increased search intensity.

An interesting aspect of the Holen study was the estimated effects of extending the maximum potential period of UI claims eligibility on compensated weeks of unemployment and subsequent wages. Extending the maximum potential eligibility period by 1 week was estimated to raise the compensated weeks of unemployment duration by 0.8 weeks and quarterly earnings by $2.50. As Holen had recognized, the positive effect of maximum potential eligibility on compensated duration does not necessarily imply that total unemployment duration would be lengthened. Those who continue to be unemployed after exhausting their benefits would naturally have their compensated spells increased by a legislative extension of the maximum entitlement period. Holen, therefore, investigated whether the extension of potential entitlement had any effect on search behavior. Her results suggested that the probability of short spells of unemployment was indeed reduced by the availability of a longer potential benefit period. Thus, the distribution of total search duration was shifted toward longer spells of unemployment.

That the UI system can have positive effects on labor supply is explored in a study by Hamermesh (1979). This study examines the entitlement effects of UI availability on labor supply and labor force.
participation among married women. The idea is that market work and labor supply are marginally more attractive to individuals who would otherwise have not worked at all, or would have worked fewer hours in the absence of the potential benefits available through the UI system.

Hamermesh drew a sample from the Panel Study of Income Dynamics for the period 1967-71. His sample consisted of married white women between the ages of 30 and 54, who were married to the same husband from 1967 to 1972, and who resided in the same state from 1970 to 1972.

First consider the subsample of women who earned between the minimum and maximum qualifying earnings for UI eligibility. For this group Hamermesh found statistical evidence for the usual negative disincentive effects of UI on desired hours of work from the weekly benefit amount and from the maximum potential duration of benefits. However, he also found a positive effect on desired hours of work from the potential benefits from the UI system of an additional hour of labor supply.

For the entire sample Hamermesh simulated the effects of a 20 percent increase in UI benefits. He estimated that the resulting disincentive effects on total hours of work (among working and nonworking women) was a reduction in labor supply of about 20 hours per year (3.1 percent of the mean hours). Among working women, the disincentive effect was estimated to be a reduction in labor supply of about 15 hours per year (1.2 percent of the mean hours). This was translated into an estimated reduction of 0.48 weeks. Labor force participation was estimated to be reduced by 1.4 percentage points. Interestingly, Hamermesh found that the positive entitlement effects on labor supply and labor force participation virtually cancel out the disincentive effects.
For the entire sample (working and nonworking women), desired hours of work were increased by the entitlement effect in the amount of 17 hours per year (2.6 percent of the mean). In the case of working women, the entitlement effect was estimated to increase desired hours of work by 12 hours (0.9 percent of the mean). This corresponds to an additional 0.38 weeks of work per year. Labor force participation was estimated to increase by 1.1 percentage points. While the net effects are slightly negative, it is hard to escape the conclusion that they are not significantly different from zero.

A study by Solon (1978) questions the desirability of measuring the work disincentive effects of the UI system by looking only at the unemployment effects. If the UI system encourages labor force participation among those who would otherwise be out of the labor force, the estimated UI effects on unemployment would overstate the true disincentive effects as measured by employment effects. Consequently, Solon estimates the effect of extended UI benefit eligibility on employment.

The data source used in the Solon study consists of a sample of former UI claimants in the state of New York who had established benefit years over the period September 1972 to August 1973, and who had also exhausted their 26 weeks of regular UI benefit entitlement. These claimants were periodically interviewed up to 6 months after their benefit exhaustions. The post benefit exhaustion period covered the periods March-September 1973 to February-August 1974. During the period of the study (February 18, 1974), the rise in the insured unemployment
rate in New York triggered extended benefits of up to an additional 13 weeks for a subset of the sample.

Solon found a marginally statistically significant negative effect of extended UI benefit eligibility on subsequent weeks of employment. His results indicated that for every 10 weeks of extended benefit eligibility, employment reduced by 1 week. This effect was mainly confined to those who had received UI benefits in 2 of the previous 5 years (repeaters). Solon’s estimates of work disincentives were smaller than what one would have inferred on the basis of unemployment effects because of the out-of-the labor force effects.

