This document contains the proceedings of the 25th annual Conference of the International Group for the Psychology of Mathematics Education (PME). It features plenary lectures, research forums, discussion groups, working sessions, short oral communications, and poster presentations. Papers in Volume 1 include: (1) "The P in PME: Progress and Problems in Mathematics Education" (Jan De Lange); (2) "Linking Home and School Mathematics" (Martin Hughes); (3) "Algorithmic and Meaningful Ways of Joining Together Representatives within the Same Mathematical Activity: An Experience with Graphing Calculators" (Rina Hershkowitz and Carolyn Kieran); (4) "Even College Students Cannot Calculate Fractions: Mathematics Goals and Students' Achievement in Japan" (Yoshinori Shimizu); and (5) "Learning from History To Solve Equations" (Barbara van Amerom). Papers in Volume 2 include: (1) "Negation in Mathematics: Obstacles Emerging from an Exploratory Study" (Samuele Antonini); (2) "From the Decimal Number as a Measure to the Decimal Number as a Mental Object" (Cinzia Bonotto); (3) "The Concept of Parameter in a Computer Algebra Environment" (Paul Drijvers); and (4) "Australian and US Preservice Teachers' Perceptions of the Gender Stereotyping of Mathematics" (Helen J. Forgasz). Papers in Volume 3 include: (1) "Research on Attitudes in Mathematics Education: A Discursive Perspective" (Uwe Gellert); (2) "Effective Teachers of Second Language Learners in Mathematics" (Lena L. Khisty); (3) "Argumentative Processes in Problem Solving Situations: The Mediation of Tools" (Catia Mogetta); and (4) "Observations on the Nature of Quiet Disengagement in the Mathematics Classroom" (Elena Nardi and Susan Steward). Papers in Volume 4 include: (1) "Mathematics Subject Knowledge Revisited" (Stephanie Prestage and Patricia Perks); (2) "Challenging a Purely Mathematical Perspective on Teachers' Competence" (Jeppe Skott); (3) "Algebraic Understanding and the Importance of Operation Sense" (Elizabeth A. Warren); and (4) "Learning To Teach Mathematics Differently: Reflection Matters" (Terry Wood). (AA)
PREFACE

PME is back home. 24 years after PME1, Utrecht is once again the spot where the International Group for Psychology of Mathematics Education meets. In 1977, one year after the birth of PME at the 3rd ICME Congress in Karlsruhe, the 1st PME conference was held in Utrecht, organized by Freudenthal. His friend Fischbein, the founder president of PME, had asked him whether IOWO would be able and inclined to do this job. The proposed organizers had some hesitation because of the short time for preparation and the expected number of participants. But there was another reason for being somewhat reluctant. To a certain degree there was a difference in scientific culture. Freudenthal and his colleagues saw themselves rather as engineers than as researchers and they were fairly critical regarding the psychologists’ and educationists’ view on mathematics education. Notwithstanding these doubts—or maybe because of them—this first conference was held in Utrecht and brought 86 people together: mathematicians, mathematics didacticians, but also psychologists and educationists. Since then, year after year they have met and inspired each other.

For the Dutch, of course, 1985 was another milestone in the history of PME. In that year, the 9th PME was held in Noordwijkerhout, organized by OW & OC with Streefland as the conference chair. Compared to the first conference—where mathematics education was more or less the working field of a number of different disciplines—now the didactics and the design of mathematics education became more and more a discipline of its own. The focus was on theory of mathematics education. Streefland saw it as a break-through. And at least for the Dutch it was so. It was the time that the theory of Realistic Mathematics Education, which so far was a theory in action, became more and more explicit.

Realistic Mathematics Education is still work in progress. The present stage of the development is characterized by revision, detacting blind spots and getting a more balanced approach. Having meetings with diverse approaches and perspectives is the best way to avoid narrow-mindedness and to create possibilities for growth. As a consequence we at the Freudenthal Institute welcomed the idea to organize the PME conference in The Netherlands in 2001. A meeting with the PME community is a guarantee for a rich variety of mathematical research domains, educational levels of mathematics education and types of research, and, last but least, including different views on the learning and teaching of mathematics.

There is still little agreement on what is the best view. Scientific research seems to support quite different approaches. Therefore it is no wonder that, today, the scientific quality of research is questioned and issues of methodology are discussed. PME is the forum par excellence to ask these questions and to discuss these issues. In this respect it is interesting to see how up-to-date the words are that Freudenthal used in his opening address to PME1. He told the audience to
"Look and listen with an open mind and have the courage to notice and to report events that most people would consider as too silly to be noticed and to be reported—there will be a minority who can appreciate them, and this minority will be right."

I think that we should interpretate his words as a warning against blindly following trends and as a stimulance of researchers' own responsibility. May this conference contribute to this.

The papers in the four volumes of the proceedings are grouped according to types of presentations: Plenary Lectures, Plenary Panel, Research Forums, Discussion Groups, Working Sessions, Short Oral Communications, Posters, and Research Reports. The plenary addresses and the research forum papers appear according to the order of presentation. The papers of the group activities are sequenced according to their number code. For the other types of presentations, within each group the papers are sequenced alphabetically by the name of the first author, with the name(s) of the presenting author(s) underlined.

There are two cross-references to help readers identify papers of interest to them:
- by research domain, according to the first author (p. 1-liii)
- by author, in the list of authors (p. 1-425).

I wish to express my appreciation to all the people who took part in the production of these proceedings. First of all, I thank all the authors of the papers who contributed to the richness and the scientific merits of the proceedings. Furthermore, I extend my thanks to the reviewers and the members of the Program Committee for their respective roles in working with the papers. After they finished their job it was hard work to get the four volumes ready for the publisher. Several people were involved in this, but I am particularly indebted to Marianne Moonen for her dedication and time devoted to the preparation of the proceedings.

Although the increase of numbers of papers brought us more work than was expected, we could not resist the temptation to go digital. So for the first time in PME history, the PME Proceedings are available on cd-rom. Thanks to the team that succeeded in getting this product finished in time.

This conference received support from several sources, without which we could not have organized it to meet PME standards. We are grateful to the University Utrecht—and in particular to its "365 YEAR KNOWLEDGE @ LA CARTE" program—and to the Royal Netherlands Academy of Arts and Sciences (KNAW) for their support and facilities.

Last, but not least, many thanks to the members of the Local Organizing Committee for their willingness to share with me the responsibilities involved in this enterprise.

Marja van den Heuvel-Panhuizen
Utrecht, July 2001

PME25 2001
# TABLE OF CONTENTS

## VOLUME 1

### Preface
Table of contents  
1-iii  
1-v

### Introduction

The International Group for the Psychology of Mathematics Education  
Proceedings of previous PME conferences  
The review process of PME25  
List of PME25 reviewers  
Index of presentations by research domains  
1-xliii  
1-xlvi  
1-xlviii  
1-1  
1-liii

### Plenary Lectures

De Lange, Jan  
*The P in PME: progress and problems in mathematics education*  
1-3

Hughes, Martin  
*Linking home and school mathematics*  
1-5

Yackel, Erna  
*Explanation, justification and argumentation in mathematics classrooms*  
1-9

Abrantes, Paulo  
*Revisiting the goals and the nature of mathematics for all in the context of a national curriculum*  
1-25

Leder, Gilah C.  
*Pathways in mathematics towards equity: a 25 year journey*  
1-41

### Plenary Panel

Sackur, Catherine  
*25 years of PME: past and future challenges*  
1-57
Bell, Alan
25 years of PME — and the next 25

Da Rocha Falcão, Jorge Tarcisio
Learning environment for mathematics in school: towards a research agenda in psychology of mathematics education

Peter-Koop, Andrea
From “teacher researchers” to “student teacher researchers” — diagnostically enriched didactics

Goffree, Fred
A consumer’s point of view

Presentation on mathematics education in The Netherlands

Gravemeijer, Koen & Kindt, Martin
“Polder mathematics” — Mathematics education in The Netherlands

Research Forums

RF1 Potential and pitfalls of technology tools in learning mathematics
Coordinators: Kieran, Carolyn & Hershkowitz, Rina

Kieran, Carolyn & Hershkowitz, Rina
Potential and pitfalls of technological tools in learning mathematics: introductory remarks

Discussion Groups

DG01 Imagery and affect in mathematical learning
Coordinators: English, Lyn & Goldin, Gerald A.

DG02 Stochastical thinking, learning and teaching
Coordinators: Truran, Kath & Greer, Brian & Truran, John

PME25 2001
DG03 **Semiotics in mathematics education**
   Coordinators: Sáenz-Ludlow, Adalira & Presmeg, Norma C.

DG04 **Culture and mathematical cognition**
   Coordinators: Li, Yeping & Watanabe, Tad

DG05 **Researching the social in mathematics education: issues of inclusion**
   Coordinators: Povey, Hilary & Hardy, Tansy & Boylan, Mark

DG06 **Searching links between conceptual and procedural mathematical knowledge**
   Coordinators: Haapasalo, Lenni & Zimmermann, Bernd

DG07 **Modeling and technology**
   Coordinators: Doerr, Helen M. & Pratt, Dave & Yerushalmy, Michal

DG08 **Facilitating the conceptual change in mathematics**
   Coordinators: Pehkonen, Erkki & Merenluoto, Kaarina

DG09 **Work-related mathematics education**
   Coordinators: Strässer, Rudolf & Williams, Julian

DG10 **Psychology of computer science education**
   Coordinators: Aharoni, Dan & Kynigos, Chronis & Lapidot, Tamar

DG11 **The importance of matching research questions and methodology to the reality of researchers' lives**
   Coordinators: Hart, Kathleen & Sullivan, Peter

DG12 **Symbolic cognition in advanced mathematics**
   Coordinators: Hegedus, Stephen & Tall, David & Eisenberg, Ted

**Working Sessions**

WS01 **Expanding researchers' ability to study student experiences**
   Organizers: Hannula, Markku S. & Breen, Chris
WS02  *Focussing on mental arithmetic*  
Organizers: Buys, Kees & Neuman, Dagmar  

WS03  *Embodiment, gesture, and mathematics education.*  
Organizers: Bolite Frant, Janete & Draisma, Jan & Edwards, Laurie  

WS04  *Observing systems*  
Organizers: Reid, David A. & Brown, Laurinda & Coles, Alf  

WS05  *Working with transcripts*  
Organizer: Ainley, Janet  

WS06  *How ICT affords the reinvention of mathematics: two examples*  
Organizers: Pijls, Monique H.J. & Doorman, Michiel  

WS07  *What counts as multiplicative thinking in younger students?*  
Organizers: Reynolds, Anne & Watanabe, Tad & Brekke, Gard  

WS08  *The Ferris wheel problem*  
Organizers: Nemirovsky, Ricardo & Solomon, Jesse  

**Short Oral Communications**  

**Albert, Jeanne**  
*A teacher’s tests can change*  

**Amundsen, Kristin**  
*Types of representation used in the presentation of trigonometry in a textbook*  

**Andersen, Charlotte Krog**  
*The computer as mediator in the development of mathematical concepts*  

**Bezuidenhout, Jan**  
*Students’ understanding of graphical aspects of derivative and of some of its underlying concepts*
Botelho, D. & Castro, J. & Morgado, L. & Parrat-Dayan, S.
A constructivist approach of error in additive arithmetic problem solving

Brekke, Gard
Affects and beliefs in school mathematics: gender differences

Brown, Tony
The social constitution of school mathematics curriculums

Bulafo, Gildo Luís
How to approach negative numbers in school

Busse, Andreas
The role of figurative context in realistic tasks

Campbell, Stephen R.
Research in mathematics education at the nexus of math, mind, brain, and world

Cannizzaro, Lucilla & Menghini, Marta
From geometrical figures to linguistic rigor: van Hiele's model and the growing of teachers' awareness

Catapani, Elaine C. & Cabral, Tânia C.B. & Godoy Penteado, Miriam
In-service calculus course: what do students and teachers wish?

César, Margarida & Rijo, Catarina & Loureiro, Marta
Inclusive schooling: from possible to undelayable

Chae, Soo D. & Tall, David
Students' concept images for period doublings as embodied objects in chaos theory

Chang, Ching-Kuch
The Taiwanese teachers' beliefs and values in mathematics education

Chung, Jing
School based inservice improvement as an effective instrument to change mode of mathematics teaching
Civil, Marta
   Children's thinking about area and perimeter in the context of a
garden theme
1-297

Cohen, Nitsa
   Preference of directions in 3-D space
1-298

Cortina, José Luis
   Three ways of using the arithmetic mean
1-299

Crowley, Lillie & Tall, David
   Attainment and potential: procedures, cognitive kit-bags and
   cognitive units
1-300

De Moor, Ed
   Plea for a simple calculator in primary schools
1-301

Dörfler, Willi
   Learning trajectories based on protocols
1-302

Feilchenfeld, David
   The usefulness of mathematics studies through the eyes of
   electronics college teachers
1-303

Fernández, Alejandro & Puig, Luis & Figueras, Olimpia
   A teaching model for ratio comparison, proportion and density
1-304

Ferreira, Rosa A.
   Student teachers' reflections on questioning, listening, and
   responding
1-305

Fourie, Mariana & Nieuwoudt, Hercules D.
   Where to with high school geometry?
1-306

Gawlick, Thomas
   A comparative study on the influence of dynamic geometry
   software on the acquisition of basic geometric notions
1-307

Gazit, Avikam
   Mathematics, language and poetry
1-308
Giménez Rodrigues, Joaquin & Almeida Bairral, Marcelo
Improving teachers’ critical thinking in a "on line" geometry course

González-López, María José
Computable representation of continuous motion in dynamic geometry environments

Gur, Hulya & Comlekoglu, Gozde & Ersoy, Yasar
Reflections from two-days seminar/workshop on using calculators in teaching of elementary school mathematics

Guzmán, José & Kieran, Carolyn & Squalli, Hassane

Open-ended tasks: the dilemma of openness or ambiguity?
INTRODUCTION
History and aims of PME

PME came into existence at the Third International Congress on Mathematics Education (ICME3) held in Karlsruhe, Germany in 1976. Its past presidents have been Efraim Fischbein (Israel), Richard R. Skemp (UK), Gerard Vergnaud (France), Kevin F. Collis (Australia), Pearl Nesher (Israel), Nicolas Balacheff (France), Kathleen Hart (UK), Carolyn Kieran (Canada) and Stephen Lerman (UK).

The major goals of the Group are:

♦ To promote international contacts and the exchange of scientific information in the psychology of mathematics education
♦ To promote and stimulate interdisciplinary research in the aforesaid area with the cooperation of psychologists, mathematicians and mathematics educators
♦ To further a deeper understanding into the psychological aspects of teaching and learning mathematics and the implications thereof.

PME membership and other information

Membership is open to people involved in active research consistent with the Group’s goals, or professionally interested in the results of such research. Membership is on an annual basis and requires payment of the membership fees ($US40 or the equivalent in local currency) per year (January to December). For participants of PME25 Conference, the membership fee is included in the Conference Deposit. Others are requested to contact their Regional Contact, or the Executive Secretary. More information about PME as an association can be obtained through its home page at: http://igpme.tripod.com or contact the Executive Secretary:

Honorary Members of PME

Hans Freudenthal (The Netherlands, deceased)
Efraim Fischbein (Israel, deceased)

Present Officers of PME

President: Gilah Leder (Australia)
Vice-president: Chris Breen (South Africa)
Secretary: Vicki Zack (Canada)
Treasurer: Gard Brekke (Norway)
Other Members of the International Committee

Janete Bolite Frant (Brazil)
Anne Cockburn (UK)
Jan Draisma (Mozambique)
Ruhama Even (Israel)
Masataka Koyama (Japan)
Nicolina Antonia Malara (Italy)
Ricardo Nemirovsky (USA)
Norma Presmeg (USA)
Catherine Sackur (France)
Peter Sullivan (Australia)
Marja van den Heuvel-Panhuizen (The Netherlands)
Tad Watanabe (USA)
Orit Zaslavsky (Israel)

Executive Secretary

Joop van Dormolen  Rehov Harofeh 48A/10
Haifa 34367, Israel
Phone: +972-4-8246239
Fax: +972-4-8258071

Paul Drijvers (FI, Utrecht University)
Koen Gravemeijer (FI, Utrecht University)
Han Hermsen (FI, Utrecht University)
Gellof Kanselaar (Utrecht University)
Ronald Keijzer (IPABO, Amsterdam / FI, Utrecht University)
Martin Kindt (FI, Utrecht University)
Henk van der Kooij (FI, Utrecht University)
Jan de Lange (FI, Utrecht University)
John Rief (FI, Utrecht University)
Dirk Siersma (Utrecht University)
Willem Uittenbogaard (Hogeschool Alkmaar / FI, Utrecht University)
Heleen Verhage (FI, Utrecht University)
Lieven Verschaffel (Catholic University of Leuven, Belgium).

Conference Secretariat:
Sonja Palha, Sylvia Eerhart, Marianne Moonen, Ellen Hanepen, Ank van der Heijden,
Wil Hofman, Effa Yulita (FI, Utrecht University),
Mariëlle Hoogendoorn, Nic Stolker, Margriet de Ruijter
(FBU Congress Bureau, Utrecht University).

Graphic design support: Tyrone Meijer.
Website staff: Mieke Abels (design), Sylvia Eerhart (maintenance).
Cd-rom production: Bas Holleman (FI, Utrecht University).
PROCEEDINGS OF PREVIOUS PME CONFERENCES

Copies of some previous PME Conference Proceedings are still available for sale. For information, see the PME home page at http://igpme.tripod.com, or contact the Executive Secretary Dr. Joop van Dormolen, Rehov Harofeh 48A, Haifa 34367, Israel; fax: +972 4 8258071; email: joop@tx.technion.ac.il.

All proceedings, except PME1, are included in ERIC. Below is a list of the proceedings with their corresponding ERIC code.

Abstracts from articles can be inspected on the ERIC web site (http://www.accesseric.org) and on the web site of ZDM/MATHDI (http://www.emis.de/MATH/DI.html).

Micro fiche with the content of the proceedings might be available for inspection at university libraries or can be bought from ERIC/CSMEE, 1929 Kenny Road, Columbus, OH 43210-1080, Tel: (614) 292-6717, Fax: (614) 292-0263, e-mail: ericse@osu.edu

MATHDI is the web version of the Zentralblatt für Didaktik der Mathematik (ZDM, English subtitle: International Reviews on Mathematical Education). For more information on ZDM/MATHDI and its prices or assistance regarding consortia contact Gerhard König, managing director, fax: +49 7247 808 461, email: gk@fiz-karlsruhe.de.
THE REVIEW PROCESS OF PME25

Research Forum

Five Research Forums had been suggested by the International Committee and the Program Committee for PME25: (1) Potential and pitfalls of technology tools in learning mathematics, (2) Early algebra, (3) Comparative views of mathematics goals and achievements, (4) Designing, researching and implementing mathematical learning environments — the research group “Mathe 2000”, (5) Realistic mathematics education: Leen Streefland’s work continues. For each Research Forum the proposed structure, the contents, the contributors and their role were reviewed and agreed by the Program Committee.

Research Reports

The Program Committee received 272 Research Report proposals. Each proposal was sent for blind review to three reviewers. As a rule, proposals with at least two recommendations for acceptance were accepted. The reviews of proposals with only one recommendation for acceptance were carefully read by at least two members of the Program Committee. When necessary, the Program Committee members read the full proposal and formally reviewed it. Proposals with three recommendations for rejection were not considered for presentation as research reports. Altogether, 171 research report proposals were accepted. When appropriate, authors of proposals that were not accepted as Research Reports were invited to re-submit their work — some in the form of a Short Oral Communication and some as a Poster Presentation.

Short Oral Communications and Poster Presentations

The Program Committee received 104 Short Oral Communication proposals and 31 Poster Presentation proposals. Each proposal was reviewed by at least two Program Committee members. From these proposals 89 Short Oral Communications and 28 Poster Presentations were accepted. Some authors of Short Oral Communication proposals were invited to re-submit their work as a Poster Presentation. Altogether, 113 Short Oral Communications and 43 Poster Presentations were accepted.

LIST OF PME25 REVIEWERS

The PME23 Program Committee thanks the following people for their help in the review process:

Adler, Jill B. (SOUTH AFRICA)
Aharoni, Dan (ISRAEL)
Ainley, Janet M. (UNITED KINGDOM)
Artigue, Michèle (FRANCE)
Azcárate, Carmen (SPAIN)
Bakker, Arthur (THE NETHERLANDS)
Baldino, Roberto R. (BRAZIL)
Bartolini Bussi, Mariolina (ITALY)
Batanero, Carmen (SPAIN)
Bazzini, Luciana (ITALY)
Becker, Joanne R. (USA)
Bednarz, Nadine (CANADA)
Bell, Alan (UNITED KINGDOM)
Ben-Chaim, David (ISRAEL)
Berenson, Sarah B. (USA)
Bills, Elizabeth (UNITED KINGDOM)
Bishop, Alan J. (AUSTRALIA)
Boavida, Ana Maria R. (PORTUGAL)
Boero, Paolo (ITALY)
Bolite Frant, Janete (BRAZIL)
Booker, George (AUSTRALIA)
Borba, Marcelo C. (BRAZIL)
Boulton-Lewis, Gillian (AUSTRALIA)
Bowers, Janet (USA)
Breen, Chris J. (SOUTH AFRICA)
Brekke, Gard (NORWAY)
Brito, Marcia R. F. (BRAZIL)
Brodie, Karen (USA)
Broekman, Harrie (THE NETHERLANDS)
Brown, Laurinda C. (UNITED KINGDOM)
Brown, Roger (UNITED KINGDOM)
Campbell, Stephen R. (USA)
Cannizzaro, Lucilla (ITALY)
Carrillo Yáñez, José (SPAIN)
Chinnappan, Mohan (AUSTRALIA)
Christou, Constantinios (CYPRUS)
Cifarelli, Victor V. (USA)
Civil, Marta (USA)
Clarkson, Philip C. (AUSTRALIA)
Coady, Carmel (AUSTRALIA)
Cobb, Paul (USA)
Cockburn, Anne D. (UNITED KINGDOM)
Confrey, Jere (USA)
Cooney, Thomas (USA)
Cooper, Tom J. (AUSTRALIA)
Csíkos, Csaba A. (HUNGARY)
Da Rocha Falcão, Jorge T. (BRAZIL)
Davis, Gary E. (UNITED KINGDOM)
De Bock, Dirk (BELGIUM)
De Moor, Ed (THE NETHERLANDS)

Dettori, Giuliana (ITALY)
Doeckler, Willi (AUSTRIA)
Doerr, Helen M. (USA)
Dolk, Maarten (THE NETHERLANDS)
Doorman, Michael (THE NETHERLANDS)
Draisma, Jan (MOZAMBIQUE)
Dreyfus, Tommy P. (ISRAEL)
Drijvers, Paul (THE NETHERLANDS)
Drouhard, Jean-Philippe (FRANCE)

INDEX OF PRESENTATIONS BY RESEARCH DOMAIN

The papers in the Proceedings are indexed below by research domain, as indicated by the authors on their proposal form. The papers are indicated by their first author and page number.

**Adult learning**
- Boavida, Ana Maria R. 1:386

**Advanced mathematical thinking**
- Aguilar, Marlene 2:025
- Alcock, Lara J. 2:033
- Antonini, Samuele 2:049
- Barnard, Tony 2:089
- Bezuidenhout, Jan G. 1:284
- Chin, Erh-Tsung 2:241
- Czarnocha, Bronislaw 2:297
- Hoffmann, Ronit 1:316
- Jahn, Einar 1:399
- Meissner, Hartwig 3:359
- Moreno, Mar 1:344
- Nardi, Elena 3:399
- Pinto, Marcia M. F. 4:057
- Reiss, Kristina M. M. 1:414
- Reiss, Kristina M. M. 4:097
- Rogalski, Janine 4:113
- Sacristán, Ana Isabel 4:129
- Safuanov, Ildar S. 1:416
- Shir, Karmi 4:161
- Sierpinska, Anna 4:177
- Thomas, Michael O.J. 4:257
- Tsai, Wen-Huan 4:295

**Affective factors**
- Bishop, Alan J. 2:169
- Campos, Yolanda 1:390
- Chin, Chien 2:249
- Christou, Constantinos 2:257
- Denvir, Hazel E. 2:337
- Di Martino, Pietro 3:351
- Forgasz, Helen J. 2:433
- Gellert, Uwe 3:033
- Hannula, Markku S. 1:314
- Hazin, Izabel 3:121
- Le Roux, Amanda 1:335
- Matos, João Filipe 1:341
- Nardi, Elena 3:407
- Op 't Eynde, Peter 4:025
- Safuanov, Ildar S. 1:362
- Schügelmann, Wolfgang 1:366
- Sinclair, Nathalie M. 4:185
- Sun, Xiaotian 1:419
- Takahashi, Hitoshi 1:372
- Williams, Gaye 1:378

**Algebraic thinking**
- Ainley, Janet M. 1:129
- Bazzini, Luciana 2:121
- Bills, Elisabeth J. 2:161
- Boero, Paolo 2:185
- Carraher, David W. 1:130
- Cerulli, Michele 2:225
- Crowley, Lillie R. F. 1:300
- Drijvers, Paul 2:385
- Feilichenfeld, David 1:303
- Filloy, Eugenio I. 2:417
- Friedlander, Alex 2:441
- Gallardo, Aurora 3:001
- Garuti, Rossella 3:009
- Gilead, Shoshana 3:041
- Iaderosa, Rosa 1:320
- Kent, Laura B. 1:401
- Lenfant, Agnès 3:297
- Linchevski, Liora 1:141
- Mariotti, M. Alessandra 3:343
- Okazaki, Masakazu 1:350
- Radford, Luis G. 1:145
- Radford, Luis G. 4:081
- San, Luis W. 1:364
- Schliemann, Analúcia D. 4:145
- Tabach, Michal 4:241
- Tall, David O. 1:149
- Teppo, Anne R. 1:153
- Tsamir, Pessia 4:303
- Ursini, Sonia 4:327
- Van Dooren, Wim 4:359
- Vlassis, Joëlle E. M. 4:375
- Warren, Elizabeth A. 1:156
- Warren, Elizabeth A. 4:399

A problem of math education in the real world

'Between a hundred and two hundred million students does not get any kind of math education'

'The statistic show that the number of illiterate citizens is rising and that in the countries of the MENA region 50% of the women will be illiterate in 2000'.

Obstacles in solving this problem

The philosophical gap:
'The question is not how we can improve the quality of education, but how we can improve the quality of formal education'.

The parrot effect:
Developing countries should look at and copy the curricula and tests from western countries.

The political vs. content gap:
Prerequisites for improving education according to World Bank: Lower the deficits; Let the GNP grow; Look for changes in the structure.

The gap between research and practice:
'Bent Christiansen would not have been comfortable in an english or american math education department. Reading, thinking, reflecting and discussing new ideas was more appriciated than the production of scientific articles and starting a production line for Ph.D's.'

The problem of mathematics in relation to math education

What is mathematics and what does this mean for math education?

Mathematics has evolved from the science of number, into the science of number and shape, into the science of number, shape and change into, at this moment, the science of patterns.

Mathematics education does not seem to reflect this development: another gap.

Mathematics and math education are under heavy pressure from society: why is mathematics important as it does not seem very relevant to the needs of society.

Modern mathematics was the mathematicians mathematics. What we want: the students mathematics. The content of students mathematics depend on the perception of the discipline, the role mathematics plays in society, the broadness of definition,
the relation with other subjects, the goals for math education. The way we teach mathematics depend on many things-one of them the results from research.

The Problem: The science of math education

In 1978 Freudenthal wrote the book: 'Preface to a Science of Mathematics Education'. The function was: To accelerate the birth of a science of mathematical education, which is seriously impeded by the unfounded view that such already exists.

That was almost 25 years ago. Where are we now?

'There is no agreement among leaders in the field about goals of research, important questions, objects of study, methods of investigation, criteria for evaluation, significant results, major theories, or usefulness of results... a field in disarray.'

'Results obtained by different research schools are very difficult to compare and researchers prefer to stay within a strictly homogeneous reference system'.

Math education as a science is under pressure: University students close schools of education; colleagues find most research papers uninteresting (they deal with marginal details) and teachers cannot synthesize results into useful forms'.

The problem: gap between research and practice

In 1980 Freudenthal stated as one of the main problems of mathematics education: 'How to design educational development as a strategy for change?'

'Failure is the only possible outcome for any approach in which researchers hand their results to curriculum developers who are than expected to apply them in their practices'

'Wouldn't it be helpful to let outstanding teachers co-determine the selection and granting of research projects?'

The problem: the results of the practice of math education

TIMSS showes clearly that the actual outcome of at least part of the results of math education in a large number of countries leaves much to desire.

TIMSS also identifies some of the causes of the relatively disappointing results.

PISA tries to identify the functionality of math education for 15 year olds-seen form the perspective of mathematical litteracy. And although most western countries do have excellent facilities: books, paper, pencils, computers etc. the mathematical literacy leaves a lot to be desired.

We should take more responsibility. We should adjust our agenda's.

We have made progress: if it were just by identifying clearly the problems as just mentioned. But we have not used the combined talents of all of us interested in math education. We have tried too much to build a research discipline. We should try to develop better math education. A research disciplin will be the result.
Abstract

In this paper I want to address what I believe to be a fundamental educational problem – namely, that there is an important difference between the kinds of learning in which children engage at school, and the kinds of learning in which they engage outside school, particularly at home. This problem is closely connected with the well-known difficulties that learners experience with the application of knowledge from one context to another, particularly in the area of mathematics. In this paper I will look at two main ways in which home and school learning might be brought together in the area of mathematics. First, I look at approaches which import ‘authentic’ out-of-school problems into the mathematics classroom, and secondly, at those which export school mathematics problems into the home. I conclude that neither approach is sufficient to break down the barriers between home and school learning, and that more radical solutions are needed.

Summary

There is growing evidence that there are fundamental differences between the kinds of learning in which children engage at school and the kinds of learning in which they engage outside school, particularly at home. School learning, for the most part, is shaped by the curriculum, regularly assessed, strictly timetabled, and focused around artificial problems. It usually takes place in large horizontal age groups, with adults as instructors, and provides few opportunities for children themselves to act as teachers. Home learning, in contrast, is shaped by interest and need, rarely assessed, usually spontaneous, and focused around authentic problems. It usually takes place in small vertical age groups, with adults as models or guides, and provides substantial opportunities for children themselves to act as teachers.
This distinction between home and school learning can usefully be related to other distinctions within different theoretical perspectives. We can, for example, see it as an instance of the well-known distinction between ‘formal’ and ‘informal’ learning (eg Coffield, 2000). We can relate it to the contrast that Donaldson (1978, 1990) makes between ‘embedded’ and ‘disembedded’ thinking. Or we can link it to the distinction between ‘cognitive’ and ‘situated’ theories of learning, widely discussed in recent issues of the AERA journal Educational Researcher, and to the metaphors of ‘acquisition’ and ‘participation’ underlying these two different theoretical approaches (eg Sfard, 1998).

Whatever theoretical perspective is adopted, I will argue that the difference between home and school learning is closely related to the widespread problem of application – namely, that knowledge acquired in one context is frequently not available or not used in another context. While this problem is widespread across many subjects, it seems to be particularly acute in mathematics. Here there is considerable evidence that mathematical knowledge acquired in school does not readily transfer to out-of-school contexts (eg Hughes, 1986). At the same time, there is also evidence that mathematics knowledge acquired out-of-school does not readily transfer to school type problems (eg Nunes, Schliemann and Carraher, 1993).

In the rest of my paper I will look at ways in which we might address this problem. I will argue that there are two main approaches to linking home and school mathematics, and illustrate these approaches, and the issues they raise, with examples and evidence from my own recent research.

One attempt to make connections between home and school mathematics is by importing examples of ‘out-of-school’ problems into the classroom. This of course is a well-known approach widely used by mathematics educators. However, while this approach can often increase students’ motivation to engage with classroom mathematics, it does not necessarily help break down the barrier between school maths and out-of-school maths. In my paper I will illustrate this approach, and the issues it raises, with examples drawn from a recent project in which we worked closely with primary school teachers trying to develop their practice (Hughes, Desforges and Mitchell, 2000).

The other main attempt to make connections between home and school is by sending home aspects of school mathematics. In many countries, this is traditionally done through ‘homework’, where students are required to work at home on problems
related to the school curriculum. While homework provides opportunities for students to make links between school learning and out-of-school learning, our own research suggests that this does not often happen (Hughes and Greenhough, 2001). Instead homework becomes simply a piece of school work which happens to be done at home.

In the UK, there has been much interest in recent years in initiatives that attempt to go beyond traditional homework and involve parents more directly in their children’s learning. One particularly well known scheme is IMPACT Maths (eg Merttens and Leather, 1993), whereby mathematical puzzles and games are sent home for children to carry out with their parents. In a recent study we looked systematically at what happens when children engage in a typical IMPACT activity with their parents, and compared this with what happens when children carry out the same activity with their teachers. Our findings suggest there are important differences between the ways in which parents and teachers help children, and that these may serve to accentuate rather than reduce the differences between home and school.

In the final section of my paper I will argue that the approaches described above, while not without merit, are not by themselves adequate to break down the barriers between home and school learning. A more radical approach is needed, one which gives greater recognition to the mathematical practices already occurring in children’s homes and attempt to link these more directly with the practices of school.

EXPLANATION, JUSTIFICATION AND ARGUMENTATION IN MATHEMATICS CLASSROOMS

Erna Yackel
Purdue University Calumet

Abstract: Current interest in mathematics learning that focuses on understanding, mathematical reasoning and meaning-making underscores the need to develop ways of analyzing classrooms that foster these types of learning. In this paper, I show that the constructs of social and sociomathematical norms, which grew out of taking a symbolic interactionist perspective, and Toulmin's scheme of argumentation, as elaborated for mathematics education by Krummheuer, provide us with a means to analyze aspects of explanation, justification and argumentation in mathematics classrooms, including means through which they may be fostered. In addition, I use the example of current research in a university-level differential equations class to show how these notions can inform instruction in higher-level mathematics.

In his plenary address to PME in 1994, John Mason said,

I have long concluded that it is very hard to say anything new that has not been said more eloquently elsewhere.... I see working on education not in terms of an edifice of knowledge, adding new theorems to old, but rather as a journey of self discovery and development in which what others have learned has to be re-experienced by each traveller, re-learned re-integrated and re-expressed in each generation. (p. 177)

He went on to say that “All you can do, if you really want to be truthful is to tell a story” (p. 177).

My purpose in this paper is to tell a story that intends to capture something of what I have experienced and learned about explanation, justification and argumentation from a variety of mathematics classrooms that I have studied. At the same time, I intend to explain why I am telling you this story—what significance this story might have for someone else. In this regard, I am following the approach that Streefland (1993) took when he said that by analyzing his experiences, in his case in instructional design, his goal was to take what was an after-image for him and make it possible for that to become a pre-image for someone else working in the same arena. Similarly, my intention is to specify various aspects of explanation, justification and argumentation that have emerged from my analyses of classrooms so it becomes possible for others to use these aspects to inform their future efforts in mathematics education research and practice.

Background

The research activity that my colleagues and I have been engaged in is classroom based and involves conducting classroom teaching experiments that range from six weeks to an entire school year or university term. It involves developing...
instructional sequences and approaches as well as investigating teaching and learning as it occurs in the classroom. In this type of research, called developmental or design research (Cobb, Stephan, McClain, & Gravemeijer, in press; Gravemeijer, 1994), the researchers conduct ongoing analyses of classroom activity and use the results to inform instructional planning and decision making. It also involves retrospective analyses that attempt to explain the nature of the learning that took place and to explicate significant aspects of the learning situation.

Through analyzing these teaching experiments, we have come to understand the importance of taking into account the social aspects of learning, including social interaction (Cobb, Yackel, & Wood, 1989; Yackel, Cobb, Wood, Wheatley, & Merkel, 1990; Yackel & Rasmussen, in press; Yackel, Rasmussen, & King, 2001). We have developed an interpretive framework for analyzing classrooms and we have explicated theoretical constructs within that framework in terms of our experiential base (Cobb & Yackel, 1996; Yackel & Cobb, 1996). Two constructs that are particularly relevant to issues of explanation, justification and argumentation are social norms and sociomathematical norms. Our investigations have pointed to the importance of these two constructs in clarifying both the functions that explanation, justification and argumentation serve and the means by which they might be fostered in the classroom. Further, the constructs of social and sociomathematical norms have been useful in clarifying how we might think of explanation, justification and argumentation in mathematics classrooms where understanding and meaning-making are the focus of instruction. In addition, in previous work, I have documented that children as young as second grade engage in sophisticated forms of explanation and justification and that their understanding of explanation advances as the school year progresses. Finally, I have argued (Yackel, 1997) that we can use Toulmin’s argumentation scheme, as elaborated for mathematics education by Krummheuer (1995), as a methodological tool to demonstrate how learning progresses in a classroom.

All of these ideas were originally developed as a result of research in elementary school classrooms. A legitimate question is whether or not any of these results, including such constructs as social and sociomathematical norms, are useful in analyzing higher-level (including university-level) mathematics instruction in which the constraints are (or are perceived to be) different from those in the elementary grades. This question is particularly relevant since the amount of research at higher levels of mathematics instruction remains relatively small.

In this paper, I first discuss symbolic interactionism as a theoretical framework. Next, I explain what I mean by explanation and justification and discuss normative aspects of mathematics classrooms relative to explanation and justification. Then I describe how Toulmin’s argumentation scheme can be used as a methodological tool

---

1 In using we I am referring to various colleagues that I have worked with to conduct and analyze teaching experiments over the past decade and a half including Paul Cobb, Terry Wood, Koeno Gravemeijer, Diana Underwood Gregg, Chris Rasmussen, and Karen King.
to document learning in the classroom. I then discuss how this approach to argumentation can be used to explicate the teacher's role in the classroom. Finally, I show how these ideas, which are after-images of research conducted in mathematics classrooms at the elementary-school level, are being used as pre-images to inform current classroom-based research in a university-level mathematics class at my university. In doing so, I demonstrate their utility at the upper levels of mathematics learning. At the same time, the crucial role of explanation, justification and argumentation in mathematics learning from the lower to the higher levels of mathematics becomes apparent. Thus, I answer in the affirmative a question that was raised by Duval (2000) in his plenary lecture to PME last year when he asked "Is there something similar in the process of mathematics learning at the first levels and at upper levels?"

Theoretical Framework

In previous attempts to investigate explanation, justification and argumentation in mathematics classrooms, we have found it useful to take a symbolic interactionist perspective. Of the various approaches to social interaction, we have taken symbolic interaction as a theoretical lens for two reasons. First, it is compatible with psychological constructivism, which forms the theoretical basis for our investigation of individual learning (Cobb & Bauersfeld, 1995). Second, as Voigt (1996) points out, the symbolic interactionist approach is particularly useful when studying students' learning in inquiry mathematics classrooms because it emphasizes both the individual's sense-making processes and the social processes without giving primacy to either one. Thus, we do not attempt to deduce an individual's learning from social processes or vice versa. Instead, individuals are seen to develop personal meanings as they participate in the ongoing negotiation of classroom norms.

The theory of symbolic interactionism has its roots in the work of George Herbert Mead, John Dewey and others and has been developed extensively by Herbert Blumer (1969). One of its defining principles is the centrality given to the process of interpretation in interaction. To put it another way, the position taken by symbolic interactionism is that in interacting with one another, individuals have to take account of (interpret) what the other is doing or about to do. Each person's actions are formed, in part, as she changes, abandons, retains, or revises her plans based on the actions of others. In this sense, social interaction is a process that forms human conduct rather than simply a setting in which human conduct takes place. As Blumer (1969) stated, "One has to fit one's own line of activity in some manner to the actions of others. The actions of others have to be taken into account and cannot be merely an arena for the expression of what one is disposed to do or sets out to do" (p. 8). Blumer further clarified that the term symbolic interactionism refers to the fact that the interaction of interest involves interpretation of action. Attempts to

---

2 I follow Richards (1991) in using the label inquiry mathematics classrooms to describe those classrooms in which students engage in genuine mathematical discussions with each other and with the teacher. See Yackel (2000) for a detailed discussion of the social and sociomathematical norms that characterize inquiry mathematics classrooms.
genuinely communicate involve understanding the meanings of another’s actions (Rommetveit, 1985), and so involve symbolic interaction.

In addition to interpreting actions of others, individuals engaged in interaction attempt to indicate to others, through their actions, what their own intentions are. Thus, actions have meanings both for the person making them and for the person(s) to whom the action is directed. In this sense there is a joint action that arises by the articulation of the participating actors’ activity. Blumer (1969) emphasized the collective nature of such joint action as follows:

A joint action, while made up of diverse component acts that enter into its formation, is different from any one of them and from their mere aggregation. The joint action has a distinctive character in its own right, a character that lies in the articulation or linkage as apart from what may be articulated or linked. Thus, the joint action may be identified as such and may be spoken of and handled without having to break it down into the separate acts that comprise it. (p. 17)

Blumer further pointed out that it is important to recognize that “the joint action of the collective is an interlinkage of the separate acts of the participants” (p. 17). As such, it has to undergo a process of formation and, even though it may be well established as a form of social action, each instance of it has to be formed once again. Consequently, the meanings and interpretations that underlie joint action are continually subject to challenge. As a result, both individual actions and the joint (collective) action of a group can change over time. Furthermore, this view of joint action supports the position that social rules, norms and values are upheld by a process of social interaction and not the other way around.

A second defining principle of symbolic interactionism, in addition to the centrality of interpretation, is that meaning is seen as a social product. Blumer (1969) elaborated this point as follows:

It [symbolic interactionism] does not regard meaning as emanating from the intrinsic makeup of the thing that has meaning, nor does it see meaning as arising through a coalescence of psychological elements in the person. Instead, it sees meaning as arising in the process of interaction between people. The meaning of a thing for a person grows out of the ways in which other persons act toward the person with regard to the thing. Their actions operate to define the thing for the person. Thus, symbolic interactionism sees meaning as social products, as creations that are formed in and through the defining activities of people as they interact. (pp. 4,5)

This view of meaning has important implications for how we interpret the results of classroom discursive activity. Since meanings grow out of social interaction, each individual’s personal meanings and understandings are formed in and through the process of interpreting that interaction. Nevertheless, normative understandings are constituted. It is as these normative understandings are constituted that students
develop their own interpretations of them. What we mean by saying that these understandings are normative is that there is evidence from classroom dialogue and activity that students’ interpretations are compatible. It is in this sense that we say that students’ interpretations or meanings are “taken-as-shared” (Cobb, Wood, Yackel, & McNeal, 1992).

Explanation and Justification

In this paper my interest is in explanation and justification as social constructs rather than as individual constructs. In this case, they are considered to be aspects of the discourse that serve communicative functions and are interactively constituted by the teacher and the students. Explanation and justification are distinguished, in part, by the functions they serve. Students and the teacher give mathematical explanations to clarify aspects of their mathematical thinking that they think might not be readily apparent to others. They give mathematical justifications in response to challenges to apparent violations of normative mathematical activity (Cobb et al., 1992). For example, consider the task “How can you figure out 16 + 8 + 14?” If a child responds, “I took one from the 16 and added it to the 14 to get 15 and 15; then I added the 15 and 15 to get 30, and the other 8 to get 38,” we would infer that she was explaining her solution to others. However, a challenge that “you first have to add the 16 and the 8 and then add 14 to that sum” is a request for a justification.

Classroom norms that relate to mathematical explanation and justification are both social and sociomathematical in nature. Norm is a sociological construct and refers to understandings or interpretations that become normative or taken-as-shared by the group. Thus, norm is not an individual but a collective notion. One way to describe norms, in our case, classroom norms, is to describe the expectations and obligations that are constituted in the classroom.

By analyzing data from our initial teaching experiments, we were able to identify a number of social norms that characterized classroom interactions. These include that students are expected to develop personally-meaningful solutions to problems, to explain and justify their thinking and solutions, to listen to and attempt to make sense of each other’s interpretations of and solutions to problems, and to ask questions and raise challenges in situations of misunderstanding or disagreement. In saying that these social norms characterized the classroom interactions, I mean that these ways of acting and of interpreting the actions of others became taken-as-shared. In subsequent classroom teaching experiments we had the constitution of these norms as an explicit goal. It is evident that each of these norms relates specifically to explanation and justification when taken as social constructs, as described above.

We were also able to identify normative aspects of interactions that are specific to mathematics. These we called sociomathematical norms (Yackel & Cobb, 1996). Normative understandings of what counts as mathematically different, sophisticated, efficient and elegant are examples of sociomathematical norms. Similarly, what
counts as an acceptable mathematical explanation and justification is a sociomathematical norm. The distinction between social norms and sociomathematical norms is subtle. For example, the understanding that students are expected to explain their solutions is a social norm, whereas the understanding of what counts as an acceptable mathematical explanation is a sociomathematical norm.

We might ask how notions such as what counts as an acceptable explanation come to have meaning for students. To answer this question, we return to the symbolic interactionist position on meaning. This position is that meaning arises through interaction. Accordingly, the meaning of acceptable mathematical explanation is not something that can be outlined in advance for students to “apply.” Instead, it is formed in and through the interactions of the participants in the classroom. As with all normative understandings, both explicit and implicit negotiations contribute to developing these understandings.

