A Theoretical Model of Sexual Assault: An Empirical Test.

PUB DATE 7 Apr 90
NOTE 12p.; Paper presented at the Annual Meeting of the
Southeastern Psychological Association (36th,
Atlanta, GA, April 4-7, 1990).

ABSTRACT Koss and Dinero's (1987) comprehensive developmental
model of sexual aggression asserts that sexual assault is in part a
result of early sexual experiences and family violence; that sexually
aggressive behaviors may be predicted by such "releaser" variables as
current sexual behavior, alcohol use, and peer group support; and
that use of aggression in heterosexual conflict predicts sexually
assaultive behavior. The model was elaborated to include measures of
religious participation and several aspects of self-concept,
including self-derogation. This elaborated model of sexual assault
was tested through administration of a survey to 229 male college
students. The hypothesized model, consisting of four categories of
variables, was tested using a hierarchical blockwise discriminant
function analysis. The results revealed that 83.8% of the cases were
successfully classified: 91.4% of the nonaggressive men and 72.0% of
the aggressive men were correctly classified. The results partially
confirm the model. Early sexual experience, personality
characteristics, peer group influence, alcohol and drug use, recent
sexual experiences, and style of conflict management were all
significant predictors. Neither family violence nor the measure of
sex role attitude was predictive. The findings support the viability
of a multidimensional model of sexual aggression and provide a
profile of the sexually aggressive male. (h-)

Recent research has identified several predictors of sexually assaultive behaviors in college men. Koss and Dinero (1987) provide the most comprehensive developmental model of sexual aggression to date. They argued that sexual assault was in part a result of early sexual experiences and family violence. In addition to various attitudinal and personality variables they suggested that sexually aggressive behaviors may also be predicted by variables known as releasers, which included current sexual behavior, alcohol use, and peer group support. They also found that use of aggression in heterosexual conflict predicted sexually assaultive behavior.

Related research on deviant and aggressive behavior has provided strong evidence that religiousity and self-derogation are also predictive of interpersonal violence. Kaplan's (1980) theory of self attitude has argued that deviant behaviors reflect...
attempts to restore one's sense of self-worth. The Koss and Dinero model was, therefore, elaborated to include measures of religious participation and self-derogation. Since self-derogation is just one aspect of one's self-concept, a multidimensional measure of self-concept was also included.

To test the elaborated model of sexual assault, an anonymous survey was administered to 229 men enrolled in introductory sociology classes. These students were primarily freshmen (58.3%) and sophomores (25.1%), white (87.2%), single (94.9%), living in a dormitory (54.3%), at home (21.9%), or in an apartment (17.8%).

Sexual aggression was assessed using the Koss and Oros (1982) Sexual Experiences Survey. This survey permitted the categorization of men into one of seven mutually exclusive categories based on the types of sexually assaultive behaviors reportedly committed. Table 1 describes the distribution of men into the various categories and shows how categories were collapsed for the purpose of data analysis. As can be seen, 62.9% of the sample reported no sexually assaultive experiences. Of the remaining sample, 37.2% admitted to engaging in some form of sexual behavior against the woman's will. It was the two categories, sexually nonaggressive and sexually aggressive, that the model attempted to predict.

The hypothesized model, consisting of four categories of variables, was tested using a hierarchical blockwise discriminant function analysis. Figure 1 describes the model. The first
category of variables was labeled Early Experiences. This included measures of family violence and sexual experiences before the age of 14. Family violence included measures of the frequency with which the child received physical blows and the frequency with which one witnessed parents hitting each other. Sexual experiences were assessed by determining whether or not a range of activities from the showing of genitals to sexual intercourse had ever occurred.

The second category consisted of attitudinal and personality measures previously implicated in sexually assaultive or deviant behaviors. The six subscales of the Spence, Helmreich, and Holahan (1979) Extended Personal Attributes Questionnaire was used to measure positive and negative self-descriptions of one's expressiveness and instrumentality. Five dimensions of self-concept were assessed using Stake's (1987) multidimensional self-concept scale; Kaplan's (1980) measure of self-derogation was also included. Religiousity was based on a composite measure of frequency of religious participation and rating of importance of religion in one's life. Finally, attitudes were assessed via a subscale of Ashmore and DelBoca's (1987) multiple components measure of gender-related attitudes and responses to a question asking about conditions under which one approves of sexual intercourse.

The third cluster of variables consisted of Current Influences. This included frequency and amount of alcohol consumption, and use of marijuana and other drugs. Importance of
peer approval and peer sex talk were also assessed. Finally, level of sexual activity was included in this cluster via measures of the individuals number of relationships and the number of different sex partners.

The fourth cluster consisted of five measures of strategies of responses to heterosexual conflict. These were based on a factor analysis of an extended version of the Straus Conflict Tactics Scale (CTS) (1979). The five strategies were rational, ignore, verbal aggression, physical aggression, and severe aggression.

A hierarchical blockwise discriminant function analysis, which entered blocks of variables in the order just described, indicated that 83.8% of the cases were successfully classified. Table 2 summarizes these results. Whereas 91.4% of the nonaggressive men were accurately classified, for a gain of 28.1%, 72.0% of the aggressive men were correctly identified, for a gain of 34.4%. Fifteen of the 36 variables significantly discriminated between the two groups. Table 3 listed these variables in order of magnitude of the standardized discriminant function coefficients. The means for each variable are also given.

The results only partially confirmed Koss and Dinero's (1987) model, in that early sexual experiences, but not family violence, were significant in the present analyses. Additionally, our measure of sex role attitudes was not predictive. However, other aspects of their model were
confirmed. In addition to early sexual experiences, personality characteristics, peer group influences, alcohol and drug use, recent sexual experiences, and style of conflict management were all significant predictors. The present results also indicate the importance of assessing religiosity, self-concept and self-derogation.

The findings support the viability of a multidimensional model of sexual aggression. There is evidence that sexually assaultive behavior is influenced by 1) intrapersonal, 2) interpersonal, and 3) sociocultural factors.

A profile of the sexually aggressive male emerges from the data. Compared to their nonviolent peers, these men 1) have had an higher than average number of childhood and recent sexual experiences; 2) tend to describe themselves in more traditional masculine terms; 3) have a lower sense of self-worth; 4) are lower in religiosity; 5) are more frequently involved in derogatory sex talk with peers; 6) use alcohol and other drugs more often; and 7) are more likely to use aggressive or ignoring tactics to express anger in romantic relationships.

Taken together, these findings suggest that at the social psychological level these traditionally masculine, but insecure, men use aggression as a way of dealing with their romantic partners in both sexual and non-sexual ways. Their aggression may, in part, provide an increased sense of control and as a consequence heighten their self-esteem.
At the subcultural level, the findings indicate that these men are more involved in explicit sex talk with their peers, are more highly sexually active, and use alcohol and other drugs more than their nonaggressive counterparts. These behaviors provide the impetus and opportunity for the expression of sexual aggression. Further, the absence of religious values undermines the influence of conventional social controls for violent behavior.