Fishe and Maddala (F-M) (1980) estimate the effects of UI benefits on the duration of unemployment from a structural model of joint wage offer determination and reservation wage determination. They explicitly incorporate the assumption of finite search horizons among unemployed workers in contrast to the infinite horizon assumption implicitly or explicitly held by most researchers. F-M used a CWBH data set for a sample of workers in Florida who had been unemployed at some point between 1971 and 1975.

The UI benefits variable in the F-M study is defined as the potential weekly benefit amount (PWBA) an unemployed worker is eligible for (equal to WBA for actual periods of compensation). F-M’s results imply that a $10 rise in PWBA raises the weekly reservation wage by $4.40 (in 1970 dollars). This corresponds to 2.8 percent of the average weekly wage. Furthermore, the exhaustion of UI benefits was estimated to drop the weekly reservation wage by a statistically significant $26.20 (16.4 percent of the average weekly wage). F-M found that the number of weeks
remaining until UI exhaustion was positively related to the reservation wage and was statistically significant. As each week passes without a job acceptance, the weekly reservation wage declines by $2.29 (1.4 percent). This result was interpreted as evidence of a declining reservation wage over the search horizon. F-M treated the finite search horizon as a parameter which they estimated to be 40.9 weeks. Thus, a worker who had not found an acceptable wage offer by the 41st week of unemployment would accept the very next offer to come along. Increasing PWBA by $10 (roughly 20 percent) would raise the duration of unemployment by 1.4 weeks.

The Moffitt and Nicholson (M-N) (1982) study examined the impact of changing the maximum duration of UI benefit eligibility on the duration of unemployment. The labor/leisure choice (leisure subsidy) model provided the theoretical underpinning for the employment (labor supply) function in the M-N study. A maximum likelihood estimation procedure was used to incorporate the kink in the unemployed worker's budget line at the point of maximum UI benefit duration eligibility. Data for the study were drawn from a sample of workers who collected UI benefits under the Federal Supplemental Benefits (FSB) Program.

A negative estimated coefficient on the non-UI, nonwage income variable indicates that weeks of unemployment is indeed a normal good. M-N estimated that increasing potential UI benefit duration by 1 week raises weeks unemployed by 0.1 weeks. This result implies that the 26 week extension of maximum duration of UI benefits triggered by the FSB program in response to the 1974-75 recession increased unemployment duration by about 2.5 weeks. The M-N study also examined the effects of
changes in the net wage replacement ratio on unemployment duration. An 10 percent increase in the replacement ratio would raise the duration of unemployment by 0.4 weeks for those with high probabilities of benefit exhaustion and by about 0.8 to 1 week for the typical claimant.

Two major issues pertaining to UI and unemployment were confronted in the Feldstein and Poterba (F-P) (1984) study. The first issue was the existence of evidence that indicated that a significant proportion of unemployed workers hold unrealistically high and socially nonoptimal reservation wages. While one might question whether some of these individuals should be considered unemployed, they are nevertheless counted as unemployed according to the official definition of unemployment. The second issue is that UI benefits exacerbate the problem of nonoptimal reservation wages by raising them further and hence prolonging unemployment.

F-P used data obtained from a special supplement to the May 1976 Current Population Survey (CPS). Unemployed workers were asked to indicate the kind of work they were seeking and the lowest wage they would accept to do the specified work. From this group, F-P selected a subsample of those unemployed who were receiving UI benefits. A reservation wage variable was constructed as the ratio of the reported reservation wage to the last wage received prior to the current spell of unemployment. F-P constructed their UI variable as the ratio of WBA received to the previous wage, adjusted for a constant marginal tax rate of 0.3.

Regression analysis revealed that the UI wage replacement variable had a statistically significant positive effect on the reservation wage.
ratio for each of the groups of UI recipients in the sample ("job losers on layoff", "other job losers", and "job leavers"). Predictably, the UI effect was largest for "other job losers". For a worker in this latter category whose gross UI wage replacement ratio is 0.5 (0.7 after taxes), a 20 percent rise in WBA would increase the reservation wage by 6 percent of the previous wage. F-P also found that the UI net wage replacement ratio had a positive statistically significant effect on the probability that an unemployed worker would have a reservation wage ratio in excess of 1.0. For the same worker as described above, a 20 percent increase in WBA would raise the probability that the reservation wage ratio exceeds 1.0 by 5 percentage points (31 percent of the "other job losers" sample had reservation wage ratios in excess of 1.0). Simulations by F-P indicated that the nonlinearities inherent in the relationship between the reservation wage ratio and the duration of unemployment made the latter more sensitive to UI for those with higher UI wage replacement ratios.