Elsewhere, I have documented second-grade children’s evolving understanding of mathematical explanation and justification (Yackel, 1992; Yackel & Cobb, 1996). That analysis showed that initially children had to learn that their explanations and justifications needed a mathematical, rather than a social, basis. In that instance, the teacher initiated explicit discussions with the children about the basis for their explanations. For example, early in the school year a pupil changed her answer when the teacher asked the class if they agreed with her. In the subsequent discussion she revealed that she had interpreted the teacher’s question as indicating that she had made an error. The teacher then used this as a paradigm case to discuss his expectation that students’ answers should be based on mathematical reasoning with their explanations reflecting that reasoning. As the school year progressed students’ explanations increasingly took on the character of descriptions of actions on objects that were experientially real for them. This expectation was both constituted and sustained, in part, through challenges that the students and the teacher made to explanations that described procedures. For example, when adding quantities such as 13 and 12 to get 25, explanations such as, “One and 1 are 2 and 3 and 2 are 5,” were challenged by remarks such as, “That’s a ten and that’s another ten, and that’s 20. And the answer is 25.” Finally, by the end of the school year, some students took explanations as explicit objects of reflection and made comments such as, “How can someone understand what you mean? They don’t know what you’re referring to.” The students making these challenge were taking the explanations as entities in and of themselves and were commenting on their overall potential as acts of communication within the classroom discourse. As with social norms, in subsequent teaching experiments we had the constitution of specific sociomathematical norms as an explicit goal, for example, that explanations should describe actions on objects that are experientially real for the students.

Argumentation

As noted earlier, my interest is in mathematical explanation and justification as interactional accomplishments and not as logical arguments. The focus is on what
the participants take as acceptable, individually and collectively, and not on whether an argument might be considered mathematically valid. In this sense my interest is in what Toulmin (1969) calls substantial rather than logical argument.

Krummheuer's work on argumentation (1995) provides the background for the approach I take. In his study of the ethology of argumentation, Krummheuer analyzes argumentation using Toulmin’s scheme of conclusion, data, warrant, and backing. According to this scheme, the conclusion is a statement that is made as though it is certain. It is a claim. The support one might give for the conclusion is the data. Warrant refers to the rationale that might be given to explain why the data are considered to provide support for the conclusion. Backing provides further support for the warrant, that is, the backing indicates why the warrant should be accepted as having authority (Toulmin, 1969). Krummheuer uses the notions of conclusions, data, warrants, and backing to explicate how argumentation is an interactive constitution of the participants. For him, an argumentation in any given situation “contains several statements that are related to each other in a specific way and that by this take over certain functions for their interactional effectiveness” (Krummheuer, 1995, p. 247). Statements do not have a function apart from the interaction in which they are situated. Thus, what constitutes data, warrants, and backing is not predetermined but is negotiated by the participants as they interact.

I have demonstrated previously (Yackel, 1997) that this approach to argumentation is useful as a methodological tool for documenting the collective learning of a class because it provides a way to demonstrate changes that take place over time. Further it helps to clarify the relationship between the individual and the collective, that is, between the explanations and justifications that individual students give in specific instances and the classroom mathematical practices that become taken-as-shared. As mathematical practices become taken-as-shared in the classroom, they are beyond justification and, hence, what is required as data, warrants and backing evolves. Similarly, the types of rationales that are given as data, warrants, and backing for explanations and justifications contribute to the development of what is taken-as-shared by the classroom community. For example, in one second-grade classroom, explanations of solution methods that involved using thinking strategies became more cryptic over time. For a problem such as 5 + 6 = ___, students initially gave explanations such as, “I know that 5 and 5 is 10 and 6 is just one more; it’s just one more on the 5, so the answer is 11; one more than 10.” Later a typical explanation was “5 and 5 is 10 so its 11.” In this case, when explanations of the second type are no longer questioned, we can assume that the warrant and backing provided in the earlier type of explanation are now taken-as-shared. At the same time, it is through explanations of the earlier type that the taken-as-shared understandings develop.

---

3 The construct of classroom mathematical practices refers to the collective development of the classroom community. See Cobb (1998) for a discussion of this construct and for an illustrative example.

4 It could be argued that students might not question this type of solution because they are disinterested or simply do not want to ask a question. We can rule out these possibilities in this case because of the classroom social norms that were
Finally, this approach to argumentation is useful for analyzing classroom dialogue to investigate the nature of the contributions made by various participants in the interaction. In particular, our analyses of second-grade classrooms show that the teacher frequently serves the role of calling for or herself making explicit data, warrants, and backing that may be only implicit in the explanations and justifications that students give (Yackel, 1997). Here again, I give an example from a second-grade class. In explaining how he figured out how much to add to 48 to get 72, Louis said, “It’s 24. How I got it was I said, 48, 58, 68, 69, 70, 71, 72.” The teacher was aware that approximately half of the children in the class did not yet know that the difference between 48 and 58 is 10. Therefore, the data that Louis gave to support his conclusion would not have explanatory relevance for them. A warrant would be needed. Without waiting for anyone to ask a question, she asked Louis to elaborate by saying, “You said 48, 58, how many is that?” Using the language of argumentation, we would say that the teacher was prompting Louis to give a warrant. After Louis responded “Ten,” she continued, “And then you went to 68, and how many was that?” Louis replied, “Twenty.” The teacher went on to say, “That was 20 in all and then you went by ones didn’t you? You went 69, 70, 71, 72. ... So you went a ten and another ten and four ones and that’s how you got 24.” In this episode we see the teacher working together with Louis to develop the needed warrant. In addition, as she and Louis were developing the verbal warrant, the teacher drew the following diagram on the chalkboard.

```
10
10

48 58 68 69 70 71 72
```

This action of drawing the diagram linked Louis’ solution to the empty number line, a pedagogical notation that was being used regularly in the class at that time. In general, the overall intention was to use the empty number line as a way to notate and record students’ thinking with the goal that it might later become a tool for students’ reasoning. In this case, the numerals written below the line recorded the information that Louis gave as data while the arcs and numerals written above the line recorded the additional information supplied in the warrant. In this sense, the diagram took on the form of a record of an argumentation because it included a record of both the data and the warrant.

In this example, the teacher initiated both the diagram and the verbal elaboration of Louis’ solution. Her actions accomplished several goals. One was to call attention to the argumentative support for the conclusion. Second, she contributed to the class’ understanding of what is taken as argumentative support. Earlier, I noted that what operative. In this class students assumed the obligation of asking questions when they disagreed or did not understand. It is for this reason that we are able to interpret lack of questions as indicating taken-as-sharedness.  

5 The empty number line has no units marked on it. Therefore, unlike the (marked) number line that is often used in elementary school classrooms as a means for computing answers, the empty number line cannot be used for computing directly. Its power comes from the imagery that students use when they think about moving forward and backward from one number to another. Information about the distance between two numbers cannot be ascertained directly from the empty number line.
constitutes data, warrant, and backing is not predetermined but is negotiated by the participants as they interact. In this case, Louis' initial comments served as data for him. The teacher was aware that the only way these could serve as data for certain other students in the class was for additional information to be given, information that explained the relevance of Louis' comments. Finally, the teacher contributed to the goal that the empty number line might become a tool for reasoning by linking the data and warrant to the number line notation.

Explanation, Justification and Argumentation in a Differential Equations Class

In this section of the paper, I use the example of a differential equations class to demonstrate how the notions of explanation, justification and argumentation can be used to analyze the nature of the activity in a university-level mathematics class.

Data and Method

Over the past four years my colleague, Chris Rasmussen, has been investigating the teaching and learning of differential equations using his own classes as sites for investigation. During this time he has conducted classroom teaching experiments for all or part of the semester on three separate occasions. In each case, I have been an observer in the classroom and have participated in regular project meetings to discuss students' ways of reasoning, potential instructional activities and social aspects of the classroom.

Data from each teaching experiment consist of videotapes of each class session, including the small group work of two groups, field notes made by the observer(s) and the instructor, copies of students' work, and records of instructional activities and instructional decisions. Students' work includes in-class work, homework assignments, weekly electronic journal entries and reflective portfolios that students submitted twice in the semester. In addition, data include videotapes and artifacts from individual student interviews that were conducted with selected students at various times throughout each teaching experiment to gain initial information about their concepts related to functions and rates of change, to assess their understanding of key concepts of the course, and to inquire about their beliefs about mathematical activity and mathematics learning.

Social and Sociomathematical Norms Relating to Explanation and Justification

A specific goal in each teaching experiment was to constitute social and sociomathematical norms characteristic of inquiry instruction. Regarding explanation and justification, these include that students explain and justify their thinking, that they listen to and attempt to make sense of the explanations of others, and that explanations describe actions on objects that are experientially real for

---

6 Students in the differential equations classes at this university are typically engineering or mathematics majors. The typical class size is from 25 to 35 students.

7 Rasmussen's work is supported by the National Science Foundation under grant number REC-9875388. I wish to thank him for permission to use episodes from his classes for this paper and to thank Jennifer Olszewski for making transcripts of selected episodes from videotapes.
them. Analysis of data from the first teaching experiment shows both that these norms were constituted and how the instructor initiated the negotiation of these norms (Yackel & Rasmussen, in press; Yackel, Rasmussen, & King, 2001).

The following example, taken from the second class session of the first teaching experiment, illustrates the constitution of social norms that foster explanation. The instructor began the class with a brief statement of the expectations he had for the students’ mathematical activity. Then he orchestrated a whole class discussion of approximately twenty minutes in which he and the students discussed the rationale behind a differential equation they had used in the prior class session to indicate the rate of change of the recovered population in an infectious disease situation. The crucial aspect of this segment for purposes of this paper is the explicit attention the instructor gave throughout to the negotiation of social norms. Most of his comments were explicitly or implicitly directed toward expectations. For example, he said things such as:

Okay, can you explain to us then why it was 1/14 times I?
What do the rest of the people think about that?
Is that similar to what you were thinking?
Anyone want to add to that explanation? Expand on it a little bit?
So let’s put that question out. So your question is ... Is that what I heard you say?

In making these remarks, the instructor was attempting to influence the interpretations students made of how to engage in the discussion. From this perspective, it might seem that the teacher is the only one who contributes to the renegotiation of social norms. However, norms are interactively constituted as individuals participate in interaction. In this case, as the episode evolved, students contributed to the negotiation of the norms by increasingly acting in accordance with the expectations. As the discussion progressed, students not only responded to the instructor’s questions, they initiated comments that showed that they were beginning to change their understanding of the classroom participation structure. For example, a few minutes into the discussion one student said, “I didn’t quite understand what he [another student] said” and a few seconds later explained what he did understand and said, “What I don’t understand, what I was asking about ...”

As the episode continued, several students asked questions, offered explanations, and asked for elaboration and clarification. In doing so, they too were contributing to the ongoing constitution of the social norms that students are expected to explain their thinking to others and ask questions and raises challenges when they do not understand. We find it encouraging that as early as the second class session understandings such as these were becoming normative. Further, analyses of classroom interactions throughout the semester provide evidence that these norms became well established. It became routine for students to explain their thinking, to ask questions and raise challenges, and to elaborate their explanations and justifications spontaneously, without prompting from the instructor. Furthermore, although we have not provided examples here, it became normative that
explanations were about actions on (mathematical) objects that were experientially real for the students. Thus, we would say that the class could be characterized as following an inquiry mathematics tradition. Classroom observations verify similar results in the subsequent teaching experiments.

**Argumentation**

When I observed Rasmussen’s class in the spring of 2001 it was immediately apparent that his instructional approach had evolved to have an even stronger emphasis on justification and argumentation than previously observed. In addition, he had developed a unique approach to collaborative learning. Further, these two aspects were intimately intertwined.

In a typical collaborative learning situation the instructor poses a task or problem, students work in groups and after some time, often sufficient for most groups to complete the task, the class engages in a discussion of the solution methods students developed in their small groups. This is, in fact, the approach that Rasmussen took in the first two differential equations teaching experiments. The dramatic difference I noticed in this most recent class was that groups often worked for little more than two minutes before sharing their thinking. Whole class discussion might then continue for as much as 15 minutes before another short segment of two to four minutes of small group work took place. Typically this cycle was repeated four to five times in an 80-minute class period. Furthermore, the students’ task during small group work was typically to “think about” some question or issue rather than to solve a specific problem. Because of the continual emphasis on reasoning, whole class discussions resulted in the emergence of key concepts, including slope fields, bifurcation diagrams and phase planes. In this sense, the instructional approach seems to have considerable potential for in-depth conceptual development that grows out of students’ discursive activity.

The following example, which is taken from the second session of the 2001 class, is used to clarify and illustrate the approach and to explain how it contributed to the emphasis on argumentation. During the 80-minute class session, there were four small group segments of two to four minutes each, interspersed between five whole class discussions. The first 20 minutes of the class was devoted to continuing a discussion from the previous class about a predator-prey situation described by a pair of differential equations. Students did not yet have any analytic techniques for recovering the solutions to the differential equations but used informal and qualitative reasoning to “make sense” of the situation. Throughout the discussion the instructor repeatedly asked the students for the reasons for their claims. When students gave reasons, he did not evaluate their validity but instead asked other students what they thought and solicited other arguments. For example, he made remarks such as, “What do you think of his idea?” and “Okay, that’s nice. Let me

---

1 I have limited the discussion to social norms for explanation. Similar analyses for sociomathematical norms have been conducted but space does not permit including them here. See Yackel and Rasmussen (in press) and Yackel, Rasmussen and King (2001) for a discussion of sociomathematical norms.
hear another argument for ...” From the point of view of norms, we would say that the instructor was initiating the expectations that students are to provide arguments to justify their claims, that they are to attempt to make sense of others’ arguments, and that there might be more than one argument to support a given claim. From the point of view of argumentation, we would say that the discussion focused on data, warrants, and backing to support conclusions but not on the conclusions themselves.

The instructor then posed a simplified version of the predator-prey problem that involved only one species, in this case fish in a lake, with the assumptions that there were unlimited resources, no competitors, and there was a continuous growth rate. With no additional information, except that the initial population was 10 units, students were instructed to “take just a few minutes, sketch for yourself and talk about it with the folks in your group what your graphs [for the number of fish over time] look like and the reasons for why you think the graphs look like that.”

Most students quickly drew either a straight line graph with positive slope or an exponential graph, beginning on the vertical axis at a height of 10, and made remarks to their peers such as “I thought it looks something like an increasing exponential curve” and “They’re unbounded so it’s just gonna continue to grow.” After less than two minutes the instructor called the class back together.

*Instructor:* All right. Let me ask you a question. ... Suppose you were in a group and that’s the way that someone offered. (The instructor draws the graph shown below on the chalkboard.) What would you—would you agree or disagree and what reasons would you give for agreeing or disagreeing with that?

\[
\begin{array}{c}
P \\
\hline
\text{t}
\end{array}
\]

In the ensuing discussion several students offered reasons why they disagreed or agreed with a linear graph. Some of the reasons given were directly related to thinking about the scenario, for example, that fish lay eggs and typically the number of eggs is large. Other reasons were related more to thinking about how to interpret the assumption of continuous reproduction. It is important to note that the students did not have any equations or functional expressions to inform their reasoning. Instead, they were in the position of having only the verbal scenario as a basis for thinking about what issues might be relevant and how to take those issues into account in developing arguments for one graph or another. As a result several important issues related to logistic growth problems were brought up by students including that population growth is dependent on the existing population and that it is reasonable to think about a growth rate parameter for a particular species.

The instructor then posed the specific case for population growth described by the differential \( \frac{dP}{dt} = 0.2*P \). He asked what appeared to be a simple question. “What are the units of the 0.2 in the equation? How do you think about what the two is?”
When one of the students he called on said that she did not know how to put it in words, the instructor asked the class to “Take a second here, talk with the person next to you and say, well how would I think about that? What is that two? What kind of quantity is that two and how do I think about what two is here?” Once again, after only about two minutes, in which students verbalized their ideas to their group partners, the instructor called the class together for a whole class discussion.

What became apparent from observing the class over many weeks and from preliminary analysis of classroom data is that these brief small-group segments resulted in extremely productive subsequent discussions. The nature of the small group task was not to solve a problem but to “think about” something and “develop reasons to support your thinking.” Even though students had little time to explore their reasons with one another in depth during the short time allotted to small group discussion, these “interruptions” in the class discussion obligated students to pursue their own ideas momentarily. Furthermore, because of the social norms that were operative in the class, students accepted the obligation and did engage in thinking about the issues at hand and in sharing their thinking within their groups. As a result, the students had a basis for participating meaningfully in the subsequent class discussion. Further, since the discussion inevitably focused on their reasons, students were in the position to compare and contrast their reasons with those of others.

In the class session discussed here, several other important ideas emerged as a result of the small group “thinking” and the subsequent whole group discussions. These included that the placement of the P (population) axis is arbitrary. Shifts to the right or left indicate different starting times. A related idea that developed is that for autonomous differential equations solution functions are horizontal shifts of one another. Before the class session ended students were beginning to think about the relationship between slope marks that they might make on a coordinate graph (a foreshadow of the slope field) and the graph of the function of population over time. In each case, these notions emerged from the students’ reasoning. However, it is important to note that the instructor took a very proactive role and had a number of semesters of prior experience on which to draw as he posed questions that he anticipated would bring forth various types of reasoning.

I have suggested that the emphasis in this class was on reasons, rather than on conclusions. Using Toulmin’s language of argumentation, the emphasis was on data, warrants, and backing. Students were less engaged in solving problems than they were in reasoning or “thinking.” Preliminary analysis of excerpts from class dialogue indicates that what became constituted as data, warrants, and backing was not fixed or predetermined by the content or by the instructor but was negotiated by the participants as they interacted. It is in this sense that we use the label “group thinking” to refer to the collective argumentation that develops as the students engage in reasoning interactively, both in their small groups and in the whole class setting. We have adopted this label from a student in the class who used it in his
second journal. As the following quotation from his journal indicates, students became keenly aware of the powerful nature of discussions for their learning.

One way of thinking about a particular problem from class that helped me enlarge my thinking is group thinking [emphasis added]. You are the first professor I had who actually tries to make us understand the material and not just spit out equations and answers to you. The group thinking lets me communicate and speak my mind. My reasoning to a particular problem might be different than someone else’s but another person in the class might also think the same way I do.

A specific problem I liked was the predator-prey problem. Everyone had a different idea about it, which made everyone have to think. The group thinking helps me sort ideas out. Also, group thinking helps me put in words what I am trying to say. Group thinking in a math class is new to me, but I like it so far.

I would argue that the reason group thinking is so powerful for students’ learning is that it emphasizes what most mathematicians and mathematics educators consider to be the essence of mathematics—mathematical reasoning and argumentation.

Conclusion

When investigating teaching and learning in the mathematics classroom there are many aspects that one might focus on. In this paper, I have pointed to aspects that relate to explanation, justification and argumentation. I have argued that a symbolic interactionist perspective gives us a way to make sense of the social aspects of the classroom such as social and sociomathematical norms. I have argued further that Krummheuer’s approach to argumentation which uses Toulmin’s scheme in a collective sense provides us with a way to explain why an emphasis on explanation and justification in a mathematics classroom leads to mathematics learning that emphasizes reasoning.

REVISITING THE GOALS AND THE NATURE OF MATHEMATICS FOR ALL IN THE CONTEXT OF A NATIONAL CURRICULUM

Paulo Abrantes, University of Lisboa
(General Director of Basic Education, Ministry of Education, Portugal)

Abstract
A movement of educational change has been developed in Portugal, aiming at giving the schools a larger autonomy in curricular decisions. In reconceiving the view about the curriculum, the concept of “competence” plays a central role while the process of innovation constitutes a major aspect. This movement is described and analysed, in particular by discussing the notion of competence and the characteristics of the process of curriculum development. A special focus is on the way in which mathematical competence for all may be interpreted and how it is related to developments in mathematics education. The analysis of obstacles emerging in a large-scale educational change may be relevant for discussion in an international context and offers some suggestions for future research and debate.

1. New trends in the Portuguese educational system
The evolution and recent developments of the Portuguese educational system in the last two decades, as well as the related perspectives on the curriculum, and on the mathematics curriculum in particular, raise some issues that might be of general interest for reflection and discussion.

1.1. The context: some contradictory aspects
In 1974, when we could finally restore the democracy after 48 years of a dictatorship, the extension of compulsory education up to 6 years of school – instead of the old and traditional primary school of 4 years – was a recent fact. This hardly reflected the reality in the poorest regions of the country. Illiteracy was very high among adult population. It was only in 1986 that a new general law for education fixed compulsory school attendance for all 6-15 year olds (that is, a “basic school” of nine years). In fact, we had to wait almost for the end of the twentieth century to see practically all our children and youngsters of those ages in our classrooms. At the same time, it was only after 1995 that pre-school education became a new reality, finally involving in 2000 the large majority of children of the 3-5 age level.

As a result of its rapid and original development, in particular due to the fact that its basis was partly designed during a sort of “revolutionary” period, this educational system has some characteristics that may be seen as contradictory.

On the one hand, we have a number of very “advanced” laws and regulations. In our system, there is a comprehensive and “inclusive” basic school of nine years for all,
similar to the Scandinavian traditional organisation, and a secondary education of three years, with different branches (general, vocational, professional) all of them giving equal access to further studies. Since 1997 teachers of all school segments, from pre-school to university, must have the same academic degree at the beginning of their profession. Moreover, all teachers may use, from time to time, a sabbatical year or they can apply to a bursary in order to develop projects or to do a postgraduate course. In the second and third cycles of basic education (10-15 year olds), teachers work a maximum of 22 and a minimum of 14 class periods of 50 minutes per week, according to their age.

On the other hand, all this was conceived and implemented on a tradition of a centralised and rigid school system, which was affected by lack of resources in many schools – a problem that has taken us many years to overcome. It was only in the nineties that a new law to increase the administrative autonomy of schools was adopted. Dominant public views about the curriculum tend to see it as a set of disciplines with “programmes” indicating for each subject what (and how) must be “covered” each school year. This process is actually mediated by the power of the textbooks – even if those programmes are aligned with modern international trends in most disciplines. Although there are no national exams except at the end of the secondary school, assessment is dominated by traditional written tests. Although there is an official logic of evaluating students progress throughout each cycle, the old “principle” of deciding that the student must repeat the same school year if he/she does not succeed in two or three disciplines still guides the way how many people think and act, both outside and inside the school.

When focusing on mathematics education, there are also other contradictory aspects in the situation, just like in most European countries. However, Portugal probably stands in a clearer contrast. In Portugal, the community of mathematics education (teachers, teacher educators and researchers) has become quite strong in these last fifteen years. All these groups support and are involved in the Association of Teachers of Mathematics (APM), the biggest association of its kind, which was created in 1986 and has now about 6000 members. This number would be equivalent (proportionally to the population) to 24000 in Spain, more than 30000 in France or UK, and approximately 9000 in Holland! About 2000 participants attend the annual meeting organised by APM. Many Portuguese teachers and researchers began to participate in international congresses on mathematics education: in ICME-8, in 1996, they formed the third largest national representation among European countries, after Spain and UK.

At the same time, a considerable number of teachers are following post-graduate studies on education, in particular on various aspects of the didactics of mathematics, and some of them are participating in projects which involve both a strong component of curricular innovation and a research dimension. Since the creation of APM, and following the experience of the MAT789 project (Abrantes, 1993), the cooperation between teachers and researchers became an interesting feature of
Portuguese mathematics education – see, for example, Oliveira et al. (1997), Ponte et al. (1998) or Porfirio and Abrantes (1999). It is not surprising that curricular innovation and teachers professional development became two major areas of research.

However, this community is under a strong public pressure, as a consequence of the scores in the exams at the end of secondary school or the very low position of Portugal in the rankings of the international comparative studies. Like elsewhere, as Keitel and Kilpatrick (1998) have pointed out, these rankings are frequently used without any serious consideration about what they mean or do not mean. They are used, for example, as an argument to propose not only the return to a greater emphasis on training routine skills, but also "solutions" like more exams and more comparative studies! Many teachers seem to have mixed feelings. They have sympathy with the new ideas about curriculum development, but they are also moving in a culture of school still dominated, inside and outside the school, by the old ideas and values.

1.2. Recent developments in basic education

In the last four years, after one year of debate and preparation, the Ministry of Education initiated a movement towards a new curricular organisation. The starting point was the consideration that the traditional structure was not adequate to ensure significant learning experiences to all children and to avoid school failure and abandon.

For the "basic education", this movement started with a project, labelled as "flexible management of the curriculum". This project aimed at giving the schools a larger autonomy in the decisions about the various disciplines and connections among them, as well as about new interdisciplinary components – a "project area", an "oriented study area" and a "citizenship area". This autonomy relates to the teaching and learning process and refers both to the activities to be developed and the time and space dedicated to each component of the curriculum. Emphasis is put on the role of the teachers and their collective structures in school, namely – at 2nd and 3rd levels of basic education (10-15 year olds) – the class council, this is, the group of professionals who work directly with each group of students.

This movement was justified by the need to promote a new conception of the curriculum, both the intended curriculum and the implemented one. The former requires the educational authorities to express the curriculum in terms of "essential competences" and types of "educational experiences" that the school should consider for all pupils (in each cycle), in opposition to the usual programmes of content topics to be covered and corresponding methods (in each year). The latter challenges the teachers and the schools to assume a much larger responsibility in the search for the adequate decisions for the specific pupils they work with, taking into account their cultural and social environment, their educational needs and the human and material resources that exist or can be made available. In other words, under the guidance of a
national curriculum expressed in general and broad terms, the process of curriculum implementation is seen like a project to be conceived and developed by the school, including more specific projects concerning each individual class.

From 1997 on, schools could participate in the so-called “flexible management of the curriculum” movement by presenting their own curricular projects, under a minimum number of general rules. This participation, on a completely free basis, began with 10 schools in 1997/98, increasing in the three following years up to 184 schools all over the country. These schools constituted a sort of informal network exchanging materials and points of view, and participating in local, regional or national meetings organised by the educational authorities.

1.3. The case of mathematics

Meanwhile, the Ministry of Education started to produce draft versions for discussion of the so-called “essential competences”. Some documents focussed on aspects crossing all school subjects, while others related specifically to the various disciplines. This activity has been developed by working groups with a strong participation of members of the associations of teachers, together with researchers and other professionals.

In the case of mathematics, the corresponding document states the ultimate end of mathematics in basic schools as follows:

Mathematics is a part of the cultural patrimony of human kind and a way of thinking, which should be made accessible to all. Every child and youngster should have the opportunity
d to contact, at an adequate level, with the fundamental ideas and methods of mathematics
and appreciate its value and nature;

d to develop the capacity of using mathematics to solve problems, reason and communicate, as well as the self-confidence to do it.

This document refers then to major aspects of “mathematical competence” for all in the following way:

The mathematical competence that all pupils should develop through the basic education integrates attitudes, skills and knowledge, and includes:

d the disposition and capacity to think mathematically, this is, to explore problematic situations, search for patterns, formulate and test conjectures, make generalisations, think logically;

d the pleasure and self-confidence in developing intellectual activities involving mathematical reasoning and the conception that the validity of a statement is related to the consistence of the logical argumentation rather than to some external authority;

d the capacity to discuss with others and communicate mathematical thoughts through the use of both written and oral language adequate to the situation;

d the understanding of notions such as conjecture, theorem and proof, as well as the capacity to examine the consequences of the use of different definitions;

d the disposition to try to understand the structure of a problem and the capacity to develop problem solving processes, analyse errors and try alternative strategies;
the capacity to decide about the plausibility of a result and to use, according to the situation, mental computational processes, written algorithms or technological devices;

- the tendency to “see” the abstract structure underlying a situation, from daily life, nature or art, involving either numerical or geometrical elements or both.

In a second part, the document elaborates on what this means, in terms of each of the main areas of the mathematics curriculum – Numbers and Operations, Geometry and Measurement, Statistics and Probability, Algebra and Functions – through all the basic education and in each of the three age level cycles. Finally, pointing out problem solving as a general guide-line, it states that all pupils in their mathematics classroom should be frequently involved in mathematical investigations, projects, practical tasks, discussions, reading and writing about mathematics, exploration of connections inside mathematics and relating it to other areas, as well as they should have various opportunities to use technology, manipulatives and games in relation to their mathematical activities.

2. Scope and meaning of the process of educational change

What is going on in Portuguese basic education is undoubtedly a change of paradigm. Other reforms in the past introduced interesting innovations, but all of them left untouched the power of central authorities in defining the curriculum, the usual way of testing and implementing it, the traditional separation between curriculum guidelines and school organisation, and the nature of teacher’s role and professional activity. The current movement, for the first time in the history of our education, has to do with changes in all these aspects. Generally speaking, it could be described as a change from the “conventional” paradigm to a new one influenced by the “constructivist” and the “critical” paradigms – to use the terms of Galbraith (1993).

The evolution of the concept of curriculum in relation to school organisation and teacher development has been largely discussed in the literature – for example, Fullan and Hargreaves (1992), Fullan (1993), Goodson (1997) and many others. From a theoretical perspective, the current movement in Portugal – tending to view the curriculum as a project in the context of the school as a learning organisation – is far from being original. In practical and political terms, we can find some similarities with the reform developed in Spain about ten years ago. On the other hand, the formulation of the intended (national) curriculum in terms of “essential competences” is not original as well – there are other cases, for example, in Belgium or in Québec.

However, the recent evolution in Portugal deserves some exploration and discussion for three major reasons. Firstly, it is worth elaborating on the adopted concept of competence since the term “competence” is not used everywhere with the same meaning. Secondly, it seems promising to explore the way in which “competence” is interpreted in the specific context of the mathematics curriculum. Thirdly, it may be relevant to focus on the process of curriculum development and innovation, which is quite unusual at a national level.
2.1. The concept of “competence”

The shift from content topics and objectives to competences requires a clarification about the meaning of the term “competence”. I do not intend to introduce a universally accepted definition, yet I would like to avoid ambiguity and misunderstanding.

Following Perrenoud (1997), it should be clear that, in spite of a possible confusion with a behaviouristic interpretation, the term “competence” does not indicate some kind of specific behaviour that “can be observed”, neither does it refer to performance. In this author’s view, competence is related to the process of activating resources (knowledge, skills, strategies) in a variety of contexts, namely problematic situations. Perrenoud quotes Chomsky (1977) to support the distinction between competence and performance, and the idea that competence is related to the capacity to improvise, but emphasising the fact that, in his view, competence develops as a result of learning and not spontaneously.

Short (1985) has shown that the concept of competence may be used (or misused) with several different meanings ranging from a connotation with behaviour and performance to an identification with a quality of a person or a state of being. In this last conception, the holistic nature of competence is emphasised. Knowledge is obviously involved, as well as the skill necessary to use it, but this use is an emancipatory action, based on reflection and implicating some degree of autonomy.

It may be interesting to note that there is a parallel evolution of the key concept used by the studies on literacy. Initially, “alphabetisation” was identified with school attendance; in a second phase, the important matter was the acquisition of the knowledge, whether or not the person had attended a given school level; finally, the focus of literacy moved from the acquisition to the use of the knowledge in concrete situations (Kirsch and Mosenthal, 1993). Since this is not necessarily limited to the direct application to routine situations, the (mathematical) literacy could be interpreted as the (mathematical) competence that all students should be helped to develop in the school.

In Portugal, the reform in the late eighties pointed out that educational goals went far beyond content knowledge, including skills and attitudes as well. The programmes stated three lists of general objectives to involve these three kinds of goals. After this, however, the programme for each school year indicated the content topics to be covered, together with “specific objectives” and methodological suggestions related to those topics. It is not surprising that a common interpretation of the intended curriculum tended to see skills (for example, deductive reasoning or problem solving strategies) and attitudes (for example, persistence or solidarity) as elements to be “added” to the content knowledge.

In the present movement, the concept of competence intends to emphasise the idea of integration of knowledge, skills and attitudes, where integration is the key idea. The choice of the expression “essential competences” is a deliberate attempt to distinguish
what is being proposed from the “basic skills” or the “minimal objectives”, which were common expressions in the official discourse some years ago. This distinction is a particularly important pedagogical and political issue in a country where education for all is a relatively recent principle and it is necessary to resist to systematic proposals to achieve this goal by creating hierarchies and inequalities among students.

2.2. Mathematical competence in a national curriculum for all

Resnick (1987) has consistently argued in favour of the idea that basic skills and higher order skills cannot be clearly separated. She also added the role of attitudes, namely by stating that the school should cultivate a broad disposition to higher order thinking. The integration of cognitive abilities and motivation is especially emphasised: “Motivation for learning will be empty if substantive cognitive abilities are not developed, and the cognitive abilities will remain unused if the disposition to thinking is not developed” (p. 50). Integration also played a central role in the definition of “mathematical power” as it was introduced by the NCTM (1989) Standards.

In the above list (section 1.3) of aspects of mathematical competence for all, the concern with the integration of knowledge, skills and attitudes is quite apparent. We should also add the clear concern with beliefs and conceptions about mathematics, which play an important role in students’ learning process (Borasi, 1990; Schoenfeld, 1992). This aspect has been almost always absent in the curricular guidelines defined at an official and national level.

Another characteristic of the above listed aspects is the explicit attention to the nature of mathematics. As Bishop (1991) points out, it is not enough to teach (some) mathematics, it is indeed necessary to educate about, through and with mathematics. In this point, it should be emphasised that the mentioned aspects of mathematical competence cannot be seen in isolation from the educational experiences that all children should live in school, namely investigations and projects involving both mathematical ideas and their relations with different sorts of problems. Obviously, the idea is not to “enrich” the knowledge of facts and the training of procedures with some sort of rhetoric about the nature of mathematics as a science.

This concern with mathematical activity in relation to understanding the nature of mathematics is a central issue in several different approaches. Bishop (1991), in the search for “mathematical similarities”, points out six activities that are “significant (...) for the development of mathematical ideas in any culture” (p. 23) – counting, locating, measuring, designing, playing and explaining. Goldenberg (1996) proposes “habits of mind” as organisers of the curriculum – for example, the tendency to describe relations and processes or the tendency to look for invariants. The NCTM (2000) states “process standards” to refer to “ways of acquiring and using content knowledge” (p. 29).
The present challenge we face is to help all children to develop their mathematical competence in a way that will avoid interpretations reinforcing the perspective of a curriculum of training procedures, skills and rules (for all) with the expectation that this kind of training will constitute (for some) a pre-requisite to future uses of mathematics. To do so, we have indeed to question the basis of the “technique-oriented” curriculum which has never been done except in some small-scale innovative projects. “A technique curriculum cannot educate (...) For the successful child it is at best a training, for the unsuccessful child it is a disaster” (Bishop, 1991, p.9). Perrenoud (1997) insists that the formulation of the curriculum in terms of competences should be strongly connected to the purpose of striving against school failure and taking into account all children, namely those with a cultural background not similar to that of the “traditional school”.

If, at the level of the intended curriculum for all, our option is to reconceive the components of the mathematical competence, together with a larger variety of kinds of educational experiences, then a consequence is a reconsideration of the extension and complexity of topics included in the curriculum. For Bishop (1991), the curriculum should be relatively broad (in the variety of contexts offered) and elementary (in the mathematical content). Similarly, when discussing the problem of the construction of competences in the school, Perrenoud (1997) points out that, if our option is education rather than instruction, then it is necessary to reverse the tendency to include the teaching of more and more topics in the compulsory school curricula.

In the current movement in Portugal, it was announced that the number of content topics considered in the curriculum, in every discipline, would be reduced. This was not yet done for reasons that have to do with the process of curriculum development that I will comment on in the next section.

2.3. The process of curriculum development

The most original aspect of the recent development in Portuguese educational system is, probably, the fact that a curricular reform at a national level (indeed not even labelled as a “reform”) is not following the RDD (standing for “research-development-dissemination”) model.

The criticism on this strongly dominant model of curriculum development and implementation is far from being recent. Twenty years ago, Howson, Keitel and Kilpatrick (1981) have discussed the origins, assumptions, values and consequences on mathematics education pointing out emergent alternative perspectives. More recently, in the context of the so-called realistic mathematics education, Dutch researchers have developed this discussion into new and promising directions.

Gravemeijer (1994) explains that, in his approach, curriculum development is embedded in a holistic framework, taken from the concept of “educational development” as Freudenthal (1991) uses it. A central idea is that the process of curriculum innovation has to consider all the actions needed from the initial purpose
to the actual change, incorporating teacher education, counselling, assessment and opinion shaping. Furthermore, unlike the RDD model, initial theory is much like a philosophy or a vision and it will evolve in the interaction between theoretical and empirical justifications.

The last reform in Portugal, in the late eighties, constituted an almost perfect example of the RDD model. Teams of invited experts prepared new programmes during two or three years; these programmes were implemented in a small number of “experimental schools” where motivated teachers worked together and prepared their own materials in the absence of textbooks; finally, after suffering slight corrections, the programmes were “generalised” to all schools. The “consumers” were introduced to the new finished “product”, usually in the form of new textbooks. The result was not surprising: to solve the visible problems of low take-up, dilution and corruption of major ideas of the intended curriculum – to use the terms of Burkhardt (1989) – those responsible for the reform claimed that intensive teacher training programmes should then be developed.

The current movement, which as already mentioned was initiated four years ago, has a very different nature. Schools have been invited to participate by elaborating their own projects of curriculum development while, at a central level, different sorts of working documents are produced, namely draft versions of the “essential competences”. These documents are discussed, criticised and modified in a process that takes into account the feedback of the schools and the contributions of universities and professional associations. As I have indicated earlier, a major principle is a large autonomy of schools, in relation both to the various disciplines and the new curricular areas dedicated to support students’ projects and periods of personal and group study under teachers’ guidance. Meanwhile, together with many formal and informal meetings organised by the Ministry and by the schools themselves, teachers participate in in-service initiatives, namely in the form of workshops and small projects – which are valued and credited for progression in the teachers’ career just like traditional courses. The co-operative work among teachers inside the school has become, probably, the hallmark of the movement.

Throughout these last four years, the number of schools joining the movement increased significantly: 10, 33, 92, 184. An interesting result of the process was that teachers leading projects in the former schools began to be more and more invited by colleagues of other schools and meeting organisers to participate in conferences, debates and workshops, a kind of activity traditionally reserved for researchers and teacher educators.

In January 2001, a new law was adopted for curricular organisation. From now on, there are not compulsory uniform regulations about the exact amount of weekly time and the precise topics to be considered year by year in each discipline. Instead of that, schools are invited to make their own decisions about a number of relevant aspects, both at a school level and at a class level. Together with general guidelines focusing on the priority of experimental and practical teaching methods, a new version of the
document stating the essential competences and educational experiences will constitute the main official reference. For each cycle, it is indicated the minimum time to be dedicated to each curricular component (group of disciplines or interdisciplinary area) and the maximum number of hours per day to compulsory activities. About 20% of the total time correspond to periods of work where there are not programmatic prescriptions at all – against the traditional 0%.

This new law includes a number of recommendations that emerged from the experience of the schools involved in the movement – which in any case may be adapted or modified. One of them is the recommendation to organise class activities in periods of 90 minutes, instead of the traditional 50 minutes. The main official arguments invoke better conditions to promote practical and investigative work in the classroom, the use of technology and other materials and the goal of reducing the number of different subject matters in each day.

It should be noted that, although we will enter into a new stage of the process of curriculum innovation, guidelines are far from being completely “ready”. For example, the way in which programmes will evolve to constitute working materials for teachers is yet to be determined. The evolution of textbooks is another issue for debate. Refusing a top-down model for development, we do not have a new “system” to be generalised in a precise moment.

In the particular case of mathematics, the present stage of the debate suggests an evolution of the working documents mentioned earlier (section 1.3). The discussions about how we could characterise the mathematical competence for all indicated, for example, that it is necessary to make more explicit the uses of mathematics in relation to other areas and the “real world”, and especially the role of mathematics in education for democratic citizenship. Generally speaking, a movement towards crossing the objectives indicated for the various curricular areas and referring them more clearly to common and central aims of the basic education will become a priority.

3. Obstacles and problems

Rather than examining the details, it may be relevant for the international community to discuss major issues and obstacles raised by a movement with the described characteristics. I will concentrate on some of them.

My first observation is that if creating an alternative to the RDD model for curriculum development is a difficult task even in small-scale projects, it becomes much harder in the context of an educational reform at a national level, especially if the tradition is that of a centralised system. The dominant conception of development claims for well-defined and “teacher-proof” curricula carefully tested before generalisation and high quality textbooks as key factors to improve teaching and learning. This seems to be a popular view shared by influential sectors of the scientific community and the society at large.
Public opinion is here a necessary, yet very complex, element to be considered. The strength of a movement based on the interaction between theoretical and practical developments, which is a gradual and long-term process in nature, seems to be at the same time its weakness. At a political level, it is not easy to respond to the accusation of delaying quick and clear answers. Guidelines appearing to be ill defined, as well as the absence of new programmes with exact and precise indications, become a factor of criticism. It is interesting to note that, in this context, the single proposal to give schools the possibility of organising classes in periods of 90 minutes is pointed out almost like a "revolution", provoking unusual public debates about education.

My second observation is that, even inside schools, together with the public pressure mentioned above, it is obviously difficult to deal with uncertainty. If the current movement constituted an opportunity for innovative teachers and school leaders to organise teaching and learning contexts more adequate to their students, for others it is a source of problems. There is a tendency to look for models in the initiatives of "more experienced" schools; however this becomes difficult when there are several different models and there is not an official one.

This tension between autonomy and security is amplified by the emergence of the rhetoric associated to the educational change. This is a common phenomenon in periods of reform, but it is particularly negative when change is a matter of process, not only of content. The tendency of emphasising the "pedagogically correct" and criticising all "deviations", characteristic of all sectors including some educational authorities and researchers, is in fact a force towards the adoption of uniform solutions and contradictory with the goal of a larger autonomy of schools and teachers.

My third observation is related to the concept of competence and, in the case of mathematics, the definition of mathematical competence. Doubts and criticism on the presented proposal showed that a broad concept is difficult to be widely accepted. Terms like disposition (to think mathematically), pleasure (in developing intellectual activities) or tendency (to look for the abstract structure) have been especially criticised with the argument that it is very difficult to make such things "operational". This seems to reflect the difficulty in getting the understanding or the acceptance of the idea that integration of cognitive and non-cognitive components is essential to the concept of competence.

Obviously, this is not a new problem, caused by the adoption of a terminology based on the concept of competence. Similar discussions tend to occur, regardless of the terms in which we base our definitions. Proposals aligned with using and applying mathematics in schools (de Lange, 1996), valuing mathematical investigations (Ernest, 1991) or adhering to the "rebirth" of project teaching (Bishop, 1995), which are consistent with the development of mathematical competence in a broad sense, are often accepted as complementary methods or a sort of applications but not necessarily as the essence of the curriculum. Clearly, the problem is the resistance to
question and abandon the technique-oriented curriculum. A central aspect of this problem has to do with assessment and control, leading to my last observation.

Several authors have pointed out that conceptions and practices about assessment did not evolve to match developments in conceptions and practices about other curricular components. For example, Niss (1993) refers to “an increasing mismatch and tension between the state of mathematics education and current assessment practices” (p. 4). Assessment of the development of mathematical competence requires observation in different situations and confidence in the teacher’s professional judgements, while the central role of standardised tests and exams may become a strong obstacle to flexibility, adequacy and diversity.

It is possible that, in the last years, a wider range of assessment modes and instruments – for example students’ written productions – has begun to be increasingly accepted and used. However, reinforcing the dominance of tests and exams, the recent influence of the way in which international comparative studies tend to be interpreted and used has a powerful effect against educational change.

These studies could be relevant to provide information about important aspects of mathematical competence. However, presenting scores as indicators of curriculum achievement, and tending to view curriculum as unproblematic, context-free and culture-free (Keitel and Kilpatrick, 1998), the use of these studies, namely the emphasis on rankings, constitutes a serious obstacle to new conceptions and practices of curriculum development.

The problem is well known. Keitel and Kilpatrick (1998) show how, in the USA and in Germany, lower scores in the TIMSS test in comparison with Asian countries are used as an argument to urge teachers to return to a curriculum based on ‘core knowledge’ or to claim for funding to develop more sophisticated instruments for measuring students’ performance. In the UK, the Secretary of State for Education and Employment says that “numeracy is an important life skill, but evidence shows that standards of school mathematics have not been high enough to enable us to compete internationally” (DfEE, 1998).

In Portugal, the situation is about the same, with the difference that scores were even lower. Porfírio and Abrantes (2000) have presented a paradigmatic example of popular notions of culture, school and mathematics, taken from a TV programme organised in the sequence of the publication of the international rankings. When a mathematics educator tried to introduce an example, the moderator immediately commented: “About mathematics we don’t understand anything beyond the Pythagoras theorem”. However, all evening, the moderator and two other opinion-makers criticised the school for the low scores of students in mathematics tests, while tried to proof the “lack of culture” of our youth by asking some questions about facts related to poetry, history and geography to some students present in the studio.

These people showed that their level of mathematical ignorance was deeper than they even could realise. (...) They view mathematics as a ‘building’ and assume that they can only
remember some pieces of that building. They don’t have any idea about the nature of
mathematical activity or about the way in which mathematical ideas are generated, develop
and relate to other ideas. For them, however, this fact is not relevant in cultural terms.
(Porfírio and Abrantes, 2000, p.278)

Presently, in Portugal, while the movement of curriculum innovation tries to
emphasise flexibility and adequacy of teaching methods to students’ characteristics
and consideration of their social and cultural backgrounds, the “societal” values of
competitiveness and standardisation – of guidelines, methods and “objective” results
– tend to favour the reinforcement of a technique-oriented curriculum. The Ministry
of Education is strongly criticised for not publicising rankings of schools based on
students’ scores in national tests. A popular argument is that everybody has the right
to know what are the “best schools”, the “best teachers” and the “best teaching
methods”. The need to compete with other countries is generally added as well,
together with the argument of “globalisation”. As Keitel (2000) observes, this
concept is ambiguous; it has frequently a connotation opposite to the values of cross-
country collaboration, interaction and co-operation at different levels.

4. Final remarks

In these last decades, much work has been done in the field of mathematics
education. Generally the research focus is on the child and relates to learning
processes or students’ conceptions. In some cases there is concern about the evolution
of these processes and conceptions in contexts of curriculum innovation, as well as
about models of curriculum development. However, the remark of Burkhardt (1989)
that the study of curriculum change on a large scale is neglected, “partly for practical
reasons but mainly because of a lack of attention to system issues” (p. 9) seems to
continue valid.

There is also a considerable work on teachers’ professional development but, again,
the emphasis is not generally in collective and social processes relating this
development to the dynamics of curriculum change, except maybe in the context of
innovative projects.

A major obstacle to develop promising approaches to curriculum innovation may be
probably found in political and social issues, namely in “popular” conceptions about
education and educational change. In particular, public conceptions about
mathematics and mathematics learning in schools seem to play a central role in
favouring the perpetuation of a technique-oriented curriculum. However, this
influence is seldom studied. When discussing the factors that cause students’ (and
teachers’) conceptions of mathematics, the literature has almost always pointed out
the way in which mathematics is presented in school and the dominant use of scores
on standardised tests as measures of academic success. There is no doubt about this
strong and direct influence. But this is not a story of teachers and students only. What
is the role of the society at large and how does it work? What about the role of the
scientific community?
We can find a few references in the literature, revealing this concern. Borasi (1990) admits that “social stereotypes (...) may certainly play a role in shaping students’ conceptions” (p. 177). As I have pointed out above, Freudenthal (1991) includes “opinion shaping” in the set of actions needed in a process of educational development. However, the recent evolution in Portuguese educational system strongly suggests that we need to know much more about these issues.

Finally, I would like to observe that the frequent shifts in my text between mathematics education and educational change at large reflect the impossibility of isolating the mathematics curriculum from the school curriculum as a whole – especially when the basic education is the context. Similarly, the shifts between a descriptive/analytic perspective and a normative one (Niss, 1996) result from the impossibility of ignoring personal values and options when the goals of mathematics education are concerned. These two aspects should not be neglected whenever research and debate focus on actual change at a national level.

Acknowledgement. I wish to thank Guida de Abreu (from the University of Luton) for her suggestions and comments on a preliminary version of this text.

ABSTRACT
A brief and selective overview of historical evidence of females’ involvement in mathematics precedes a review of developments in research on gender and mathematics learning over the past 25 years. Evidence is presented that gender equity concerns have attracted considerable research attention by (mathematics) educators in many countries, and that over time the body of work on gender and mathematics education has increasingly reflected a greater diversity of inquiry methods used to examine and unpack critical factors. Research Reports presented at PME contain only limited evidence of these trends.

INTRODUCTION
Before turning to the main theme of this paper, developments in research on gender and mathematics learning since the founding of PME, it is appropriate to offer some brief, if inevitably selective, glimpses of females’ involvement in mathematics in earlier times.

The first eminent woman mathematician
“It’s true”, wrote Woolfe (1996) in a popular novel, “that Hypatia, the ancient Greek mathematician, was the first eminent woman mathematician ... that anyone seems to know about” (p. 7). Readers are left in no doubt that her prowess in mathematics was both revered and feared.

She had a huge following, and distinguished students came from Europe, Asia and Africa to hear her.... Cyril was fearful of her popularity and her religion, and incited a mob of fanatics, who dragged her to a church, murdered her with shells, and then burned her. This happened at the height of her fame, when she was 45. All her writings have been lost. (Woolfe, 1996, p. 7)

Hypatia’s life, it appears, continues to fascinate those inside and outside the mathematics community. A brief biographical sketch, with reference to her mathematical excellence and her violent death, was recently included in the Five things you didn’t know about regular column in a popular daily metropolitan newspaper (Hill-Douglas, 2001).

The Ladies Diary
A less spectacular, but more pervasive, example of females’ involvement in mathematics is also worth mentioning. Some 300 years ago, in 1704 to be more precise, John Tipper launched the first almanack specifically aimed at women, under
the title “The Ladies Dairy or the Women’s Almanack”. Considered to be the prototype of the popular eighteenth century ladies’ pocket books and diaries, it was itself highly successful, with an unbroken publication run until 1840 when it combined with the Gentleman’s Dairy and continued to be published under the latter name for another 30 years.

The contents of The Ladies Dairy make fascinating reading, with hints about choosing a life partner, optimistic messages about the status of women, and pithy advertisements:

Never marry a vicious man in hopes of reclaiming him afterwards; for those who are habituated to any manner of debauching or vice, if you think to reclaim by fair means, or by foul, you will find yourself fatally mistaken. (The Ladies Diary, 1704, p. 5)

The method that God observed in the creation, plainly shows women to be the most excellent of created beings. Which method of proceeding was from the less to the more noble beings, namely from the mineral to the vegetable; from thence to the animal kingdom; all of which being finished, he made men, and last of all women, in whom all the creation was perfected and its beauty complete. God having made women, ended his work, having nothing else more excellent to create... (The Ladies Diary, 1705, p. 15)

Artificial teeth, set in so firm, as to eat with them, and so exact, as not to be distinguished from natural; they are not to be taken out at night, as is by some falsely suggested, but may be worn years together .... (They) are an ornament to the mouth and greatly help the speech. (The Ladies Diary, 1979, p. 48)

It is not clear why Tipper included two mathematics problems in the Ladies Diary of 1707. As master at Bablake school and a mathematician of considerable ability, he was certainly qualified to do so. At the same time, “the law, which the first contributors imposed on themselves, of not only proposing, but also answering all questions in rhyme, was not favourable to the development of Mathematical genius” (Leybourn, 1817, p. viii). Nevertheless, the inclusion of mathematics problems in all subsequent issues explains my interest in the Ladies Diary.

Tipper’s formula proved successful. “My almanac sold this year beyond mine and the company of Stationers’ expectations, so that of 4000 which they printed, they had not one left by New Year’s tide” (Ellis, 1843, p. 314), he wrote in a letter to a friend. Some years later, the then editor of the Diary wrote:

I believe that the Diary has the good fortune to fall into a multitude of hands which mathematical books seldom or never would ... [T]he fair

---

1 Or Ladies’ Diary in later issues
2 I am indebted to Dr Teri Perl for her willingness to share her Ladies Diary materials with me
3 The spelling in this and subsequent Diary extracts has been modernized
sex may be encouraged to attempt mathematics and philosophical knowledge, they here see, that their sex have as clear judgements, a sprightly quick wit, a penetrating genius, and as discerning and sagacious faculties as ours, and to my knowledge do, and can, carry them thro’ the most difficult problems. I have seen them solve, and am fully convinc’d, their works in the Ladies Diary are their own solutions and compositions….Foreigners would be amaz’d when I show them no less than 4 or 500 several letters from so many several women, with solutions geometrical, arithmetical, algebraical, astronomical and philosophical. (The Ladies Diary, Editorial, 1718)

Reference to the “discerning and sagacious faculties as ours” suggests that editor Beighton assumed that the Diary would be read by males. His words also foreshadow a theme to be mentioned later in the paper - the belief that for women to be the equal of males was high praise indeed.

The passage of time and the inadequacy of historical records make it difficult to quantify the full impact of the Ladies Diary. Yet, there is little doubt that the mathematical content of the Ladies Diary was taken seriously. In due course two substantial collections of “the useful and entertaining parts, both mathematical and poetical” of the Diary were published – the first by Charles Hutton (1775), professor of mathematics at the Royal Military Academy, and editor of the Diary from 1774 to 1818, the second by Thomas Leybourn (1817).

Problems, taken from the Ladies Diary of 1707, 1769, and 1814 respectively, and shown below, give some idea of the publication’s mathematical content^4.

If to my age there added be
One half, one third, and three times three;
Six score and ten the sum you’d see,
Pray find out what my age may be. (Question 2, Ladies Diary, 1707)

Dear ladies, you with ease may find*
A matchless hero’s name,
Who was beloved by mankind,
And mounted up to fame:
To serve his country boldly dar’d,
Hot sulphur, smoke, and fire,
And long campaigns’ fatigue he shar’d,
To conquer proud Monsieur.

* viz. From the equations

\[ w + x + y + z = 52 \]
\[ wx + yz = 360 \]
\[ wz + xy = 280 \]
\[ wy + xz = 315 \]

^4 The selection is biased by concerns about space constraints. I have selected shorter rather than longer problems.
where \( w, x, y, \) and \( z \) denote the places of the letters in the alphabet composing the gentleman’s name. (Question 597, proposed by the frequent contributor Mr Tho. Sadler, *Ladies Diary*, 1969)

If a globe, of 1½ foot diameter, be put to float in common water; required the area of the section at the surface of the water, when the specific gravity of the globe, to that of water, is as 3 to 5? (Question 1269, proposed by Mr Joseph Williams, of Canterbury, *Ladies Diary*, 1814)

Although the overwhelming majority of problems were posed and answered by males, there is evidence of females’ mathematical activities scattered throughout issues of the *Ladies Diary*. The address to “Dear ladies” in the second of the problems reproduced is suggestive. Included among the seven correct answers for the third problem printed in the *Diary* was one from a Miss Susannah Jackson from Mile End.

The decision by a succession of editors to award a prize for the first correct solution received to selected mathematical problems enables at least partial tracing of those who engaged in mathematical problem solving. Perusal of other records shows that the surnames of many of the early female contributors matched those of well known male mathematicians or scientists. Thus having a brother or husband knowledgeable about, and sympathetic to, mathematics and scientific pursuits appeared a distinct advantage for females interested in mathematics. Significantly, contemporary research findings have revealed the benefits of a nurturing environment, access to needed materials, and support from critical others as facilitating achievement in mathematics. Perl’s (1979) assertion that the solutions contributed by women were confined mainly to arithmetic or algebra problems is also consistent with females’ preferences in mathematics reported in some contemporary research.

Those familiar with the life of Mary Somerville, the Scottish mathematician, have further indirect evidence of the importance of publications like the *Ladies Diary*. Mary was born in 1780. Her family attached far greater importance to the education of their sons than of their daughter. For her it was deemed sufficient to be taught to read the Bible by her mother, although when she was ten she was sent to a fashionable boarding school for 12 months. From there she emerged “with a taste for reading, some notion of simple arithmetic, a smattering of grammar and French, poor handwriting and abominable spelling” (Patterson, 1974. p. 270). Some years later, quite fortuitously, she came across an algebra problem which aroused her curiosity. In Mary’s own words:

> At the end of the magazine, I read what appeared to me to be simply an arithmetical question, but on turning the page I was surprised to see strange looking lines mixed with letters, chiefly Xs and Ys, and asked “What is that”? “Oh”, said (my) friend, “it’s a kind of arithmetic; they call it Algebra; but I can tell you nothing about it”... On going home I
thought I would look if any of our books could tell me what was meant by Algebra. (Somerville, 1873, p. 54)

Instead of encouraging this thirst for knowledge, her father forbade her studying mathematics. “We must put a stop to this”, Mary recounted him saying, “or we shall have Mary in a straitjacket”. Such beliefs also proved persistent. Decades later an American physiologist argued that “a young woman might learn algebra, but [he added] when the limited sum of energy flowed to the overwrought brain, it harmed the natural growth of ovaries” (Tyack & Hansot, 1988, p. 37). Nevertheless, Mary persevered with her mathematical studies. Her most effective mentor was the Scotsman William Wallace, then editor of the Gentlemen’s Diary, to which she sent a number of contributions. The close relationship between it and the Ladies Diary was fostered through cross references between the two publications. The eventual merging of the two publications has already been mentioned.

In Mary Somerville’s case the influence of a popular magazine that also contained mathematics problems has been recorded for posterity. It is tempting to speculate that many other intelligent women were stimulated to achieve mathematical literacy through the mathematics section of the Ladies Diary. That copies of the Diary found their way into Australian libraries may reflect the priorities of some of that country’s early settlers.

After this brief historical context, it is time to consider more recent trends, starting with the period approximating PME’s creation.

MATHEMATICS AND GENDER

Who Cares?

In a recent article, Lubienski and Bowen (2000) reported the results of their attempt to identify major areas of mathematics education research activity, including “the attention given to various equity groups and topics by the mathematics education research community” (p, 627). Their data source comprised 48 major national and international educational research journals accessible through ERIC and likely to include at least some mathematics education-related research. Eventually 3,000 articles were counted and categorized over the period selected: 1982 to 1998. The accuracy of their results, Lubienski and Bowen readily admitted, was heavily dependent on the accuracy of the ERIC descriptors and their categorization of those descriptors. Nevertheless, their findings offer a useful, if rough, measure of research interest among mathematics educators in gender issues.

According to their search, approximately 20 % of the articles (623 out of the total 3,011) concerned with mathematics education contained an equity theme, i.e., they contained a focus on gender, ethnicity, class, or disability. The majority of these, 323, were concerned with gender. In other words, some 10 % of all the articles identified contained gender as a factor of interest. Frequency of such articles varied with journal type. For example, in journals broadly classified as general educational and psychological, 15.2 % and 14.1 % articles of the articles respectively contained a
gender theme; for those grouped under US and international mathematics education journals the figures were 8.9 % and 7.7 % respectively. The thrust of these articles is the focus of the next section.

**Identifying a "problem"**

During the 1970s, much research effort was directed at documenting gender differences in participation in mathematics courses and in performance on mathematical tasks and tests. A then timely “state of the art” summary read as follows:

Are there sex differences in mathematics achievement? ... No significant differences between boys’ and girls’ mathematics achievement were found before boys and girls entered elementary school or during early elementary years. In upper elementary and early high school years significant differences were not always apparent. However, when significant differences did appear they were more apt to be in the boys’ favor when higher-level cognitive tasks were being measured and in the girls’ favor when lower-level cognitive tasks were being measured.... Is there “sexism” in mathematics education? If mathematics educators believe that there is a sex difference in learning mathematics (as was evidenced in the reviews cited) and have not attempted to help girls achieve at a similar level to boys, then this question must be answered in the affirmative. (Fennema, 1974, p. 137)

That concern about females’ participation and performance in mathematics was not confined to the USA is evident from the excerpt below, taken from the report of the Victorian (Australia) Committee on Equal Opportunity in Schools:

A large portion of mathematical ability resides in women and is potentially untapped. It has been a long-term aim of our educational system to develop individual talent, and the serious imbalance apparent in inculcating mathematics competence in men compared to women, demonstrates how far our achievement has fallen short of that ideal. (1977, p. 152)

**Developments and explanations**

The presentation below of the different phases in research on gender and mathematics education as sequential is simplistic and convenient rather than an accurate chronological representation. Trends described in earlier time spans have persisted in later research work; elements of those highlighted in the discussion of later years could be gleaned in earlier work.

---

5 The contents of this and following sections were shaped by collaborations and discussions with many colleagues. Of these, I wish to single out Elizabeth Fennema and Helen Forgasz as being particularly influential.
Early trends

Documenting current performance and participation differences, exploring likely contributing factors, and assessing the effectiveness of selected intervention strategies succinctly described the scope of research and scholarly activities with a focus on gender and mathematics in the mid 1970s and much of the 1980s. Gender differences in mathematics learning were typically assumed to be the consequences of inadequate educational opportunities, social barriers, or biased instructional methods and materials. It was further assumed that the removal of school and curriculum barriers, and if necessary the resocialisation of females, would prove to be fruitful paths for achieving gender equity. Male (white and western) norms of performance, standards, participation levels, and approach to work were generally accepted uncritically as optimum and to be attained by all students. When failing to reach these, females were considered deficient, or to use a theme from Kaiser and Rogers (1985), perceived as a problem in mathematics. They were to be encouraged and helped to assimilate. This notion, helping females attain achievements equal to those of males was consistent with the tenets of liberal feminism.

The 1980s

The assimilationist and deficit model approaches proved persistent throughout the 1980s and continued to guide many of the intervention initiatives aimed at achieving gender equity. Levels of males’ and females’ participation and performance in mathematics subjects continued to be reported in research studies, but now more frequently with an attempt at analysis - perhaps in conjunction with an examination of government policies. At the same time, different voices were beginning to be heard, undoubtedly influenced by work developed in the broader research community. The themes fuelled by Gilligan’s (1982) *In a different voice*, and the feminist critiques of the sciences and of the Western notions of knowledge were particularly powerful. What other factors might be contributing to gender differences in mathematics education? Should we accept, uncritically, the way in which mathematics was being taught and valued? Should young women strive to become like young men or should the formers’ goals, ambitions, and values instead be celebrated? What, crucially, might differentiate between a single-sex and co-educational school or class environment? Should we aim for uniformity or ‘can different be equal’? In which setting might mathematics be taught and learnt more effectively by males and females? Should we accept only those conditions and approaches favoured by males? Such questions led to interventions which attempted to make the contents of mathematics less alienating to females. Rather than expect them to aim for male norms, attempts were made to use females' experiences and interests to shape the mathematics taught and methods of instruction. Females were to be perceived as central to mathematics and mathematics as being reconstructed (Kaiser & Rogers, 1985).

The assumptions of the “women as central to mathematics” phase were not without danger. Attempts to focus on women with exceptional and rare mathematical talents
proved problematic. Some of these portrayals, it seemed, simply confirmed how
difficult it was for an “ordinary” (female) student to become an “extraordinary”
mathematician, what hardships needed to be endured, what challenges to be
overcome, what prices to be paid? Programs which valued and nourished qualities
and characteristics presumed to be exclusively female could be thought to imply,
directly or indirectly, that these were innate to females and alienate those who did not
possess them. This essentialism risked perpetuating traditional gender stereotypes
rather than redressing gender inequities. Nevertheless, recognition that previously
unchallenged assumptions, traditions, and cultural exclusivity needed to be examined
and possibly redefined was overdue.

The more critical attempts to analyse and deconstruct explanations for gender
differences in mathematics learning and the clearer recognition that different
perspectives inevitably lead to differences in the ways in which the interventions
aimed at challenging inequities were framed were noteworthy developments in the
later years of the 1980s. The attempts to make females more central to mathematics
and of exploring the reconstruction of mathematics soon accelerated and diversified.
The assumptions of liberal feminism that discrimination and inequalities faced by
females were the result of social practices and outdated laws were no longer deemed
sufficient or necessary explanations. Instead, emphasis began to be placed on the
pervasive power structures imposed by males for males. The acceptance of (white,
western) male norms, the assumption that females aspire to these standards and
modes of behaviours, and the presentation of a deficit model of womanhood in which
girls and women are positioned as victims with deficit aims and desires were also
challenged. Some researchers wished to settle for nothing less than making
fundamental changes to society. Advocates of this approach, often classed as radical
feminists, considered that the long term impact of traditional power relations between
men and women more broadly, and in mathematics more specifically, could only be
redressed through such means.

Further changes – beyond the 1980s
Attempts to explore the interaction between gender and other background variables -
socio-economic status and cultural and ethnic affiliations, for example – have
intensified in the past decade. The concerns of social feminists voiced in the
community at large, that females from working class backgrounds are often
particularly disadvantaged in the home, in the labour force, and in access to leisure
pursuits, have also influenced research in mathematics education. The genuine efforts
made to mirror as comprehensively as possible the complex web of factors - personal,
situational, and social - which might shed light on issues of gender and mathematics
are reflected in more complex research designs and in designs relying for their
conception, execution, and data analysis on multiple research methods.

An interim summary
In brief, gender equity concerns have represented a significant item on the research
agenda of (mathematics) educators in many countries - in highly technological
societies as well as developing nations. International comparisons, formal and informal, have highlighted the roles of class and culture. For a given society, the status of mathematics in the lives of females is invariably linked to their status in that society. Male norms, and acceptance of difference without value judgments, have been more likely to be challenged in countries with active and long standing concerns about equity issues. Collectively, the body of work on gender and mathematics education reflects an increasing diversity in the inquiry methods used to examine and unpack critical factors. More radical feminist perspectives are being adopted, females are less frequently considered as a homogeneous group, and scholarly evaluations of interventions are becoming more prevalent. At the same time there is a clearer recognition of the extent to which the personal beliefs and theoretical orientation of the researchers undertaking the work influence inclusion and exclusion of variables and modes of data gathering. No longer is it simplistically assumed that the planning, execution, reporting, and interpretation of research are value free.

It is difficult to quantify the extent to which perceptions about gender and mathematics learning have changed. A recent research study (Leder & Forgasz, 2000) provides one measure. A sample of approximately 860 students in coeducational high schools in Victoria, Australia, completed a questionnaire aimed at tapping gender stereotypes about aspects related to the learning of mathematics. For each of 30 statements students were asked to indicate whether they believed (1) the statement to be definitely more likely to be true for boys than girls, (2) probably more likely to be true for boys than girls, (3) there was no difference between boys and girls, (4) probably more likely to be true for girls than boys, or (5) definitely more likely to be true for girls than boys. The data obtained from administration of that questionnaire were compared with findings reported in previous relevant research (see Table 1).

There were only eight items, it can be seen from Table 1, for which the responses were consistent with previous findings. These items were largely related to the learning environment and to peers. For example, boys were still believed more likely to distract others from their work (Item 16) and to like using computers to solve problems (Item 24). Girls, there continued to be agreement, were more likely to get on with their work in class (item 28). In the past, boys were generally believed to have more natural ability for mathematics than girls, were considered to enjoy mathematics more, and to find it more interesting than did girls. Yet the more recent data revealed that, on average, students now consider boys more likely than girls to give up when they find a problem too challenging (Item 4), to find mathematics difficult (Items 27 & 18), and to need additional help (Item 20). Girls were considered more likely than boys to enjoy mathematics (Item 6) and find mathematics interesting (Item 29). Responses on so many items inconsistent with previous findings surely implies that changes have occurred over time in gendered perceptions related to mathematics education, that, in other words, the energy expended on documenting gender inequities and attempting to redress them have left

1 - 50 PME25 2001
their mark. It is perhaps worth adding that the gendered perceptions captured by the questionnaires are fully consistent with interview data gathered in recent studies involving students from elementary school to university (Forgasz & Leder, 2001; Landvogt, Leder, & Forgasz, 1998).

A focus on gender and PME activities

Comparisons of research attention on mathematics and gender between the wider mathematics education and PME communities reveal an ambiguous picture. On the one hand, females have figured quite prominently in PME activities. Four of the ten presidents to date have been female (though the first four presidents were males). From the outset, females have been active presenters of Research Reports: females were sole or co-authors of more than one-third of the Research Reports presented at the third PME conference, for example.

Yet those leafing through PME Proceedings will observe a more subdued emphasis on research concerned with gender and mathematics among the PME community than within the mathematics education research community at large. This may be a reflection of the beliefs expressed by participants at the earliest PME conferences that issues of gender differences were considered irrelevant in their own countries.

Inspection of PME Proceedings soon reveals an inconsistency in the listings of Research Reports, with Proceedings editors clustering them by category in some years, but not in others. When clustering occurred, there was considerable variation in the number of articles listed under each heading. For example, the Research Reports delivered by the 70 presenters at PME2, and included in the 1978 Proceedings, were grouped into five themes: The Acquisition of Mathematical Concepts, The Learning of Generalisation and Proof, Interpersonal Aspects of Communication, The Nature of Mathematical Thinking, and Intuitive and Reflection Processes in Mathematics. The 1982 Proceedings were divided into 12 categories, with the number of entries ranging from nine (Concept Formation) to one (Discovery Learning and Neurophysiology); the 1993 PME Proceedings contained 16 different categories, with entries ranging from eleven (Epistemology, Metacognition, and Social Construction and Problem Solving) to one (Probability, Statistics, and Combinatorics). These examples show that having few Research Reports in a particular category was no barrier to that topic being highlighted on the Contents pages. Yet even in years in which a number of Research Reports contained the words “sex” or “gender” in the title, inclusion of gender as a category heading was rare, with the 1984 Proceedings in which two papers were listed under the heading Girls and Mathematics a notable exception.

Presumably, then, the interest for research into gender and mathematics exhibited by some PME participants was not necessarily shared by the editor(s) of the PME Proceedings. Greater attention to the key words provided by Research Report authors to describe the content of their paper might provide a more equitable listing in future.

---

6 I am indebted to Alan Bishop for sharing with me his recollections about the early PME conferences.
As it stands, it is no easy task to trace how the topic of gender and mathematics has been explored in PME Research Reports.

**PME and research on gender and mathematics**

In the time and space available, it is impossible to give a comprehensive summary of all papers with a strong gender theme delivered at PME conferences. To summarise briefly and with no attempt at full coverage of Research Reports which included "gender" or "sex" in the title:

- Compared with other topics covered, gender issues have apparently been of limited interest to those presenting Research Reports at PME.
- Sample details in the early papers rarely included the numbers of males and females involved in the research study, though this information was included in later reports.
- Early papers in particular contained the “females are deficient” theme (e.g., Barboza, 1984).7
- Others contained the “male norms are the standard measure for comparison” theme (e.g., Collis & Taplin, 1984; Leder, 1986; Mukuni, 1987; Kuyper & Otten, 1989, Visser 1988).
- The variety and complexity of the methodologies and instruments used for data collection increased with time, in line with the research reported in other settings and vehicles (e.g., Underwood, 1992).
- Early findings were increasingly revisited and previous assertions about the effect of gender on mathematics learning challenged (e.g., Forgasz, Leder & Gardner, 1996; Forgasz & Leder, 2000 – gender stereotyping of mathematics; George, 1999 and Gorgorio, 1992 – gender differences in visual representation; Pehkonen, 2000 – mathematical reasoning).

As indicated earlier, this list is most aptly described as indicative of the scope of research reported at PME, and does not aim to be exhaustive. Yet it prompts an inevitable question. To judge from the contents of the Research Reports included in Conference Proceedings, would those hoping to hear cutting edge research - whether experimental or theoretical, qualitative or quantitative - be more likely to be satisfied or disappointed by the fare at PME conferences? Where are the reports of research studies, detailed in other venues, in which more radical feminist perspectives are being adopted, females are less frequently considered as a homogeneous group, and fine grained rather than collective data are presented? Where are the reports of scholarly evaluations of large scale interventions? Or detailed case studies which focus on individual rather than group differences? Or reflective accounts of the impact of the personal beliefs and theoretical orientation of the researchers undertaking the research on design of the study, data gathering decisions, choice of instrumentation? From personal experience I know that these issues are of interest to members of PME and are discussed within venues such as Discussion and Project.

---

7 Papers which appeared in *PME Proceedings* are not cited separately in the reference list.
Groups - group activities which have scant permanent or written records. It does not take long to decide that the format adopted for PME written Research Reports, and let me add a format carefully and sensibly selected for many good reasons, favours the reporting of studies with certain data and research designs but discourages the reporting of others. Tracing the debate on gender and mathematics within the Proceedings of PME conferences has been an instructive and, for me, provocative exercise.

           Jorge Falcão, University of Pernambuco, Recife, Brazil
           Andrea Peter-Koop, University of Muenster, Germany
           Fred Goffree, Freudenthal Institute, Utrecht, The Netherlands

Coordinator: Catherine Sackur GECO-IREM, Nice, France

Introduction
In 1977, PME 1 took place in Utrecht; PME 25, in 2001, is now coming back to Utrecht.
After infancy, childhood and teenage, 25 is the age of adulthood.
What are the characteristics of adulthood? autonomy and responsibility.
Let’s leave aside the dreams of childhood, forget the passions of teenage and face the responsibilities that we have towards the international community: that of presenting a coherent body of researches in mathematics education for the future.
In this panel, four experts will analyze the work which has already been done by the members of our community, will examine the way questions and ideas have developed and will try to give guidelines for future work.
Our four experts are: a psychologist (Jorge Falcão), a teacher (Andrea Peter-Koop), a teachers’ educator (Fred Goffree) and a researcher in mathematics education (Alan Bell).

Alan Bell will start with a review of major trends throughout the 25 years of PME; comparing PME 2 and PME 23 he will make clear that some topics still need investigation.
The second expert will be Jorge Falcão, whose presentation will lead us to the discussion of the contribution of psychology to our field.
Andrea Peter-Koop will talk about the necessity of research for in-service and pre-service teachers. We’ll discuss what kind of research is most appropriate for them.
The first part of the panel will end with Fred Goffree’s talk. Fred Goffree has been working with student teachers in various institutions. He has experienced different techniques and methods, being close to Hans Freudenthal, here in Utrecht. He intents to question the links between theory and practice, and “developmental research“.
After the four presentations, we will ask you to discuss some proposals for new trends in mathematics education’s research.
I went through the very rich texts which have been proposed to us, and I would like now to share with you some of the questions which came to my mind.

- You will certainly notice that two of our experts are concerned by the great number of Research Reports presented in our PME meetings, and by the difficulty to have an integrated view of the actual research in our community. Does this mean that, in the future, we should change the ways in which PME members present their research, or should ‘we’ devote some time in building synthesis? who could be this ‘we’?
- Do we need more psychology to understand mathematics learning and teaching? Should there be more psychology in the training of mathematics’ teachers?
- Are the concepts of metaphors and competencies-in-action useful to describe mathematical concepts? If metaphors are useful for mathematics education, could they at the same time be didactic obstacles?
- About research and teacher education (inservice or preservice teachers), there are different questions: shall we take for granted that research should be part of the training of teachers? if the answer is yes, what is the role of research in teacher education? how much research should we devoted to teacher education?
- One can observe a change in the methodology of our work: large scale researches seem to be more or less abandoned in favor of classroom researches or observation of rather small groups of students. Could this phenomena be linked to a questioning about mathematics education: are teachers supposed to “teach skills“ (the evaluation being then easily feasible through large scale studies), or is mathematics education “learning to act like a mathematician“ (which study requires another methodology)?

No doubt that you will have many other questions to debate with the panelists. To the P, the M, the E of PME we will, of course, add the R of Research.

The answer to these questions should lead us to some sort of « agenda » for the next 25 years of PME.

May this panel contribute to bring PME to its full development. Rendez-Vous in Utrecht in 2026!
25 Years of PME – and the next 25

Alan Bell

To review adequately 25 years of work in PME and make suggestions for the future is a daunting task. In the time available for preparation, and for presentation now, I can only highlight some trends which I perceive; I hope to provoke every one here to contribute and to make this a review more representative of the perceptions of all of us of this very substantial and growing work of ours. I decided to look at the first published PME proceedings - PME2, Osnabrueck 1978, and to compare them with those of a recent meeting, PME23 in Haifa, 1999. focusing on questions such as

- What new knowledge do we now have on the themes addressed in that early meeting?
- In what ways have the methodologies changed?

At PME2 there were 70 participants from 11 countries, and 26 talks were given – so they were all plenary. In the one 400-page volume, some of them occupy over 30 pages; the mean is about 15. The following were among the main themes addressed; these are the ones I will try to trace in later work.

- **Students’ understanding of particular mathematical concepts**, common intuitive preconceptions & misconceptions & normal development
- **Students’ understanding and learning of general strategies** - of Mathematics and of Problem-solving, including mathematical thinking and the place of these aspects in the curriculum
- **Teaching/Learning Interactions** in the classroom
- **The Learning Process** and the role of **Reflection**
- **Dissemination and Implementation in School Practice**

**Students’ understanding of concepts**

This theme has attracted by far the greatest volume of work in PME. In 1978, Vergnaud spoke about practical arithmetic problems, requiring identification and use of one of the four basic operations. Such problems embody a much greater variety of mathematical structures than the four operations themselves, when one takes into account the actual context, the order of events, and whether quantities are involved or pure numbers, and are typically solved by students in many different ways, relating to different symbolic and diagrammatic representations.

Problems with the initial quantity unknown are markedly more difficult than the others, requiring a reversal of thought and resistance to the conventional associations of cue-words for subtraction or addition.
Studies such as this, which analyse the space of problems in a given conceptual field, and observe students’ approaches to them, identifying key difficulties and misconceptions, have formed a rich vein of study throughout the 25 years of PME. For example, there have been many studies focusing on difficulties with decimals, and, more recently, on probability. At PME23, Amir & Linchevski identified a 'representativeness' misconception which fails to distinguish sufficiently between the probability of a particular order of TTHHTH compared with TTTTTT, and the probability of these (unordered) combinations of T and H; and Ayres & Way show how children’s predictions in sampling are influenced by the success or otherwise of their immediately prior prediction.

Also at PME23, Silver reported a study of students’ generation of all the different nets of a cube, identifying the modes of classification they used. This year (PME25) there is a study of the stages young children pass through in coming to make up composite geometric shapes from basic pieces. These last two were descriptive studies in classroom learning settings, in contrast to the quoted earlier ones, which used a more rigorous comparison of responses to carefully designed questions. This tension between realism and rigour is visible in many recent studies. There is also the question Are these stages obvious, or is there anything surprising about the results?

- **Do we now have enough knowledge of student concepts and misconceptions in the major mathematical fields, or is more still needed?**
- **Is such work best incorporated in teaching studies?**

Some of this earlier work has led to the development of general teaching methodologies. Our own Diagnostic Teaching Project (Bell, 1993) used a 'conflict-discussion' method, in which a lesson started with a few critical problems (chosen in the light of the previous research), some soluble in the 'obvious' way, others intended to elicit a particular misconception and thus creating a cognitive conflict which would be resolved by inter-pupil discussion. In an equal-time comparison with a 'positive-only' method, which taught the correct concepts before posing the critical problems, the conflict method showed great superiority in retention over several months, in spite of the smaller (because more intensive) coverage of the material. Carpenter’s Cognitively Guided Instruction project had a similar philosophy.

**The Learning of General Processes**

My 1978 paper considered both general problem-solving strategies and the more mathematics-specific processes of generalisation and proof. On the former I was able to quote a study reported by Scott (1977) which showed superior results in 16 year-old maths exams for students who, in primary school, had taken part in weekly scientific problem-solving sessions, in which they were faced with puzzling science situations (eg some objects floating & others sinking) and had to find explanations by formulating questions to ask of the teacher, who would only respond Yes or No. In
view of the significance of this transfer of general strategy training to concept learning it is surprising that it has not been followed up.

More recent studies of students’ work in open problem-situations include one in PME23 by English on problem posing and model generation and a Discussion Group in PME22 supported by a substantial publication by Pehkonen on open-ended problems and their use in the classroom. But these were descriptive, not experimental studies of transfer. What we have (in the paper by English) is more detailed report of the students’ work on one of the tasks.

On the learning of general mathematical strategies, there has been ongoing work focused on the learning of proof. In my 1978 talk, using a number of simple generalisations, to be found or verified for truth, I distinguished levels of proof-explanations in students’ responses. Most pupils up to age 15 relied on incomplete checks of a few cases, few gave explanations in terms of more basic principles, and none reached a higher stage of using explicitly stated starting points.

Three examples can be given from PME23 of work in this field. Boero identifies four ‘processes generating conditionality’ which link with proving activities. This could be the beginning of a study which might develop in a similar way to that on arithmetic problems discussed earlier. In another paper, Douek explores the explicit and implicit problem-solving and proof strategies which undergraduates use; she argues that the imposition of formal proof structures is harmful and that effective proof activity depends on intellectual qualities fully developed during ordinary, demanding argumentative activities other than proving.

In this field there are broad underlying questions about transfer.

- How far does the acquisition of general strategies for problem-solving, generalising and proving improve the subsequent learning of particular mathematical concepts, skills and applications – or of learning in general?

- What aspects of mathematics are the most important for students’ education – the knowledge of particular concepts, OR the experience of exploring problems like a mathematician?

How do we attack these questions?

The social environment for learning

These questions can be seen as relating to the depth of learning, since it is in the quest for deeper understanding of mathematics that we are led to think about these general strategies. Another step along the same path raises questions about the social and personal environment in which learning takes place, and how far it is attuned to the ways of thinking and feeling of the learners. A relevant study in PME23 was that
of Boaler, who compared the very different mathematical learning environments in two English schools. One was traditional and hard working; in the other, the students engaged in a variety of individual and group projects in an informal social environment. This group out-performed the other in the standard exams. We cannot be sure, of course, that all other aspects of the two situations were similar, which suggests a need for a more extended study.

**Teaching/learning interactions**

Bauersfeld's 1978 talk identified a number of characteristic question-and-answer sequences common in mathematics classrooms; one he called 'funnelling', in which the questions led the pupils steadily closer to an answer the teacher had in mind. Subsequent work has included the study of transcripts of such exchanges, more recently using videotape as well. Such activity is clearly especially valuable for groups of teachers, who can discuss their interpretations of what they see or read, and become aware of possibly unsuspected aspects of their own practice. In PME23, this field was the subject of a plenary lecture by Steinbring and of meetings of an ongoing project group and discussion group. My question here is

Do we have here mainly a methodology for gaining insights, or are there also significant new concepts for teachers to use?

**Learning Processes and The Role of Reflection**

Though this is widely acknowledged as a most important theme, it has received little explicit attention. It can be argued that reflection is an essential component of the notion of advance organisers, of the institutionalisation phase of the French didacticians’ teaching/learning problematique, and of the cognitive conflict which figures in the teaching experiments mentioned above. But if the psychologists are right, it is a powerful enhancer of learning which should appear in every teaching episode. Two recent projects with this focus are the Australian Project for Enhancing Effective Learning (PEEL) and our own Pupils' Awareness of their Learning Processes. (for both, see Bell et al, PME21). The former work arose from the perception that, in the typical secondary classroom, students participated rather passively in an activity designed and controlled by teacher and school, and that learning could be improved if they became more aware of the purposes of the various activities and took part in decisions about what and how they studied. This achieved some success, but was hard to establish and maintain, as it proved to require the involvement of the teachers taking the classes in question for most of their subjects. In our work, pupils devised their own tests, taught other pupils, interviewed each other on recent work and took part in their own assessment. They also discussed the purposes of different lessons, such as those for practising skills, learning concepts, developing strategies for investigation. Questionnaire results showed improvements in these perceptions, but the circumstances of the project (insufficient length, in particular) did not enable us to evaluate changes in mathematics test performance.
Do we need more focused studies of the ways in which reflection can enhance learning?

**Dissemination and Implementation**

The general problem of assimilation of new insights into the school system is a long-term one. Jack Easley addressed it in a talk at PME2. He had conducted an intensive study of the lack of adoption of well-founded innovations, particularly in science education, reporting that teachers reject the recommendations of experts as unworkable with the students they have, and much inservice activity fails to achieve a meeting of minds. Not so many studies of dissemination have been reported at PME, in spite of its great importance. Such work requires more substantial time and resources than are available to most of our members. However, there was a welcome contribution to PME23 on this theme, in a plenary lecture by Ruthven on the development and attempted dissemination of a calculator-aware curriculum in the UK, initially led by Hilary Shuard. He concluded that a successful innovation required a very thorough analysis of the entire content, progression and teaching methods of the curriculum, and its adoption as part of a coherent and committed programme of school development and ultimately of systemic reform, rather than the isolated responsibility of individual teachers. Such a programme the National Numeracy Initiative, has in fact been developed and prescribed by the UK government, with detailed lesson programmes and considerable inservice support. However, this has coincided with a politically inspired ban on calculator use until the last two years of primary education! Such are the hazards securing useful implementation of our work.

Another substantial study was conducted by Brown and her London team, on Effective Teachers of Numeracy. A substantial sample of Primary schools was used, and each teacher’s success in improving pupils’ performance on the standard tests over a year was correlated with various teacher characteristics. The most successful were those who had a well-connected relational understanding of the mathematics curriculum, often gained from in-service courses with this aim.

- **How can we find out more about the processes by which new knowledge and insights eventually influence the education of our students?**

**Methodological Trends**

In general, there has been a great expansion in the number of works presented, and many have been on a smaller scale than in 1978. Much detail has been filled in, especially in the field of students’ understanding, and more work has been done in realistic classroom settings. At the same time, there has been perhaps less work integrating all these particulars into coherent bodies of knowledge. The Research Fora give more opportunities for extended exposition and critique, and this is a
significant development; but they tend to adopt their own theories, and aim to display the power of the theory to provide a framework for constructing a teaching material, and explaining the results of its use. Aspects of the theory itself are not generally tested.

- How can we encourage more critical tests of major theories?
- Do we need more integrative review studies?

The trend in methodology I see is towards more observational studies of students’ responses, often in classroom settings, to some innovatory curriculum element. The purpose of these is usually to demonstrate the superior effectiveness of the innovation, but there is often no formal comparison; one draws conclusions by reference to a mental comparison with what one would normally expect in the topic in question.

This raises the question of how to read and interpret such reports. We have moved a long way from the assumption that we are establishing hard scientific generalisations beyond reasonable doubt. So the way in which knowledge accumulates for each of us is by reading many reports, each very specific in terms of topic, method, underlying theoretical assumptions, and integrating them in much the same way as we do our general knowledge of the world. I used to think of this as being like reading good novels, which generally have some general insights to convey about the human condition, but clothed in a specific story which adds interest and also convinces us by showing how such things might happen. The analogy is not perfect, because our reports are not meant to contain a fictional element! But the fact remains that what is taken from it depends on the perceptions and preconceptions of the reader.

- Is this an appropriate way of conducting and reporting research in our field?

1. A little historical introduction...

In February 16th 1630, a Dutch naval fleet arrived at the coast of Pernambuco, by this time a province of Brazil, owned by Portugal. The Dutch army took possession of Pernambuco and three other neighbor-provinces; in Pernambuco, the historical village of Olinda (by this time the capital of the province) was easily dominated, but Dutch military responsible soon realized that this village would be very hard to keep military, because of its topological irregular relief with many hills. Because of this, Dutch governor Waerdenburch decided to burn Olinda, and to move to a small village of fishermen at about 10 kilometers at the south.

Three aspects pleased the Dutch and made this specific village their final choice for establishing a fortified military nucleus: it was topologically regular, had a very good natural sea port and was situated at the estuary of two rivers, Capibaribe and Beberibe. Besides, the medium height of the village considering the sea level was negative in some regions, what made it very familiar to people coming from Holland, “the country stolen from the North Sea” (Gonsalves de Mello, 1978).

Count Mauricio de Nassau is an important character in this historical scenario: he arrives at Pernambuco in 1637, as a general governor sent by Dutch Western Indians Company. Once arrived, he decides to build a real town, his town, in the village occupied by the Dutch after the burning of Olinda. This town took the name of “Mauritisstadt” or “Stadt Mauritia”, the first Dutch name of the village of Recife, today capital of the state of Pernambuco. Among many important initiatives in economy and political administration, Count Maurício de Nassau was also interested in public education, since he believed that the Dutch domain over Brazilian lands could not be completely established without an educational effort addressed to Brazilian natives (and Portuguese descendents born in Brazil). Because of this point of view, Nassau founded the very first public school of Recife (by this time Mauritsstad), open to Dutch children (descendents of free Dutch citizens – “vrijeluijden”), Brazilian-Portuguese children, Brazilian natives (Brazilian indians – specially from the tribes Tapuia and Tupi) and even Brazilian-African black children, by this time slaves. A public day school was created, where Brazilian and Dutch boys could start learning from 5 years of age; in these schools they could learn Dutch language, religion, and handicraft works (“hantwerken”). During this first period of education, mathematics and science were not offered: Dutch authorities believed that a long period of preparation would be necessary before offering such school subjects; besides, they believed that only few students would be able to go ahead, facing mathematical and scientific learning. There are some historical evidences showing that mathematical and scientific knowledge were considered crucial to the Dutch military and political project for Mauritisstadt and the whole province. This approach
allows important Brazilian historians to consider that Maurício de Nassau founded "(...) the most modern and original cultural center not only in Brazil but also in the hole XVIIth century America (Gonsalves de Mello, op. cit.). The Dutch, nevertheless, had no time to test their political educational and strategically propositions in Pernambuco: in 1654, a Brazilian-Portuguese army has successfully taken Pernambuco back to Portuguese domain.

2. Learning environment for mathematics in school: from past to future

Dutch conquerors seemed to be the very first group in the history of Pernambuco to demonstrate a clear preoccupation towards education as civil right to be largely offered to all citizens (including native indians and black slaves - and not a privilege to be restricted to very few aristocrats and their descendents). They highlighted some other important aspects: 1. Efforts in order to offer an adequate curriculum at school; 2. Dialogue between school/formal knowledge and outside-school knowledge; 3. Place of mathematics and science in school curriculum (what mathematics to offer, and when). Today, 347 years later, these aspects are far from being implemented, particularly when we think about schooling in the context of a poor state (Pernambuco) in a so-called "emergent country" (Brazil). Important psychological aspects are connected to these questions, being good issues to a research agenda in psychology of mathematics education. These aspects are mentioned and discussed in two main sections below. Discussing them in this Dutch PME, nowadays, is an amazing task for a psychologist from former Mauritsstadt, today Recife (Pernambuco), with far family roots in the Dutch community that tried the Mauritsstad utopia in these tropical and luxuriously beautiful lands.