The Moffitt (1985) study is an attempt to deal with the problem of wide ranging estimates of UI effects. Specifically, Moffitt focused on the effects of the maximum potential duration of benefits. His study adopted a uniform specification and estimation strategy across four selected data sets. The objective was to generate a narrower range of UI effects as well as to ascertain how much of the differences in estimates can be attributed to differences in data bases.

The four data sets used were (1) CWBH (1978-83), (2) the Employment Opportunity Pilot Project (EOPP) (1979-81) (also known as the Job Search Assistance Research Project), (3) the Federal Supplemental Benefits (FSB)
Follow-Up Survey (1975-77), and (4) the Newton-Rosen data set (1974-76). The EOPP data base was generated from a demonstration project consisting of 10 treatment sites and 10 comparison sites. This project was concerned with determining the effects of employment and job search assistance to disadvantaged workers. The FSB Follow-Up Survey was a household survey conducted by Mathematica Policy Research Inc. for the purpose of analyzing the effects of an FSB program. The Newton-Rosen data set was drawn from a data base of UI records in Georgia.

Moffitt's study yielded estimated effects of an additional week of potential duration of UI benefits that ranged from 0.17 to 0.45 additional weeks of unemployment for males and 0.10 to 0.37 additional weeks of unemployment for females. There was some hint that these effects were somewhat larger when the unemployment rate was higher. Also, Moffitt found that the effect of an additional week of potential duration on combined weeks of unemployment and out of the labor force was 0.52 weeks for males and 0.66 weeks for females. Moffitt found no strong evidence that increased potential duration had any effect on the labor supply of other members of a UI recipient's family. Finally, Moffitt failed to find any convincing evidence of an effect of potential duration on post unemployment earnings.

The Katz and Meyer (K-M) (1988) study used hazard rate analysis to estimate the impact of potential duration and UI benefit level on the duration of compensated unemployment and on the timing of exits from unemployment. K-M used two data sources for their study: (a) a sample of heads of households from the Panel Study of Income Dynamics (PSID) over the period 1980-81, and (b) a sample of males from the CWBH data.

A significant finding from the K-M study was that among UI recipients there were sharp spikes in the escape rates from unemployment at about the duration when UI benefits were about to be exhausted (26 and 39 weeks). No such sharp pattern in escape rates was found for non UI recipients. Although the statistical significances of the potential duration and UI benefit level in the hazard models were marginal, the estimated effects were in the anticipated directions. These results imply that a 1 week increase in potential duration is estimated to raise compensated duration by 0.16 to 0.20 weeks. A 10 percentage point rise in the wage replacement ratio (a 20 percent rise in UI for an individual with a replacement ratio of 0.5) is estimated to increase the length of a compensated spell of unemployment by 1.5 weeks.

*Part II: Field and laboratory experiments*

Applied econometric studies of the effects of UI, such as those reviewed in Part I, establish statistical associations between UI benefits and unemployment duration, wage gains, and other variables of interest to policy makers. However, interpretations of these results in terms of search intensity, labor/leisure substitutions, etc. require the use of theoretical models as maintained hypotheses. Many econometric studies of UI employ either a finite or an infinite horizon search model as a maintained hypothesis (Devine and Kiefer, 1988). Therefore, if the job search/job acceptance behavior of economic agents is not consistent
with the search models then the interpretations of the results of the applied research can be misleading. Hence, it is essential that search models be subjected to direct empirical testing to learn whether they can be falsified.

The literature contains some very ingenious studies that use econometric techniques designed to test search models with data from the historical record. Among these are Kiefer and Neumann (1979a, 1979b), Warner et al. (1980), and Lancaster and Chesher (1983). However, the properties of search models pose inherent limitations on what can be learned with this approach. Consider some of the difficulties in attempting to use nonexperimental data to test job search theory. The models imply that the feasibility of recalling past wage offers, the length of the search horizon, and/or agent information about the distribution of wage offers are central determinants of an optimal search strategy. But possibilities of wage offer recall, the length of search horizons, and agent information on wage offer distributions are not observable in nonexperimental data sources. Hence such data are not very useful for learning whether job search models can be falsified by observations of job search behavior. In contrast, controlled experiments have some unique advantages for empirical evaluation of search models. The relative advantages of laboratory experiments and field experiments are somewhat different, and thus we will discuss both types.