2.1. Conceptualization in mathematics

2.1.1. Mathematical concepts as models, instead of taxonomic categories.

- There are not "mathematical essences" (radical anti-Platonic perspective).
- There are not exemplary-concrete cases for mathematical concepts: mathematical concepts are metaphorical models.

According to G. Lakoff and R. Núñez, there is a strong "mythology" concerning conceptualization in mathematics, a kind of "romance of mathematics" (sic), according to which mathematics would be "abstract and disembodied" (yet it is certainly real), having "objective existence", providing "structure to the universe" and being "independent of and transcending the existence of human beings or any beings at all" (Lakoff & Núñez, 2000, pp. xv). We refuse this belief about mathematics, proposing, in accordance with these authors, that mathematics comes from us (human beings), instead of from heaven or the outer universe. Mathematics is definitely a human construction, not the way towards platonic-transcendent truths of the universe. By human construction we mean, quoting once more the authors above, not (...) a mere historically contingent social construction", but "(...) a product of the neural capacities of our brains, the nature of our bodies, our evolution, our
environment, and our long social and cultural history" (Lakoff & Núñez, op. cit., pp. 09; italics added). Two important conclusions emerge from this epistemological assumption: first, mathematical concepts are rooted in human bodily realities, as well as in socio-cultural activities; second, the learning of these concepts can not be limited to the experience of receiving axioms and developing (by direct imitation, perhaps) the "right" way of thinking (mathematical proof).

We agree with philosopher E. Cassirer propositions about conceptual development, specially when he stresses the role of modeling in concept formation and development (Cassirer, 1977). In fact, concepts in general are much more than descriptive, taxonomic categories based on common aspects, as proposed by many psychologists in the past (see, for example, the classic research work started by E. Heidbreder (1946), followed by Bruner, Goodnow & Austin (1956), and many other psychologists up to present days). This is especially true in the case of mathematical concepts; from a mathematical standpoint, mathematical concepts express functions; from a psychological perspective, they express relations issued from perceptual input and gathering. These relations are psychologically represented through symbolic tools like natural or formal language, in many degrees of combination. These combinations open the way to the didactically important psychological activity of metaphorization, as illustrated below:

$$60g = x + 20g \text{ then } 60g - 20g = x + 20g - 20g$$

(because of the metaphorical connection between the balance scale and the principle of equivalence in the treatment of algebraic equations).

$$40g = x$$

(then, the unknown weight is 40g, which is the final step of the algebraic algorithm).

Figure 1: The metaphorical connection between balance scales and algebra
(Reproduced from Da Rocha Falcão, 1995).

Symbolic representation is a key psychological aspect in the development of algebra and many other conceptual fields (Vergnaud, 1990) in mathematics because of two points: first, it is not a result or superstructure of operational structures, as proposed in the context of Piagetian theory (Piaget, 1970) but rather a constituent of concepts, with operational invariants and situational links that gives socially shared meaning to knowledge (Vygotsky, 1985); second, it opens to a particular individual a wide range of symbolic cultural tools that, as cultural amplifiers (Bruner, 1972), enables one to access new instances of conceptual construction. So, representations provide metaphors that can be useful as pedagogical tools; these metaphors help in amplifying pre-existing schemes, since they provide semantic links between structured knowledge and new pieces of information. In this process of enrichment of meaning, a quite important psychological sub-process is represented by the
explicitation of *theorems-in-action* (Vergnaud, op. cit.), upon which are established many practical competencies exercised in daily life. The proposal of the two-pan balance scale represents an effort of offering a metaphor of algebraic equivalence between equations, based in the conservation of a pre-established functional equality between each side of an equation. The construction of meaning for the equivalence of equations (essential aspect for the comprehension of algebraic algorithms) is initially connected to the familiar idea of *equilibrium*, in the context of a culturally familiar artifact, the balance-scale. This idea of equilibrium is frequently poorly explicited, although people can make a competent use of a two-pan balance scale in order to sell or buy fish in Brazilian popular markets; nevertheless, equilibrium as *theorem-in-action* is based upon *explicitable* principles. As a metaphor, the balance-scale offers a context of cultural functioning where complex mathematical concepts (algebraic equivalence and algorithmic manipulation) can be initially rooted in competencies and theorems-in-action, enriching pre-existing schemes. This last aspect, concerning the mobilization of competencies-in-action for conceptualization in mathematics, led us to the next point of this brief theoretical navigation.

2.1.2. **Concepts as schemes are not only limited to the language domain, but also cover competencies-in-action.**

- **Mathematical competence (as many other complex social competencies) cannot be restricted to the domain of language: language constitutes cognition, but cognition is larger than language.**

The theoretical position defended here tries to establish the relations between thought and language in the context of what we propose to call the *psychology of human gesture* (Vergnaud, 1998). The human gesture, in its functional richness, was once part of H. Wallon's theoretical contributions, who distinguished three levels of evolution development: the *automated* or *habitual* gesture, the *adaptative-motoric* gesture in interaction with the external ambient, and finally the *symbolic* gesture, connected to an objet not empirically present (Wallon & Lurçat, 1962). The gesture, as a theoretical subject in cognitive psychology, is directly connected to the notion of *scheme*, as defined by Gérard Vergnaud: it is a prototype of human cognitive activity, present in all periods of human development, from childhood to adult life (Vergnaud, op. cit.). As an organizing and organized structure based on schemes, the human gesture is characterized by the following aspects: a) a *goal*, eventually divided in secondary or sub-goals: a pre-linguistic 18 months old child can look for a small ball which has disappeared under a table, making bodily gestures with his/her head towards the direction he/she imagines the small ball is going to re-appear (the opposite side of the table under which the child saw the ball disappearing); b) an *ordered set of actions*: the same child in the example above will be able to organize his/her actions in order to achieve his/her main goal; c) *identification of material tools and empirical information*: in his/her efforts to recuperate the small ball, the same child will be able to take into account situational variations and constancy, like those concerning the speed of the ball, length of the table under which the ball moves,
calculations concerning the actions to be performed, information to be coordinated, controls to carry out: a gesture action, when performed many times with the same goal, can be reformulated in the course of the action itself, in order to take into account a certain degree of situational variation. In other words, the child is able to modulate his/her gesture actions in the context of a certain (and necessarily limited) spectrum of variations.

The previous considerations allow us to refine the definition of human gesture in terms of an invariant organization of behavior for a limited class of situations. It must be said that this same definition can be used to schemes in general and concepts in particular. Among human schemes, it is important to mention the competencies-in-action, like those shown by handicraft workers, but also some competencies of very high-level (in terms of their educational capital) workers (researchers, engineers, specialized technicians, and so on). These so-called competencies-in-action have two major characteristics: firstly, they are effective, in the sense that they are cultural tools for daily (and culturally situated) life; secondly, these competencies are very hard to express by any symbolic means (natural language, graphic representations, mathematical models, and so on). Taking these competencies into account in mathematical conceptualization implies in connecting school activity to other socio-cultural contexts, as discussed in the next section.

2.2. Learning mathematics as a cultural activity: interest of negotiations between teacher and students.

- **Didactic contract is a very effective variable in the process of teaching and learning of mathematics**

- **Argumentation (seen as the process of changing of opinion in an interlocutory context) is a key process in the learning of mathematics, but it is not the only effective (pedagogically speaking) process.**

Mathematical teaching and learning, as a specific cultural activity, is organized by certain consensual rules, most of them not explicitly expressed. These rules express previously established goals (both behavioral and attitudinal), giving rise to a didactic contract that guides social activity in the classroom (Schubauer-Leoni & Perret-Clermont, 1997). Examples of such rules are, for example, “a mathematical problem has always one (and only one) answer”, or “the teacher always knows the answers for mathematical problems”. There is a clear interest in the use of these rules as didactic variables (Brousseau, 1998), in a research context, since many psychological schemes can be addressed and amplified in the context of classroom activity. It seems to be possible, as shown by Da Rocha Falcão and colleagues, to propose certain activities by previous contract, even if these activities are completely discrepant concerning usual school habits and rules (Da Rocha Falcão et. al., 2000). These researchers were able to propose symbolic manipulation of literal symbols, in the context of algebraic sentences, to very young school children; the classroom contract that allowed this activity is illustrated below. The students were invited to compare two plastic boxes containing different and unknown quantities of small balls, these deposits being covered with paper in order not to allow visual inspection of the
quantity of balls inside them. Two students were invited to hold the deposits in front of the group; each of these two students was “marked” by an icon of a happy face (😊) for the one owning more balls, and a sad face (☹) for the other owning fewer balls (the icons were drawn in sheets of paper and put on the floor, in front of each student: see illustration on the left). It was then proposed to the students that we would represent the unknown quantity of balls by a letter (they suggested to adopt the first letter of the name of the student holding the plastic box). All the group of students was able to model a relationship using letters to represent the quantity of balls in each deposit: G > J as well as the passage to the equality considering the difference (if G > J, then \( G = J + D \) or \( J = G - D \), representing the unknown difference by the letter \( D \)).

When the protocols of the activity above were closely examined in terms of argumentative exchanges, we could realize the occurrence of three kinds of discursive actions, according to the analytical model proposed by S. Leitão (see Leitão, 2000): 1. Pragmatic actions, proposing situational conditions in order to allow argumentation; 2. Argumentative actions, i.e., speech turns addressing the negotiation of divergent points of view; 3. Epistemic actions, consisting of offering specific information about the topic in discussion. These three actions were not equally distributed in the didactic sequence proposed (Araújo et. al., 2001): there was an preponderance of epistemic actions, in the context of which the teacher offered information and tried to justify what he was proposing (allowing the students to ask questions and to express their doubts). These data show that even when we make special didactic efforts to propose a certain topic, there is not any guarantee that argumentative speech-actions will occur. On the other hand, even though we strongly believe in the role of argumentative actions in knowledge building, these specific speech actions are one among other possibilities in the context of discursive (and effective) pedagogical exchanges in the context of classroom.

3. Conclusions and final remarks

Research about conceptualization is seen here as central in a research agenda proposed by psychologists, in the interdisciplinary field of mathematics education. The psychological nature of mathematical concepts, the context of development and learning of them and the place of symbolical representation in concept building are important theoretical domains for psychological inquiry. For Dutch conquerors, in the XVIIth century, education in general, and scientific / mathematical education in particular, were crucial to build a modern society, based on free opinion, trade and religion. For us, psychological researchers in mathematical education from a “melting-pot” country like Brazil, these issues are crucial for us to survive inside mathematics education research community.

FROM "TEACHER RESEARCHERS" TO "STUDENT TEACHER RESEARCHERS" – DIAGNOSTICALLY ENRICHED DIDACTICS

Andrea Peter-Koop, University of Muenster, Germany

Being in the "age of adulthood", our professional responsibility also requires that we focus our attention and efforts more closely on the dichotomy between classroom teachers and researchers. This seems to be of crucial importance since numerous studies report that teachers often view research as having little relevance to their practice or specific classrooms. Therefore, inservice activities designed by educational researchers based on (their) research results frequently fail to "achieve a meeting of minds" as Alan Bell has phrased it in his previous paper. Furthermore, looking at the historical issues of "teachers as researchers" Dawn Brown (1997) stresses the fact that classroom research has traditionally been viewed as the domain of researchers and university lecturers and NOT as that of classroom teachers. Despite the acknowledgeable efforts of individuals, I think this view is still shared on both sides by many teachers and researchers.

I do not want to deny the importance of research from an "external" perspective, i.e. with respect to the psychological aspects of learning environments in school mathematics that Jorge Falcao has outlined and which clearly require the expertise of psychologists in order to document and analyse respective phenomena. On the other hand, teacher inquiry does not only foster the development of their own professional skills but can offer insights, i.e. on patterns of student interaction, while constructing mathematical meaning, based on long-term data that is hardly accessible by temporary visitors to the classroom, or even during clinical interviews. Therefore, their findings inform mathematics education research and curriculum development.

In the following I will argue as to why I think that teachers as researchers and especially student teachers as researchers should be given more attention with respect to teacher education in the future. But before I elaborate on this notion and our experiences with this approach, I briefly want to "look back" and highlight the achievements and contributions of PME members that inspired and guided the work with student teachers.

Teachers as researchers: The work of PME members

During the past 25 years an increasing number of single research reports, short orals and posters focussing on the challenges faced and insights gained by teachers research but also on its constraints have been presented and discussed and this panel presentation does not allow me to report all of them or even a selection. However, this work is well documented in the PME proceedings and therefore accessible to everybody interested in this facet of mathematics education research and development. Instead, for my "look back" at previous PME work I want to refer to the treatment of this topic over a period of time in a collaborative setting.
Between 1988 and 1996 a group of PME members continuously worked on and in the context of teachers as researchers. A discussion group initiated by Stephen Lerman and Rosalinde Scott-Hodgetts transformed into a working group in 1990 as interest grew and membership stabilised. Over the years, the participants of the working group explored the dialectical relationship between teaching and classroom research in the belief that mathematics teachers can and should carry out research in their classrooms. In 1997 their work resulted in the publication of a book titled „Developing practice: Teachers’ inquiry and educational change“ which was edited by Vicky Zack, Judy Mousley and Chris Breen. The 18 chapters of the various authors working in different cultural settings document quite clearly that the teacher as researcher approach has led to an impetus and encouragement for teachers to actively participate in educational inquiry, its increasing integration in inservice training programs, and the need for collaboration among teacher-researchers themselves and with university-based-researchers and administrators. These trends with respect to mathematics teacher professional development are also reflected in two other publications that have resulted from PME working groups focussing on teacher professional development in the last decade – however these books do not primarily focus on teacher-researchers:

- “Working towards a common goal: Collaborative paths in mathematics teacher education” (Peter-Koop, Begg, Breen & Santos-Wagner, forthcoming)

In addition, the chapters in a book on teachers’ inquiry (Zack et al.1997) highlight a number of important questions and desires which characterise and determine teacher research and which are also relevant for the notion of student teacher research.

The difference between teacher research and teacher experience

A frequently raised question is concerned with the difference between teacher research and experience, since (most) teachers carefully plan units and individual lessons, implement these plans, observe and reflect on results and consequently adapt their preparations and actions accordingly. In this context, Mousley (1997, 2) understands research in a similar way to algebraic expressions which have been generalised from particular situations:

I believe that research transcends the limitations of experience, in that what is learned from experience is abstracted and articulated to the extent that it can be applied in new areas (i.e. elsewhere in time or place or content etc.) ... Teacher inquiry also transcends experience in that it involves more than making space in our lives for alternative practices: it entails the construction of a new level of thought.

Reflection seems to play a crucial part in the research process which clearly differs from reflective processes involved in experience. Kemnis (1985) stresses the political dimension of reflection in teacher research, pointing out that it goes beyond inward
looking and arguing that it has meaning in relation to historically embedded contexts – thus it stimulates social change as well as personal change. Another difference between individual experience and research is concerned with the need for reporting the design, methodological approaches and outcomes of research. Student teachers who under the supervision of an university researcher engage in classroom research as part of their initial teacher training program, at the same time learn how to reflect and report their findings in an academic manner.

The chapters by Eileen Philipps and Vicki Zack clearly demonstrate the benefits of teacher inquiry for the teacher professionalisation process. Phillips (1997, 16) in this context uses the metaphor “to make the transition from searching to researching” while Zack (1997, 181) characterises researching from the inside as “generative and transformative”. With respect to introducing student-teachers to classroom research that could mean that one can plant a long-term seed towards teachers’ own research which can foster and sustain improvements in mathematics teaching and learning. However, both Philipp’s and Zack’s chapters also stress the enormous challenges and commitments that the engagement in teacher research puts on an already demanding profession – “one is speaking of two jobs” (Zack 1997, 187).

The need for different levels of support for teacher-researchers

Support and acknowledgement from university-based colleagues as well as school administrators are therefore crucial factors. Valero, Gómez and Perry (1997) in their chapter recognise that administrators need to be involved in school-based research in two ways – to contribute their expertise and to provide the necessary support for the teachers. However, Barbara Jaworski (1997, 178) furthermore raises an important question: “In what ways can the development of teaching through teacher research be a concept originating with and driven by teachers themselves?” Chris Breen (1997) obviously shares a similar concern with respect to teachers who want to focus on their classroom as part of postgraduate studies and stresses their vulnerability which leads them to engage in research projects which they originally would not have chosen themselves. Student teacher researchers therefore should be encouraged to develop their own research questions as they grow professionally. The experience of collaborative relationships with peers might help to assist with the development of further research questions and the implementation and reporting of this research.

Student teachers as researchers

The involvement of student teachers as ‘teacher researchers’ concurs with the idea of developing a community of practice (Lave & Wenger 1991) in which they can experience how scientific analyses can help enlighten them to those aspects of classroom practice, professional skills and knowledge that they personally perceive as important (Jungwirth et al. 2001). In the context of a pre-service education system, student teachers can benefit in a similar way to classroom teachers. The Austrian/German mathematics education researchers Jungwirth, Steinbring, Voigt and
Wollring (2001) for example have shown this with respect to the 'interpretative classroom research' approach. They found that interpretative studies carried out by teacher researchers can help to reveal what is hidden in practice and what one has to understand in order to learn how to teach effectively and/or to change mathematics teaching. Respectively, Krainer (1998, 7) notes a current international trend in teacher education:

There are more and more international reports about involving (prospective or practising) mathematics teachers in research projects and integrating research components in teacher education courses where reflection and networking are important dimensions.

The participation of student teachers1 in qualitative mathematics education research projects has become increasingly popular in several German universities. The current trend towards the integration of student teachers in qualitative research projects from the perspective of the responsible university lecturers has the following reasons:

While the student teachers are usually concerned with one sub-question within the research project, they also become familiar with the global research interest, methodological considerations and the analysis of a substantial part of the data because they work in co-operation with fellow student teachers who are also involved in the study. They have the opportunity to draw their own conclusions and consequences with respect to research results obtained from their own and their fellow students' involvement. Therefore they are not solely dependent on research findings described in the literature and/or lectures.

They become sensitive to empirical findings and the respective research designs. Furthermore, they frequently experience how difficult it is to translate a supposedly rather simple empirical question into an appropriate research design, how many specifications are comprised in such a design and how differentially a respective finding has to be assessed.

It is also expected that the active involvement in a didactical research project will help them not only to develop a rather 'imperative' perspective with respect to mathematics education in the sense of learning how to teach (best) but also in addition a 'diagnostical' perspective. This means that the students should learn what to expect in certain teaching and learning environments in order to adjust their instruction and individual student support accordingly.

This approach which is referred to as 'diagnostically enriched didactics' corresponds with recent developments with respect to the improvement of mathematics teaching and learning at the school level. Reform-oriented curriculum documents which follow a constructivist framework describe desirable teaching and learning environments in the mathematics classroom as open towards a variety of different ways to solve a set

---

1 The student teachers usually use the results of their interpretative analyses as a basis for their first teacher state exam thesis which clearly has a scientific character and which together with written and oral exams concludes the university teacher based training program.
goal (a specific task or problem etc.), supportive of the different individual approaches and strategies, and communicative with respect to the discussion of individual approaches and results in order to reflect on sensible and necessary standardisations in mathematics.

In order to be able to manage the variety of different approaches chosen and explored by the pupils, the teacher has to be able to assess how each of these approaches can contribute to and influence the joint discussion. Therefore he/she will need diagnostic abilities on the basis of mathematical subject knowledge as well as knowledge about the social-interactive dimension of mathematics learning. Furthermore, it is a highly desirable aim of teacher education programs to enable prospective teachers to realise and understand the ‘universal in the special case’ and to approach the special case in a diagnostic way. Such a diagnostic approach is required in the daily practice of classroom teachers. This explains why classroom oriented research (and especially projects that include student teachers as qualitative researchers) should not solely focus on ‘typical’ effects in the sense of frequent classroom occurrence but also reflect on significant however less frequent cases. These cases and not so much the rather common and widespread ones present crucial challenges for teachers.

**Interpretative classroom research**

Most of the current German mathematics education research projects that involve student teachers are based on the 'interpretative research paradigm'. This methodological approach was developed by Heinrich Bauersfeld and his colleagues (1988). Interpretative classroom research seeks to investigate typical structures by analysing single cases which are regarded as exemplary. Their focus is the ‘universal in the special case’ and the goal of the interpretation is to comprehensively perceive and understand the (inter)actions of the observed individuals.

The significance of the interpretative research paradigm is related to an international change from content-based and individual-psychological approaches towards interpersonal human relations in (mathematics) education in the past decade. Current theoretically based research contributions increasingly stress the social dimension of both mathematics (Davis & Hersh 1981) and mathematics learning (Steffe et al. 1996) for the development and extension of mathematical knowledge.

The data collection and interpretation phases of studies employing the interpretative classroom approach usually follow a strict procedure consisting of four stages:

1. video recordings
2. comprehensive transcriptions of the video recordings with respect to either the full document or selected segments of the recording that are relevant to a respective research question(s)
3. the *sequential interpretation* of the data by an ‘interpretation team’ of four or five individuals (student teachers, teachers, teacher researcher)
4. the specific interpretation of the results on the basis of relevant literature and research findings by an individual student teacher researcher.

Interim findings with respect to student teachers’ learning processes

According to the experiences of the author and fellow German colleagues, the student teachers’ perception of the observed ‘classroom research reality’ demonstrates several phases (Wollring 1994). Immediately after the recording the participating students seem to underrate the richness of the pupils’ contributions while they tend to overrate their own moderation and instructional abilities. Quite frequently they express their initial disappointment with the quality of the data collection and question the suitability of the data sample for in-depth-analysis. During the first viewings of the video document however these perceptions start to change and the performance of the children involved in the study appears to be richer than first envisaged. This impression often continuously increases during the transcription process when suddenly very informative and highly differentiated perspectives on the observed classroom episode arise. The following interpretative analyses frequently lead to the identification of further ‘deeper’ i.e. more differentiated/specialised research questions.

The value of the participation of the student teachers as ‘teacher-researchers’ in a current study on third and fourth graders’ co-operative problem solving strategies (Peter-Koop) as well as in Wollring’s (1994) study on kindergarten and elementary school children’s understanding of probability is reflected in the self-evaluation of their work. An evaluation questionnaire that was given to the student teachers after the completion of their sub-project addressed the following aspects:

- individual motivation for their involvement in this interpretative project
- their learning about the underlying mathematical topic
- their experiences with co-operative learning during group work
- their dealing with the technical requirements of the study
- their experiences with the preparation of transcripts and data interpretation
- the benefits and difficulties of peer co-operation during the interpretation process
- their reflection on pupils’ learning and their individual teacher behaviour.

Conclusions

In summary, the analyses of the student teachers’ retrospective responses to the evaluation questionnaire suggest that the benefits of the interpretative classroom approach with respect to teacher preparation can be seen on three different levels, which of course may partly overlap:

The student teachers learn about an important aspect of elementary mathematics. However, one can argue that other learning environments within teacher education courses also facilitate learning about mathematical ‘content knowledge’ as well as
‘pedagogical content knowledge’. Their statements demonstrate that the student teachers learn to ‘listen’ to pupils with respect to their thinking and – in Peter-Koop’s current study – their collaborative problem solving strategies.

All student teachers who participated to date indicated that they appreciate their involvement, because it provides them with opportunities for intense observation of children and children’s learning. They deal with and reflect on real examples of pupils’ behaviour, learning, interaction etc., which are believed to be more powerful than examples created by the lecturer (Jungwirth et al. 2001).

Finally, research designs that are based on the interpretative approach can enable the involved student teachers to learn about themselves as teachers. During the interpretation stages most student teachers used the opportunity to critically reflect on their individual classroom behaviour, interaction and instruction skills that became evident during their assistance of the pupils’ group work. One student teacher’s conclusion, which is representative for the majority of the replies, highlights the importance of active involvement and the opportunity for personal reflection of one’s actions for the individual student teacher:

*In my opinion interpretative analyses are an important addition to lectures and school practicals. But you have to conduct the teaching yourself, be responsible for the transcription and actively involved in the interpretation of your transcript. Only then you can find out how well you can relate to children, learn about your mistakes and how children react to you.*

Acknowledgement

The substantial contribution of Bernd Wollring during our discussions on the development of the idea of student teachers as researchers with respect to diagnostically enriched didactics is most gratefully acknowledged.

A consumer's point of view
Fred Goffree

1 What are we aiming for exactly?
There have been twenty-five PMEs since the forming of the study group in 1976
(Karlsruhe) and the first meeting in Utrecht. Were the initial expectations too high?
Probably, although I can’t produce any figures from the PME 1977 proceedings that
would prove the validity of this assumption – they could not be found anywhere.
What no one certainly would have expected was the tremendous growth of the PME
community in those 25 years. The proceedings from Osnabrück 1978 (a very modest
brochure) to Hiroshima 2000 (a four-part, wonderfully finished volume) all bear
witness to that. As a comparative PME outsider, I had to make do with the
proceedings. Arranged next to each other in the FI bookcase, they take up almost a
metre of shelf space, so I needed seven-league boots to get through them.
Fortunately, to provide an answer to the question ‘what are we aiming for exactly?’, I
had already chosen a context, a domain, a position, a perspective and a viewing
direction:

<table>
<thead>
<tr>
<th>Context</th>

<td>Active consumer of research (processes and outcomes)</td>
</tr>
<tr>
<td>Perspective</td>
<td>Can the education of primary teachers gain more from PME research?</td>
</tr>
<tr>
<td>Viewing direction</td>
<td>Where theory and practice come together</td>
</tr>
</tbody>
</table>

To run ahead of my findings, I can say right away that there are indeed prospects, but
only on condition that researchers opt more frequently for developmental research as
defined by Hans Freudenthal and as conducted in the institute bearing his name.
Besides that, other methods of reporting need to be learned, maybe using IT potential.

2 Background
It is obvious that the above did not appear just like that; as is the case with every
researcher, my personal history did enter into it. Although researchers have the
tendency to side-step personal issues in their work, I would like to say something on
that score.
After ten years of designing maths lessons whilst working as a teacher educator with
student teachers at a Teacher Training College in the Netherlands, round about 1968,
I joined the CMLW, the predecessor of IOWO (Institute for the Development of
Mathematics Education) that later became the Freudenthal Institute. The ten IOWO
years were dominated by the Wiskobas (mathematics in primary schools) project,
which modernised mathematics education in the Netherlands. The working methods
of developmental research flourished in the Wiskobas team: idea, design, debate, tryout, reflection, discussion, revision, etc. Practice and theory converged in this developmental research and, in addition to that, new theories were framed. As Freudenthal used to say, 'like sparks flying off real work', or, as Leen Streefland later put it: 'The development of a researcher is the source of theory formation.'

I was one of the two members of the Wiskobas team who were mainly interested in the effects the developmental research activities had on teacher education and I learned to see educational research work from the teacher education perspective. Not only were practical results and theoretical conclusions of interest, so was the cycle of designing and research in the classroom. Piaget's method of clinical interviews with children was adopted and modified to Freudenthal's method, which had become known from publications as 'Walks with Bastiaan'. In those day, instead of teaching the 'class as a whole', student teachers conducted conversations with small groups of children about mathematical tasks or phenomena from daily life which they attempted to link to mathematics with the children.

After the IOWO had closed, on 1 January 1981, I wrote a 3-volume course book for student teachers, 'Mathematics & Didactics', a reflection on my 10 years of research and development work. The book included admirable designs, discussions of theory in the team, practical experience with it in class, comments made by pupils, to name a few. That way, students were invited to experience for themselves the Wiskobas routine - linking theory and practice, the recurring bottleneck in this corner of the scientific community, as a matter of course.

Midway through the 1990s, the work done by Lampert and Bell in Michigan (1998) offered a new stimulus to research and development work on teacher education in the Netherlands, resulting in the Mile project. Wil Oonk will be telling us more about this project in his presentation.

3 The (pre-service) education of primary mathematics teachers.
The first conference of a new European research community (in formation) was held in 1999, in Osnabrück: European Research in Mathematics Education. Working Group No. 3 was engaged in research work on mathematics teacher education. (Krainer, Goffree and Berger, 1999). There we distinguished between:
1. Research in the perspective of teacher education (the researcher does not have teacher education in mind).
2. Research in the context of teacher education (the researcher is a teacher educator, a teacher or a student teacher).
3. Research in teacher education (teacher education is itself the object of research).

Keeping my five special points of interest in mind, I glance through the list of proceedings of 24 PMEs.
Most hits fall under category 1. My attention was drawn to the paper by Bednar and Janvier (Bernadette), which they presented in Warwick (1979): ‘The understanding of place value’. In my view, the points that receive special attention in this paper are of relevance to student teachers and the way the research is presented and written certainly has student teachers in mind. I would mention the following:

- The mathematical beginning: clarify the notion of place value (content knowledge, according to Shulman 1986).
- Next, a didactical follow-up: what is meant by ‘understanding place value’ (pedagogical content knowledge).
- Apply this knowledge to design a series of problems:
  - for diagnostic testing;
  - for learning units.
- Single out the main difficulties and strategies of the children.

What is it about this research that makes it so appropriate from the teacher education perspective?. It takes as its point of departure the student teacher’s own level of proficiency (what is place value?). The topic (understanding) is then ‘didactised’. Following that, the ‘theory’ is applied to the design of teaching after which focused tests are done with children. The long and the short of it is that previously acquired (theoretical) knowledge is applied both for the benefit of practice and in the practical situation itself.

Whilst saying this, I could also cite Alan Bell, who also ventured into this field at the PME in Berkeley a year later: ‘Designing teaching in the light of research on understanding’. So this is about theoretical knowledge that has been produced in research done by ‘others’, and can be regarded as a continuation of what Bednar and Janvier proposed.

In the 1997 proceedings my attention is also attracted by several papers related to the use made of ‘clinical interviews’ in the spirit of Piaget and Freudenthal ("Some reflections on the construction of the idea of number in 6-year-olds", "How does reflective thinking develop?", "A child’s eye view of learning mathematics. Has Piaget found it?").

4 A philosophy of primary mathematics teacher education
The way in which I have picked out the best bits of PME research in the examples I have given above has a lot to do with my outlook on teacher education. As I mentioned before, I wrote a course (work)book for student teachers based on my experiences as member of the Wiskobas team (1971-1981). That was why in the early 1980s I was frequently on the look-out for useful material in research and development work. Material I then found suitable was material that illustrated, as it were, my vision of training, which itself was still in the making. Now, a good many years, development projects and investigations later, I am able to enumerate the building blocks that constitute my perception. Together, they form the underlying
criteria for picking out the best bits, far more so than the 5 limitations I referred to previously. In connection with this, I would like to bring them to the fore to use them as an impetus towards the wishes I want to give to PME.

- As a school subject, mathematics provides excellent working material for prospective primary school teachers. (PML 1998)
- Where possible, practical situations form a starting point in teacher education.
- Elementary school practice is not solely represented by what crops up during fieldwork. Digitised teaching episodes (real teaching and real TV) make the study of practice possible. (Goffree & Oonk, 2001a & b)
- Student teachers 'construct' practical knowledge through the investigation of real teaching practice. (Lampert & Ball 1998; Oonk 1997)
- 'Practical knowledge is what 'moves' the teacher. It is a way of narrative knowing'. (Gudmundsdottir 1995)
- Theory becomes integrated in practice (situations) by following Donald Schön's 'reflective conversations'. (Schön 1983)

The latter especially is of vital importance because teacher educators can demonstrate their expertise in the form of 'theory in action'.

_I hope therefore that the work done by researchers will yield multiple practice situations complete with theoretical reflections by the researchers themselves. The researcher could, in his reflections, also include his own development and the onset of theory formulation._

The PME 1985 proceedings again caught my eye. It was one of the two meetings I attended in person. Richard Lesh presented his 'idea analysis', which had been worked out two years earlier in the book (Lesh and Landau 1983) that made a profound impression on me. How do mathematical concepts come about, from intuitive notions to formal mathematics, the influence of education and environment, and so on. Food for the reflective practitioners among the teacher educators, was my first thought.

5 Narrative knowing

Practical knowledge is therefore to a considerable extent made up of practical episodes. I had also collected a wide selection of episodes of my own when I wrote my Mathematics & Didactics. Those are written episodes about education in the classroom, with pupils and a teacher. (Among the favourites were John Holt, Herbert Ginsburg, Erlwängler). Later on, the filmed episodes from Mile were added, which the student teachers are actually required to use for making up their own episodes.

At the time, I opted for a very short episode that Alan Bishop showed me whilst we were working together in BACOMET on the chapter 'Classroom organisation and dynamics'. (Christiansen, Howson and Otte 1986). You can find it in the 1985 PME
proceedings. I cite the episode and a possible reflective conversation. The background to this is the question to what extent PME research can contribute to realising such episodes + theories, which contain relevant practical knowledge (prospective) teachers have. (Harvey et al. 1982, p.28).

<td>Oh, so you’ve got three lots of 5 minutes makes a quarter of an hour.</td>
</tr>
<tr>
<td>D</td>
<td>Yes. No. Yes, yes, yes.</td>
</tr>
</tbody>
</table>

A reflective conversation with the situation
Here, ‘David’ is the situation and in his reflective conversation, the educator can approach this from three different angles, thinking out aloud.

“Starting from the structure of pedagogical content knowledge:
It is possible to envisage ‘models’ between the intuitive notions of children and formal mathematics, which make connecting the two easier. These models are sometimes given in the book or provided by the teacher (just think of…), but sometimes the children think up models themselves. That is what David does, he links the dial of a clock to fractions. This is not really that extraordinary, several educationalists did the same thing with fraction circles, except that, in principle, they did not include the ready-made 12x5 minute structure. A lucky thing for David that
you can divide the number 12 (the dial) up in so many ways. Just think how many fractions are possible using it. (...)  

But there is more than that. We can learn something from the teacher as well. He attempted to project himself into the role of pupil, on the basis of his own knowledge of fractions (educational content and teaching method). That didn’t go very well. We can understand how and as a result of what he was set on the wrong track. But take care, he did not proceed on the assumption that David was talking nonsense. An important didactic principle: Do not presume that a pupil just says things off the top of his head. He has thought it through, although it might be completely wrong. (...)  

Imagining the thought process pupils go through is vital in arithmetic and mathematics and indispensable in interactive lessons and discussing solutions afterwards.”

6 As a conclusion  
Here, I was adopting the teacher educator position and that of a consumer of educational research. I take an eclectic stance as I draw what I want from the rich source that can be used. My wish to create practice situations and to couple them to a (descriptive, explanatory or creative) theory so as to enable student teachers to acquire (construct) adequate knowledge of practice, calls for research to be done on the shop floor of mathematics teaching. The researcher, who, with regard to teacher education, is customer-oriented, allows none of the data to go to waste and he also keeps his own reflective notes and thoughts on his personal development during the research work. Video and audio recordings can be made (using information technology), anecdotes, remarks made by pupils, their written work, teachers’ logbooks, tests and marks, and any other things that make mathematical classrooms a rich fund of learning for children and their future teachers.

My wish is that future PME research be conducted and reported in large part in the way outlined above, from the perspective of teacher education.

"POLDER MATHEMATICS"

MATHEMATICS EDUCATION IN THE NETHERLANDS

Koeno Gravemeijer & Martin Kindt
Freudenthal Institute, Utrecht University

Sheltered behind its dikes, the Netherlands more or less escaped the New-Math wave that swept the world in the 1960's. Inspired by Freudenthal, the Netherlands developed its own brand of mathematics education, currently known as realistic mathematics education (RME). His adagio of “mathematics as a human activity” was worked out by members of the Freudenthal Institute and its predecessors, IOWO, and OW&OC. New ideas have taken shape in prototypes of instructional sequences that are construed in developmental research (or design research). Teacher enhancement materials, tests, and background publications accompany these prototypical sequences. These materials form a source for textbook authors, teacher trainers, and school councillors and test developers. Mediated by this group, the new ideas have found their way to the instructional practice in schools.

In our presentation we will try to give an overview of what is going on in mathematics education in Dutch schools. We will use the innovation of mathematics education as pursued by the Freudenthal Institute as a background. In doing so, we will start by elaborating Freudenthal’s idea of mathematics as a human activity. Subsequently we will describe the Dutch school system and the curricular innovations that lead to the current curriculum. Next we will look at the use of context problems, followed by examples of the reinvention approach in Dutch textbooks. Next, will look at the role of technology, and we will close with a discussion of the Dutch approach to geometry.

Mathematics as a human activity
Freudenthal was an outspoken opponent of the ‘new mathematics’ of the 1960s that took its starting point in a one-side structuralistic interpretation of the attainments of modern mathematics, especially set theory. Since the applicability of mathematics was also often problematic, he concluded that mathematics had to be taught in order to be useful. He observed that this could not be accomplished by simply teaching a ‘useful mathematics’; that would inevitably result in a kind of mathematics that was useful only in a limited set of contexts. However, he also rejected the alternative: ‘If this means teaching pure mathematics and afterwards showing how to apply it, I’m afraid we shall be no better off. I think this is just the wrong order’ (Freudenthal 1968: 5). Instead, mathematics should be taught as mathematizing, and this view of the task of school mathematics was not only motivated by its importance for usefulness. For Freudenthal mathematics was first and foremost an activity. As a research mathematician, doing mathematics
was more important to Freudenthal than mathematics as a ready-made product. In his view, the same should hold true for mathematics education: mathematics education was a process of doing mathematics that led to a result, mathematics-as-a-product. In traditional mathematics education the result of the mathematical activities of others was taken as a starting point for instruction. Freudenthal (1973) characterized this as an anti-didactical inversion. Things were upside down if one started by teaching the result of an activity rather than by teaching the activity itself.

**History & school system**

We will discuss some of the history of the many innovations in mathematics education in the Netherlands to offer some background for a sketch the mathematics curriculum in the Dutch schools. We will start out with the first projects of the IOWO, the Wiskobas project that aimed at primary school and Wiskivon that aimed at lower secondary. While changes in the primary-school curriculum were the result of a cumulative effect of a long-term process of gradual changes, the government usually mandated the changes in secondary education. In the former case, there was an indirect influence by the Wiskobas project and its successors. In the latter case, the government systematically gave our institute the responsibility of developing (prototypes of) new curricula—as was the case with the Hewet project and the Hawex project (both upper secondary), the project W12-16 (for the age group 12-16; together with the National Institute for Curriculum Development, SLO), and the recent Profi project (new curriculum for the ‘exact’ stream in upper secondary education). Current projects involve goals and learning route for primary school, special education, lower secondary and vocational training.

**What is “realistic”?**

In RME context problems play a role from the start onwards. Here they are defined as problems of which the problem situation is experientially real to the student. Under this definition, a pure mathematical problem can be a context problem too. Provided that the mathematics involved offers a context, that is to say, is experientially real for the student. In RME, the point of departure is that context problems can function as anchoring points for the reinvention of mathematics by the students themselves.

**Reinvention**

Freudenthal proposed ‘guided reinvention’ as an alternative for the ‘anti-didactical inversion’. Moreover, guided reinvention offers a way out of the generally perceived dilemma of how to bridge the gap between informal knowledge and formal mathematics. This principle is elaborated in many instructional sequences. As an example of the reinvention of an algorithm in primary school, we will discuss the reinvention of the long division. Further we will describe how reinvention plays out in some topics in algebra.
Text books
Most curricular changes in secondary school are based on government decisions. Usually the Freudenthal Institute would be asked to develop new curricula. The government then would mandate these new curricula, and textbook authors would use the prototypical materials that were developed to ground the new curriculum as the basis for the new textbook series. In primary school the influence was more indirect, here inspiring results of developmental research would find their way to textbooks via (journal) publications, conferences and personal contacts. In both cases, differences are to be expected between the original intent of the researchers and the actual textbooks, and their use.

Technology
The role of technology in mathematics education is growing that also holds for the Netherlands. We will show some examples of software that is used in primary and secondary education. This will include the use of web-based applets. In addition to this we will special attention to the use of graphic calculators. These are integrated in the Dutch curriculum; moreover, the use of graphic calculators is an integral part of the final exams.

Geometry
Geometry in the Dutch curriculum can be type-casted as “vision geometry”. The informal experiential knowledge that students have is taken as a starting point for geometry instruction. We will present some examples of vision geometry from primary- and secondary-school textbooks. Further we will discuss how geometry is used in the new Profi-curriculum to foster the students’ experience with proving.

POTENTIAL AND PITFALLS OF TECHNOLOGICAL TOOLS IN LEARNING MATHEMATICS: INTRODUCTORY REMARKS

Research Forum Coordinators: Carolyn Kieran and Rina Hershkowitz

For the past two decades, various computer and calculator technologies have been making their way into the teaching and learning of school mathematics. Much of the theoretical and empirical research that has been carried out with these new environments has tended to look for the value-added component provided by the technology. However, there are research works that show that this value-added component is not easily achieved and that, in certain contexts, the use of technology may block learning processes such as problem solving, justifying, and so on. The aim of this research forum is to present a balanced picture of the role being played by technology in the teaching of mathematics, while considering, in particular, the issue of the potential and pitfalls of technological tools in learning mathematics. Two main papers and two related commentaries discuss this issue from various perspectives and approaches.

In many respects, the two main papers are quite different. One is a meta-study drawn from a corpus of 662 research papers and is led by the goal "of building tools for understanding" the integration of technological tools in the classrooms. The other is a case study investigating a special situation of such integration in a particular classroom and is led by the goal of better understanding the cognitive and contextual aspects in such a situation of mathematical learning.

Nevertheless, as is expressed in the commentary papers, there are several threads that tie the contributions together. Both of the main papers are aware and even fascinated by the potential of the technological tools in learning mathematics but argue that this potential has to be investigated deeply and massively in order to be able to use them properly. Both differentiate between the potential of the tool itself and the mental structure that is built by the learner with the mediation of the tool. The meta-study paper emphasizes that "the instrumental dimension of the IC Technologies distinguishes a technological artefact and the instrument that a human being is able to build from this artefact." The case study paper follows the ways in which students produce and use, or try to use, technological artefacts (the representatives) in order to construct mathematical meaning while investigating a problem situation.

Finally, the authors of both papers and both commentaries believe that, without understanding the ways in which technological artefacts mediate the construction of the learner's mental structures, our considerations and decisions about technology-based mathematics learning might be ill-founded, and potentials might become pitfalls.
ALGORITHMIC AND MEANINGFUL WAYS OF JOINING TOGETHER REPRESENTATIVES WITHIN THE SAME MATHEMATICAL ACTIVITY: AN EXPERIENCE WITH GRAPHING CALCULATORS

Rina Hershkowitz
Carolyn Kieran
Weizmann Institute of Science Université du Québec à Montréal

In designing mathematics learning with the mediation of computerized tools, one of the crucial questions to be considered is how much and in what way we would like the tool «to do the work» for the students. In problem situations where the solution is achieved mostly via graphical representatives, and algebraic models are mostly used as «keys» for obtaining graphical representatives on the screen, the algebraic representatives and their form seem minimized in importance, and students may tend to generate them from tables by mechanistic-algorithmic procedures. The above questions will be mainly demonstrated within the description and analysis of a case study involving a group of three 10th graders (about 16 years of age) working together to investigate and solve a problem situation on the topic of functions, having graphing calculators (TI-83 Plus) at their disposal. The role of contextual factors is highlighted by means of contrasts with the work of students on the same problem from another country.

Introduction

In designing as well as in studying a classroom learning activity in a computerized mathematics learning environment, one should consider contextual factors of various origins, like: (a) the mathematical content to be learned and its epistemological structure; (b) the learners, their mathematical knowledge, culture, and the history with which they started the researched activity; (c) the classroom culture and norms, the role of the teacher, the learning organization—in small groups or individually—etc.; and (d) the potential «contribution» of the computerized tool.

This study discusses questions related to the above factors and how they lead students to use a computerized tool and benefit from it mathematically or the opposite. The questions will be mainly demonstrated within the description and analysis of a case study involving a group of three 10th graders working together to investigate and solve a problem situation on the topic of functions, having graphing calculators (TI-83 Plus) at their disposal. The protocol analysis of the group work will reveal a dialectical problem-solving process that develops between two ways of making use of the computerized tool: a mechanistic-algorithmic one and another one that is led by students’ search for meaning.

Contrasting the work of the group against the work of groups in a classroom from a different country will shed some light on the roles of the above contextual factors in students’ making beneficial use of the computerized tool.

Some Theoretical Comments

During the past 20 years or so, the potential of computerized tools to develop and support mathematization by students working on problem situations has disclosed many positive aspects of their integration into school curricula. This can take the
form of amplification and reorganization (Pea, 1985; Dörfler, 1993) and of experiencing new "mathematical realism" (Balacheff & Kaput, 1996). A common claim is that the computerized tools can play an advantageous role in assisting students to make connections between and within various representations of the same mathematical entity (e.g., Kaput, 1992). Teasley and Roschelle (1995) have documented instances of computer environments serving to disambiguate student thinking in the exploration of novel mathematical phenomena, by easy flexible transformations between representations. The power of a grapher to smoothly transform a function from its algebraic to its graphical representation, and the availability of the corresponding numerical data directly from the graph (by "walking on it"), make it possible to deal with problem situations involving complicated functions at an early stage of learning.

However, students have also been found to use technological tools in non-thinking and non-productive ways. Goldenberg (1988) has, for instance, warned of the ways in which students can misinterpret computer-based graphical representations of functions because they have not chosen an appropriate window; while Guin and Trouche (1998/1999) have argued that a surprising result produced by a graphing calculator does not necessarily induce a question on the part of students.

Looking closer at the interaction that learners have with a computerized tool in the classroom, one should take into account the epistemological power of the technology (Balacheff & Kaput, 1996), for example, the ways in which this power emerges from the multi-representational nature of the tool, the availability of different representations and different representatives of the same mathematical object (i.e., displays within the representations, Schwarz & Dreyfus, 1995), and the smooth transformation between them. Schwarz and Hershkowitz (in press) investigated how representatives can mediate the construction of meaning in mathematics learning. They claimed that from an epistemological point of view the relations between the mathematical entity and its representatives are inherently ambiguous. Representatives either may represent mainly the most prototypical examples of the mathematical entity or, because they are partial, may often be ambiguous in the sense that only some of the critical properties of the entity are displayed in the representative.

The ambiguity and the power of the computerized tool encourage the production of various representatives upon need, and also stimulate students' requirement for and ability with interweaving representatives together. In so doing, students may extract the invariant properties of the mathematical entity and thus overcome the ambiguity within the single representative. This process is part of the students' search for mathematical meaning. On the other hand, technological environments can induce students to reach «false representatives» (those that do not represent the critical properties of the mathematical entity at all) or to interweave representatives together in a non-meaningful, algorithmic fashion, as for example in the automatic extending of the numerical values of a spreadsheet column (Ponte & Carreira, 1992).
In this paper, we discuss two ways in which students interweave together the tool-based representatives: a mechanistic-algorithmic way (where students combine representatives in non-thinking, rote ways), and a meaningful way. Moreover, we tell the story of the use of two kinds of representatives in the process of problem solving: representatives that do not represent the properties of the mathematical objects involved at all, and representatives that do.

The Study

The case study involves three 10th graders from a Montreal high school working together to investigate and solve a mathematical problem situation, having graphing calculators (TI-83 Plus) at their disposal. The analysis of their activity is described in four rounds. On the whole, the investigative activity done by this group and their solution strategies are monitored by their need for a search for meaning. But, in Rounds 1 and 2, the process of "joining together tool-based representatives," which the students engage in, is mostly of the first kind, the mechanistic-algorithmic, which leads students towards some «false representatives.» Rounds 3 and 4 provide evidence of a different way of joining together representatives, one that is clearly characterized by a search for meaning. The progress of the group from Rounds 1 and 2 into Rounds 3 and 4 is led by critical thinking and is supported by the students' control of the "joining-together-representatives" functions, which are part of the strength of the graphing calculator.

The problem situation and some comments about its history

The following are the parts of the problem situation that are relevant to this paper.

Growing Rectangles

*Each of the following three families of rectangles has its growth pattern:*

![Diagram of Growing Rectangles](image)
In family A the width grows each year by one unit; the length remains constant at 8 units. In B the width and the length of the rectangle grow each year by one unit. In C the length doubles each year, and the width remains equal to 1/4.

Please investigate the problem in groups. At first try to generate various hypotheses concerning the following questions:

1. Please compare the areas of the 3 families of rectangles over the years. What are their initial situations? Which family (or families) takes over the other families (or family) and when?

2. In which years will the area of each family exceed 1000 square units?

Now check your hypotheses with mathematical tools (the help of the graphing calculator is recommended). Try to be as accurate as possible.

Please write a report as a common product of your group. Try to describe your conjectures and what they were based on. What kinds of debates did your group have?

Try to describe the ways in which you solved the problem and in what ways you were using the graphing calculator.

This activity was first tried in an introductory one-year-long course on functions with the mediation of graphical calculators (TI-81) in Grade 9 in Israel (for details see Hershkowitz & Schwarz, 1999). It took place during the sixth week of the course. At that stage, students had practiced the actions and passages between and within representations and representatives. They were aware of the fact that obtaining a graph representing a given phenomenon required an algebraic model.

The students in the Israeli class were first invited to suggest hypotheses without using the computerized tool, then to use it to check them. Students tried to figure out which family would eventually take the lead by using intuition and/or by computing "by hand" the areas of the three families of rectangles for a few values. Then students (in most of the groups) translated the situation into algebraic representations (with some difficulties in generating the function-area for Family C, \(y=\frac{1}{4} \cdot 2^x\)), and then obtained the graphs with their graphical calculators (see Figure 1 below for a stylized representation of the graphing window).
After the groups had finished, the teacher discussed with the class the mathematical findings and strategies. Students reported that in the eighth year (\(x=8\)), the three rectangles had the same area, and that from that year on, Family C took the lead from Family A. Family B remained in between. The evidence provided by the different representations was accepted even if, for some students, it was unexpected; no student declared the computer wrong. Nevertheless, they tried to reinterpret the situation, and even to overcome wrong intuitions, by matching together representatives from different representations; the algebraic, the numerical, the graphic, and the phenomenon itself. The sociomathematical norm of what constitutes evidence in problem situations was formed here as a consequence of students' interactions with the tool.

**What happened in the case-study group**

Before setting off to work in groups of threes on the problem situation, the research class from the Montreal school was asked also to read the problem and to vote on whether they thought that Family A, B, or C would have the largest area over the long term. A couple of students voted for Family A; most voted for Family B; and a few abstained. No one predicted that Family C would eventually have the largest area. Teams then started to work on the problem situation. They also had to produce a written report on the problem-solving process, as a common product of the team, and then to present it orally in front of the whole class during the concluding discussion. This activity was two periods long (an hour and a half in all).

The team to be featured will tell the story of the dialectical process between the mechanistic and the meaningful, with the search for meaning as the guiding thread of the dialectical process.

**Round 1: Making the technological tool generate the algebraic expression for the situation.**

After reading the problem questions, the group of Kay, Ema, and Sam (two girls and a boy) began immediately to create a table of values on paper. They entered the numbers 1 to 10 in the left-most column, headed "year." They labeled the next three columns "Family A," "Family B," and "Family C." To fill the Family A column, they calculated 8 x 1, 8 x 2, 8 x 3, and continued by increasing each entry by 8. Kay remarked: "It is going by 8 each year." To fill the Family B column, Sam suggested "the year where it is, just square that number and you will get the area." When the Family B column was completed, by computing the area of the growing rectangles in their heads, Sam began to compare the 1st and 10th entries for Families A and B. Kay remarked that "so far, B has more over the long term." She then stated: "We can do equations for each one and compare on the graph of the calculator to see where they all intersect." Sam nevertheless wanted them to first complete their table.

To fill the Family C column, they multiplied the given length of 2 for the first year by 1/4 (with the help of the calculator); they then took the length of the previous year, doubled it, and multiplied by 1/4. Thus, for the initial values of each of the columns,
the procedure used for filling them reflected the operations suggested by the text of the problem situation (e.g., "in C the length doubles each year and the width remains equal to 1/4"). But the filling-in of the table was not done with the aim of detecting the relationship between x and y values so as to yield an expression for the function. It was done simply to have 10 values for each Family so as to be able to calculate the differences between the 1st and 10th values, and check their initial hypothesis as to which Family had the largest area over the long term. Their attention was on the global differences. It is worth noting that while the calculations for Families A and C were done in a recursive fashion, the calculations for family B were based on an explicit generalization for x (the year number) – Sam said: "the year where it is, just square that number and you will get the area," and yet he did not reach or use a closed-form algebraic expression.

After completing column C, Sam announced that they had been wrong in their prediction that Family C would be ahead. He then said that "by having all this, you can now just make up equations for each one." It is hard to know what Sam meant by this; either he was ready now to generate from the situation and the tables the algebraic expressions for the growth of the three families, or something else. In any case, the objective of the three of them seemed to be to look for intersection points on a graph. Kay, at that point, seemed to have a very clear strategy in mind: "Let's do a linear regression." Sam added: "So, if they want to know when they take over, you have to do an equation and find out where they meet." Kay continued his sentence: "And you have to find the point of intersection."

The group had finished answering the front-end question that we had posed regarding their initial hypothesis and could now get on with the main task at hand. As in the Israeli class, the objective of all of them seemed to be to draw the graphs in order to be able to compare the three families by having intersection points. They were also aware that, in order to obtain a graph representing a given phenomenon, it is necessary to have an algebraic model. However, the way in which the group members went on to find the equation for each Family was quite unexpected. With the experience we had from the first class, we had thought that they would either analyze the given problem situation with its patterns of rectangles, or look at the numerical values they had generated for their tables in order to find an expression for the relation between the x values (the years) and the corresponding y values (the areas). The way in which they chose to join the paper-and-pencil and technology-based representatives in order to obtain the graphs and the intersection point/s is a crucial part of our story and is described in the following paragraphs.

After rapidly entering the first five values of each column from the paper table of values into STAT-Edit lists of her graphing calculator, and then selecting LinReg (ax + b) of the STAT-Calc menu, Kay obtained the following three LINEAR functional expressions for Families A, B, and C: 8x; 6x - 7; 1.8x - 2.3. She suggested to her team-mates that they enter these "equations" into the Y= editor of the calculator and then ask for the graphs, which they did. She, who was the fastest at using the
calculator, soon announced, "OK, guys, these are the graphs," while turning her calculator toward them so that they could see her screen (see Figure 2).

It is noted that this team was not alone in its use of the calculator's linear regression tool as a means of generating the area expressions for the three families of rectangles. The teacher, when questioned, disclosed that the class had used regression for two or three weeks, about half a year earlier when they were dealing with problems involving real-world data. Students had learned to model (i.e., obtain equations for) these "real-world" situations with the help of the linear and quadratic regression tool of their calculator.

![Figure 2](image1.png)  ![Figure 3](image2.png)

We can conclude that the above regression procedure, which is often the only way to get an algebraic rule for the so-called regularities of real-life phenomena, was adopted by these students as the most efficient way to get the algebraic model of a problem situation, even if this particular problem situation involved idealized mathematical data. The students appeared to trust the algorithmic routine involved in using the regression tool of the calculator and did not feel any immediate need to verify empirically the correctness of the expressions that had been generated by the calculator with the data that they already had in their paper-and-pencil table.

Nevertheless, one is led to ask why the group mechanistically used the calculator to generate and to join together the representatives (the numerical and algebraic representatives) instead of looking more carefully at their table where the answer to the question "WHEN?" was there all along (in Year 8, all the families had an area of 64). Did they consider the graphical representation more reliable? Or is a functional algebraic rule, and its joined-together graph, a stronger argument than mere numerical evidence? Or was it important for them that what they had been able to conclude by means of the numerical table (that Family C had the larger area over the long term) be supported by confirmatory and matching evidence from the graphical representation as well, that is, that they be able to join together the paper-based numerical representatives with the graphical tool-based representatives? Or were they just carried away by the above algorithm that begs to be executed once one has generated tables of data for a given phenomenon?
Round 2: Failure at getting the technological tool to work for them: a turning point.

From the beginning of applying the regression option of the calculator tool and up to this moment, the group had appeared to be marching along a mechanistic path in a kind of automatic fashion, without doing very much in the way of reflection. When the graphs they generated did not look as they had expected them to (Sam: "They don't all intersect at the same point" --as seen in Figure 2), Kay changed the scales immediately. But, that did not help her to obtain the meeting point she wanted to see (see Figure 3). Repeated scale changes (even up to 1500 years) did not produce the elusive point of intersection that they had intuitively been expecting. Kay then suggested they try the CALC-Intersect option to have the calculator provide some information with respect to the point of intersection. The error message of "no sign change" suggested that there was no point of intersection in the given window and confirmed for them what had been evident from their reading of the graphs, graphs that had been produced by the expressions of the linear regression option. Yet, there was a sense of unease. They had failed in their attempt to get the technology to work for them. They had expected a single point of intersection somewhere in the first quadrant.

Round 3: A shift of attention.

This round starts with Kay beginning to think more about the situation: "We try to find how much it increases, which one grows the most." They returned to the text of the problem situation and reread it: "Which family (or families) takes over the other families (or family) and when?" Kay emphasized the "AND WHEN." Sam began to look at the paper-and-pencil table of values and said: "We already figured out who is going bigger, but we can't answer when, because ..." Then Sam and Kay noticed in the table that, at 8 years, all three families had an area of 64, and so Sam asked three times: "So why aren't they meeting?" They now paid attention to the hard numerical evidence that there was a single point of intersection. Their inability to match this evidence and the graphical representatives they had obtained became very clear and waited to be resolved and explained.

Kay substituted 8 into their algebraic expressions for Families B and C and obtained 41 and 12.1, instead of the desired 64, and she said: "We did something wrong." In an attempt to make sense of what was going on, the students restarted the process of joining-together-representatives, again with the regression option of the calculator tool. But, this time they were equipped with the critical thinking they had developed from the above comparison of the numerical and graphical representatives. They recalculated the linear regression for Family B and this time noticed that the value of the correlation coefficient was not 1, but .98. Sam remarked that the resulting expression was therefore not 100% sure. Kay insisted: "Even so, we were way off."

Sam began to systematically substitute values into the expression for Family B: "6(1) - 7 is -1: that's wrong; it's not having a negative area." With his substitution of 2
into the same expression, he became even surer that they were wrong. Kay wondered aloud: "So do we make up our own equation; maybe it's not a linear regression." Sam, who was still substituting, said, "We're getting further apart; even C goes off."

In this round, their mechanistic approach to joining-together-representatives was being put into question by a more meaningful one. It is not clear if they started to suspect the mechanistic routine itself or the way they had performed it. However, as will be seen in the next round, rather than abandoning the process carried out with the technology, they insisted that it be made to work for them.

**Round 4: Insisting that the technology be made to work for them.**

Kay decided to check the way that they had used the regression algorithm by trying other forms of regression available on the calculator tool. She went to cubic regression and realized that the correct equation was \( y = x^2 \) -- because of the neat parameters and the correlation coefficient of 1. She added: *1 squared is 1, 2 squared is 4, 3 squared is 9.* Soon Sam reacted: "I don't know why I didn't figure it out from the beginning. I said it, why didn't I see it?" Even Ema expressed that they had been carried away by the regression routine: *"It's because we were so absorbed by our calculators."

Meanwhile, Kay ran through other regression choices for Family C until she hit upon the exponential regression, which yielded \( y = 0.25 \times 2^x \) with a correlation coefficient of 1. Just to be sure, she entered an x-value of 1 to see if the calculator would produce the same y value as she had in her paper-and-pencil table. One value seemed to satisfy her that the equation was correct, but she stated that she did not really understand the equation.

Sam too seemed a little uncomfortable with the expression for Family C. They had never before experienced exponential equations. Kay seemed prepared to go on to the next question. After all, they had earlier realized from their paper-and-pencil table of values that the point of intersection was \((8, 64)\), and they now knew that they had equations that corresponded with the values of their paper table of values. However, Sam wanted more. He wanted to be sure that their newly-found equations did, in fact, yield graphs that intersected at the point \((8, 64)\). He suggested that they enter the new equations in the Y= editor and graph them with a scale involving a y-maximum of 70: *"We should see that they are all meeting at 64."* He smiled visibly at the result. It is not clear, however, that Kay paid any attention to this last exercise in consistency.

The technology had now been made to work for them. The graphs, the equations, the paper-and-pencil table of values, and the situation all fit together. Doerr and Zangor (1999) have emphasized the importance of leading students to *"develop a reasonable skepticism about calculator-generated results"* and encouraging the establishment of classroom *"norms that require results to be justified on mathematical grounds, not simply taken as calculator results"* (pp. 271-272). It is noted that these
students did not throw aside their calculator tool when the graphs it produced could not be justified on mathematical grounds; they continued with it until it could be made to deliver correct mathematical representations.

In short, we can conclude that the group completed its answer to Question 1 by means of actions involving "joining together representatives" which, at the starting point as well as at the end, were controlled by the need to have meaning. But the sequence as a whole was an intertwining one where both the mechanistic and the meaningful were dialectically connected. The regression routines were the mechanistic parts of the sequence. The to-ing and fro-ing between the mechanistic and meaningful joining-together-of-representatives was at times characterized by lengthy segments of mechanistic activity. Nevertheless, the search for meaning always prevailed.

Discussion

As mentioned before, when we speak of computerized tools in learning we usually speak of their «positive» potential in mediating learning. The above example showed that such mediation might raise dilemmas for learning. A crucial dilemma is how much and in what way we would like the tool «to do the work» for the students. And more specifically, do we value that students be able to express a problem situation with algebraic models, and that they produce themselves this algebraic model?

Both classes were driven by a search for meaning in comparing the growth of the three families and were looking for the three graphs and their intersection points, knowing that the algebraic models were the keys for obtaining the graphs. The first class, which had a more limited tool (TI-81), started immediately to construct the algebraic models of the three families from the problem situation itself. This was not so easy for Family C and a few groups in this class failed. Our group from the second class trusted from the beginning the mediation power of their more advanced tool (TI-83 Plus) to do the work of generating the algebraic models for them. But in the first round they failed to get the right algebraic models, even for Family B. During that stage, they had used the tool in a mechanistic way, without engaging critical thinking, and thus obtained «false representatives.»

What is the source of the differences between the two classes? It is obvious that the tool itself may explain part of the difference because the TI-81 has only a quite limited regression option. But, the dissimilar history of mathematics learning in the two classes is likely a major contributing factor. As we mentioned above, our second class had the experience of dealing with real world problems with non-idealized data, which usually do not fit perfectly an algebraic model. This encourages the use of regression techniques as a means of obtaining an algebraic model. So the students imposed the same kind of modeling technique on the «Growing Rectangles» problem situation. For students who have difficulty in modeling the growth of an exponential
function from the situation itself, such as was experienced with the Family C rectangle, this technique may serve as a temporary scaffolding.

Students may rely on a similar kind of scaffolding when using spreadsheets for modeling. We have observed younger students investigating similar problems of exponential growth with EXCEL (Hershkowitz, 1999). Some of these 7th graders tended to generalize phenomena like the growth of Family C into a recursive model by carrying out actions such as the following:

Enter 2 into cell A1, and then in cell A2 punch in "=A1+A1" and drag down to produce the lengths of the Family C rectangles; then in column B enter into the B1 cell "=1/4*A1" and drag down to obtain the area of the Family C rectangles. In this way, the spreadsheet tool allowed students to combine the use of recursive formulae and dragging, and thus to overcome the local property of recursion.

In fact, if we look at the process which our group used to fill the table for Family C in Round 1 -- doubling the previous length and then multiplying it by 1/4 -- we may conclude that the recursive approach is much easier than trying to generate a closed-form rule where the independent variable is the number of the year. Recursive approaches might even be more natural, at least in the case of exponential growth. In this sense, the tool--either the TI-83 or EXCEL--with its scaffolding affordances enables students to act meaningfully on quite high-level objects, such as exponential functions, even before they have learned formally about them.

The other side of this coin is that this scaffolding may stay longer then we, as mathematics educators, would like in the process of learning algebra. We had examples of students working on a problem situation in which exponential growth was investigated, where students were quite close to generating a closed-form exponential formula. But, when they discovered the EXCEL option of generating a recursive expression + dragging, as a quite efficient alternative for obtaining a whole set of data for the phenomenon, they curtailed their efforts to mathematize the problem situation in a higher level manner. While it might be argued that these students were engaging in a kind of algebraic thinking (Kieran, 1996), might the use of computerized tools in learning algebra reduce students’ needs for high level algebraic activity?

In addition, we face an even more crucial dilemma; the algebraic representation and its form seem minimized in importance for students. Our case-study group, like groups in the other class, knew that the algebraic formula was the key, but perhaps because of their more advanced tool, and because of their learning history, the shape of the algebraic model seemed unimportant. In fact, students can now go from entering lists to a graphical representation without ever seeing or having to examine the algebraic representation of the situation. Does the use of these tools in algebra signal the beginning of the loss of the algebraic representation from our mathematical classes at the secondary level?
Acknowledgments

We wish to acknowledge the research support provided by the Social Sciences and Humanities Research Council of Canada (grant # 410-99-1515). Our thanks are also extended to Hassane Squalli and Nathalie Prévost for their assistance during various phases of the research. Last, but not least, we are grateful to the participating students and teachers, without whose cooperation this research would not have been possible.

References

Almost 20 years after I carried out my first mathematics education research on students’ learning of algebraic ideas within a Logo environment I am again starting a new project on teaching and learning with new technologies. What have I learned in this intervening period? Firstly I know that although in the UK we are moving towards a ratio of 1 computer to 8 students in every school, mathematics teachers are amongst the most resistant of teachers to incorporate computer activities into their teaching. I know that although in our earlier research we theorised learning we did not adequately take into account the student’s history of learning mathematics, the culture of the classroom, the culture of the school and the culture of the mathematics curriculum as influenced by both mathematics and national policy. I know that however beautiful the new technology there is nothing essential about this technology which implies it will be used in a particular way (although I do believe that it is possible to talk about the ‘affordances’ of a technology (Gibson, 1977)). Unfortunately in our consumer culture those who advocate new technologies tend to ‘sell’ them as if there is a cause and effect relationship between the use of the technology and student’s learning. In particular I have sat through many presentations on the use of graphics calculators in which the presenter focuses on ‘what the calculator can do’ as opposed to ‘what the student-plus-calculator might do when using a calculator’. Thus I welcomed an invitation to participate in the PME Research Forum on the potential and pitfalls of technological tools in learning mathematics.

In Hershkowitz and Kieran’s paper they discuss the ways in which students in both Israel and Canada work with a graphics calculator on an investigative activity which involves predicting the growth patterns of the areas of three families of rectangles (which have been represented to them figuratively). The group of students in Israel chose from the outset to represent the areas of each family of rectangles as algebraic functions and then graphed these functions with their graphics calculators. This led to a graphical representation which they could interpret from the point of view of deciding on the relationship between the growth of each family of rectangles.

The group of students in Canada took a different approach. They used 2 x 10 tables to represent the growth for each family of rectangles. For each table they firstly entered a column 1,2,3...10. The task then became one of filling in the correct area for each family of rectangles for the first 10 years of growth. They managed to do this correctly. The rules to generate the 1st and 2nd family of rectangles were computed in a recursive manner ‘in their heads’ as opposed to using an algebraic rule in the
calculator. However they did use a universal rule for the 2nd family of rectangles (which was increasing squares), although it is not clear in the paper whether they represented this rule in their calculators. By the end of this beginning activity they had produced a table of values for each family of squares. They knew that they needed to produce an algebraic model in order to plot graphs of growth and one student suggested "let's do a linear regression".

Hershkowitz and Kieran ask why the students so mechanistically used the calculator to produce an algebraic rule when the tables they had produced could be 'read' for the information which they had been asked to obtain. However the authors point out that these students had previously worked for several weeks on problems which involved finding models for real-world data and they had used linear regression in this respect. My interpretation of what is happening here is rather different. The students are firstly making sense of the problem presented to them by drawing on their previous experience of finding rules to represent data generated from real-world situations. In these previous situations fitting a straight line was a way of modelling a situation which may or may not have been underpinned by a linear relationship. Their approach to these messy real-world situations had been to start from data and then find a model which fitted the data. So for me it is not surprising that when presented with an investigative problem (which was underpinned by explicit algebraic models) they first decided to generate data from the situation and then tried to find rules to fit this data. They did not use the visual representations of the families of rectangles to find algebraic rules and they did not read the tables of data which they produced in order to find the relationship in the growth patterns. I would describe their behaviour as making-sense-for-them although it might not have made sense to an observer who had expected another approach. In this respect I disagree with Hershkowitz and Kieran's analysis that "from the beginning of applying the regression option of the calculator tool and up to this moment, the group had appeared to be marching along a mechanistic path in a kind of automatic fashion, without doing very much in the way of reflection".

When this group of students had produced graphs using linear regression they then began to question their approach, because the graphs produced did not tie up with how they were reading the table and the figurative representation of the problem. For me the story is one of students' actively making sense, working with the calculator, the problem and multiple representations generated until they can make sense of the whole. The first phase of the problem seems to have been a getting-started phase which drew on previous experience of working with real-world messy data, in which it is not usually possible to read patterns from the data. They needed to generate algebraic rules from their data in order to produce graphs with their graphics calculators and the calculator's regression function was how they had previously learned to do this. In the final section of the paper Hershkowitz and Kieran depart from their earlier analysis and start to discuss the students' approach in a similar way: "Our second class had the experience of dealing with real world problems with non-
idealized data, which usually do not fit perfectly an algebraic model. This encourages the use of regression techniques as a means of obtaining an algebraic model”.

The starting point of the paper centred around the idea of two kinds of representatives “representatives that do not represent the properties of the mathematical objects involved at all, and representatives that do”. This perspective, I suggest invests too much power in the representatives and not enough in the person plus representative (Perkins, 1999). It also suggests that ‘if only students produced the ‘prototypical’ representative then they would be able to ‘see’ what the teacher wants them to see’. The case discussed throughout the paper has raised very important issues about learning mathematics with new technologies. The comparison between the students in Israel and the students in Canada tells us that students with different backgrounds can approach the same problem and the same technology in very different ways (similar issues have been discussed in Sutherland & Balacheff, 1999).

The question for me is how can we understand student’s sense making in these situations? The paper has provoked me into thinking whether it would be possible to develop a theoretical model of teaching and learning mathematics which would enable us to predict that the Canadian and Israeli students might have been likely to approach the problem in the ways in which they did. For me, such a model would place the student as a central sense-making agent who works with whatever resources and theories are available (technologies, representations, language) and brings a history of working with resources and theories in order to solve the problem presented to them. In this model there would be no ‘best’ representation and no ‘best’ technology although each representation and each technology would ‘afford’ a range of different potentialities.

Working with both the graphics calculator and real-world data problems as a way into algebra is likely to lead to an under-emphasis of the power of algebraic formulae for representing patterns. It could also be argued that this type of work is more like science than mathematics. The paper does not ask why the students in Israel took such a different approach and there is no discussion of the previous experiences of these students. My final question to the authors is where was the teacher in all this work? A teacher on-hand could discuss with the Canadian students the difference between data which derives from real-world situations and data which has already been generated by an algebraic formula. There is much work to be done here and I anticipate a very fruitful discussion at the PME Research Forum.

A META STUDY ON IC TECHNOLOGIES IN EDUCATION.
Towards a multidimensional framework to tackle their integration

Jean-baptiste Lagrange, IUFM de Bretagne (Rennes, France)
Michèle Artigue, équipe DIDIREM (Paris, France)
Colette Laborde, Laboratoire Leibniz (Grenoble, France)
Luc Trouche, équipe ERES (Montpellier, France)

A survey of literature about educational uses of IC Technologies in mathematics education was done by a team issuing from five French laboratories working in various fields. A quantitative analysis of a corpus of 662 papers and two qualitative analyses of a sub-corpus helped to specify “dimensions” for the analysis of this very varied mass of innovation and research. Then, cluster analysis performed on each of the dimensions led to informative partitions. The method of analysis and the picture resulting from the partitions are offered as means to tackle the complex integration of IC Technologies into teaching and learning.

Introduction

This paper originates from a call by the French Ministry of Education to make use of existing published works to answer questions about educational use of Information and Communication (IC) Technologies. The opportunity of doing a meta-study was appealing to us because of the mass of published works existing in this field, contrasting with a general lack of precise understanding of what really happens when introducing IC Technologies. We thought that it was interesting not to do another research project, but to try to see what synthesis could be drawn and how it could be drawn.

The ministry’s questions were: “How are IC Technologies used inside the educational system? Do they change the nature of learning? Do they modify the notions and the methods? What is their influence on students and teachers?” As for us, we were concerned by the discrepancy between promising IC Technologies and their difficult integration in schools. Our view was that teaching and learning involve complex processes, that bringing in elaborate technology adds even more complexity and that technologies proposed for educational use are quite varied. For these reasons we did not expect that a meta-study could bring the ministry’s questions direct answers. Our aim was to build tools for the understanding of integration rather than to collect findings on objective changes brought by technologies.

1 A complete documentation on this research, including the material for the statistical analysis is available on the Internet: http://www.maths.univ-rennes1.fr/~lagrange/cncre/rapport.htm. A longer version of this contribution is also available for download. The longer version presents detailed numerical data summarised here.
Aims and approach

Building a methodology for analysing innovation or research, and using this methodology to identify trends in a corpus of works were two aims that we thought about together. A classical meta-study “translates results to a common metric and statistically explores relations between study characteristics and findings” (Bangert-Drowns & Rudner, 1991). Because of the above complexity and because of the diversity of the characteristics and findings of papers in the field of IC Technologies, we did not try to define a single metric. It appeared to us that looking at the integration of technology requires a plurality of perspectives or approaches and that a first stage of this “meta-work” would consist in a precise identification of these perspectives. Our methodology was to conceive of possible perspectives or factors (that we named “dimensions”) using our knowledge of research work. Then we had to analyse writings on the introduction of IC Technologies. As a writing focuses on a necessarily limited number of perspectives, we wanted to be able to identify in which dimension(s) its contribution is and what specific approach and results it brings into this(these) dimension(s).

We had to make the dimensions operational by identifying each of these by a set of adequate questions. In our mind, this identification could not be done only from a theoretical reflection but had to be drawn from the existing literature. This is why we decided to carry out a qualitative analysis of a corpus as large as possible, covering the diversity of fields defined by a specific technology: (dynamic) geometry, computer algebra and other algebraic software, arithmetic and graphical calculators, computerised learning environments... We chose also to consider French publications in order to specify our own cultural and institutional context and also as many papers as possible from other countries to identify alternative approaches.

Methodology

The specification of the dimensions was the goal of a first stage analysis and a statistical analysis of a corpus in each of the dimensions was the goal of a second stage analysis. In the first stage analysis, we considered a whole range of publications regarding the nationality of the author(s), the type of work, the type of software and hardware used, the domain of knowledge... We decided to cover years 1994 to 1999, which appeared to include enough diversity. We used a variety of international sources as well as French works. This resulted in a corpus of 662 published works.

The exploitation of this "first stage" corpus was:
1. a quantitative identification of the repartition with respect to nationality, mathematical field, school levels, type of study,
2. a qualitative classification of questions (or "problématiques") that we did on a topical subset (we chose Computer Algebra), in order to establish the various dimensions in the approach of the use of technology,
3. the selection of a corpus for the "second stage" analysis.
The selection for the second stage analysis was necessary because not all papers in the first stage corpus had sufficient matter. The selection was to be large enough to respect the diversity of approaches and to avoid biases, but we had also to consider that the second stage analysis was expected to take several hours working on each paper. The principles of selection were:

- to have publications with sufficiently developed "problématiques", methodology and findings,
- to avoid papers too close in their analysis and findings,
- to have a distribution of nations, types of hardware and software, domains and levels similar to the initial corpus.

We selected 79 papers, judging this selection to be a good compromise between in depth analysis and respect of diversity. For each of these papers, one of the participants of the project established a detailed review. The exploitation of this "second stage" corpus was:

1. a qualitative analysis of a dimension (we choose the cognitive dimension) in order to get a first evaluation of the diversity of the approaches in this corpus
2. a statistical classification giving informative partitions of the corpus with regard to the various dimensions.

A quantitative identification of the corpus

We started this study with the hypothesis that the great variety of types of publications in the field of the use of IC Technologies gives evidence of a lively field but also makes difficult the search for convergent findings. Of course we had also an intuition of what this variety could be. Thus, the simple quantitative findings reported in this paragraph were intended to provide evidence of the diversity of the publications as well as provide a check of the conformity of the corpus as compared to what we thought of the general production.

**Type of analysis and mathematical field.** Research publications were not a majority (37%). This is relevant for our aim to analyse the use of IC Technologies as a whole, looking at classroom innovation, and speculation as well as at research studies. Geometry is well represented. Few papers are about arithmetic and algebra alone, probably reflecting the smaller amount of writings about the pre-college level, outside geometry, in the corpus. A number of papers do not specify a mathematical field, focusing on the support of technology in "general" mathematical learning.

**Type of technology.** Varied technologies were represented. Their repartition shows that, although simple and graphical calculators are everyday instruments for many students all over the world, papers tend to focus on "smarter" technologies, like computer software or symbolic calculators. Emergent technologies (Internet, etc...) although very present in discourses are rarely addressed by papers in our corpus. We thought this repartition was not a misleading picture of the varied writings about the introduction of IC Technologies in the period of time that we considered.
Countries. Our corpus represented also a great variety of countries. Of course there was a bias towards France because it was easier to get hold of publications in France like thesis, professional teachers' journals and congress and professional meetings reports that we wanted to include beside papers from international journals. The part of all the "Latin" and "Latino-American" world appeared to us reduced compared to what we had expected, a bias that we attributed to the sources we had in hand.

Two qualitative pictures

As indicated above we did two qualitative analyses, firstly to have a general picture of the publications in the initial corpus before selecting the second stage corpus, and secondly to get an evaluation of the diversity of the approaches in this latter corpus.

A qualitative classification of "problématiques" in the first stage corpus

To prepare for the second stage analyses, we considered the "problématiques". The "problématique" of a publication is the field of connected problems or questions that the publication addresses. This idea of "problématique" is important in our research because it aims at the study of the way questions are posed in the field of IC Technologies. A reason for the discrepancy between the favourable opinions on their use and their poor integration lies in the difficulty of addressing appropriately the problems really involved in a given experiment.

For each publication in the first stage corpus, we established a small text summarising its "problématique". An analysis of the "problématiques" of the whole corpus would have been too time-consuming for a qualitative picture. So we decided to restrict this analysis to a specific field: the educational use of Computer Algebra Systems (CAS). We chose this field because it appeared with a high percentage, reflecting the great number of papers written in this field. Another reason was that the corpus included all the papers issued from a journal dedicated to CAS educational use, the IJCAME. As this journal encourages research papers as well as articles about teaching issues, activities for class use and opinions, we were particularly sure of having a variety of papers in this field. The CAS sub-corpus also included thirty percent of publications on CAS use from a great variety of other journals or books.

We found that the publications of the CAS sub-corpus could be classified into five types of "problématique" that we summarise below.

Technical descriptions of possibilities of CAS (53 %). These papers stress the capabilities of CAS that they find relevant for educational use. Optimism is a very common feature of these papers and only a few articles stress the need for students' training to avoid pitfalls.

Descriptions of innovative classroom activities (13 %). These papers go farther, presenting actual CAS use in classrooms. Presentations of national projects for experimenting and integrating CAS (like French or Austrian projects) and of new curricular projects influenced by CAS capabilities are examples of these.
Papers starting from assumptions (18 %). These papers are more research-oriented studies, with hypotheses, experimentation and conclusions. Hypotheses come from general views on mathematics teaching and learning and on technology and are often backed by a theoretical cognitive approach.

Papers starting from questions about the use of CAS (31 %). In contrast with the above papers they do not presuppose advantages of this use. They present innovations, experimentation or examples of use not for themselves, but as a tool to address the questions.

Papers focusing on integration (7 %). These papers address the issue of the conditions for CAS to be used, such as paper and pencil in the everyday practice of teaching and learning in existing school institutions.

This classification reflects the diversity of reflection, research and experiment on the use of IC Technologies. The papers with a mere technical approach of possible use of IC Technologies (type 1) prevail. The mass of papers produced in this approach is representative of the interest raised by a technology like CAS among a part of the teachers. Papers arguing in favour of classroom innovations (type 2) are much less common, but seem useful especially when they report on long-time experiment of students' use of CAS. A weakness is that they generally do not discuss the teacher's options.

Among research papers, our classification distinguishes publications starting with assumptions on expected improvements resulting from students' use of CAS (type 3) from others starting with questions about this use (type 4). Ten years ago, in the first stream of research about CAS use, many papers were of type 3. In the period 1994-1999, the papers of type 4 are nearly twice as frequent as papers of type 3. We can take it as an indication that at this stage of development of research about IC Technologies, formulating and trying assumptions on improvements is no longer very productive. The assumptions and questions have in common their focus on the epistemological and semiotic dimension: they generally consider the mathematical knowledge at stake in technological settings and the possible effects of its computer implementation. Type 3 and 4 papers share also a common interest for a "cognitive" dimension: the assumptions of improvements and the question about the use of IC Technologies are generally based on a theoretical framework about the student’s functioning and learning processes.

The last class (type 5) gathers a minority of papers explicitly addressing the issue of integration, which implies a study of questions like those in type 4 papers, but with a specific approach of an ecologically sustainable use. Questions on tasks, procedures and conceptualisation, as well as on CAS as an instrument exist in the type 4 papers. In the type 5 publications they appear as not to be missed dimensions that we briefly characterise below:

- The "instrumental" dimension of IC Technologies distinguishes a technological artefact and the instrument that a human being is able to build from this artefact.
While the artefact refers to the objective tool, the instrument refers to a mental construction of the tool by the user. The instrument is not given with the artefact, it is built in a complex instrumental genesis and it shapes the mathematical activity and thinking. (see Trouche, 2000).

- The "institutional" dimension investigates to what extent content to be taught as well as tasks and procedures (or "techniques") are affected by the institution in which they are taught. Institution has to be understood in a broad sense: a specific classroom with a specific teacher may be considered as an institution as well as a general school level for a country (see Lagrange, to appear).

So this classification helps to consider the varied types of "problématiques" and dimensions that can be used to analyse the use of IC Technologies. It helps also to look at the selection we did for the second stage corpus. Because they generally lack sufficient data and analysis, we could not integrate most of the papers of type 1 and 2 in the second stage corpus.

A qualitative analysis of the theoretical frames in the second stage corpus

As most publications in the second stage corpus are research papers, they generally offer a theoretical basis for their analysis. We chose to look qualitatively at this basis as means for preparing the quantitative analysis by showing convergence and diversity in the mass of papers that we selected.

As expected from the above study of "problématiques", we found a strong convergence of the theoretical frames in the predominance of cognitive approaches. Where constructivist views prevail, papers very generally base their analysis on theories of the student’s functioning and learning processes. Within this general picture, diversity appears through more local theories, attached to specific research trends, such as for instance, the "process / object" approach, or the emphasis put on Piagetian processes of assimilation and equilibration. It appears also in specific theoretical constructs issued from the research on the use of IC Technologies like the notion of cognitive tool and conceptual reorganisations. Specific environments such as for instance dynamic geometry software, graphic calculators, CAS... tend to focus on specific approaches.

In spite of this diversity, we could find convergent elements of an evolution. This evolution reflects the progress of global educational research, especially towards socio-constructivist, socio-cultural and anthropological approaches, showing how the research on IC Technologies depends on the global context. Beyond this dependence, the evolution of the theoretical approaches of the use of IC Technologies marks also a sensitivity towards specific dimensions and provides for specific elaboration.

A specificity of research on the use of IC Technologies is a special sensitivity to the role played by perception in cognitive processes. It is interesting to notice that, even within the short period taken into account, some convergent evolution seems to occur in the way perception and visualisation are approached. Some texts remain still in what we could call the "naïve phase": the visual potential of technology is
emphasised, illustrated by judicious examples, but is seen as a means for improving mathematics understanding and conceptualisation, per se. Most texts in the corpus are situated beyond this naïve attitude. The cognitive power of visualisation tools, the underlying cognitive processes, have become a matter of investigation. In some papers, this leads to the opposition of perceptive and conceptual approaches.

Nevertheless, most recent texts tend to present the relationships between perception and conceptualisation in more dialectic ways. For instance, accessing geometrical knowledge is no longer presented as resulting from the rejection of some perceptive apprehension of geometrical objects, but from the ability of relying efficiently both on spatial and geometrical competencies. More emphasis is put on the characteristics of problems and situations which can foster the dialectic interplay between these competencies of different nature and thus contribute to the development of geometrical expertise (Laborde 1998). The same sensitivity and evolution can be observed as regards the role played in conceptualisation processes by the interaction between the different semiotic registers of representation and as regards the "contextualisation of knowledge" (Noss and Hoyles, 1996).

From this qualitative analysis, we see that even in a specific dimension like the theoretical cognitive framework, diversity makes research advances not easy to synthesise and that relying on such synthesis for a development of the field will be difficult. A useful convergence can be found in the consistent evolutions noticed above.

The quantitative second stage analysis: data and method

Eight dimensions for the analysis of the integration of technology were derived from the above qualitative analysis. Five were briefly described above: the general approach of the integration ("problematiques"), the epistemological and semiotic, the cognitive, the institutional and the instrumental dimensions. Three other dimensions were considered: the "situational" dimension which refers to the changes that the introduction of technology brings into the didactical situations, the dimension of "human-machine interaction" which analyses students' activity and interaction with the technological tools and the teacher dimension which looks at the teacher's beliefs and at the way (s)he organises the classroom activity.

For each of the dimensions a set of questions was designed resulting in a questionnaire of 96 questions. The answers to the questionnaire for each publication of the second stage corpus was assumed to give a picture of how this work takes each specific dimension into account. The identification of trends in writings about the introduction of technology could then be carried out through a statistical procedure. This procedure was designed on the basis of a cluster analysis. Applying this procedure to each dimension, we obtained specific partitions, data to explain clusters and one or two papers at the centre of each cluster.
The quantitative second stage analysis: results and interpretation

In this section we will detail and discuss the results of the "instrumental" partition as an example of the data that the procedure handles and of the type of insight that it provides for. Then we will draw more briefly on other partitions.

The "instrumental" partition

The instrumental approach was briefly introduced above. It is a rather new approach; older studies took into account neither the learning processes attached to the use of the tool, nor their evolution over time. This approach may be relevant for investigating how students make use of technologies, how the way they use it evolves over time under the influence of evolution of their knowledge in mathematics and about the technology. This approach may also be relevant for investigating how the teaching takes into account the construction of the instrument and its relationships with the learning of mathematics. Several points of our analysis are concerned with this approach.

The types of questions attached to this dimension in the questionnaire are:
- is time evoked as important (q1)?
- are features of the technology or constraints of the technology evoked (q2)?
- are possible organisations of students' work taken into account in the analysis (q3)?
- is the distinction social/individual part of the analysis (q4)?
- are the instrumentation processes part of the analysis (q5)?

This partition is made of six clusters but only three of them are informative.

Cluster 1 (14 papers from 8 countries, 6 Anglo-american and 5 French papers)

This cluster gathers papers that take into account
- the availability of technology, its features (type q2),
- the organisation of work (type q3),
- the social dimension (type q4),
- but not always the time (types q1 and q5).

Two papers, which are very different under several aspects, are in the centre of this cluster and may thus represent it.

This paper dealing with the use of CAS in college algebra emphasises the role of permanent availability of technology for all students. Students having permanent access to technology acquire a better ability to analyse graphical representations and symbolic expressions. Just partial availability may imply frustration and antagonism toward technology. The paper calls for the integration of technology not only in activities but also in the course and for considering the interrelationship of the procedural knowledge developed about technology and mathematical knowledge.

The paper describes a two-year experiment in which pupils from primary school had laptop computers. They used Logo and a dynamic geometry environment (Cabri) on their own, deciding themselves about their projects. The pupils used mainly Cabri as a drawing tool rather than as a construction tool and were not eager to produce drawings whose shape is preserved by the drag mode. Only explicit teacher interventions in specific tasks made the pupils move from a drawing activity to a construction activity.

Although these two papers deal with different technologies, school level, and mathematical topics, they share key features with other papers of the cluster, like empirical data in a long-term experiment of students' activities, fine-grained observations, accounts of the characteristics of technology, the fact that positive results of IC Technologies are not taken for granted but questioned through empirical data. Their balanced findings differ from more general papers which are imbued with optimistic appreciation.

Cluster 2 (6 papers, 4 American, 1 Australian, 1 French)

Papers of this cluster all focus on the importance of time in the instrumental process (types q1 and q5) and do not consider the organisation of teaching (types q2, q3 and q4). Five of the six papers deal with geometry. The centre of this cluster is Goldenberg P., 1995, *Ruminations about Dynamic Imagery (a strong plea for research)*

This paper analyses how the continuous transformation of diagrams in geometry may completely change geometrical properties (a geometrical theorem may become a property of a function) and conceptualising processes of students. This cluster gathers papers which do not consider the classroom but mainly analyse features of the technology and their implications on possibilities of action and on conceptualisation. From this analysis, they find that, even with technology, instant mathematical conceptualisation cannot happen and thus time is necessary for students to understand the mathematical implications of the use of the instrument.

Cluster 3 (8 papers, 4 French, 2 Austrian, 1 English, and 1 American).

The only explicit type in this cluster is time (q5) but it is considered in very different manners among the papers. Half of them consider that technology provides a wealth of opportunities for a “more conceptual” use of time while the other half is doubtful and claims that this issue of time deserves more reflection. The two central papers reflect this dichotomy of the cluster.

This paper reports on a teaching experiment at high school level on geometrical transformations using a graphic package. In the author’s view, the use of technology makes classroom time more conceptually productive. Students’ mathematical activity is reported as dense and involving deep mathematical ideas. Even the constraints of the computer representation are, in the author’s view, pedagogically beneficial.
Mayes R., 1994, *Implications of Research on CAS in College Algebra*. This paper describes a curriculum in algebra based on DERIVE, aiming at developing abilities in modelling, problem solving and conceptual understanding. In the author’s hypotheses, DERIVE was crucial to allow “a reduction of the amount of time spent doing tedious manipulations...” An experimental group and a control group are contrasted. This comparison gives no evidence of significant difference among computation and manipulation skills and a marginal improvement in problem solving competence. The only difference is the critical point of view developed by the experimental group: “they felt the increased burden of problem solving and multiple approach”.