Laboratory experiments designed to test finite horizon search models were conducted by Cox and Oaxaca (1989). In these experiments the researchers can control, and thereby observe, the possibility of
recalling past wage offers, the length of the search horizon, and agent information about the wage offers distribution. Also under experimental control are theoretically-hypothesized determinants of search behavior such as the discounting rate of interest and the cost or subsidy to search. Thus, such laboratory experiments are well-suited for learning whether people are capable of making choices in a dynamic, uncertain decision environment as if they were finding the optimal solutions to stochastic dynamic decision problems. This is the type of behavior that is modeled in job search theory and that is used as a maintained hypothesis in much econometric research on UI.

The Cox and Oaxaca (1989) laboratory experiments were conducted with sixty subjects who participated in baseline and various treatment trials. The experimental treatments consisted of variation of the rate of interest, the subsidy to search, the riskiness of the wage offers distribution, the probability of obtaining a job offer, and the length of the search horizon. The picture that emerges from these experiments is one of reasonably close agreement between the predictions of the risk neutral search model and observed subject behavior. Overall, subjects terminated search exactly at the point predicted by the risk neutral model in 77 percent of 600 trials. However, there was significant evidence of risk averse behavior. The risk averse or risk neutral (concave) model survived the experimental tests remarkably well. Fully 94 percent of the search terminations in 600 trials were consistent with this concave search model. The accuracy of the concave search model in predicting search behavior is supported by several parametric and nonparametric tests reported in the paper.
There are six field experiments with the UI program that have either recently been completed or are currently at some stage of planning or implementation. The first of these was the completed Illinois reemployment bonus experiment. Further experiments with alternative bonus formulas are currently in progress in Washington. The completed New Jersey experiments involved several treatments that included combinations of reemployment bonuses, job search assistance, job training, and relocation assistance. The New Jersey experiments were targeted on structurally unemployed workers. Experiments currently in progress in Pennsylvania involve treatments that use alternative reemployment bonus formulas and job search assistance. Two other experiments that are currently in progress are the Washington and the Three State Self-Employment Demonstration Projects. These experiments involve treatments that consist of self-employment allowances and various support services to assist UI recipients who want to become self-employed. The Illinois and New Jersey experiments are the only ones for which results are currently available; hence we will focus our discussion on these two.

Results from the Illinois experiment are presented in Spiegelman and Woodbury (1987) and Woodbury and Spiegelman (1987). In this experiment, individuals in a selected subset of UI claimants were randomly assigned to one of two treatment groups or a control group. An individual who was assigned to the claimant treatment group was eligible for a $500 reemployment bonus if he returned to work with either his old employer or a new employer within eleven weeks of filing the UI claim and remained on that job for at least four months. If an employer hired
an individual who was assigned to the employer treatment group then the employer was eligible for a $500 bonus if the worker met the eleven week and four month filing and employment conditions. Bonus-qualifying jobs for both treatment groups had to provide at least thirty hours per week of employment.

The results of the Illinois experiment support the conclusion that reemployment bonuses can significantly affect the job finding behavior of UI recipients. Individuals in the claimant treatment group had an average of 1.37 fewer weeks of unemployment than those in the control group during the first spell and 1.15 fewer weeks during the benefit year. The average differences between the employer treatment and control groups were 0.67 weeks in the first spell and 0.36 weeks during the benefit year. All of these figures except the 0.36 benefit year figure are significantly different from zero at the five percent significance level. Furthermore, the three significant reductions in weeks of unemployment also involve significant reductions in total UI benefits paid out, inclusive of the $500 bonuses. In addition, the lower average number of weeks of unemployment for the treatment groups does not appear to have been achieved at the cost of lower post-unemployment earnings.

Further analysis of data from the Illinois experiment is presented in Meyer (1988). He also discusses some ways in which the results of this field experiment might not be indicative of the effects of a permanent national reemployment bonus program. The Illinois experiment lasted only seventeen weeks and was not publicized; hence it is unlikely that it induced firms to change their layoff and recall policies.
However, if recalled workers were eligible for bonuses in a permanent program, this would provide a substantial subsidy to temporary layoffs. The responses by firms and workers to the incentive provided by this subsidy might lead to a substantial increase in UI claims. In contrast, if recalled workers were not eligible for bonuses (as in the New Jersey and Washington experiments) this would provide an incentive to break up employer/employee matches. Any response to this incentive by workers would increase UI claims and impose other costs on the economy. However, there could be an offsetting effect on firms in that they might reduce layoff frequency in order to avoid having their employees respond to the bonus incentive to join other firms.