In our interpretation of the instrumental dimension in this paper, the issue of time becomes central when the author’s initial hypothesis is that technology is able to save time for conceptualisation and when the results are students feeling an increased burden and claiming for more “hours credit”. We have to recognise that more complex problems generally associated with a “conceptual” introduction of IC Technologies bring students heavier cognitive load and technology does not, by itself, solve this difficulty. As the author concludes, time and explicit intervention of the teacher on strategies (or "techniques", as the institutional approach now calls them) would be essential for conceptual improvements. So Mayes is representative of a trend in this cluster: an evolution towards a more balanced view of the influence of technology upon conceptualisation and towards the necessity of a careful organisation of time in order that students benefit from technology.

**Discussion**

The above presentation of the "instrumental" partition shows that each cluster contains papers from varied countries and fields. We can see also that papers in a cluster share common concerns for key variables in the dimension. Their findings are varied but are clearly influenced by these concerns. Looking at the interpretation, we see that instrumentation is a big issue with at least three main entries. The time that technology could save or not is probably the more naive entry (cluster 3), but, seriously questioned, it provides interesting discussions. The time requested by a real mathematical instrumentation is another entry (cluster 2) raising deep interrogations on the nature of conceptualisation. It is otherwise interesting to see that papers focusing on the instrumental dimension (cluster 1) do not consider time as the main variable. Our interpretation is that in the experimental settings, the technology was always available; time constraints are not so important in such a case.

**A synthesis of partitions**

Looking at other partitions, we found that the largest clusters focus on the students, providing a mass of interesting data and results on the learner, certainly insufficient in themselves for a study of the integration but also a basis for this study. We found especially that the evolution of the cognitive theoretical framework generally used for the analysis of the introduction of technology is sustained by these data and results.
Large clusters are also centred on the epistemological dimension. This is evidence of the attention paid to the relationship between the content knowledge at stake and the new teaching means provided by IC Technologies. On the other hand evidence appears that epistemological relevance is not sufficient in itself when no attention is paid to instrumental constraints and ecological viability.

One of the clusters starts with varied postulates converging on the fact that technology enhances teaching or learning. A wider and more varied set of clusters questions this claim and investigates to what extent technology improves learning. With this posture, researchers consider the students’ difficulties in the use of technologies as well as the demands that technology brings into the educational system. These clusters call for a wider approach which should include the instrumental, institutional and teacher dimension. References to these dimensions are sparse, although promising as we could notice in the detailed analysis of the "instrumental" partition. A similar analysis of the "institutional" partition should point out the questions of the tasks offered to the students (tasks especially designed to be solved with technology or “ordinary” tasks), of new instrumental techniques and their mathematical productivity, of the teacher's organisation of classroom activities, as important for the future.

**Biases and limits**

The most obvious sources for biases were ourselves, the researchers, because we came from five different research teams working in various fields of the use of IC Technologies. At the beginning, this brought many distortions in the coding, and we had to discuss every item of the questionnaire. From the observation of statistical indicators, we are now reasonably confident that the initial heterogeneity was overcome. A critical circumstance is that we were researchers from a single country and “cultural” biases may exist. Another limitation was that we could not analyse methods for learning mathematics on CD-ROM or on the Internet because we found only short presentations which were not sufficiently informative.

**Conclusion**

We saw the huge literature on the use of IC Technologies for teaching and learning mathematics as data representative of the efforts of a big and varied community of teachers, innovators and researchers. We had the intuition that knowledge about integration could be derived from an analysis of this data. Starting from a corpus as large as possible we got a first picture of what this literature is. Technical presentations and reports on innovative classroom use make the bigger part of this corpus. Because they look at the new applications appearing day after day, these papers are potentially interesting contributions on the use of up to date technology. On the other hand, the qualitative study of papers in the CAS sub-corpus shows that the ideas in these presentations and reports are generally weakly supported by reflection and experimentation and cannot address the complexity of the educational situations. Looking qualitatively at the more research-oriented second stage corpus,
we saw a slow evolution towards attention to more varied aspects of educational use of IC Technologies and more dialectical cognitive approaches. So the difficult integration can be seen through this picture: innovations present a wealth of ideas and propositions whose diffusion is problematic; research struggles to tackle the complexity of the integration of evolving technologies.

Our aim was to build a framework as a method to look at research and experimentation. This framework was done using several dimensions which arose from a theoretical reflection, that the qualitative study of the global corpus helped to specify into a questionnaire. A statistical procedure was used to identify clusters of studies sharing a common concern in one of the dimensions. Then, looking at outcomes in each cluster, we could identify concerns and findings. In practice, this framework should help innovators or researchers to characterise a project or a field of research by means of the questionnaire and then to get insight on its specific contribution by looking at its position in the partitions. In our mind, this method is a tool to grasp the complexity of the introduction of technology or, more precisely, to tackle the integration of IC Technologies with a "multidimensional problématique”.

1. Global reaction
The work of Lagrange, Artigue, Laborde and Trouche is impressive. The French team surveyed an immense number (662!) of publications on technology use in mathematics education. For a researcher in this field, it is very fascinating to read this synthesis of such a massive corpus of literature. The virtue of the study is that it helps in identifying trends, developments and progress in research into technology use in mathematics teaching and learning. Looking back at the work of the last decade enables us to better see the headlines, the dead ends, the topics 'in fashion' and the issues to be elaborated. Also, as the authors indicate, the described framework can help innovators or researchers to characterise a project or a study and to position it in a broader perspective. To me, those are the most important merits of this study.

However, some questions can be raised. My first 'question mark' concerns the aims of the study. Related to this is the point of the dimensions that the study wants to identify. What exactly are these dimensions and what are they used for? Furthermore, depending on the aims of the study, the value of the conducted cluster analysis can be questioned. To summarize, I feel that the quantitative part of the study is too far away from the concrete integration of technology in the classroom to contribute to the 'understanding of integration' that the authors are searching for.

Let me address each of these issues briefly and then come back to the theory of instrumentation.

2. The aims of the study
The first issue I would like to raise is that of the aim of the study. What are the goals of the research presented here? In their introduction, the authors mention their concern about the discrepancy between promising Information and Communication Technologies (ICT) and low actual integration in the classroom. 'Our aim was to build tools for the understanding of integration ...'. Further on in the paper, two aims are distinguished: building a methodology for analyzing research, and identifying trends. I think these last two goals are achieved, although maybe it is better to speak about an investigation of diversity than about a synthesis. However, the study, as it is presented here, did not succeed in contributing to the understanding of the integration of technological tools. The subject of the study, as I see it, is not the integration of
technology in the mathematics classroom, but literature on this issue. In this sense, it is really a meta-perspective, as is indicated in the title of the paper. The paper is far away from the mathematics classroom; it is a survey of literature on the teaching and learning of mathematics using ICT. Of course, it is quite legitimate and useful to serve a meta-goal. But as long as results and details of research projects are not considered, a cumulating understanding of what happens in the heads of the students cannot be expected.

3. What are dimensions?
The second point, the meaning of the word ‘dimensions’, is related to the question of the aim of the study. To me it remains unclear what exactly is meant by a dimension. Is it ‘a perspective’, is it ‘an approach’, is it set of questions in the questionnaire that was used in the analysis? If I look at the eight dimensions that are defined and were applied to a subset of 79 papers, it is not clear to me what they stand for and if there are any relations between them.

Furthermore, the way in which the dimensions are identified by the researchers is not explained. I regret that the researchers did not (explicitly) take their impressive expertise in this field as a point of departure for such an identification in order to compare this with the massive data they gathered. The only dimension that is discussed somewhat in detail, the dimension of the ‘problematiques’, seems to be related to the CAS research where it is derived from. The question arises whether dimensions inferred from studies concerning CAS are also valid for research into technology in education in general. Nevertheless, the identification of the most important aspects or themes that play a role in the integration of technology in the mathematics classroom is an interesting goal.

As far as the development of research is concerned, I recognize two of the mentioned trends from my personal perspective:

- The trend from a rather naïve and optimistic perspective (‘technology improves teaching and learning’) to a view with more nuances and with attention to the complicating aspects of technology use, the pitfalls as they are mentioned in the title of this research forum. The presentation of Hershkowitz and Kieran provides a nice example of this approach.

- The development of research into technology that stands more and more in the tradition of research on mathematics education in general. The presence of a constructivist theoretical framework in many studies, which is mentioned by the authors, illustrates this.

4. The cluster analysis

After the dimensions were identified, they were made operational in a questionnaire. The ‘instrumental’ dimension that is elaborated in the paper illustrates some of the
difficulties with this. For example, the question q5 addresses the instrumentation process over time. My impression is that in the papers that are discussed, the time element concerns the question of efficiency and time savings, which is in my opinion not relevant in the instrumentation process; more important are the changes in student behavior over time. For example, it is not clear what the papers cited in cluster 1 have to do with instrumentation. Also, the role of time in the paper of Mayes in cluster 3 is not made explicit. I was also surprised to see that the three clusters that are described as informative together only contain 28 out of 79 papers.

The questionnaire is applied to a second stage corpus of 79 papers. It would have been interesting to know a bit more about the way the team selected the second corpus papers out of the first corpus. Of course one can’t explain all the details in a paper like this, but I would appreciate having some more information on the criteria for this crucial selection.

5. The relevance of instrumentation

The exemplary partition of the instrumental dimension reveals the background of the authors: they have contributed much to the development of the concept of instrumentation of ICT tools. In my perception, the relevance of this theory is that it can help to interpret and to understand the behavior of students using technology. The first paper of this research forum, presented by Hershkowitz and Kieran, can serve to illustrate this.

In the contribution of Hershkowitz and Kieran, students use the linear regression procedure on a graphing calculator to fit a line through five data points that were calculated. The underlying algebraic relationship between the variables, however, was non-linear in some of the cases. Apparently, the students mastered the (non-trivial!) technical part of the instrumentation scheme. However, they are unaware of the mathematical meaning of this command. The accompanying mental scheme of what it means to apply a linear regression and when it is an appropriate technique seems to be lacking.

Thanks to the graphing calculator, teachers may be inclined to use regression with their students, maybe even for fitting a line through two given points, thus freeing the students from some algebra. However, if the teachers forget to pay attention to the limitations of the method and to the difficulties of curve fitting, the resulting instrumentation scheme will be incomplete. I suppose many teachers of a curve fitting course have experiences with students obtaining a perfect fit through n given data points using a polynomial of degree \((n - 1)\) without wondering if the algebraic model is appropriate. In my opinion, the dialectic relationship between ICT technique and mathematical concept, the interplay between the two, is very important in the theory of instrumentation and in the understanding of student behavior while using ICT.
RESEARCH FORUM 2

Theme
Early algebra

Coordinator
Janet Ainley

Session 1

• “Can young students operate on unknowns?” David Carraher, Analúcia D. Schliemann, Bárbara M. Brizuela

Reactions

• “Operating on the unknowns: what does it really mean?” Liora Linchevski
• “Of course they can!” Luis Radford
• “Reflections on early algebra” David Tall
• “Unknowns or place holders?” Anne R. Teppo
• “The unknown that does not have to be known” Elizabeth Warren and Tom J. Cooper

• Audience discussion in small groups

Session 2

• Brief introduction and re-cap of questions
• Audience discussion in small groups continue
• Plenary panel
RESEARCH FORUM ON EARLY ALGEBRA

Co-ordinator: Janet Ainley
MERC, University of Warwick, UK

The purpose of this Research Forum is to debate, in the context of both well established and more recent research evidence, issues about the relationship between arithmetic and algebra, including their mathematical similarities and differences, their relative places in the school curriculum, the apparent difficulties of the transition from arithmetic to algebra and pedagogic approaches which address this transition.

To create a context for this debate, David Carraher, Analucia Schlieman and Barbara Brizuela were asked to write a stimulus paper based on their research into algebraic thinking with 8-9 year olds. Their paper, which follows, challenges some assumptions embodied in school curricula. It was made available on the PME25 website, and anyone planning to attend the conference was invited to contribute a short written reaction.

Because of limitations of space in these Proceedings, I had the difficult task of selecting from these reactions five which represented the range of issues raised. These reactions, from Liora Linchevski, Luis Radford, David Tall, Anne Teppo, and Elizabeth Warren and Tom Cooper, are printed here. I am very pleased that most of those reactors whose papers could not be included have accepted the invitation to contribute a short written reaction.

The organisation of the Forum

In the first session, David Carraher and his colleagues will make a presentation based on their paper, including some video footage, to give a shared context for discussion. The authors of the five Reaction papers will then each make a short response, and raise some specific questions for discussion. There will then be a substantial time for group discussions, running over into the second session.

The second session will also contain an opportunity for groups to report on their discussions, and a 'plenary panel' discussion with the paper authors.

If you plan to participate in the Forum, please try to read the papers in this section before the first session.
CAN YOUNG STUDENTS OPERATE ON UNKNOWNS?¹

David Carraher, TERC
Anaúcia D. Schliemann, Tufts University
Bárbara M. Brizuela, TERC and Harvard University

Algebra instruction has traditionally been delayed until adolescence because of mistaken assumptions about the nature of arithmetic and about young students’ capabilities. Arithmetic is algebraic to the extent that it provides opportunities for making and expressing generalizations. We provide examples of nine-year-old children using algebraic notation to represent a problem of additive relations. They not only operate on unknowns; they can understand the unknown to stand for all of the possible values that an entity can take on. When they do so, they are reasoning about variables.

Mathematics educators have long believed that arithmetic should precede algebra because it provides the foundations for algebra. Arithmetic presumably deals with operations involving particular numbers; algebra would deal with generalized numbers, variables and functions. Hence instructors of young learners focus upon number facts, number sense, and word problems involving particular values. Algebra teachers pick up at the point where letters are used to stand for unknowns and sets of numbers. Although there are good reasons for this natural order it lends itself to discontinuities and tensions between arithmetic and algebra.

The difficulties adolescents show in learning algebra (Booth, 1984; Filloy & Rojano, 1989; Kieran, 1985, 1989; Sfard & Linchevsky, 1994; Steinberg, Sleeman & Ktorza, 1990; Vergnaud, 1985) has led to an even starker separation of arithmetic from algebra. Many have believed that algebraic reasoning is closely tied to and constrained by students’ levels of cognitive development. For them, algebraic concepts and reasoning require a degree of abstraction and cognitive maturity that most primary school students, and even many adolescents, do not yet possess. Some have suggested that it would be developmentally inappropriate to expect algebraic reasoning of children who have not reached, for example, the period of formal operations (e.g. Collis, 1975). Others (Filloy & Rojano, 1989; Sfard, 1995; Sfard & Linchevsky, 1994) have drawn upon historical analyses such as Harper’s (1987) to support the idea that algebraic thinking develops through ordered and qualitatively distinct stages. Filloy and Rojano (1989) note that western culture took many centuries to finally develop, around the time of Viète, a means for representing and operating on unknowns; they propose that something analogous occurs at the level of individual thought and that there is a “cut-point” separating one kind of thought from the other, “a break in the development of operations on the unknown (op. cit., p. 19)”. Herscovics and Linchevski (1994) proposed that student’s difficulties are associated with a cognitive gap between arithmetic and algebra, “the students’ inability to operate spontaneously with or on the unknown” (p. 59). Function concepts and their associated algebraic notation are postponed until adolescence for similar reasons.

¹This work has been supported by grant #9909591 of the National Science Foundation. We thank Anne Goodrow, Susanna Lara-Roth, and Darrell Earnest for their contributions to the empirical study.
We do not wish to deny that there are developmental prerequisites for learning algebra. And we agree that there is a large gap between arithmetic and algebra in mathematics education from Kindergarten to grade 12. The question is: does it have to be this way? Is the gap set by developmental levels largely out of the sphere of influence of educators? Or is it to a great extent a matter of learning? Or of teaching itself? Does the fact that there presently is a large gap signify that there must always be such a gap?

It is crucial for students to learn to represent and manipulate unknowns. However, we believe it is a mistake to attribute the late emergence of this ability to developmental constraints. We believe it emerges late because algebra enters the mathematics curriculum too late and at odds with students’ knowledge and intuitions about arithmetic.

**Arithmetic As Inherently Algebraic: Functions and Unknowns**

Arithmetic derives much of its meaning from algebra. The expression, “+ 3”, can represent both an operation for acting on a particular number and a relationship among a set of input values and a set of output values. This is borne out by the fact that we can use functional, mapping notation, “n → n +3”, to capture the relationship between two interdependent variables, n and n plus three (Schliemann, Carraher, & Brizuela, 2000; Carraher, Schliemann, & Brizuela, 2000). So the objects of arithmetic can be thought of as both particular (if n = 5 then n+3 = 5+3 = 8) and general (n → n +3, for all values of n); arithmetic encompasses number facts but also the general patterns that underlie the facts. Word stories need not be merely about working with particular values but working with sets of possible values and hence about variables and their relations.

Arithmetic also involves representing and performing operations on unknowns. This is easy to forget since arithmetic problems are typically worded so that students need invest a minimum of effort to using written notation to describe known relations. The relations tend to be expressed by students in final form, where the unknown corresponds to empty space to the right of an equals sign. Were arithmetic problems sufficiently complex that students could not straightaway represent the relations in final form, it would become easier to appreciate how central algebraic notation is to solving arithmetic problems.

We are suggesting that arithmetic can and should be infused with algebraic meaning from the very beginning of mathematics education. The algebraic meaning of arithmetical operations is not an optional “icing on the cake” but rather an essential ingredient of the cake itself. In this sense, we believe that algebraic concepts and notation are part of arithmetic and should be part of arithmetic curricula for young learners.

During the last three years we have been working with children between 8 and 10 years of age to explore how to bring out the algebraic character of arithmetic (see Brizuela, Carraher, & Schliemann, 2000; Carraher, Brizuela, & Schliemann, 2000; Carraher, Schliemann, & Brizuela, 2000; Schliemann, Carraher, & Brizuela, 1999). Our work focuses on how 8 to 10 year-old students think about and represent functions and unknowns, using both their own representations and those from conventional mathematics. This work is guided by the ideas that: (1) children’s understanding of additive structures provides a fruitful point of departure for “algebraic arithmetic”; (2) additive structures require that children develop an early awareness of negative numbers and quantities and to their representation in number lines (3) multiple problems and representations for handling unknowns and variables—including
algebraic notation—should become part of children's repertoires as early as possible; and
(4) meaning and children's spontaneous notations should provide a footing for syntactical
structures during initial learning even though syntactical reasoning based on the structure of
mathematical expressions should become relatively autonomous over time.

Here we will look at evidence that young children can represent and operate on unknowns.
Our examples are taken from our longitudinal investigation with the students of three third-
grade classrooms in a public elementary school from a multi-cultural working-class
community in Greater Boston. When the children were 8 and 9 years of age, we held eight
90-minute weekly meetings in each of three classes, working with additive structures.
Descriptions of our class materials are available at www.earlyalgebra.terc.edu. Our
examples come from the seventh lesson we held in one of the three classrooms. There were
16 students in the class that day. Our team of researchers included a teacher, Bárbara, and
two camerapersons who occasionally interviewed children as they worked through
problems. The students' regular classroom teacher was also present. The following problem
served as the basis for discussion and individual work:

Mary and John each have a piggy bank.
On Sunday they both had the same amount in their piggy banks.
On Monday, their grandmother comes to visit them and gives 3 dollars to each of them.
On Tuesday, they go together to the bookstore. Mary spends $3 on Harry Potter's new
book. John spends $5 on a 2001 calendar with dog's pictures on it.
On Wednesday, John washes his neighbor's car and makes $4. Mary also made $4
babysitting. They run to put their money in their piggy banks.
On Thursday Mary opens her piggy bank and finds that she has $9.

We initially displayed the problem in its entirety, so that the students could understand that
it consisted of a number of parts. But then we covered up all days excepting Sunday.

Representing An Unknown Amount

The student's first problem sheet contained information only about Sunday. It also
contained the following variable number line (or N-number line):

<table>
<thead>
<tr>
<th>N-3</th>
<th>N-2</th>
<th>N-1</th>
<th>N</th>
<th>N+1</th>
<th>N+2</th>
<th>N+3</th>
<th>N+4</th>
<th>N+5</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

After reading what happened each day, students worked alone or in pairs, trying to represent
on paper what was described in the problem. During this time, members of the research
team walked up to children, asking them to explain what they were doing and questioning
them in ways that helped them to refine their representations.

Sunday: After Kimberley reads the Sunday part for the whole class, Bárbara asks whether
they know how much money each of the characters in the story has. The children state a
unison "No" and do not appear to be bothered by that. A few utter: "N" and Talik states:
"N, it's for anything". Other children shout "any number" and "anything".

When Bárbara asks the children what they are going to show on their worksheets for this
first step in the problem, Filipe says "You could make some money in them [the piggy
Bárbara reminds him that we don’t know what the amount is. He suggests that he could write N and Jeffrey says that this is what he will do. The children start writing and Bárbara reminds them that they can use the N-number line on their worksheets if they so wished. She also draws a copy of the line on the board.

Jennifer used N to represent the initial amount in each bank. She draws two piggy banks, labeling one for Mary, the other for John, and writes next to them a large N along with the statement "Don’t know?" David points to “N” on her handout and asks:

David: Why did you write that down?
Jennifer: Because you don’t know. You don’t know how much amount they have.
David: [...] What does that mean to you?
Jennifer: N means any number.
David: Do they each have N, or do they have N together?
Jennifer: (no response).
David: How much does Mary have?
Jennifer: N.
David: And how about John?
Jennifer: N.
David: Is that the same N or do they have different Ns?
Jennifer: They’re the same, because it said on Sunday that they had the same amount of money.
David: And so, if we say that John has N, is it that they have, like, ten dollars each?
Jennifer: No.
David: Why not?
Jennifer: Because we don’t know how much they have.

The children themselves propose using N to represent an unknown quantity. We had introduced the convention before in other contexts but now it was making its way into their own repertoire of representational tools. Several children seem comfortable with the notation for an unknown and with the idea that they could work with quantities that might remain unknown. Some start by attributing a particular value to the unknown amounts in the piggy banks but, as they discuss what they are doing, most of them seem to accept that this was only a guess. Their written work shows that, by the end of the class, 13 of the 16 children adopt N to represent how much money Mary and John started out with. One of the children chose to represent the unknown quantities by question marks and only two children persist using an initial specific amount in their worksheets.

**Talking About Changes in Unknown Amounts**

Monday: When the children read that on Monday each child received $3, they inferred that Mary and John would continue having the same amount of money as each other, and that they both had $3 more than the day before. As Talik explains:

Talik: ... before they had the same amount of money, plus three, [now] they both had three more, so it’s the same amount.

Bárbara then asks the children to propose a way to show the amounts on Monday. Nathan proposes that on Monday they would each have N plus 3, explaining:
Nathan: ...because we don’t know how much money they had on Sunday, and they got plus, and they got three more dollars on Monday.

Talik proposes drawing a picture showing Grandma giving money to the children. Filipe represents the amounts on Monday as “? + 3”. Jeffrey says that he wrote “three more” because their grandmother gave them three more dollars. But when David asks him how much they had on Sunday he incorrectly answers, “zero”. Max, sitting next to him then says, “you don’t know.” The drawing in this page shows Jeffrey’s spontaneous depiction of $N + 3$. Note the 3 units drawn atop each quantity, $N$, of unspecified amount.

James proposes and writes on his paper that on Sunday each would have “$N + 2$” and therefore on Monday they would have $N + 5$. Carolina writes $N + 3$. Jennifer writes $N + 3$ in a vertical arrangement with an explanation underneath: “3 more for each”. Talik writes $N + 3 = N + 3$. Carolina, Arianna, and Andy write $N + 3$ inside or next to each piggy bank under the heading Monday. Jimmy, who first represented the amounts on Sunday as question marks, now writes $N + 3$ with connections to Mary and John’s schematic representation of piggy banks and explains:

**Jimmy:** Because when the Grandmother came to visit them they had like, $N$. And then she gave Mary and John three dollars. That’s why I say [pointing to $N + 3$] $N$ plus three.

Bárbara comments on Filipe’s use of question marks. He and other children acknowledge that $N$ is another way to show the question marks. She tells the class that some of the children proposed specific values for the amounts on Sunday. Filipe says nobody knows and James says that they’re wrong. Jennifer says that it *could* be one of those numbers.

Only three children do not write $N + 3$ as a representation for the amounts on Monday.

**Operating on Unknowns with Multiple Representations**

**Tuesday:** When they consider what happened on Tuesday, some of the students begin to feel uncomfortable because the characters have begun to spend money and the students feel the need to assure themselves that the characters have enough in their piggy banks. A child says that they probably have ten dollars. Most of the children assume that there must be at least $5 in their piggy banks by the end of Monday; otherwise John could not have bought a $5 calendar (they seemed uncomfortable with him spending money he didn’t have).

Bárbara recalls for the class what happened on Sunday and Monday. The children agree that on Monday they had the same amounts. When she asks Arianna about their amounts on Tuesday, she and other children agree that they will have different amounts of money because John spent more money, leaving Mary with more money.

Jennifer then describes what happened from Sunday to Tuesday, concluding that on Tuesday Mary ends up with the same amount of money that she had on Sunday, “because she spends her three dollars.” At this point Bárbara encourages the children to use the $N$-number line on the board. She draws green arrows going from $N$ to $N + 3$ and then back to $N$.
again to show the changes in Mary’s amounts. She shows the same thing with the notation, narrating the changes from Sunday to Tuesday, step by step, and getting the children’s input while she writes \( N +3-3 \). She then writes a bracket under \( +3-3 \) and a zero below it, comments that \(+3-3\) is the same as zero, and extends the notation to \( N +3-3=N+0=N \). Jennifer then explains how the 3 dollars spent negates the 3 dollars given by the grandmother: “Because you added three, right? And then she took, she spent those three and she has the number she started with.”

Using the N-number line Bárbara then leads the students through John’s transactions, drawing arrows from \( N \) to \( N +3 \), then \( N -2 \), for each step of her drawing. While sketching each arrow, she repeatedly draws upon the student’s comments to arrive at the notation \( N +3-5 \). Some children suggest that this is equal to “N minus 2”. Bárbara continues, writing \( N +3-5=N-2 \). She asks Jennifer to point to, on the number line on the board, the difference between John and Mary’s amounts on Tuesday. Jennifer first points ambiguously to a position between \( N -2 \) and \( N -1 \). When Bárbara asks her to show exactly where the difference starts and ends, Jennifer correctly points to \( N -2 \) and to \( N \) as the endpoints. David asks Jennifer how much John would have to receive to have the amount he had on Sunday. She answers that we would have to give two dollars to John and explains, showing on the number line, that, if he is at \( N -2 \) and we add 2, we get back to \( N \). Bárbara represents what Jennifer has said as: \( N -2+2=N \). Jennifer grabs the marker from Bárbara’s hand, brackets the sub-expression, “\(-2+2\)”, and writes a zero under it. Bárbara asks why it equals zero and, together with Jennifer, goes through the steps corresponding to \( N -2+2 \) on the number line showing how \( N -2+2 \) ends up at \( N \).

Talik shows how this works if \( N \) were 150. Bárbara uses his example of \( N =150 \) and shows how one returns to the point of departure on the line.

Nathan’s drawing (right) shows Sunday (top), Monday (bottom left), and Tuesday (bottom right). For Tuesday, he drew iconic representations of the calendar and the book next to the values $5 and $3, respectively, with the images and dollar values connected by an equals sign. During his discussion with Anne, a member of the research team, and using the number line as support for his decisions, he writes the two equations \( N +3-5=N-2 \) and \( N +3-3=N \). Later, when he learned that \( N \) was equal to 5 (after looking at the information about Thursday) he wrote 8 next to \( N +3 \) on the Monday section of his worksheet.

Wednesday: Filipe reads the Wednesday step of the problem. Bárbara asks whether Mary and John will end up with the same amount as they had on Monday. James says “No.” Arianna then explains that Mary will have \( N +4 \) and John will have \( N +2 \).
Bárbara draws an \( N \)-number line and asks Arianna to tell the story using the line. Arianna represents the changes for John and for Mary on the \( N \)-number line. Bárbara then writes out the notations, \( N +4=N+4 \), then \( N -2+4 = N +2 \). Talik volunteers to explain this. He says that if you take 2 from the 4, it will equal up to 2. To clarify where the 2 comes from, Bárbara represents the following operations on a regular number line: \(-2+4 = 2\).

Bárbara asks if anyone can explain the equation referring to Mary’s situation, namely, \( N+3-3+4=N+4 \). Talik volunteers to do so and crosses out the \(+3-3\) saying that we don’t need that anymore. This is a significant moment because no one has ever introduced the procedure of striking out the sum of a number and its additive inverse (although they had used brackets to simplify sums). It may well represent the meaningful emergence of a syntactical rule.

Bárbara brackets the numbers and shows that \(+3-3\) yields zero. She proposes to write out the “long” equation for John, \( N +3-5+4 = N +2 \). The students help her to go through each step in the story and build the equation from scratch. But they do not get the result, \( N +2 \), immediately. When the variable number line comes into the picture they see that the result is \( N +2 \). Bárbara asks Jennifer to show how the equation can be simplified. Jennifer thinks for a while, Bárbara points out that this problem regarding John’s amount is harder than the former regarding Mary. Bárbara asks her to start out with \(+3-5\); Jennifer says \(-2\). Then they bracket the second part at \(-2+4\), and Jennifer, counting on her fingers, says it is \(+2\).

Talik explains, “\( N \) is anything, plus 3, minus 5 is minus 2; \( N \) minus 2 plus 4, equals (counting on his fingers) \( N \) plus 2. He tries to group the numbers differently, adding 3 and 4 and then proposing to take away 5. Bárbara helps him and shows that \(+3+4\) yields \(+7\). When she subtracts 5, she ends up at \(+2\), the same place suggested by Jennifer.

\textbf{Thursday:} Amir reads the Thursday part of the problem, stating that Mary ended with $9.00, to which several students respond that \( N \) has to be 5. Bárbara asks, “How much does John have in his piggy bank?” Some say (incorrectly) that he has two more; other children say that he has 7. Some of the students figure out from adding 5+2, others from the fact that John was known to have 2 less than Mary, since \( N +2 \) is two less than \( N +4 \).

Bárbara ends by filling out a data table that included the names of Mary and John and the different days of the week with the children’s suggestions for how much money each one had on each of the different days. Some students suggest using expressions containing \( N \) and others suggest expressions containing the now known value, 5.

\textbf{Some Reflections}

Many students began by making iconic drawings and assigning particular values to unknowns. But over time, in this lesson, and in others like it, the students increasingly came to use algebraic and number line representations to describe the relations in stories.

We should be careful not to interpret their behavior as totally spontaneous; in fact, children’s behavior, even when indicative of their own personal thinking, expresses itself through culturally grounded systems, including mathematical representations of the various sorts we introduced.

Number line representations are a case in point. By the time our students had reached the class we analyzed above, they had already spent several hours working with number lines. They also learned to express such short cuts or simplifications notationally: “\(+7 -10\)” could
be represented as "-3" since each expression had the same effect. We introduced the variable number line (N-number line) as a means of talking about operations on unknowns. "Minus four" could be treated as a displacement of four spaces leftward from N, regardless of what number N stood for. It could equally well represent a displacement from, say, \(N + 3\) to \(N - 1\). At the projector students interpreted values of N when the N-number line was set just above and slid over the regular number line. They also gradually realized they could infer the values of, say, \(N + 43\) (even though it was not visible on the projection screen) from seeing that \(N + 7\) sat above 4 on the regular number line. The connections to solving algebraic equations should be obvious to the reader.

We have found that children as young as eight and nine years of age can learn to comfortably use letters to represent unknown values and can operate on representations involving letters and numbers without having to assign values. To conclude that the sequence of operations \(N+3-5+4\) is equal to \(N + 2\), and to be able to explain, as many children were able to, in lesson 7, that \(N + 2\) must equal two more than what John started out with, \textit{whatever that value might be}, is a significant feat—one that many people would think young children incapable of understanding. Yet we found such cases to be frequent and not confined to any particular kind of problem context. It would be a mistake to dismiss such advances as mere concrete solutions, unworthy of the term "algebraic". Children were able to operate on unknown values and draw inferences about these operations while fully realizing that they did not know the values of the unknowns.

In addition, we have elsewhere (Schliemann, Carraher, & Brizuela, 2000; Carraher, Schliemann, & Brizuela, 2000) found that children can treat the unknowns in additive situations as having multiple possible solutions. For example, in a simple comparison problem where we described one child as having three more candies than another, our students from grade three were able to propose that one child would have \(N\) candies and the other would have \(N + 3\) candies. Furthermore, they found it perfectly reasonable to view a host of ordered pairs, \((3, 6), (9, 12), (5, 8)\) as \textit{all} being valid solutions for the case at hand even though they knew that in any given situation, only one solution could be true. They even were able to express the pattern in a table of such pairs through statements such as, "the number that comes out is always three larger than the number you start with". When children make statements of such a general nature they are essentially talking about relations among variables and not simply unknowns restricted to single values.

By arguing that children can learn algebraic concepts early we are not denying their developmental nature, much less asserting that any mathematical concept can be learned at any time. Algebraic understanding will evolve slowly over the course of many years; but we need not await adolescence to help its evolution.

Final Remarks

Over the last several decades several mathematics educators have begun to suggest that algebra should enter the early mathematics curriculum (e. g., Davis, 1985, 1989; Davydov, 1991; Kaput, 1995; Lins & Gimenez, 1997; Vergnaud, 1988; NCTM, 2000). Some have initiated systematic studies in the area and begun to put into practice ideas akin to those expressed here (Ainley, 1999; Bellisio & Maher, 1999; Blanton & Kaput, 2000; Brito Lima & da Rocha Falcao, 1997; Carpenter & Levy, 2000; da Rocha Falcao & al., 2000; Davis, 1971-72; Kaput & Blanton, 1999; Schifter, 1998; Slavitt, 1999; Smith, 2000).
Still, much remains to be done. "Early algebra education" is not yet a well-established field. Surprisingly little is known about children's ability to make mathematical generalizations and to use algebraic notation. As far as we can tell, at the present moment, not a single major textbook in the English language offers a coherent vision of algebraic arithmetic. It will take many years for the mathematics education community to develop practices and learning structures consistent with this vision.

We view algebraic arithmetic as an exciting proposition, but one for which the ramifications can only be known if a significant number of people undertake systematic teaching experiments and research. The ramifications will extend into many topics of mathematical learning, teacher development, and mathematical content itself. It will take a long time for teacher education departments to come to realize that the times have changed and to adjust their teacher preparation programs accordingly. We hope that the mathematics education community and its sources of funding recognize the importance of this venture.

References

Carragher, Schliemann, and Brizuela raise in their paper a fundamental question: when is a decision to teach a subject at a certain age or in a certain sequence soundly based on some developmental prerequisites and when is it simply a result of a long unquestioned educational tradition? For them this question is crucial not because of time wasted or students’ potential not fully developed but because a delayed introduction, they believe, in and of itself might be the very reason for future conceptual difficulties. They claim that sometimes we postpone the introduction of a mathematical topic until the emergence of some theoretically required ability while the late emergence of this ability is a direct result of the late introduction.

The mathematical topic Carragher et al deal with in this paper is the transition from arithmetic to algebra and more specifically the ability of beginning algebra students to operate on the unknowns. They believe that the research reported on “cut-points” separating arithmetical from algebraic thought (Filloy and Rojano, 1989), on “cognitive-gaps” between arithmetic and algebra (Herscovics and Linchevski, 1994), and other well-documented difficulties in early algebra (e.g. Collis, 1975; Kieran, 1985, 1989; Steinberg, Sleeman and Ktorza, 1990; Sfard and Linchevski, 1994; Sfard, 1995) has played a major role in educators’ decision to introduce algebra only at higher grades. They question this universally accepted decision claiming that these well-documented cognitive-gaps are so widely detected among beginning algebra students because algebra enters the mathematics curriculum too late and with odds with students’ knowledge and intuitions about arithmetic.

The lesson
The children’s performance while negotiating the event of the story is interesting and it, indeed, challenges the idea of a “gap”. The problem presented to the children consisted of several parts where the departure information is an unknown number. According to the paper some of the children treated this unknown initial value as a “known” and were even able to use the algebraic notation – the N – to represent it. Moreover, the later parts of the story – which contain only specific numbers – were translated into the mathematical language and added sequentially to the initial value (e.g. N + 3), the obtained expressions were treated as numbers albeit not yet known. Intermediate manipulations were carried out by the children (e.g. N + 3 −3 = N, or even the more impressive example N + 3 −5 = N - 2) leading to equivalent expressions.

The authors report that their teaching interventions included an explicit introduction of the letter as representing an unknown (or any) quantity and the “N-number line” as the
model to be used for representing operations on letters, numbers, or combinations of the two. It can be concluded from the paper that the researchers, who served also as teachers/interviewers, also brought the mathematical voice into the class. For example, sentences like: "N, it’s for any number" were initially introduced by them.

Some Reflections

It will be helpful to further elaborate on some of the theoretical ideas this paper challenges and to reexamine these ideas in the light of the reported teaching experiment.

Using letters to represent unknown numbers

It is widely accepted that letters can be used meaningfully within children’s arithmetic experience. Carraher et al takes this idea far beyond what is considered the norm in many classes. The debate, however, is whether the presence of letters in and of itself guarantees that algebra has been introduced. Some people tend to see algebra everywhere and claim that whenever letters or missing addends are present the children are “doing algebra”. Others claim that the presence or absence of letters cannot be considered as the indicator for algebraic thinking, claiming that the criterion is not to be found in the displayed task (whether it contains letters or not) but rather in the solver strategy. If letters are part of the expression at hand, one of the requirements the solver has to meet is the ability to perceive “letters” as numbers. This ability is a combination of several aspects.

I. The Lack of Closure

Collis (1974) observed that children at the age of 7 require that two elements connected by an operation be actually replaced by a third element. From the age of 10 onwards, they do not find it necessary. This observation lead to the conclusion that algebraic expressions cannot be introduced to children before the age of 10 (generally speaking) since the operations performed on letters cannot be closed as in arithmetic. The research conducted by Carraher et al seriously challenges these observations; their young pupils referred to N + 3 (for example) as a number and did not rejected it as uncompleted or unclosed process. From this perspective these children perceived the unknown as a number. However, Herscovics and Linchevski (1994) note that Collis’ age levels have to be taken in some caution since the algebraic expressions used in his work were formal and detached from any context.

II. Operating on and with the unknown

In Herscovics and Linchevski (1994) we write: “...the idea (of Collis) of a pronumeral evolving into a generalized number is quite enlightening. However, it is not sufficient to endow it with "the same properties as any number", for this can be interpreted quite passively, as for example “let n be an even number”. (let N be the initial amount of money in the piggy bank.) In fact, the pronumeral must also be endowed with the operational properties of number; the unknown must be perceived as a generalized
number that can be subjected to all operations performed with or on the numbers. Perhaps the expression “operational generalized number” describes this necessary evaluation...”.

What does it mean? Operating on and with the unknown implies understanding that the letter is a number. It does not only symbolize a number, stand for a number, and it does not only a tag/label/sign for an unknown number; it is a number. And from this understanding the ability to operate on and with the unknown is emerged. The ability to perform operations on the letters is derived from this perception. Thus, student that has constructed this concept has the ability to add, subtract, bracket..., unknown numbers exactly as he or she has in the context of numbers. To transform, for example, \( X + 3X \), into \( 4X \) realizing that while doing it he or she were adding numbers and not just executing formal rules. Moreover, these pupils are expected to be able to use, for example, inverse operations on variables as naturally and as spontaneously as they do it on numbers. For example, the solution of an equation like \( 32 + X = 3X \) should trigger the use of inverse operation on the \( X \) on the left hand-side of the equation thus transforming this equation to \( 32 = 3X - X \), exactly as it occurs with an equation like \( X + 15 = 31 \) where they intuitively say that \( X \) equals to 31-15. (This last sentence puts Filloy and Rojano’s notion of the didactic-cut in context). Thus, transforming an expression like \( N + 3 - 3 \) to \( N \) (as appears in the current paper), does not satisfies this criterion since these transformations do not involve the unknown. It is what we labeled as “static view of the literal symbol” (Linchevski and Herscovics, 1996) or “working around the literal symbol”. The ability of the children in Carraher, Schliemann, and Brizuela’s research to manipulate the numbers in an expression with one occurrence of the unknown and a string of numbers, is described in details in Herscovics and Linchevski (1994), and Linchevski and Herscovics (1994, 1996). Moreover, in these papers it was reported that sixth and seventh graders operated on the numbers in algebraic expressions of this sort spontaneously, without any prior instruction in algebra. The fact that the research population of these studies was sixth and seventh graders does not imply that younger students would not react in the same way. However, it certainly implies that the choice of the target population was heavily influenced by the current curriculum where algebra is usually introduced in the seventh grade. From this perspective Carraher et al’s research is a major step forward. Nevertheless, we have to bear in mind that in their study an intensive and direct teaching interventions took place while the other papers reported on spontaneous development.

III. The cognitive gap

The existence of a cognitive gap (as defined in Herscovics and Linchevski, 1994) implies that the students were encouraged to proceed on their own as far as they wish and as long as their own procedures and approaches satisfied them. And a teaching intervention took place only at the point where their intuitive methods, drawn from their existence knowledge and their interaction with the new material, reached an upper limit and they became aware of the limits of their methods thus looking for new
points of view. The notion cognitive gap is reserved to these steps in the pupil’s learning experience where without a teaching intervention (to our best judgment and research methodology) he or she would not make a certain step. Some of these junctures might be different for different people and some are shared by many. Operating on and with the unknown as discussed in the previous paragraph is one of this junctures. Thus, after identifying a cognitive gap it is trivial to find it in (almost) every age if teaching has not taken place and it is less surprising not to find it after teaching took place.

However, this explanation still leaves the question with regard to the “optimal” age in which the teaching should take place, what are the desired interventions and what differences would be traced in the future is still unanswered. Carraher et al’s research is a trial to start answering these questions. They do not reject the need for an explicit teaching intervention that provides the students with new tools and new mathematical language: thus they are actually accepting the existence of the cognitive gap.

In fact their study does not refute the existence of the cognitive gap. It explores the possibilities of crossing it earlier. It does not prove that indeed the gap has been crossed but it definitely shows that to a certain extent it might be crossed earlier and that young children can speak in the “algebraic voice”.

OF COURSE THEY CAN!

Luis Radford
Université Laurentienne, Ontario, Canada

In their enlightening paper, D. Carraher, A. Schielmann and B. Brizuela ask several questions and mention some problems that have been at the core of the research conducted in the learning and teaching of algebra for many years. The central question that they ask – namely, Can Young Students Operate on Unknowns? – is rooted in the idea that novice students find it difficult to operate on unknowns. This idea, however, has been refuted experimentally and historically many years ago. Hence a more appropriate question and more in line with their research intentions would be: When can young students start operating on unknowns? Carraher et al. suggest that arithmetical operations bear an algebraic meaning and that an early contact with algebra can help infuse this meaning into the children’s arithmetic. I will discuss in Section 2 of this reaction the possibilities of such an enterprise, when I will comment, from a semiotic-cultural perspective, on some salient aspects of the classroom episode. In Section 1, before mentioning some of the historical and contemporary experimental data that show that the operation on unknowns is not an intrinsic problem arising in the transition from arithmetic to algebra, I will argue that, in adopting a traditional view in which algebra relates to arithmetic only, Carraher et al. restrict the scope of their endeavor and miss important chances to infuse arithmetic concepts from other fields and to talk about e.g. geometrified arithmetic.

1. Operating on the unknown

Without denying developmental prerequisites for the learning of algebra, Carraher et al. seem reluctant to accept that a gap set by developmental levels could be the reason for which children cannot operate on the unknown in algebra and that such a gap would be out of the sphere of influence of educators. They suggest that it is probably a question of teaching and that it is wrong to attribute the gap to developmental constraints.

Carraher et al.’s refusal of a teleological idea of development and its entailed kind of determinism (“that there must always be such a gap”) is well tuned with current anthropological views on cognition and conceptual development, where closer attention has been paid to the role of the context and of the others in the conceptual growth of the child, leading to the elaboration of new approaches in which biological lines of development appear dialectically interwoven with cultural ones, so that development becomes inseparable from context (Radford 2000). In their reference to the history of mathematics, they leave without questioning, however, the fact that to operate on the unknown in a certain historical period is not necessarily equivalent to operate on the unknown on a different period. They failed to notice that mathematical concepts are framed by cultural modes of knowing and that several cultures have conceptualized numbers and unknowns in different ways –sometimes more arithmetically (as in Diophantus’ work), sometimes more geometrically (as in Babylonian mathematics). In adopting the traditional view that algebra relates to arithmetic only, they reduced the scope of their endeavour and narrowed the possibilities to deal with what is one of their more important submitted problems, that is, the infusion of new meanings into arithmetic. Many years ago, I presented a communication in a meeting held at the CIRADE, in Montreal. I titled my presentation: “Why does algebra not come from arithmetic?” (It later appeared with a slightly different
title in a volume edited by Bednardz, Kieran & Lee: see Radford 1996). In that paper I wanted to show that algebra is much more than a generalized arithmetic and that the algebra that we know owes a lot to geometry too (to witness the term square root) and argued for a broader view in considering the students’ introduction to algebra.