Results from the New Jersey experiment are reported in Corson, et al. (1988). In this experiment, individuals in a selected subset of UI claimants were randomly assigned to one of three treatment groups or a control group. The three experimental treatments were: (1) job search assistance; (2) job search assistance combined with training or relocation assistance; and (3) job search assistance combined with a reemployment bonus. The eligibility screens that were used in selecting individuals for inclusion in the experiment were intended to select displaced workers (the target group). This was partially successful although other UI recipients were included. Not surprisingly, the experimental treatments were more effective for individuals not in the target group.

The reemployment bonus formula in the New Jersey experiment was different than the one used in the Illinois experiment that is described above. The New Jersey bonus formula offered individuals one half of
their remaining UI entitlement if they started work by the end of the second full week following the assessment/counseling interview. This implies that bonus eligibility began about the seventh week after an eligible claimant filed for UI. The amount that could be claimed during the first week of bonus eligibility averaged $1,644. In subsequent weeks the bonus declined by about 10 percent of the original amount each week.

Data from the New Jersey experiment indicates that each of three experimental treatments significantly reduced both the number of weeks that claimants collected UI and the amount that they collected. Furthermore, the treatment with the reemployment bonus had the largest effect in reducing both weeks of UI duration and dollars of UI paid. The results also indicate that all three treatments increase both employment and earnings in the year following the UI claim. Thus the experimental treatments do not appear to have lowered reservation wages. Finally, various benefit-cost analyses are reported. They indicate that none of the treatments led to positive net benefits for the Labor Department. However, two of the treatments yielded positive net benefits for the government sector and, most importantly, all three of the treatments yielded positive net benefits to society as a whole and to claimants.

Although the results of the Illinois and New Jersey experiments appear to be favorable, Meyer (1988) explains why these results do not support policy conclusions. Both of these experiments were short-lived and were not widely advertised to workers and firms. Hence, it is reasonable to suppose that neither workers nor firms made strategic
responses to the existence of the experimental treatments. However, the possibility of such strategic responses to a permanent program implies that the results of the experiments might not be a good predictor of the impacts of a permanent program.

Consider the possibility of strategic responses by workers to a permanent reemployment bonus program. The bonus formulas from the New Jersey and Illinois experiments provide good examples to illustrate the problem. The New Jersey bonus became available in the seventh week after a UI claim was filed. The average initial bonus of $1,644 was about five weeks average wages. Thus, anyone who was planning to start a job after two weeks of UI could increase his income by waiting a few more weeks to become eligible for the bonus. In contrast, the Illinois bonus was available immediately after a UI claim was filed. Immediate availability of a bonus would provide an incentive for some people to file UI claims who otherwise might not file. The most obvious example of this would be someone who had a new job lined up upon termination of the previous job. With either type of strategic response, the larger number of benefit payments caused by added claimants might eliminate any cost savings of a bonus program. Therefore, the findings of positive net benefits for reemployment bonuses in the Illinois and New Jersey experiments do not support the prediction that a permanent bonus program of either type would yield positive net benefits.

Another question that was not addressed by the Illinois and New Jersey experiments is the possibility of displacement effects. That is, individuals in the experimental treatment groups who found jobs more quickly may have done so at the expense of others who took longer to
find jobs. Any such displacement effects would detract from the calculated net benefits of the experimental treatments. The Pennsylvania experiment will attempt to examine this question by comparing the experiences of the control groups to similar groups in other labor markets. It remains to be seen whether this can be done effectively.