However, the main point that I want to discuss now is the operation on the unknown. Historico-epistemological research has evidenced that the operation on the unknown did not seem to have presented particular difficulties to past mathematicians. This is attested to in the Old Babylonian period, the Antiquity, the Middle Ages and the Renaissance. As concerning the rhetoric pre-Vietan period of the Renaissance, this can found in many abacus treatises. For example, in Raffaello Canacci’s *Ragionamenti d’algebra*, we find different ways to operate on and with the unknown. In solving a problem with the means of rhetoric algebra, Canacci (a Florentine algebraist of the second half of the 15th Century) was led to an equation that, for brevity, we can put into modern notations as follows: 

\[ t + 12 = 35t - 60 \]

Canacci operated the unknown and easily solved the problem. In an earlier book, Fibonacci’s *Liber Abaci* (1202), we find Fibonacci (also working within the representational possibilities of rhetoric algebra) solving the equation \( 12t^2 = 54 - 9t \). He transformed it into \( t^2 + 54 = 21t \) and then solved it by canonical procedures (the problems are discussed at length in Radford 1995. Concerning the operation on the unknown in the Antiquity, see Radford 1991/92; and for examples in Babylonian mathematics see Radford 2001, p.35 footnote 36). In each case, the way the unknown was handled was different: it depended, in particular, on the concept of number.

The successful operation on the unknown has also been reported in contemporary students with no prior knowledge of algebra. This is what Pirie & Martin did in 1997. In light of their experimental research they suggested, referring to the operation with the unknown, that “Rather than an inherent difficulty in the solution of linear equations, the cognitive obstacle is created by the very method which purports to provide a logical introduction to equation solution.” (Pirie & Martin 1997, p. 161). A similar conclusion was reached in a previous teaching setting inspired by the history of mathematics. The engineering of the lessons was based on a use of manipulatives that allowed the students to act on concrete objects and then undergo a progressive semiotic process affording the production of meaning and the elaboration of more and more complex representations of the unknown and its operation (Radford & Grenier 1996a, 1996b).

To sum up, the question of the operation of the unknown in algebra has received a positive answer for many years, from a historical and from an educational point of view. When can young students start operating the unknown is, in contrast, a new question. Carraher et al. relate this question to their idea that arithmetic can be infused with algebraic meaning in early mathematics education. I would like to comment on this idea in terms of the kind of algebraic meanings that novice students may attain and how it relates to their symbols and repertoire of representational tools. To do so, I will refer to the students’ mathematical activity as provided in the paper.

### 2. Some remarks on the mathematical activity

The paper describes the teacher’s attempt to bring the students into contact with some elements of algebra and the way the students gained insights and underwent a process of progressive understanding of key concepts of algebra. I will limit my discussion to some aspects of the children’s conceptualization, representation and operation of the unknown.
In general terms, the students seem to have reached a certain level of algebraic understanding. Time and movement were two vital ingredients in the activity. The problem itself was set in terms of steps, where amounts of money were changing. However, time and movement were intermingled with speech, gestures, written symbols, arrows and cultural artefacts—such as geometrical N-number line. These elements constituted the arena where the activity and the production of meaning unfolded.

2.1 The concept of unknown, its representation and operation

The activity provided the students to conceptualize the unknown in a meaningful way. Indeed, the idea of using a piggy bank permitted the students to think of the unknown as a hidden amount of money. Yet this was not enough. A semiotic act still had to be accomplished: the unknown had to be named or represented. The representation of the unknown is a very important step because, through this representation, the students objectify a new mathematical entity that can be applied not only to the piggy bank context but to other completely different contexts as well. An 'all-purpose-or-so' name/sign was hence needed. In the teaching episode, we saw that many students suggested the letter N. Of course, it was not through an individual well-inspired creative act of thought that the students suggested N. The activity was preceded by other activities where the idea of using a letter to represent an unknown number was introduced. The choices, of course are many. Diophantus used the term arithmos (number), Al-Khwarizmi used root and the Italian algebraists used res, and later cosa (the thing). But what did the letter N represent? The dialogue suggests that for the students the difference between any number and a-not-yet-known number was not completely clear. Furthermore, even if the students realized that N is a-not-yet-known number, some of them showed a strong tendency in adjudicating to N one of the possible numbers in the range of possible values, as in the Monday episode. As to the children's operation on the unknown, strictly speaking, in the classroom episode there was no operation on the unknown. For instance, unknown terms were not added or subtracted. The operations were performed on numbers (3, 5 etc.).

2.2 The geometrico-algebrafied arithmetic and the rise of meaning

Carraher et al.'s idea of starting algebra earlier than usual is related to the infusion of algebraic meaning in arithmetic. If we were to answer the question: Where does arithmetic really become geometrico-algebrafied? I would suggest that it is in reaching the expression \( N+3 \). The movement along the \( N \)-number line, is crucial for the construction of meaning. And it acquires a more dramatic tone when the students arrived at \( N+3-5 \) and identified as \( N-2 \) (on the Tuesday episode) and arrived at \( N+3-3+4 \) that they identified as \( N+4 \) (Wednesday episode). These experiences are impossible to reach within the confines of arithmetic. Let us analyze the meaning arising from these experiences. Concerning the first one, Arabian mathematicians would make sense of \( N-2 \) in thinking of \( N \) as being deprived of 2 units (and then, in the process that we now call 'the isolation of the unknown', they would have hurried up to 'repair' \( N \) that they would have imagined as a 'broken' segment. To 'repair' it, they would have then applied the rule of al-gabr, from where the name algebra derives). Concerning the second one (referring to \( N+3-5 \)), a Babylonian scribe would have said that 5 is 'detached' from \( N+3 \), and would have associated the latter to the width of a field that he would have imagined in the mind or would have drawn on a clay tablet. There is a marvellous Mesopotamian problem in which the scribe arrives at a subtraction of equal terms, and to remove them he says: "not worth speaking about" (transcription and analysis in: Høyrup, 1994, p. 9). Talik, in the video-taped episode,
thinking of ‘n’, ‘3’ and ‘-3’ in terms of money, and coordinating the symbolic expression with movements along the N-number line, says that +3-3 is not needed anymore. We see how cultural conceptualizations and their meanings, rooted in different semiotic systems, enacted in mathematical activities and objectified in speech, may be different. Still the point is that as different as they may be, the richness of the conceptualizations results from the variety of contexts and the management of varied semiotic resources (speech, gestures, drawings, etc.) to produce meaning. The students’ grasping of certain algebraic ideas in Carraher et al.’s lesson is related precisely to the richness of the cultural representational repertoire with which the students were provided and to the students’ and teacher's progressive integration of such a repertoire in the mediated space of interactions.

Conclusion

We saw that Carraher et al. started asking an incorrectly founded question. Their research, however, opens up new avenues. The idea of infusing algebraic meaning into arithmetic appears appealing. Yet it still has to be demonstrated how the learning of arithmetic is really enhanced or if it is merely a question of starting algebra earlier. Their work suggests that 8 and 9 year-old students can attain a certain understanding of the algebraic unknown. The scope of this understanding requires further research. Another point that deserves more reflection is the status of negative numbers. I don’t want to venture saying that the students secured a strong concept of negative numbers. Nevertheless, it is clear that the beginning of a conceptualization was started in the course of the lessons.

REFLECTIONS ON EARLY ALGEBRA

David Tall

Mathematics Education Research Centre
University of Warwick, UK
David.Tall@warwick.ac.uk

Introduction

At this conference we celebrate 25 years of research meetings organised by the International Group for the Psychology of Mathematics Education. It is therefore fitting to place this response within this context. Carraher, Schliemann and Brizuela (2001) refer broadly to a range of previous research, partly to report observed difficulties and partly to respond to suggestions to ‘bring out the algebraic character of arithmetic’. This means that, apart from using the advice to ‘algebrafy’ arithmetic, the 25 years of previous research is not used in any foundational way. My analysis of their paper therefore uses a global theory of developing symbolism to place the research in context.

Analysis

Carraher et al (2001) base their research in a ‘typical’ class of 9 year-olds and is implicitly an approach to teach ‘algebra for all’. I begin, therefore, by looking at their data to see if they are actually reaching every child in the class and also to analyse precisely what kind of algebra the children appear to be learning.

The class is presented with a story in which two children start with the same unspecified amount of money on Sunday and spend and receive specific amounts on successive days. When the researcher Bárbara asks the class if they know how much money they have, ‘the children state a unison “no”’, but ‘a few utter “N” and Talik states “N, it’s for anything.”’ Thus we have some children who have already met the idea of using a letter to stand for a number and some who presumably have not. Our first piece of evidence is that, faced with adding 3 dollars to the initial unspecified amount, we are told that ‘only three children do not write N+3 as a representation for the amounts on Monday.’ What is missing is an analysis of what the children individually bring to the class from their previous development and why some children are more adept at algebraic thinking than others. This in turn requires a theory of longer-term development that is consonant with empirical evidence.

Tall et al (2000) present a theory of symbolic development arising from earlier work of Gray & Tall (1994) and many others. This reveals a bifurcation in performance in arithmetic between those who become entrenched in a procedural mode of counting and those who develop proceptual thinking involving the flexible use of symbols as both process and concept. This is not to be interpreted as a naïve prescription that the successful always get better and the less successful get worse.
The case of Emily (Gray and Pitta, 1997) reveals a child growing from counting procedures to flexible number concepts by being given support using a calculator that carries out the procedures for her so that she can concentrate on the conceptual relationships. However, the theory does intimate that what children bring to a given situation—depending on their preceding development—radically affects how and what they learn. It can have a profound effect on early algebra.

For instance, the National Curriculum for England and Wales intended to use arithmetic problems such as the following as a precursor of algebra:

\[
\]

Although these look like algebra, they are certainly not. Children perform them using their repertoire of methods of counting and deriving or knowing facts. Question (1) can be done by any counting method, (2) can be done by ‘count-on’ from 3 to find how many are counted to get to 7. Equation (3) is more subtle. If the child senses that the order of addition does not matter, the problem is essentially the same as (2); and can be solved by count-on from 3. If not, the child who counts has a far more difficult task to find out ‘at what number do I start to count-on 3 to get 7?’ This involves trying various starting points to count-up using a ‘guess-and-test’ strategy.

Foster (1994) used these three types of question in a study of ‘typical’ children in the first three years of an English Primary School. He found a significant spectrum of performance in the first year where the lower third were almost totally unable to respond to questions of types (2) and (3). By the third year the top two-thirds of the class obtained almost 100% correct responses but the lower third obtained 93% correct on type (1), 73% correct on type (2) and 53% on type (3). Seen in the light of procept theory, this suggests that the lower third operate more in a procedural than a flexible proceptual level. This would be consistent with the lower third of a class in Grade 3 in the USA including children who are more procedural than proceptual, which, in turn is consistent with difficulties with algebraic qualities of arithmetic exhibited by some children in this study. I would counsel, therefore, that in carrying this activity out in a classroom context, some children are already struggling and need special individual care. Even those who succeed in writing down the symbolism ‘N+3’ are likely to be using it in a manner different from that observed by an expert.

When the symbols introduced into the work of Carraher et al are analysed, they are all of the form of an unknown quantity followed by successive numerical additions and subtractions, such as \(N+3-5\). (On the web-site related to the paper, there are also considerations of equivalence of expressions such as \(N+3-5\) and \(3+N-5\).) The children can, and will, make their own interpretations of the meaning of the symbolism.

The researcher Bárbara leads a discussion using ‘the number line centred on \(N\)’ to visualise the symbols \(N+3-3\) in terms of shifts along the line starting from \(N\). The paper describes how she ‘writes a bracket under 3–3 and a zero below it […] and
extends the notation to \(N+3-3 = N+0 = N\).’ This is the description of what she—the expert in this case—sees. But does each individual children see and think in this way?

A wide array of literature reports children conceptualize the ‘equals’ sign as an operation, not as an equality between two expressions. It is here that procept theory helps. Bábara and her co-researchers have the ability to switch between seeing the symbol \(N+3-3\) as an expression for a single mental concept on the one hand and as a process of successive steps on the other. She can see the ‘equality’ of the two concepts. As the discussion unfolds, it is Bábara who writes \(N+3-5 = N-2\) and the authors of the paper who call 3–5 a ‘sub-expression’, claiming that Jenny ‘writes a zero under it’. However, we have a reproduction of the work of Nathan, who writes not zero, but ‘\(=0\)’. An alternative, and more likely, explanation is that some (perhaps most) of the children are interpreting the symbols as processes to be performed rather than as expressions.

As all the formulae in the paper consist of an unknown \(N\) followed by number operations, the context allows the children to operate essentially in an arithmetic mode. They are not asked to operate directly on the unknown, rather this is the starting point from which arithmetic operations occur and can be the main focus of attention.

There is evidence that some children work with \(N\) as an unknown. For instance, ‘Talik shows how this works if \(N=150\).’ This inhabits an intermediate stage that Thomas & Tall (2001) call evaluation algebra in which expressions are used to represent a general arithmetic operation (as, for instance, they do in a spreadsheet). This is an earlier stage than full-blown manipulation algebra where the symbols are freely manipulable entities as expressions and sub-expressions. In evaluation algebra, symbolic expressions are seen as processes of evaluation. Manipulation algebra sees them as procepts representing either process or manipulable concept.

Carraher et al (2001) ask in their title: ‘can young children operate on unknowns?’ The evidence they provide reveals that their approach has absolutely no operation on unknowns in the sense of symbol manipulation. There is evidence of evaluation by substitution (as a by-product rather than a direct focus of the activity). In general, the children’s activity involves arithmetic operations on arithmetic symbols.

Is this a problem? Absolutely not. Some children are evidently becoming familiar with the use of a letter to represent a specific but (to them) unknown number. Thus at least one aspect of the development of algebra is beginning to take root. However, the journey through evaluation algebra and on to manipulation algebra is a long one and for many but not all children it will involve difficult cognitive reconstructions.

All the symbols used in the activities are read in the usual left-to-right direction in Western languages. There is still a long way to go for children to cope with
expressions such as $2+3x$ where the product of 3 and $x$ must be performed before 2 is added to it.

The work of Carraher et al is certainly a first step, but it needs to be explicitly aware of what individual children might bring to the task and where they might go later.

**Concluding Remarks**

I have suggested that the study of 'early algebra' needs to be seen not only as an activity in itself but also as part of a longer-term development. The activities need to be carefully analysed to see as clearly as possible what it is that the children have to build on and what it is that they are likely to be thinking. In the analysis presented here I have indicated conceptions that children may bring to the enterprise that may hinder or help them (for example, arithmetic as procedures or as flexible process-and-concept). I have analysed what some children might be doing with the symbols (operating with them as processes, rather than seeing them as expressions). I have emphasized the chosen limitations (symbolism read from left to right, starting with an unknown that may be left on its own, allowing a focus on the arithmetic operations that follow). There is the evidence that some children (eg Talik) have taken the first step into evaluation algebra by substituting a number for the unknown. However, it is less clear as to who sees the symbolism $N+3-5 = N-2$ as an arithmetic process and who see it as an equality of mental expressions (concepts).

A step has been taken by some (many?) of the children. It is a significant step. But it has implicit properties (reading an expression left to right, perhaps seeing the expression as 'a process to do' rather than 'a concept to manipulate', perhaps coping by working only at an arithmetic level). Such properties may become part of the child's mental structure that needs reconstructing at a later stage. The major cognitive obstacles of manipulation algebra that afflict many, but not all, children in the bifurcating spectrum of performance still remain to be addressed in the future. If the bifurcation we have observed continues to occur (and it seems to be very persistent), it may be that some may be profitably focused on evaluation algebra that has powerful uses in computer contexts whilst others develop proceptual flexibility required for manipulation algebra.

**References**

This reaction paper examines the cluster of algebraic concepts associated with variables used either as unknowns or as place holders. *Unknowns* are variables that represent particular numbers. As such, these variables appear in equations, whose solutions are a particular number, and the equations, themselves are about that number. In contrast, *place holders* are variables that represent any number. Such variables appear in identities and functions. These algebraic sentences are generalizations about particular operations and the order in which these are applied.

In the paper by Carraher, Schliemann, and Brizuela, a distinction is not clearly made between the particular algebraic meanings associated with each of these two variables. The term “unknown” is sometimes loosely used by the authors, and the children in the study make little distinction between “N” as a representative of an unknown quantity or as a generalization for “any number.”

**Unknowns and Equations**

The solution of the piggy bank problem utilizes unknowns. Even though the initial amount of money in each child’s bank is not given, the context of the problem makes it clear that this amount, while not specified, can only be a certain value. Thus, the reasoning that takes place as the children work through the activity is that of determining the exact value of this amount. The words that several of the children use as they talk about the problem do not align with this notion of variable.

For example, as the children discuss the quantity of money in the banks on Sunday, several students state that “N” could stand for “anything” or “any number.” Conceptually, this is not correct. N stands for a particular amount of money that is actually in the bank, an amount that the children can find if they reason through the given situation.

The classroom emphasis on N as a number that is not known is important. It is clear that the children are able to perform operations on such an entity and can comfortably explain the quantitative relationships that exits on the different days described in the piggy bank problem. However, it is also important to help the children understand that, while unknown, the number in the given context cannot be "anything."

The solution to the piggy bank problem embodies the algebraic concept of *equation*. The implicit understanding of the activity is that it is possible to
perform operations on an unknown number, within the constraints of a given situation, in order to determine the value of this number. In the classroom, the use of expressions involving N and the N-number line provide an alternative representation for the conventional symbol string that comprises an algebraic equation in one unknown.

It would be useful to have held a discussion, before the children began their number line representations, about whether it could be possible to find the exact amount of money contained in each bank on Sunday. Children should have been able, given the result that Mary had $9 in her bank on Thursday, to have decided that the original amount would have had certain limits placed on its possible value. For instance, Mary would have needed to have spent a great deal more money if she had started with $100 in her bank on Sunday and ended up, on Thursday, with only $9 left.

Then, the activity could proceed as it did, with comments on the fact that the amount of money is not known at that time. After the specific value had been found at the end of the activity, it would also be appropriate for the teacher to remind the children that, by working through all the changes to the unknown that were given in the problem, they were able to find the exact amount originally in each piggy bank. It would have been a valuable extension to the activity if some reflective discussion could have been included to lay the foundation for the notion of an equation as a useful algebraic tool for finding the value of an unknown.

**Dummy Variables and Functions**

A second example of children dealing with an algebraic situation is briefly mentioned at the end of the paper. Here, children are discussing a comparison situation in which one child has three more candies than another. This example utilizes place holders rather than unknowns. However, the authors’ use of the term “unknown” in the comment “that children can treat the unknowns ... as having multiple solutions,” has the potential for mixing conceptual entities. The authors do continue their discussion by commenting that “when children make statements of such a general nature they are essentially talking about relations among variables and not simply unknowns restricted to single variables.”

In the comparison example, the children, as the authors correctly point out, are dealing with different conceptual entities than those used in the piggy bank problem. Here, the undetermined amount can take on any value, and the expression “N+3” represents a function. This expression provides information about a particular order of operations (“add three”), and the focus of the activity is not on finding a number, but on stating a relationship.

**Discussion**

It is important to use separate names to distinguish the two different uses for algebraic variables, since each use represents a different type of algebraic entity. Unknowns occur in equations that are essentially numeric in focus. The goal of
using such symbols is to model a quantitative situation in which certain constraints make it possible to reach a numerical result. On the other hand, dummy variables are used as place holders to make general statements about mathematical relations, expressed as a particular sequence of operations.

The authors' descriptions (in the section “Some Reflections”) of the ways in which the students used the number line illustrate how easy it is to blur the distinctions between the two clusters of algebraic entities. In a single paragraph, examples are given of representations for both functions and equations. In one case, students treat “minus four” as a displacement of four spaces, and recognize that the result of this operation can be represented as N-4 and as the movement from N+3 to N-1. In conventional algebraic symbolization, this is equivalent to, “if \( f(x) = x - 4 \), then \( f(x+3) = x - 1 \).” In a second instance, students “infer” the value of N+43 from observing that N+7 is above the number 4. This is equivalent to solving the two-variable system of equations “\( x + 7 = 4 \) and \( y = x + 43 \).”

In their concluding remarks, the authors state that “little is known about children’s ability to make mathematical generalizations and to use algebraic notation.” This statement is ambiguous in light of the previous remarks. It is not clear how the authors link “making generalizations” to particular uses of algebraic notation. I would prefer to make a clear distinction between using notation to make generalizations (place holders and functions) and using notation to find numerical results (unknowns and equations).

The authors’ examples of young children using algebraic notation and number-line representations raise some interesting questions.

- Should the mathematical distinction between unknowns and place holders be a matter of concern in introductory algebraic experiences? (This distinction is one that many college-level students do not necessarily understand.)
- At what point in their educational experience should students first implicitly, and then explicitly deal with these conceptual issues?
- How deeply should teachers understand the algebraic structure behind particular introductory activities?

I agree with the authors that research is needed to investigate the extent to which difficulties in the development of algebraic understanding are either developmental or the result of educational practice. I would like to extend the focus of such investigations further, however, to include a careful understanding of algebraic entities themselves. Unless we as mathematics educators can fully unpack, for ourselves, this complex field of reasoning, we can only partially address the concerns of educating others.
In response to the misconceptions students are experiencing in the algebraic domain, there has been a call to begin algebraic thinking early. Kaput (1999) believed that algebraic understanding evolves from viewing algebra as the study of structures abstracted from computation and relations, and as a study of functions (a static and dynamic dimension). The arithmetic knowledge base that is needed for algebra comprises an understanding of (i) arithmetic operations, (ii) the equal sign as equivalence, (iii) the operational laws, and (iv) the concept of variable (Ohlsson, 1993). Usiskin (1988) argued that the notion of variable could be introduced through three approaches: solving equations with unknowns; generalisations of patterns; and relationships between quantities. He contended that, in the long run, these notions had to be combined and abstracted to develop the concept that variable was a member of an abstract system. While some researchers (e.g., Chalouh & Herscovics, 1988) argued that unknown was not an appropriate algebraic conception for variable as it does not represent multiple meanings, Graham and Thomas (1997) contended that an appreciation of unknown could allow students to better assimilate later concepts. For this to happen, they argued that activities with unknown should cover a wide variety of situations including recognising unknown situations, substituting for unknowns, considering solutions as values that make the equation true, and finding solutions through arithmetic and algebraic methods.

Carraher, Schliemann, and Brizuela's paper explores young students' ability to operate on and represent unknowns in a relational situation as a precursor to developing understanding of the variable. They describe an example of classroom activity (two children starting with the same unknown amount of money) to provide evidence that "children as young as eight and nine years can learn to comfortably use letters to represent unknown values, and can operate on representations involving letters and numbers without having to instantiate them" (p. 7).

**Power, formal letters and the limits of number lines**

*The power of the activity.* We applaud the power of Carraher, Schliemann, and Brizuela's classroom activity. First, it presents arithmetic as change rather than solely as relationship; that is, it is a dynamic form of arithmetic in that it represents +3 as a movement on the number line from 2 to 5. Second, because of this focus on change, it allows the notion of backtracking (undoing the changes) to be introduced. Although limited (Stacey & McGregor, 1999), backtracking is a useful procedure for solving equations with one instance of unknown. Third, it involves sequences of
operations which, initially, are not capable of closure. Fourth, it encourages children
to interrelate a rich array of representations when articulating their understanding
(e.g., verbal and written language, diagrams, number lines, and symbols), thus
developing rich representational scheme. All these signify a significant move away
from the traditional approach most children of this age experience in their everyday
classroom.

The use of N. However, the use of the symbol N in the activity is a concern and raises
questions. Even though the activity reflects Herscovics and Linchevski (1994)
suggestion that the transition to formal algebra involves considering numerical
relations of a situation, discussing them explicitly in simple everyday language, and
eventually learning to represent them with letters, we wonder whether the use of N in
the activity reflects a limited view of algebra (as "arithmetic with letters" rather than
as the "mathematics of generalization"). Do you need letters to do algebra? To us,
the answer is no; we see algebraic thinking as predominantly the ability to operate in
generalized abstraction and prefer that the students use normal language (e.g., "the
beginning money") or their own invented "symbolisation/notation" (e.g., "apb" -
amount in piggy bank). We believe this use of language or invented terms are as
algebraic as "N", and maybe less dangerous. We are not convinced that the children
in the activity are not seeing the "N" as "the piggy bank" or as a specific number,
derstandings of N that are inappropriate for algebra (Küchemann, 1978).

The number line representation. The use of the number line in the activity also raises
questions and concerns. While the number line contextualisation of the activity is
very powerful, the change represented is linear movement (back and forward on the
number line for addition and subtraction). How do we deal with situations where the
change involves multiplication and division (e.g., he doubles the amount of money in
the piggy bank or shares it among three friends)? How do we prevent prototypic
thinking (Schwarz and Hershowitz, 1999). The number line also seems to restrict the
type of problem that children can explore. It is difficult to see how the number line
will model a problem where the unknown is not the starting point or it appears more
than once. For example, Mary had $15 in her piggy bank on Sunday, was given some
money on Monday, spent $6 on Tuesday, and opened her piggy bank to find
$30 on Thursday? And with the unknown as the starting point, closure is available for all
other computations. In fact, it is possible to simply ignore the unknown.

Unknowns, young students’ understanding and equals

The approach to variable used in the Carraher, Schliemann, and Brizuela’s classroom
activity falls into the category of unknown (Usiskin, 1988). While the activity uses a
dynamic broader understanding of arithmetic that offers opportunities for developing
algebraic ideas not available in traditional classrooms, we have concerns with young
students’ capacity to understand unknown. We have recently investigated this with a
sample of 87 children of average age 8 years and 6 months attending four schools
across metropolitan Brisbane. In an interview, the children were asked to explain
how they could find the unknown in the following two situations:
The script was as follows: What is the card asking you to do? How can you find the missing number? What is the missing number?

Initial analysis of the scripts indicated that all the children understood that the task was to find the missing number, and most could do this for the first example. For this example, the common strategy was counting on and the common response was: You go 16 and then you count from 16 to 49. Can I do it in my head - can I just count in my head 17, 18, 19, 20. Most difficulties involved keeping track of how many had been counted on, I just keep losing track of it. Some simply counted from 6 to 9 and from 1 to 4 giving the solution of 33, put a 3 on the 6 equals 9, put a 3 on the 1 equals 4. Only four students found the unknown by using subtraction, you can find the something by taking 16 from 49. Very few children could find the unknown in the second task, for a variety of reasons that all seemed to relate to everyday classroom experiences. A common obstacle was the non-standard formatting of the question: 12 minus can't equal this. This is a wrong one because 12 minus can't equal 54. It's backwards. Many children could not go beyond this point. This seemed to occur for two reasons. First the position of the = sign caused difficulties. When directed to explain what the problem was asking them to do, many said: Fifty four take something equals 12 - you have to find the something. Second, the position of the unknown also seemed to cause problems: It is all mixed around. You can't have 12 minus something. Most believed that the unknown should occur on its own after the equal sign: 12-54 = something. It would be a little number – it would be 0 because if you get 12 and take away a big number you would only get 1 and then an extra number would be 0 it would be 1 or 0. Some simply dealt with this problem by: flipping it over, 54-12=42. Or you could just do 54-42=12. Only two students found the missing number by converting the problem into the correct addition situation: You find the missing number by adding 12 onto 54. Understandings abstracted from classroom experiences seemed to be acting as cognitive obstacles to solving equations with unknowns.

Conclusions

Commonly, classroom activities present arithmetic equations in the form 3+4=7, computation on the left and solution on the right. Unknowns presented in the same format (e.g., □+6=11) are simpler for young children. Different formats, sequences of operations that cannot be closed (e.g. 4+□+9) or two or more instances of unknowns (e.g., □+7+□=15) are much more difficult. “I am a number” activities can work at quite young ages because the “unknown” is first and can be ignored while the numbers are computed (e.g., I am a number. I have been multiplied by 3 and 5 has been added. I am now 23, what was I?). Does replacing □ by “N” make the
activity more algebraic? Does drawing a number line with N in the middle mean that the students are handling unknowns and understand the meaning of N+3?

Carraher, Schliemann, and Brizuela's classroom activity prepares students for algebra in its dynamic presentation of sequences operations, its potential to prevent closure (at least in the first operation), and its integration of problems, language and activity. However, the activity's use of N is not compelling and the number line places limitations on the position of the unknown that means it does not have to be known during the remainder of the operations. The activity should be extended to include all the components suggested by Graham and Thomas (1997) and combined with activity on operations that prepares students for non-standard formats and a variety of positions of unknowns. The challenge is to develop a number and operations sense that leads to algebra (and algebraic sense).

  by Gabriele Kaiser, Yoshinori Shimizu, Murad Jurdak, and Thomas Romberg
• Open discussion of the questions with the audience
This Research Forum in educational policy research focuses on the differences in perspectives across countries with respect to mathematics goals and achievement. Each of the four participants will present a brief paper on the mathematical goals for three groups of students in their country (non-college-bound students, college-bound liberal arts students, and college-bound mathematics and science students) and on the evidence on achievement of mathematics goals with respect to three levels (knowledge of concepts and procedures, understanding of the relationship of mathematical ideas in specific domains, and the use of mathematics to mathematize unfamiliar problem situations).

These papers provide background information related to the policy implications of the recent international comparative studies (e.g., TIMSS) and of OECD’s forthcoming PISA project. Too often politicians and other policymakers fail to understand that differences in student achievement in mathematics need to be seen in light of each country’s goals for its students and the quality of evidence related to achieving those goals.
A DESCRIPTION FROM GERMANY

Gabriele Kaiser, University of Hamburg

Abstract: This paper concentrates on the goals of mathematics education in Germany after compulsory education. The school system is first explained briefly. In what then follows, it is demonstrated that, based on an analysis of the curricula and results from the TIMSS study, German general education and the various kinds of vocational education differ very much from each other concerning goals of mathematics teaching as well as in the students' achievements. Finally, it is stated that mathematics teaching only barely attains the goals formulated in the curricula and that in international comparisons the weaknesses of German mathematical teaching are becoming obvious.

The Structure of the German School System

This paper concentrates on mathematics education after compulsory education has been completed. In order to better understand what follows, the German school system is first briefly described.

In Germany, compulsory schooling commences at the age of 6 and finishes at 18. Nine or 10 of these years, depending on the school system of each federal state, must be spent in full-time schooling, and the remaining 2 or 3 years spent either in full-time schooling or in part-time vocational schools in conjunction with a trade or apprenticeship programme.

Lower secondary level for students aged 10 to 16 offers differentiated teaching in accordance with student ability, talent, and inclination. Students are placed into one column of a three-column-system, within which there is no streaming.

Upper secondary level, for students aged 16 to 19, takes place, as already mentioned, in two systems: a general education system and a vocational system.

Overview of the General Education System

In the general education system, a three-year course qualifying students to enter university is offered. Courses are offered at two different levels in terms of academic standards and teaching time: basic or advanced courses (Grundkurse and Leistungskurse, respectively). The basic courses are intended to ensure that all students acquire a broad general education of the subject in question whereas the advanced courses are meant to provide further specialist knowledge and serve as an in-depth introduction to academic study.

Many limitations are placed on students' choices to ensure that all students achieve a broad range of knowledge. Students must select at least two advanced courses, one of which must be either German, a foreign language, mathematics, or a science subject.

Mathematics as advanced course is chosen as a second course most often by 35% of the students, but with a great difference between boys (47%) and girls (26%); as well as between the western (32%) and the eastern (41%) federal states. There is a significant difference in teaching time (3 vs. 5 hours weekly) between basic and
advanced courses. Currently, mathematics is a compulsory subject and must be taken
at least at a basic level until Grade 13. Until recently, students in some states were
able to drop mathematics in Grade 13, which on average 10% of the students did.

Those students whose aim after school is to study mathematics, science, or technical
sciences choose mathematics as an advanced course; those oriented more toward
linguistics and social sciences tend to take basic courses in mathematics. Those
attending basic courses of mathematics can be described as college-bound liberal arts
students; the students participating in advanced courses are generally college-bound
mathematics and science students.

The upper secondary level also encompasses full-time and part-time vocational
education. The Western German dual system of vocational education involves
cooperative apprenticeship at two learning sites: the school and the workplace.
Enterprise-based vocational training has two sponsors: the governments of the federal
states, which establish and finance vocational schools; and the enterprises themselves,
which finance and provide apprenticeships. Full-time vocational education comprises
many mixed forms of schooling, which shall not be differentiated here. These students
may be considered non-college-bound.

Of students 17–19 years old in the upper secondary level, 31% are in the gymnasium
and comprehensive schools, Grades 11 to 13; nearly 16% are in full-time vocational
education; and about 53% are in part-time vocational education.

**Goals of Mathematics Education for General Education**

The curriculum for mathematics in Germany is laid down in curricula for each state
and for each of the different types of schools.

In general, the curricula state that the general aims of mathematics education are to—

- Provide fundamental knowledge and skills in important areas of mathematics.
- Provide mastery of the techniques, algorithms, and concepts necessary for
everyday life in society.
- Develop the ability to describe facts mathematically, to interpret the contents of
mathematical formulae, and to enhance the solving and understanding of
nonmathematical or environmental phenomenon through mathematics.
- Teach pupils to think critically and to question.
- Give examples of mathematics as a cultural creation in the historical development
of civilisation.
- Provide terms, methods, and ways of thinking useful in other subjects.
During the last few years, the curricula have undergone changes, but the trends of changes are more apparent in approach than in content. Thus, the new orientation for mathematics teaching is to—

- Present mathematics both as a theoretical study and as a tool for solving problems in the natural and social sciences.
- Provide experience with the fundamental mathematical idea of generalisation, the need for proofs, structural aspects, algorithms, the idea of infinity, and deterministic versus stochastic thinking.
- Use inductive and deductive reasoning, methods for providing proof, axiomatics, normalisation, generalisation and specification, and heuristic work.
- Provide variation in argumentation and representation levels in all fields and aspects of mathematics teaching.
- Teach historical aspects of mathematics.

These goals, indicated as common learning objectives of mathematics teaching, can be regarded as consensus among mathematics educators and, among others, are therefore explicated in the expertise on mathematics teaching in the upper secondary level (Borneleit et al., 2000). The main difference between basic and advanced courses is that objectives formulated for advanced courses are oriented more toward mathematics as science, whereas those for basic courses stress algorithms and mathematics formulae. Both courses are based on the same three pillars of mathematics education: calculus, linear algebra/analytical geometry, and probability and statistics. Among these, calculus is the most important and gets the largest portion of teaching time. The first two strands were found in curricula already at the beginning of the 20th century, but probability and statistics have been added only in the last 10-15 years. These unshakable pillars of mathematics teaching are firmly laid down in the German baccalaureate (Abitur) standards for all states of the German Republic. Further specifications and differentiation of goals vary very much from state to state.

**Goals of Mathematics Education for Vocational Education**

In vocational education, the importance given to mathematics varies very much, and there is a wide spectrum of goals in mathematics teaching. The TIMSS study on the upper secondary level divides the fields of vocational education into three groups: (a) professions closely related to mathematics, including professions in the trades; (b) professions closely related to technology, including professions in the fields of metal, electrical/electronic, and construction industries; and (c) professions not closely related to mathematics or technology professions, including those found in the fields of agriculture, housekeeping, social services, and nursing (see Baumert, Bos, & Lehmann, 2000, Vol. 1). In each of these three categories, mathematics is of different importance. Often, in vocational education not closely related to mathematics, mathematics does not exist as a separate subject, but is integrated into content-related subjects. In nearly all fields, in fact, the learning objectives depend on content-related
contexts. Therefore, mathematical literacy should be taught, as it has been tested by the TIMSS study, focusing on the following competencies:

- Everyday real-world-related conclusions.
- Application of basic routines.
- Elementary modeling and linking of mathematical operations.
- Mathematical reasoning, especially through graphs.

Interviews with experts show that, in technical education and education for manual work, mathematical modeling is given special emphasis and that, in the commercial fields beyond those dealing with graphs, that emphasis is also needed. Mathematics in social services and nursing mostly focuses on everyday real-world reasoning and conclusions as well as application of routines.

Achievement of German Students

The above mentioned TIMSS study provides an overview of the real achievements of German students. In the following, I refer to these results.

Achievement of Students in General Education Schools

In basic course lessons, only a small portion of the students (almost one fifth) reached a level that enabled them to apply safely and independently what they had learned to solve standard problems. If the context of items they were familiar with was changed, nearly all students had great problems in solving the problems. The results of more than four fifths of the students in the basic course did not exceed the level of application of simple mathematical concepts and rules. Students who dropped mathematics almost never stepped beyond this threshold. As one would assume, in advanced courses, a significantly higher level of student achievement was found. Nevertheless, fewer than one in eight students showed an ability to deal successfully with mathematical problems when the solutions were not directly evident (see Table 1). With the tested topic fields divided as for TIMSS, in geometry German students showed above-average results, whereas in algebra (number and equations) and calculus, they perform more or less below average. In international comparisons, women obtained clearly worse results (Mullis et al., 1998, pp. 145ff).

Altogether, from interviews of the students it became clear that German mathematics lessons are structured strongly receptive and focusing on practising skills. Unlike the learning objectives formulated in the curricula, the support of understanding and applying of mathematics to everyday problems plays only a minor role. However, obviously the basic courses did not develop a didactic form of its own and give the impression as being advanced course on a reduced level of achievement demand. Furthermore, teaching in these courses is less application and understanding oriented, which leads students to take a more strongly receptive attitude (Baumert, Bos, Lehmann, 2000, Vol. 2, pp 275ff).

Note. From Baumert, Bos, & Lehmann, 2000, Vol. 2, pp. 193ff)

Achievement of Students in Vocational Education

The TIMSS results make clear that in the broad tendency, German students face greater difficulties with items that demand more complex operations, the application of mathematical models, and individual mathematical argumentation. Generally, the strongest capabilities of German students were found in solving routine mathematical items and items close to their mathematical experiences. Specifically, 22% of the students achieved only a competency level of everyday reasoning/conclusions, 43% remained at the level of applying simple routines, 32% reached the level of simple modeling, and only 3% achieved the highest standard of mathematical argumentation. There was a great gap between classroom reality and the curricula claiming conceptual understanding, the ability to combine elementary operations, and the transfer of trained skills to new contexts (Baumert, Bos, & Lehmann, 2000, Vol. 1, pp. 199ff).

An analysis of achievement in the three groups of vocational education show substantially great leaps between the levels, and four achievement groups can be recognised: Bankers achieved the best test results, followed by garage mechanics and industrial mechanics. The third group consisted of retail merchants and trained office clerks; hairdresser trainees obtained the worst results. The differences between achievement levels strongly depended on the educational level in the lower secondary level. Students achieving better results generally had a higher education qualification than those who obtained worse results. Furthermore, great gender-dependent differences, to the disadvantage of women, can be recognised. Foreign students whose families were still strongly rooted in a non-German culture also produced clearly worse results (Baumert, Bos, & Lehmann, 2000, Vol. 1, pp. 227ff, 295ff).
**Final Remarks**

Summarising, it can be stated that German mathematics teaching in reality only barely attains the goals formulated in the curricula. This applies to students of all three education groups: students in vocational education/non-college-bound students and students in general education with its two levels of differentiation, college-bound liberal arts students and college-bound mathematics and science students. In international comparisons, in which German students ranked in the lower or average achievement level, the weaknesses of the German mathematical teaching are also becoming extremely clear.

EVEN COLLEGE STUDENTS CANNOT CALCULATE FRACTIONS:
MATHEMATICS GOALS AND STUDENTS’ ACHIEVEMENT IN JAPAN

Yoshinori Shimizu, Tokyo Gakugei University

Abstract: The goals and content of the current "Core and Option Module Curriculum" at the upper secondary schools in Japan are briefly reviewed to discuss mathematics goals for the different groups of students. Students’ achievement in mathematics is discussed, referring to the results from large-scaled international comparisons of mathematics and smaller-scaled national achievement tests. It appears that the academic achievement of Japanese students is satisfactory with respect to knowledge of concepts and procedures at the lower secondary school level. At the upper secondary and tertiary level, however, there are signs that students’ achievement has declined with the growth of enrollment ratio of students to those levels.

Japanese mathematics educators, like their counterparts in other countries, recognize mathematics as the basic discipline for science, technology, and other areas of human activities. At the time of transition to the new curricula based on the revised curriculum guidelines just released, however, it is not so clear that school mathematics meets the expectations of our society.

In this paper, the author discusses goals of mathematics education in Japan for various groups of students and reports on the evidence that students are achieving those goals with respect to three levels of achievement.

The goals and content of the current “Core and Option Module Curriculum” at the upper secondary schools in Japan are briefly reviewed to discuss mathematics goals for the different groups of students at this age. Then, students’ achievement in mathematics is discussed at three levels, referring to the results from both large-scale international comparisons of mathematics and smaller-scale national achievement tests. Finally, some issues of mathematics education remaining to be explored will be discussed as a basis for setting research questions in this area.

Goals of Mathematics Education in Japanese High Schools

In the Japanese educational system, a national curriculum standard, the Course of Study, describes the goals of school education and basic guidelines for school curricula (Ministry of Education, Science, Sports, and Culture, 1989). The educational expectations are communicated through the Course of Study, as well as through other additional materials issued by the Japanese Ministry of Education.

A Core and Option Module Curriculum has been implemented in mathematics at the upper secondary school level in Japan since 1989. There are three major factors for using curricula of this type rather than the former uniform curricula.

First, about 96.8% of graduates of lower secondary students entered upper secondary school in 1998 (94.7% in 1989). This means that there were great differences among
students in their aptitudes, interests, career plans, and so on. It is very difficult to cope with such diverse differences in the uniform curriculum.

Second, the growth of enrollment of students in upper secondary schools has led to polarization among students. Namely, we can typically find two major streams of students in the upper secondary schools. The proportion of the age group going on to universities and junior colleges was 42.5% in 1998. About 22.7% (male 25.0 / female 20.5) of upper secondary school graduates went to the work force. About one fourth of the group were college-bound mathematics and science students; the remaining were college-bound liberal arts students.

Third, there are the requirements of the information age. The role of technology in mathematics education should be considered for setting mathematics goals with respect to the students of different groups.

The "philosophy" about the goals of mathematics education in Japanese high school underlying the current Course of Study is as follows. Cultivation of "mathematical intelligence" should be emphasized as the goal of mathematics education. "Cultivation of mathematical intelligence" includes fostering sound "mathematical literacy" for the majority of students, as well as the development of deep mathematical potential among the brighter students (Fujita, Miwa, & Becker, 1990).

In the revised Course of Study that will be implemented beginning in 2003, a new subject, “Basic Mathematics,” which incorporates mathematical history and statistical processing of daily events, will be introduced (Ministry of Education, Culture, Sports, Science, and Technology, 1998)). It will be an elective required subject; that is, students will be required to take one of two courses: “Mathematics I” or “Basic Mathematics.”

Students' Achievement in Mathematics

In this section, students' achievement in mathematics is discussed with respect to three levels of achievement: knowledge of concepts and procedures, understanding of the relationship of mathematical ideas in specific domains, and use of mathematics to mathematize unfamiliar problem situations.

Relatively little survey research has been done to find the levels of Japanese students' achievement in mathematics at the upper secondary school level. A few large-scale international comparisons of mathematics achievement like SIMS included Japanese students in the final year of upper secondary school. An overview of the results from both large-scaled international comparisons of mathematics and smaller-scale national achievement tests is given here with respect to the following three groups of students: (a) non-college-bound students, (b) college-bound liberal arts students, and (c) college-bound mathematics and sciences students.
A Quick Review of the SIMS, TIMSS, and TIMSS-R

One of the findings of the SIMS was the superior mathematical achievement of students from eastern countries like Japan compared with countries like the United States, Canada, and New Zealand.

Under the present curriculum, the academic achievement of Japanese students seems to be satisfactory with respect to knowledge of concepts and procedures at the lower secondary school level. On the other hand, Japanese students’ negative attitude toward mathematics has been found through the SIMS and the TIMSS. Many students want to do well in mathematics and feel that their parents also hope they will, but in reality many of them are not very diligent about learning mathematics and do so passively. Further, not a few students do not realize the power of mathematics in applied work and see mathematics merely as exercise for solving given problems.

At the upper secondary and tertiary level, there are signs that students’ achievement has declined in recent years, possibly with the growth of the enrollment ratio of students in higher education.

An eight-year longitudinal study on science and mathematics education was conducted by the National Institute for Educational Research (NIER, 1998). Using the data from three groups of students (n > 2000 for each group) in 11th grade, in 1989, 1992, and 1995, we can compare student achievement levels. Achievement has slightly declined from 1989 to 1995 on some items:

- **Item 55**, 20% of 125, "Knowledge"
  Correct answer: 85.9% in 1989, 84.0% in 1992, 83.2% in 1995.

- **Item 17**, Range of the square root of 75, "Understanding"
  Correct answer: 62.0% in 1989, 57.8% in 1992, 55.4% in 1995.

- **Item 66**, linear function, "Use"
  Correct answer: 86.4% in 1989, 80.2% in 1992, 79.6% in 1995.

Another study done by a group of mathematicians shows that achievement of liberal arts students even in prestigious universities is relatively low (Tose & Nishimura, 1999). In particular, the achievement of college students who did not take a mathematics test as part of the entrance examination was inferior to those who did. It should be noted that students simply do not take further mathematics than required, if the entrance examination to the university to which they wish to go does not include mathematics.

**Final Remarks**

The current goals of mathematics education in Japan for various groups of students are described in the national curriculum guidelines. However, the evidence that students are achieving those goals with respect to three levels of achievement has not been explored systematically. We need to assess students' understanding of the relationship
of mathematical ideas in specific domains and their use of mathematics to mathematize unfamiliar problem situations.