Part III: Implications for research and policy

For all of the many differences in techniques, model specifications, time periods, and data sets that characterize empirical studies of UI effects on individual workers, it is remarkable that these studies all point to the same qualitative effect of UI benefits on work incentives - UI prolongs spells of unemployment and lowers employment among its recipients. Unfortunately, the magnitudes of these estimated effects vary more than one would like. A single best estimate at this point is that a 20 percent rise in WBA for a UI claimant with a wage replacement ratio of 0.5 would increase the duration of his spell of unemployment by about a week. Another source of work disincentives is the maximum potential duration of UI benefits. Given the range of estimates in the literature, a best guess at this point is that an additional week of potential duration increases a spell of unemployment by no more than 0.5 weeks. If one regards weeks of employment as a better measure of work disincentives, then the evidence thus far shows that at least extended benefits beyond the exhaustion of regular UI benefits has very small negative effects on employment.
The empirical evidence on the wage gain aspects of UI is not even in agreement on the existence of such an effect let alone on its magnitude. This goes to the heart of the issue of whether the job search or the leisure subsidy hypothesis is the most appropriate for understanding the effects of UI on spells of unemployment. While some studies show a wage gain, others do not. At the present time one can find no compelling evidence in support of the proposition that UI increases wages because of better job matches and increased job stability. This does not necessarily mean that there are no such effects, but only that significant data problems prevent the research community from being able to properly test for their presence.

It should be appreciated that different estimated UI effects that merely reflect demographic differences are not necessarily a statistical problem. Different worker responses to UI can be anticipated when workers differ in their personal characteristics. This does, however, present a policy problem because of the political and legal difficulties in adopting UI legislation that treats potential UI recipients differently depending on their non job related personal characteristics.

What are the implications of previous research for the future UI research agenda? These implications fall into two categories: (a) appropriate data bases, and (b) research topics. Virtually all of the empirical evidence on UI to date is derived from non experimental sources. These include administrative records and household surveys. Few of the authors of these studies have been too inhibited to point out severe limitations of the data bases used by others (and sometimes even their own!). It seems clear that there is a consensus that using data
based on only compensated spells of unemployment introduces unacceptable estimation biases when analyzing total duration of unemployment spells. But even with household survey data that yield information on completed spells of unemployment, there are too many important factors that go unobserved. These include the length of a worker's search horizon, the worker's discounting rate of interest, a worker's search costs, etc.

An essential concept of the search paradigm that provides the theoretical basis for most of the UI studies on individual worker behavior is the reservation wage. Yet this theoretical construct is not observed in the data. What about the question in the May 1976 CPS that asked unemployed workers to state the lowest wage they would accept for the kind of job they were seeking? We maintain that there is no basis for interpreting the answers to this question as corresponding to the theoretical notion of a reservation wage. In their actual job acceptance decisions, workers are in no sense bound by their answers to the reservation wage question. One might more plausibly argue that the answer to this question reflects a hoped for or desired wage.

Consistent with this view is the evidence found in Feldstein and Poterba (1984) that shows little or no decay in the ratio of stated reservation wages to the previous wage with the number of weeks the individual had been unemployed. Accordingly, we are not prepared to draw any policy conclusions from the magnitude of the estimated UI effect on the reported reservation wage in the F-P study. This is an important issue because in the search paradigm it is the effect of UI on the reservation wage that produces the association between UI and the duration of unemployment. The absence of data on this variable could potentially be
managed if one could observe all offers received by an unemployed worker instead of only the accepted offer. Unfortunately, traditional data sources do not provide information on all offers received.

One of the significant advantages of controlled experiments is that they can make some variables observable that would otherwise be unobservable. This is especially true of laboratory experiments in which such factors as the feasibility of recalling past wage offers, the length of the search horizon, and agent information about the distribution of wage offers are controllable and therefore observable. These theoretical determinants of job search behavior are inherently unobservable in non experimental data sources and difficult or impossible to observe in field experimental data sources. Although fewer variables are observable in field experiments than in laboratory experiments, the former have the obvious advantage of being conducted in an environment that is closer to the naturally-occurring economy in which UI programs actually operate.

The UI research agenda of the future should include the topics described below.

The effects of UI on post unemployment earnings and on the quality of post unemployment job matches is still very much an open question. The answer to this question bears on how much we regard UI in its traditional role as income maintenance for workers on temporary lay off as opposed to its potential role for improving the efficiency of job search.

More research is needed to determine what effects UI has on search intensity. Changes in the UI system to provide monetary incentives to
shorten the duration of UI claims may possibly work through some combination of lowering the reservation wage and increasing job search intensity. The fear some may have about the former is that poorer job matches may be encouraged.

If UI is found to raise post unemployment earnings through better job matches, then a cost-benefit analysis should be performed to determine whether the social gains offset the social costs of longer job searches.

The incentive effects of UI over the business cycle need to be examined more systematically. It seems reasonable to suppose that an additional dollar of UI benefits or an additional week of maximum potential duration will have different effects on search decisions depending upon where the economy is in the business cycle.

Moffitt (1985) makes a convincing case for the need to better model the dynamics of the search process of unemployed workers as time varying variables such as potential duration, the unemployment rate, etc. change during the search process. Changes in these factors can influence the efficacy of UI policy. This topic is related to the immediately preceding one.

More research is needed on the formal modeling and empirical testing of simultaneous search by firms for workers and search by workers for jobs. How does the UI system simultaneously affect both sides of the labor market?

Without awaiting the definitive work on the effects of UI on work incentives, there are some policy implications that can be raised at this point.
If the UI system were found to produce better job matches, then why should there be a public subsidy to productive job search? A divergence between private and social gains could be one justification. The existence of imperfect capital markets might be a justification for a public subsidy. As argued in Classen (1977), such a justification need not require outright UI grants. Rather, one could make an argument that a subsidized unemployment loan program could address the problem of imperfect capital markets.

Policymakers are continually faced with the task of limiting the benefit costs of the UI program. To the extent that the costs of the UI program are ultimately borne by employers and by workers in the covered sector, both parties have an interest in cost effective UI plans. Aggregate benefit costs could be lowered by legislating reduced weekly benefit amounts and/or maximum weeks of UI entitlement. However, such measures would degrade the adequacy of UI benefits as an effective form of income maintenance during temporary spells of unemployment. Another cost-saving measure would be to tighten up on eligibility requirements in the nonmonetary determinations. This already occurs to some extent because claims deputies can give closer scrutiny to UI claims without the need for formal legislative changes.

The desire to reduce both the transfer payments of UI and its administrative costs can be accommodated by making the program function more like insurance rather than as income maintenance. The reemployment bonus payment plan is a step in this direction. There are of course the usual moral hazard problems to be concerned with. Furthermore, the results from completed UI bonus field experiments have not provided
adequate evidence to support the conclusion that a permanent reemployment bonus program would be cost effective.

Given the likelihood that the effects of the UI system are not invariant over the business cycle, it is unfortunate that the current UI system offers little flexibility in dealing with this issue. About the only automatic response is the Extended Benefits (EB) program which is triggered by a state's insured unemployment rate reaching 6 percent for states with such provisions or a 5 percent rate that is at least 20 percent higher than the average for the corresponding period in the previous two years. One could imagine different UI payment schedules being triggered by a high unemployment rate. For example, consider a UI bonus plan in which a job acceptance bonus declines the longer a claimant goes without accepting a job. One possibility is that the UI bonus payment decreases at an increasing rate. This plan would provide the strongest incentives to accept an offer early in the spell of unemployment. This would make sense in periods of relatively low unemployment when the probabilities of receiving job offers are high. In periods of high unemployment the incentive for early job acceptance would be frustrated by the low probabilities of receiving job offers. During these periods it might make more sense to implement a UI bonus payment schedule that provided more incentive farther along in a worker's spell of unemployment. Such a plan would offer a UI bonus schedule that declined at a decreasing rate during a spell of insured unemployment.

We believe that such plans as we have discussed above are feasible and could meet the objective of adequate income maintenance assistance.
for the involuntarily unemployed without unacceptable work disincentives. They would be good candidates for inclusion in future field experiments.

Other future field experiments should be designed so as to not be subject to the major shortcoming of the present experiments that we discussed in detail in Part II. This shortcoming is that the results of the completed and in-progress experiments with reemployment bonuses, etc. may not be good predictors of the effects of a permanent policy because of differences in feasibility of strategic responses by workers and firms. There is no low cost solution to this experimental design problem. In order to incorporate in an experiment the same possibility for strategic responses that would exist with a permanent program the experiment must continue for a longer time period than has previously been tried with UI experiments. Of course the incentive features of the experimental treatments would also need to be widely advertised.

As important as the association between the UI benefit award structure and the duration of unemployment is politically and economically, there are other aspects of the UI system that can be examined from the worker’s perspective. These include the issue of eligible non-filers and the issue of recidivism in the collection of UI benefits over the life cycle. A comprehensive treatment of these and related issues merits a separate review.