Mathematics Goals and Achievements:
The Case of Lebanon

Murad Jurdak, American University of Beirut

Abstract: Though the goals of the new mathematics curriculum in Lebanon include the three levels of mathematical abilities (procedural knowledge, conceptual understanding, and problem solving), they are content based and decontextualized. In basic education (ages 6–15), the focus is on mathematical literacy whereas, for college-bound secondary school (ages 16–18), the goals are more specialized and differentiated by scope and level of treatment. Evidence from a national study indicates that the overall achievement of goals is partial and low (mastery level is less than 40%). The achievement index for individual abilities, in descending order, was procedural knowledge, conceptual understanding, and problem solving. Private schools (autonomous, with middle and higher socioeconomic students) had higher achievement indices in each of the three abilities.

One striking peculiarity of education in Lebanon is the predominance, both in size and quality, of private schooling compared to public (or state) education (65% of students are in private schools compared to 35% in public schools). Since the early 19th century when Christian missionaries started to establish schools, private schools have multiplied and developed to include schools belonging to other religious groups or to secular groups or individuals. The private schools, being tuition based, normally attract students from the middle and high socioeconomic classes. On the other hand, public schools, which started much later, have grown at a much slower pace. The public schools are under the direct control of the central Ministry of Education (MOE) whereas the private schools are nominally supervised by the MOE. The three primary tools of government control over private schools are the licensing of the schools, the general structure and content of the curriculum, and the public examination and certification. English or French was the language of instruction of mathematics and sciences in the early missionary schools, and that tradition became a general practice protected by state policies. The issue of the language of instruction is heavily entangled with cultural and political controversies (Jurdak, 1988). The independence of private schools is so valued by the different groups in Lebanon that it was incorporated in the most recent constitutional amendment in 1990.

The year 1993 marked the beginning of a planning process for the rehabilitation of post-war Lebanon. The focus of this process was the rehabilitation of the country’s infrastructure, including that of the education sector. These efforts materialized in producing a national curriculum document (CERD, 1997), which was implemented during 1998–2001. The new curriculum introduced structural as well as content changes. The educational ladder was changed from 5 elementary, 4 intermediate, and 3 secondary, to 9 basic and 3 secondary. The basic stage is further divided into three substages: first cycle (Grades 1–3), second cycle (Grades 4–6), and intermediate (Grades 7–9). By the end of basic education, students can go to technical secondary education or to general secondary education (normally college-bound). The tracks in
the general secondary education were changed from three (math, science, philosophy) to four (literature and humanities, sociology and economics, general sciences, life sciences). New subjects were introduced for the first time (informatics, technology, cultural studies, sociology, economics). The contents of existing subjects were updated and detailed in terms of general, special, and instructional objectives. Mathematics was maintained as a common core subject in basic education (Grades 1–9), as well as a required subject, though differentiated in scope and level according to the track, in all three classes of the four tracks in secondary school.

The new curricula were implemented over a period of three years: the new curricula for Grades 1, 4, 7, and 10 in 1998–1999; those for Grades 2, 5, 8, and 11 in 1999–2000; and those for Grades 3, 6, 9, and 12 in 2000–2001.

Mathematics Goals Before 1997

Prior to the last attempt at educational reform in the country in 1997, mathematics goals were not made explicit except in terms of mathematical content. The only change occurred in 1969–1970, and its purpose was to align the mathematical content in the curricula with the then popular “new mathematics” movement. However, it is not difficult to infer the goals of mathematics at that time from the structure and goals of the general curriculum plan then in effect. The predominance of content reflected the value attached to mathematics as a critical subject for academic purposes embodied in successful promotion of students through the school system. The purpose of mathematics in the elementary stage (Grades 6–9) was basically arithmetical literacy, injected after 1970 with a low dose of mathematical literacy. The middle stage (Grades 6–9), including mathematics, was to prepare student for secondary school, which catered primarily to college-bound students.

Mathematics Goals in the New Curricula

The goals of the new mathematics curriculum are different from those of the old ones in many ways (CERD, 1997). First, the mathematics goals are made explicit and include mathematical reasoning, problem solving, connections and applications, mathematical communication, and the valuing of mathematics. Second, specific instructional objectives were formulated and made part of the curriculum documents. Third, standards were defined in the form of competencies. Fourth, mathematical literacy was widened in scope as part of basic education and in depth in terms of preaching the constructing of meaningful learning.

There were many changes in the content of the curriculum. Table 1 gives the distribution of content strands over the cycles. New strands such as statistics and solid geometry were introduced starting from the second cycle. Measurement concepts were given more attention in the first and second cycles. Probability was treated more systematically in the secondary cycle. However, the new math curricula remain within the confines of the traditional paradigm in being content based within a closed system of the concepts and skills of mathematics, decontextualized, and not responsive to the demands of mathematical literacy in the information age.

Competencies

In 1999, two years into the implementation of the curriculum, a new competency-based student assessment system was introduced. The competency used in the system is a performance-based objective encompassing a number of related instructional objectives that cut across lessons, units, and even subjects. As an example, the competency “perform operations on algebraic expressions” (Grade 8) cuts across different units in Grades 7, 8, and 9. However, the textbooks, teacher guides, and assessment had been already implemented on the basis of the objective-based curriculum.

Achievements of Goals

Achievement data are available from a national study on student achievement (Jurdak, 2001), which was one in a series of studies to assess the new curricula. This study was conducted in spring 2000 as the first phase of a two-phase project. The purpose of the first phase was to provide quantitative data on the achievement of the competencies in seven basic subjects (including mathematics) of the new curricula in Lebanon. Specifically, this study aimed at—

1. Assessing and comparing achievement profiles of each of the seven subjects in four grades: Grades 5 and 8 (studying the new curricula) and Grades 6 and 9 (still studying the old curricula).
2. Identifying the strengths and weaknesses in the achievement of the competencies in the seven subjects.

3. Identifying the differences in the achievement of competencies associated with educational–organizational variables, teacher variables, and school variables.

4. Establishing baseline data for phase two of the study, to be conducted in May 2001, at which time the curriculum would be fully implemented.

Criterion-referenced tests based on the competencies as defined and published by the Center for Educational Research and Development (CERD, 1999) were constructed for each of the four grades. The tests were content-validated by experts and piloted before being used in the target sample. A national sample of 5350 students in Grades 5, 6, 8, and 9 was selected by stratified cluster sampling techniques; of these, 950 students in the four grades took the mathematics tests.

Figure 1 presents the achievement profiles by mathematical ability (procedural knowledge, conceptual understanding, problem solving) and by achievement mean index (defined as the ratio of the mean score of a set of items to the maximum score of that set). The results are as follows:

1. The overall achievement index for all grades combined and for each of the four grades is less than 0.

2. The achievement index for procedural knowledge was the highest followed by conceptual understanding and problem solving (which was the lowest).

3. In the great majority of cases, grades that have studied the new curricula (Grades 5 and 8) had a higher mean achievement index than grades that had studied the old curricula (Grades 6 and 9).

![Figure 1. Achievement profiles by grade and level.](image-url)
Of the many independent variables studied, differences associated with "sector" were largest in favor of the private sector (see Figure 2). Needless to say, this bundle of variables cannot be disentangled easily from each other and include factors related to students, teachers, facilities, school culture, degree of centralization, and others.

![Figure 2. Achievement profiles by sector and level (Grades 5, 8).](image)

One variable that showed an impact on achievement in Grade 5 was the language of instruction in mathematics. The results support the inference that instruction in Arabic was associated with higher achievement index than instruction in a foreign language (English or French; see Figure 3). It was not possible to make a similar comparison for other grades because in those the language of instruction in mathematics was either English or French.

![Figure 3. Achievement profiles by level and language of instruction.](image)
Conclusion
The declared goals of the new mathematics curriculum in Lebanon include the three levels of mathematical abilities: procedural knowledge, conceptual understanding, and problem solving at all levels of education. In basic education (ages 6–15), the emphasis is on mathematical literacy whereas in secondary school (ages 16–18), the goals for the four tracks are more specialized and are differentiated by scope and level of treatment. The goals of mathematics, whether for mathematical literacy or for specialization, remain within the confines of the traditional paradigm in being content based within a closed system of the concepts and skills of mathematics, decontextualized, and not responsive to the demands of mathematical literacy in the information age.

Evidence from a national study for the basic education stage indicates that the achievement of mathematical goals is partial and low (mastery level is less than 40%). Improper alignment of instruction with the assessment competencies and unfavorable school teaching/learning conditions may have significantly contributed to the low level of achievement.

The level of mastery was higher in procedural knowledge than in conceptual understanding, with both higher than the level of mastery in problem solving. Private schools, which normally attract students from middle and higher socioeconomic levels and which enjoy autonomy, had higher achievement indices in the three levels (procedural, conceptual, and problem solving). Anecdotal and impressionistic reports confirm the same pattern in secondary school and also confirm that mathematization is a goal that is neither targeted nor achieved.

MATHEMATICS GOALS AND ACHIEVEMENT IN THE UNITED STATES

Thomas Romberg, University of Wisconsin–Madison

Abstract: In this paper, the goals of both traditional and contemporary reform school mathematics are first situated in the complex public school system of the United States. This is followed by a discussion of the methods of gathering achievement in schools and states. The conclusion is that there is no way one can aggregate data across districts or states to summarize achievement for the three different categories of students at the three levels of achievement for the nation.

Describing the mathematics goals and achievement in U.S. schools is not easy for two reasons: (a) the complexity of the public school systems and (b) the current efforts to reform school mathematics. One of the most striking features of U.S. schools to foreign visitors is the diversity of schooling practices, particularly with respect to governance and to the ways policy decisions are made, a result of the fact that educational policy is not national. The writers of the Constitution of the United States, in omitting any reference to education, left decisions about education to the states. With the exception of Hawaii, the states have, in varying degrees, turned over the control of schools to local communities with locally elected school boards. Today there are over 15,000 school districts that hire administrators and teachers, approve programs, select texts, and so on. As a consequence of shared state and local control, and shared state and local taxes to support schools, there are vast differences in the quality of programs, facilities, staff, and teachers both across and within states. There is no national curriculum, no national set of standards for the licensing or retention of teachers, no common policies for student assessment of progress or admission to higher education, and so forth.

Traditional Mathematics Goals

Until the past decade, in spite of the diversity in school governance, there was considerable similarity in practice and expectations for school mathematics. The curriculum reflected the 19th century compromise, described by Jahnke (1986), to formalize school mathematics as a closed unified system rather than as a sequence of methods for analyzing and understanding our world. Scientific management of this system resulted in a fragmented, hierarchical classification of mathematical concepts and skills. Scope-and-sequence charts, which specify behavioral objectives to be mastered by students at each grade level, were commonly produced. The goal for all students was that they sequentially master one concept or skill after another, and their primary task was to get correct answers to well-defined problems or exercises. This method of segmenting and sequencing school mathematics led to the assumption that there was a strict partial ordering to the discipline.

Another way of describing what mathematics has been taught to students in schools is to describe the topics covered in various grades. The emphasis in the elementary and middle schools was on computational proficiency in arithmetic. The standard topics
included addition, subtraction, multiplication, and division of whole numbers, fractions, and decimals; some experience-based geometry; and a few word problems. At the secondary school level, there was a 4-year “layer-cake” sequence with a year of algebra at Grade 9, followed by a year of Euclidean geometry at Grade 10, another year of algebra at Grade 11, and a year of pre-calculus mathematics at Grade 12. The goals for different groups of students varied only in how far along the sequence of topics students were expected to study. The college-bound mathematics and science students were to complete the entire 12-year sequence. Students planning to go to college but not planning to study mathematics or the sciences were expected to complete 10 years of the same sequence of courses. For students not college bound, eight or nine years were usually required. Finally, in some schools a few “accelerated” students started algebra in Grade 8 and took a calculus course in Grade 12. This portrayal of school mathematics was universal in the United States until the past decade and is still the dominant picture in the majority of schools today.

**Reform Mathematics Goals**

With the publication of *A Nation at Risk* (National Commission on Excellence in Education, 1983) and *Educating Americans for the 21st Century* (National Science Board Commission, 1983), it was apparent that our schools were not adequately preparing most of our students to participate meaningfully in the real world of work, personal life, and higher education; or in the country’s social and political institutions. The initial response to these concerns in most states and school districts was to continue the same sequence of mathematics courses but to shift the expectations for the college-bound mathematics and science students to algebra in Grade 8 and a year of calculus in Grade 12 and to add an additional year of mathematics to the education of both college-bound liberal arts students and non-college-bound students.

However, on reflection it was clear that the traditional course sequence in our schools was designed to meet the demands of an earlier industrial age. The transition to an information society has created new demands on U.S. citizens. The mathematical sciences education community argued that learning must be generative: that students learn mathematics in ways that provide a basis for lifelong learning and for solving problems that cannot be anticipated today. The “standards-based reform movement” now under way in many states and schools is based on NCTM’s three standards documents (NCTM, 1989, 1991, 1995) and its recently published *Principles and Standards for School Mathematics* (2000). The vision espoused in these documents involves a shift in the epistemology of learning mathematics, systemic notions about schooling that follow from that shift, the need for appropriate evidence related to the notions of schooling practices, and new assessments. The central tenet underlying the shift in epistemology is that students should become mathematically “literate.” For a person to be literate in a language implies that the person knows many of the design resources of the language and is able to use those resources for several different social functions (Gee, 1998). Analogously becoming mathematically literate implies that students must not only learn the concepts and procedures of mathematics (its design
features), but must also learn to use such ideas to solve nonroutine problems and to be able to mathematize a variety of situations (its social functions).

A set of assumptions about instruction and schooling practices has been associated with this vision of mathematical literacy. First, all students can and must learn more and somewhat different mathematics than has been expected in the past in order to be productive citizens in tomorrow's world. In particular, all students need to have the opportunity to learn important mathematics regardless of socioeconomic class, gender, and ethnicity. Second, some of the important notions we expect students to learn have changed due to changes in technology and new applications. Thus, at every stage in the design of instructional settings one must continually ask, Are these ideas in mathematics important for students to understand? Third, technological tools increasingly make it possible to create new, different, and engaging instructional environments. Finally, the critical learning of mathematics by students occurs as a consequence of building on prior knowledge via purposeful engagement in activities and by discourse with other students and teachers in classrooms. The point is that, with appropriate guidance from teachers, a student's informal notions can evolve into models for increasingly abstract mathematical and scientific reasoning. The development of ways of symbolizing problem situations and the transition from informal to formal semiotics are important aspects of these instructional assumptions.

What is envisioned in the reform documents is that all students will study an integrated mathematics program for at least 11 years. Integration includes activities from such strands as number, algebra, geometry, and statistics, and so forth from the early grades through Grade 11. This provides students with an opportunity to explore, in an informal manner, topics traditionally taught in high school and to proceed from such informal notions to more formal mathematics in the later grades. It also provides teachers with considerable flexibility to organize instruction to meet the specific needs of their students. In this vision, there is no distinction in goals between the non-college-bound and the college-bound liberal arts students. For the college-bound mathematics and science students, an additional year of more formal mathematics is required.

The problem with the reform vision of school mathematics is that it is based on ideas put forward by educational leaders, policymakers, and professors about what mathematical content and pedagogy should be. Implementation of such ideals can be undermined by a number of factors. For example, not everyone agrees with the goal of mathematical literacy for all; some influential people believe that the current course of study works reasonably well (particularly for their children), and so forth. In fact, as Labaree pointed out, during the past century, calls for reform have had "remarkably little effect on the character of teaching and learning in American classrooms" (1999, p. 42). Instead of changing conventional practices, the common response to calls for reform has been "nominal" adoption of the reform ideas. Schools adopted the reform labels but not most of the practices advocated, and it is often a political necessity for schools and teachers to claim they are using a standards-based, reform program even
if classroom practices have not changed. Thus, to document the impact of any reform efforts in U.S. classrooms, one needs to examine the degree to which the reform vision has actually been implemented.

In summary, there are no consensual mathematics goals in the United States for the three groups of students. However, what traditionally was and is proposed for the college-bound mathematics and science students seems reasonable. Traditionally, no special provisions were considered for college-bound liberal arts students or non-college-bound students. The reform recommendations, on the other hand, are tailored to meet the assumed needs of these groups.

**Student Achievement**

Traditionally, U.S. schools judge students' knowledge of mathematics either from quizzes and tests made and administered by teachers in order to prepare a formal report (usually to give a grade) or from externally developed (and often mandated) tests. Although grades are commonly used for a variety of purposes, including admission to higher education, there are no common criteria for assigning grades and no way to summarize achievement for the three categories of students based on the grades.

Most school districts periodically administer an external norm-referenced standardized test, and all but one state administers some form of state test at one or more grades. The typical test used by school districts in the United States measures the number of correct answers to questions about knowledge of facts, representing, recognizing equivalents, recalling mathematical objects and properties, performing routine procedures, applying standard algorithms, manipulating expressions containing symbols and formulae in standard form, and doing calculations. Such tests reflect the fragmentation of content and the corresponding emphasis on low-level objectives of the curriculum. Multiple-choice questions on concepts and skills emphasize the independence rather than the interdependence of ideas and reward right answers rather than the use of reasonable procedures. Unfortunately, none of the existing instruments commonly used to judge student performances in mathematics were designed to assess mathematical literacy. As such, at best they measure a student’s knowledge of some of the “design features” associated with mathematical literacy. Some items on these tests may measure understanding of such features, but none make any serious attempt to assess student ability to mathematize. Thus, because of these characteristics and the variety of different tests used, there is no way to aggregate data across districts or states to summarize achievement for the three different categories of students at the three levels of achievement for the nation.

To be consistent with the standards-based vision, the quality of student performance should be judged in terms of whether students are mathematically literate. Information needs to be gathered about what concepts and procedures students know with understanding and the ways students use such knowledge to mathematize a variety of nonroutine problem situations. Only then can one judge whether student performance meets the reform vision and, in turn, whether the curriculum and teaching changes
meet society's needs. To assess the intended impact of standards-based reforms in mathematics education, new assessment systems are now being developed. For example, the new international assessment framework emphasizing literacy (reading, mathematical, and scientific) prepared for the Programme for International Student Assessment (PISA) by the Organisation for Economic Cooperation and Development (OECD, 1999) was designed to monitor on a regular basis the mathematical literacy of students as they approach the end of secondary school.

The only summary data for the nation comes from the periodically administered National Assessment of Educational Progress (NAEP; OERI, 1997) and from international studies such as the Third International Mathematics and Science Study (TIMSS; OERI, 1996). These external tests are administered to a national sample of students via matrix sampling. They provide a general profile of achievement and can be summarized for different groups of students (e.g., by gender, ethnicity), but not for districts, schools, or classrooms. In 1995, on the TIMSS tests, U.S. students tested slightly above the international average in mathematics at Grade 4 and below at Grades 8 and 12. On the NAEP tests in 1996, students in 44 (of 50) states were tested and showed improvement in scores at Grades 4, 8, and 12 when compared to scores in 1990 and 1992. It should also be noted that although these assessments included a few open-response items designed to assess understanding, they do not test mathematizing and, thus, do not provide information about the three levels of achievement. Neither do they provide information about the three groups of students. However, in TIMSS, the results of a sample of the top 10–20% of students who had taken or were taking precalculus or calculus (generally college-bound mathematics and science students) were compared to those of advanced mathematics students in other countries. The U.S. students scored considerably lower than the international average.

Overall, no summary data is available to judge how well the three groups of students were achieving the three levels of performance for either the traditional or reform goals for school mathematics.

**Conclusion**

For the United States, characterizing the goals (both traditional and reform) for three groups of mathematics students and their achievements at three performance levels is not possible, at least with any confidence. This fact, however, does not stop policymakers, administrators, and politicians from making inferences about U.S. students.

Reactors: Ken Ruthven (Cambridge, UK), Lieven Verschaffel (Leuven, Belgium)

Origin

In 1985 the State of Nordrhein-Westfalen adopted a new syllabus for mathematics at the primary level (grades 1 to 4). This syllabus is essentially due to Heinrich Winter, one of the leading German mathematics educators, who chaired the commission preparing the document. For three reasons this syllabus marked an important turning point in the history of mathematical education in Germany:

- The list of objectives also contains the so-called general objectives "mathematizing", "exploring", "reasoning" and "communicating" which reflect basic components of doing mathematics at all levels.
- The complementarity of the structural and the applied aspect of mathematics is stated explicitly and its consequences for teaching are described in some detail.
- The principle of learning by discovery is explicitly prescribed as the basic principle of teaching and learning.

In order to support teachers in putting this syllabus into practice the project "mathe 2000" was founded at the University of Dortmund in 1987 as a joint venture of the chairs "Didactics of Mathematics at the Primary Level" (Gerhard N. Müller) and "Foundations of Didactics of Mathematics" (Erich Ch. Wittmann). In 1993 Heinz Steinbring joined the project and brought in the missing empirical component. Since its inception "mathe 2000" has been based mainly on the brains of its members and so has been independent of funds although some of its research was funded.
Basic philosophy

According to a conception of mathematics education as a "design science" three areas of research and development are closely linked and pursued simultaneously:

- the design of substantial learning environments and curricula,
- practical work (pre-service and in-service teacher education in both mathematics and didactics, school development, counselling),
- empirical studies into children's thinking and into communication in the classroom.

The five papers presented at the research forum try in an exemplary way to cover the whole range of the project work and to display a special feature of the project, namely the systematic reference to learning environments: Erich Ch. Wittmann gives an example of design ("Arithmogons") and points to its implications for teacher education. By referring to "Number chains" Christoph Selter explains how teacher education can be systematically related to developmental research. The other three papers are concerned with empirical research: Anna S. Steinweg's paper indicates how number patterns from the "mathe 2000" textbook can be used for qualitative research into children's thinking. Elisabeth Moser Opitz reports on a quantitative study which revealed that the "mathe 2000" approach is feasible also for children with special needs. Heinz Steinbring gives an example of his qualitative studies into classroom interaction in which he used "number pyramids" as research instruments. A special feature of his studies is that they relate psychological processes and communication in the classroom to the epistemological structure of subject matter.

The five papers also shed light on four principles which are at the heart of the project:
- Fundamental ideas of mathematics as guidelines (epistemological orientation)
- Learning as a constructive and social process (socio-psychological orientation)
- Teaching as organising learning processes (practical orientation)
- Co-operation with teachers (systemic orientation).

The arch fathers

The roots of the present reform of mathematical education date back to at least the late 19th century. "mathe 2000" is understood as part of this process and draws heavily on ideas developed in the past, in particular on four "arch fathers":

1 - 190
• John Dewey (1859-1953), for his clear decision for education in a democratic society and for conceiving of theory as a guide to an enlightened societal practice at all levels (as developed, for example, in "Democracy and Education", "The Child and the Curriculum", "The Relation of Theory and Practice in Education", "The Sources of a Science of Education")

• Johannes Kühnel (1869-1928), for his precise description of the shift from "guidance and receptivity" towards "organisation and activity" (cf., his classical books "Neubau des Rechenunterrichts" [Reconstructing the Teaching of Arithmetic] and "Die alte Schule" [The Old School])

• Jean Piaget (1896-1980), for displaying the overwhelming importance of the learner's "constructive activity" in his pioneering work in genetic epistemology and psychology ("Psychology of Intelligence", "Mathematical Epistemology and Psychology", "Biology and Knowledge", "Theories and Models of Modern Education")

• Hans Freudenthal (1905-1990), for his fundamental contributions to understanding mathematics as a human activity and as an educational task as well as for his insistence on developmental research as the core of mathematics education ("Mathematics as an Educational Task", "Weeding and Sowing", "Didactical Phenomenology of Mathematical Structures", "Revisiting Mathematics Education").

Publications
The research conducted by project members is documented in numerous articles and some books. As mentioned before a special mark of almost all papers is that they are systematically related to learning environments. A booklet with selected papers in English will be available at the conference.

Materials
It was a strategic decision at the very beginning to present the basic message of "mathe 2000" in a "Handbuch produktiver Rechenübungen" [Handbook of practicing skills in a productive way] (2 vols. published in 1990 and 1992). The "Handbuch" contains a systematic epistemological analysis of arithmetic from grades 1 to 4 in the form of substantial learning environments which combine the practice of skills with higher mathematical activities.

The "Handbuch" inspired many teachers to conduct teaching experiments. These experiments were very successful. So it was teachers who demanded a new textbook consistent with the "Handbuch". In collaboration with a group of teachers the four volumes of "Das Zahlenbuch" were developed and tested from 1993 to 1997.

Since the middle of the nineties the book has spread over Germany and crossed the borders to some neighbouring countries (Switzerland, Belgium, and the Netherlands).
In addition to the "Handbuch" and the "Zahlenbuch" the "Programm mathe 2000" published by Ernst Klett Grundschulverlag contains other materials for teaching primary mathematics (including the CD ROM "Blitzrechnen"/"Calculighting", with an option in English, and the booklet "Double Mirror Magic" in English). The complete "Programm mathe 2000" will be exhibited at the conference.

By means of an example (arithmogons) it is shown how the design of substantial learning environments for both students and student teachers is based upon the progressive elaboration of the epistemological structure of elementary mathematics.

Progress in group theory depends primarily on an intimate knowledge of a large number of special groups.

Graham Higman (1957)

In the first volume of the "mathe 2000" textbook the learning environment "Rechendreiecke" is introduced in the following way:

A triangle is divided in three fields. We put counters or write numbers in these fields. The simple rule is as follows: Add the numbers in two adjacent fields and write the sum in the box of the corresponding side (see Fig. 1).

Various problems arise from this context: When starting from the numbers inside, the numbers outside can be obtained by addition. When one or two numbers inside and respectively two or one number outside are given, the missing numbers can be calculated by addition or subtraction. When the three numbers outside are given, we have a problem that does not allow for direct calculation but requires some thinking. Firstgraders can find the solution by (more or less) systematically varying the number of counters in the inner fields. There are, however; also systematic solutions.
of counters in the inner fields. There are, however; also systematic solutions. By studying the behaviour of a "Rechendreieck" one understands why there is exactly one solution. Interestingly, the solutions are not always natural numbers. If the sum of any two of the outer numbers is smaller than the third number at least one of the inner numbers is negative. If one outer number or all three are odd the inner numbers are fractions (denominator 2). So "Rechendreiecke" is a nice context to cross borders even in grade 1.

It is obvious that "Rechendreiecke" forms a substantial learning environment in the following sense (Wittmann 2001):

1. It represents central objectives, contents and principles of teaching mathematics at a certain level.
2. It is related to significant mathematical contents, processes and procedures beyond this level, and is a rich source of mathematical activities.
3. It is flexible and can be adapted to the special conditions of a classroom.
4. It integrates mathematical, psychological and pedagogical aspects of teaching mathematics, and so it forms a rich field for empirical research.

In order to illustrate the driving forces behind the design process it will be explained in the following how in "mathe 2000" learning environments come to life and find their way into the curriculum: elementary mathematics provides the raw material and the above properties of a substantial learning environment serve as a checklist.

The following problem of elementary geometry is well-known (Fig. 2): For a given triangle with sides a, b, c construct three tangent circles around the vertices.

![Diagram of a triangle with circles around its vertices](image)
Solution: The unknown radii $x$, $y$, $z$ fulfil the relations $x + y = c$, $y + z = a$ and $x + z = b$. Therefore $c + a = x + z + 2y = b + 2y$ and $y = \frac{1}{2} (c + a - b)$. Correspondingly $x = \frac{1}{2} (b + c - a)$ and $z = \frac{1}{2} (a + b - c)$ are derived.

The analogous problem for quadrilaterals has a somewhat different structure: It is solvable if and only if the quadrilateral has a circumcircle. In this case the set of solutions is infinite. A closer investigation shows that the case of triangles is typical for polygons with an odd number of vertices and the case of quadrilaterals typical for polygons with even vertices.

This geometric problem appeared in Sawyer 1963 (p. 150 ff.) in the disguise of the "bears problem": Someone wants to mount gates on each of three posts A, B, C such that gates $x$ and $y$ close side $c$, gates $x$ and $z$ close side $b$, and gates $y$ and $z$ close side $a$ (in order to keep bears coming from various directions away).

The problem is also generalized by Sawyer to more than three posts.

McIntosh&Quadling (1975) chose another algebraic setting for this problem: An equal number of circles and squares are arranged like the vertices and sides of a polygon. Numbers have to be filled in such that each square carries the sum of the numbers in the adjacent circles (Fig. 3).

![Fig. 3](image)

The authors elaborated the mathematics underlying this structure: The mapping $(x_1,\ldots,x_n) \rightarrow (y_1,\ldots,y_n)$ is a linear mapping from $\mathbb{R}^n$ into $\mathbb{R}^n$. The corresponding matrix is non-singular for odd $n$ and singular for even $n$ (rank $n-1$).

Another important step forward was made by Walther 1985 who transformed arithmogons into "arithmetic chains" in order to get a richer variety of activities: When the sums (lower row) are given children can investigate how the target number (and the other numbers) depend on the start number (Fig. 4). In particular children can find out if it is possible to have the same number as start and target.
Like McIntosh & Quadling Walther traced arithmetical chains through the grades up to the upper secondary level by unfolding richer and richer algebraic structures.

In subsequent papers the structure of "arithmetical chains" was generalized to other chains and the analytical background (fixpoints of functions) was elaborated further.

There was no question that arithmogons because of their mathematical substance should become part of the mathe 2000 curriculum. However, the question was at which place and in which form they should be introduced. As in the project it is a general principle to introduce fundamental ideas as early as possible the above version of a "Rechendreieck" was chosen as an appropriate format for grade 1: counters can easily be moved around and thus favour children's exploratory activities and early reasoning.

The mathematical substance behind arithmogons (property 2) allows not only for revisiting this context over the grades but also for using them in teacher education. In a course on "Elementary Algebra" for primary student teachers with mathematics as a major subject the structure of arithmogons has been generalized to polyhedra in an obvious way: Numbers are assigned to vertices and faces such that the numbers assigned to the faces are the sum of the numbers assigned to the vertices of this face.

In this way a rich universe of examples arises which can be explored by student teachers. All phenomena and all concepts relevant for the theory of systems of linear equations occur and can be studied and explained in this context: linear mappings, independence of a system of vectors, kernel of a linear mapping, image space, rank of a matrix, rank of the augmented matrix, basis and dimension of a subspace, Steinitz' theorem, dimension theorem. The theory, however, does not hover in the air. It is developed "just as far as is necessary to frame a certain class of problems" (Giovanni Prodi).

In this context even systems of linear equations over a finite field make sense: As shown above a "Rechendreieck" does not allow for an integer solution if one outside number or all three are odd. As the properties "even" and "odd" can be represented by the numbers 0 and 1 of the field $\mathbb{Z}_2$ we get a system of three linear equations over $\mathbb{Z}_2$ (Fig. 5). The rank of the corresponding matrix (Fig. 6) is only 2, not 3 as before.
When Gaussian elimination is applied to the augmented matrix (Fig. 7) we get \( a + b + c = 0 \) as a necessary and sufficient condition for the solvability of the system. In ordinary language this means that either none of the numbers or two of them are 1 (which means “odd”). For student teachers it is intriguing to see how “abstract” algebra applies to “concrete” numbers.

Concluding remark

“Arithmogons” is an example of local design. However, the “mathe 2000” research is not restricted to designing isolated learning environments. In fact the project’s central publication is the “Handbuch” (Wittmann&Müller 1990/92) in which a comprehensive concept of teaching arithmetic in the primary grades is given in the form of coherent systems of substantial learning environments. The main emphasis in the “Handbuch” is on the epistemological structure of the subject matter. This does not mean that we consider psychological and social studies into learning processes as less important, but that we consider a profound knowledge of the epistemological structure of the subject matter as a pre-requisite for teaching as well as for these studies. In addition we strongly believe that providing teachers with substantial learning environments and the necessary epistemological background strengthens their role as reflective practitioners.

Teachers' background knowledge is surely a precondition for their professionalism. However, they actually become professionals while they are teaching (Bromme 1994; Thompson 1992; Cooney & Krainer 1996). Consequently, the present paper sketches how (prospective) teachers should be encouraged to build up background knowledge as well as to develop awareness regarding (1) their own mathematical activity (mathematical component), (2) children's thinking and learning (psychological component), (3) subject-matter-specific didactics (didactical component) and (4) teaching practice (practical component). Activities from the context of one substantial learning environment are used as representative examples to illustrate this conception.

2.1 Understanding mathematics

An important goal of mathematical components in elementary teacher education is to contribute to breaking a vicious circle. Many (prospective) teachers do not feel confident with mathematics due to their own prior negative learning experiences. Thus, they are likely to perpetuate their limited understanding to their own students. In this context, (prospective) teachers' encounters with mathematics courses play a crucial role, as they offer opportunities to encourage them to develop a lively relation to the activity of doing mathematics.

Number chains - challenging mathematical activities

The context 'number chains' shall serve as a representative example (Price, Hoskin & May 1991, 12; Selter & Scherer 1996): Choose two start numbers and write them down beside each other; then note their sum as the third number. Now add the second and third number and write down this sum. Finally, put down the sum of the third and fourth numbers (the so-called target number), e.g., 1, 4, 5, 9, 14 or 66, 23, 89, 112, 201. One activity for third graders consists of finding two (non-negative integer) start numbers that lead to the target number 50. Besides this problem, there are many different ones up to university level, such as: (1) What happens, if you take a different target number? (2) If you work on number chains of a different length (4, 6, 7, ..., n numbers)? Use examples first! (3) Is there a relationship between different target numbers and the number of solution pairs? (4) Is there a solution pair for each target number? (5) If not, is there a largest one that cannot be reached? (6) Is there a relation between the length of the chain, the target number and the number of solutions?

Doing mathematics (sensu Freudenthal)

Number chains are a typical example within the conception developed in the 'mathe 2000' project. In this context, one of its arch fathers, Hans Freudenthal, should be quoted who criticized what he called anti-didactic inversion: taking the ready-made system as the starting point of the teaching-learning process. In his terms, learning is not to be understood as duplicating, but as guided reinvention (Freudenthal 1991, 48). Children should learn mathematizing instead of consuming the finished product 'mathematics'. Thus, he developed his didactical phenomenology (Freudenthal 1983):
starting with phenomena that are meaningful for learners and thus provoke learning processes. Consequently, the mathematical components of teacher education courses should deal with an informal, process- and problem-oriented mathematics (Müller 1997; Wittmann, in press; Müller et al. 2001). In addition, the courses need to be organized in a way that provides (prospective) teachers with learning experiences that they will want their students to experience. The culture of teacher education should be similar to the favorable culture of teaching practice (Wittmann 1989).

2.2 Understanding children

With respect to the psychological component one is confronted with another vicious circle. Quite a couple of (prospective) teachers have learned as students, that it was of crucial importance to understand the ways their own teacher thought, whereas their own thinking often was regarded as not really important. They are likely to adopt this point of view for their own teaching as well. Thus, (prospective) teachers should learn about children's ways of thinking and learning.

**Solution strategies for number chains**

To illustrate this, the 'number chains' are revisited (Selter & Spiegel 1997, 68). Third graders were asked to find all number chains with target 100 (see besides). (1) How do/did you solve the problem yourself? (2) In how far did they work systematically? (3) Which similarities and differences do you notice between their ways of working and your own approach?

**Looking through children's eyes (sensu Piaget)**

Activities of this kind were designed for (prospective) teachers in order to learn to look through children's eyes, a crucial idea inseparably connected with Jean Piaget's work (1972). An extensive number of his writings has convincingly shown that even very small children interact with their environment and actively construct their own knowledge by modifying already existing schemes. Piaget was among the first who scientifically proved that children have their own ways of thinking, that make sense from their perspective, although it does not seem to be so at first sight.
Reflecting on children's documents by analyzing documents like videos, transcripts or own productions can sensitize to their perspectives. (Prospective) Teachers can learn to understand that children often think differently from (1) how we think, (2) what we assume how they think, (3) how other children think and (4) how they think in different situations dealing with basically the same (Selter & Spiegel 1997).

2.3 Understanding didactics

A third vicious circle comes to the fore with respect to the didactical component of teacher education. The (prospective) teachers' own learning experiences shape their beliefs regarding what it means to teach and to learn. Formerly the teacher gave them the relevant information that had to be learned in order to pass the next test. Consequently, nowadays the mathematics educator is expected to tell them the subject matter needed to get good marks in the exams. Although (prospective) teachers often have a critical scepticism with respect to didactical ideas, they often do not make their doubts public. As they understand the mathematics educators' remarks as academic truth, they often accept it as part of their teacher education knowledge to be learned, without sufficiently making it part of their own thinking. Thus, a fruitful discussion should be encouraged instead in which arguments are exchanged and teachers as well as teacher educators can learn.

*Number chains and arithmetic domino – two types of practicing*

An example is given in the following. Work on the two tasks and analyze them according to following questions: (1) What are the goals of each of them? (2) Which are the advantages of each of both? (3) Which difficulties do you expect in teaching practice? (4) Which variations are possible in order to cope with different abilities of students? (5) Which task would you prefer, if addition in the domain up to 100 has to be practiced in your class? Give arguments for your decision!

*Arithmetic domino:* Cut out the domino cards. Take any card and work out the respective problem. Lay down the card containing the correct result next to it, work out its problem, and so forth. If you do not find a card that fits, you have to work out the problem again.

*Number chains:* Write down two start numbers one beside the other, add them and put down their sum as third number. Finally, write down the sum of the second and the third number, e.g., 36, 23, 59, 82. Add 1, 2, 3, ... to the *first* (the *second, both*) start number(s). What happens to the other numbers? Explain!
Taking didactical theories as a basis for own decisions (sensu Kühnel)

Activities of this kind were designed to stimulate (prospective) teachers to critically relate knowledge input from different sources to their own theories. In this context, it is worthwhile to quote the German pedagogue and mathematics educator Johannes Kühnel (1925, 137) who postulated "Not guidance and receptivity, but organization and activity!" as central principles for teaching as well as for teacher education. His goal was to educate active and reflective personalities who do not just blindly copy didactical decisions others have made, but who are able to develop their own or modify existing conceptions based on different didactical theories (Kühnel 1923, 88).

2.4 Understanding teaching

The fourth and last vicious circle with respect to teacher education to be dealt with in this section is the following one: As German (prospective) teachers normally do not have any opportunities to experience something different, they continue to more or less teach as they were taught. This often happened according to a traditional approach counter-productive to modern conceptions of teaching and learning. One example shall be given to illustrate, how a higher degree of awareness can be developed with respect to a so-called progressive conception of teaching.

Number chains - analysis of a teaching episode

A group of (prospective) teachers commonly observes a lesson on number chains that one of them is giving. In order to focus their perceptions as well as their interpretations they have developed several criteria in collaboration with the teacher educator, such as (1) Did the teacher lucidly explain the problem? (2) Are the children aware of what (s)he expects? (3) Were the numbers chosen in the explanation appropriate (or too small, too big, too similar)? (4) Did (s)he give enough time for the children's own work? (5) Did (s)he maintain an atmosphere that, in principle, enabled all students to think for themselves and to contribute to whole-class or small-group discussions? (6) Did the teacher have advice available for children who experienced difficulties? (7) Did (s)he provide challenging activities for children who solved the problem faster than others?

Learning to teach according to the laboratory conception (sensu Dewey)

The goal of activities like these ones is to focus the (prospective) teachers' observations. This conception relates to a paper by John Dewey (1904), in which he distinguishes two different approaches: On the one hand, practical components can provide teachers with necessary tools of their profession, like the technique of whole-class instruction. With this aim in view, practical work is of the nature of an apprenticeship training, the aim is to form the actual teacher. On the other hand, practical work can make (prospective) teachers reflective and attentive, by relating theoretical aspects to what they can observe within the classroom – the laboratory conception. Here the goal is to equip the teacher with the intellectual methods and with materials of good workmanship instead of creating the good workman on the spot. Dewey does not re-
duce these two points of view to an 'either-or'. According to him, the apprenticeship and the laboratory conception give the limiting terms within all practical work falls.

2.5 Coherence of components

The present paper describes important principles of teacher education developed within the project 'mathe 2000' (see Selter 1995; Wittmann, in press). As teaching and learning are complex phenomena, it is obvious that a coherent view integrating all four components is needed. In this context, Wittmann (1984) has elaborated how substantial learning environments – like number chains – can fulfill this multiple function and form the integrating core of teacher education.

CHAPTER 3: CHILDREN’S UNDERSTANDING OF NUMBER PATTERNS
Anna S. Steinweg, IEEM University of Dortmund

One of the main aims of the maths 2000 project is to take both the child and the subject seriously (cf. Dewey, 1974). According to Devlin (cf. 1997), mathematics is seen as the science of patterns. Patterns can arise in geometrical themes as well as in arithmetical ones. The latter are called number patterns.

Looking through the maths 2000 textbooks (cf. Wittmann et al., 2000/01) one can find several examples of number pattern tasks offered to the students. The adaptation of mathematics as the science of patterns into textbooks is innovative for German schools and is not found in daily schoolwork. Reservations against patterns formed by ‘pure’ numbers are common. Mathematics is regarded as a boring subject and tasks with supposed connections to the child’s daily life and its daily needs are believed as the appropriate approach. My dissertation research project (cf. Steinweg, 2001), which was inspired by the pattern in the maths 2000 textbooks and the special situation in German math lessons, focused on two major questions:

I  How do children across ages react to the given number pattern, which are unfamiliar to them?
II  To what extent can a kind of natural or genetic development of understanding of number patterns with advancing age be found?

Design and Theoretical Framework of the Research

The different tasks should offer children of all skill levels the opportunity to show their competence in dealing with number patterns. The themes polygonal numbers, sequences, number pairs with functional relation, number pyramids, and so called beautiful ‘packages’ were selected as tasks for the research because they show typical characteristics of mathematical patterns, and different appropriate approaches are possible. The various tasks can be divided into three types. Type A describes patterns formed by numbers, type B patterns formed by shape, which have to be recognised and continued. Type C are a series of calculation tasks (beautiful ‘packages’), which are connected by patterns. One of the tasks in the ‘package’ does not fit into in the pattern and has to be replaced by a fitting one.

The understanding of number patterns is theoretically structured in three levels:

I  Recognising and (intuitive) Continuing of the pattern
II  Describing the pattern
III  Explaining the pattern

These levels do not mirror a development schema but are understood as interdependent. They serve to both analyse the result and design the research. On the one hand the construct of levels allows different reactions of the students categorised qualitatively. On the other hand the research project has to be designed in such a way that the participating students have the opportunity to show their competencies of all
levels. In consequence two different designs were created. The first one to determine the level I - competencies of the children in a paper-and-pencil-test and the second one, an interview study, to offer the students the opportunity to show their competencies in all three levels.

A sample of 257 students (111 female / 146 male) across ages (6/7 to 9/10 year-olds) of the German primary school was tested in the paper-and-pencil-tests. They came from three different schools with very different social backgrounds. Number patterns were not taught in any of the participating schools prior to the test. The test took place during the daily maths lessons. There was a limitation of time to one school lesson (45 min.). The students were free to do the tasks in their individual order.

In the interview study 60 children (34 female / 26 male) took part in the interview study, 15 of each age group (6/7, 7/8, 8/9, 9/10 year-olds). The interviews were held during school in a separate room. Each interview was videotaped. The interviews were designed for a 20 min. time period for the youngest ones (6 to 7 year-olds) and up to 45 min. for the oldest students (9 to 10 year-olds).

Analysis of the Children's Solutions

Every number pattern task could be solved in different mathematically correct ways. Nevertheless the solutions had to and could be categorised in an epistemologically evident way. Four categories were fixed, which will be described by examples of children's solutions to a 'beautiful package' (a type C - task for 2nd graders, 7 to 8 year-olds).

(1) solved with the solution which suggests itself

<table>
<thead>
<tr>
<th>Task</th>
<th>Solution</th>
</tr>
</thead>
<tbody>
<tr>
<td>51 - 6 = 45</td>
<td></td>
</tr>
<tr>
<td>62 - 16 = 46</td>
<td></td>
</tr>
<tr>
<td>73 - 26 = 47</td>
<td></td>
</tr>
<tr>
<td>84 - 37 = 47, 84 - 36 = 48</td>
<td></td>
</tr>
<tr>
<td>95 - 46 = 49</td>
<td></td>
</tr>
</tbody>
</table>

Kim replaces the fourth task by 84 - 36 = 48. She comments: “everywhere here is 6, 6, 6 ... and there is a 7.”

(2) solved with aspects of the pattern having been considered

<table>
<thead>
<tr>
<th>Task</th>
<th>Solution</th>
</tr>
</thead>
<tbody>
<tr>
<td>51 - 6 = 45</td>
<td></td>
</tr>
<tr>
<td>62 - 16 = 46</td>
<td></td>
</tr>
<tr>
<td>73 - 26 = 47</td>
<td></td>
</tr>
<tr>
<td>84 - 37 = 47</td>
<td></td>
</tr>
<tr>
<td>95 - 46 = 49</td>
<td></td>
</tr>
</tbody>
</table>

Rene tries to find the non-fitting task by searching the results. He recognises the double 47 and replaces the fourth task by 50 - 2 = 48.

(3) solved without an apparent connection with the pattern

<table>
<thead>
<tr>
<th>Task</th>
<th>Solution</th>
</tr>
</thead>
<tbody>
<tr>
<td>51 - 6 = 45</td>
<td></td>
</tr>
<tr>
<td>62 - 16 = 46</td>
<td></td>
</tr>
<tr>
<td>73 - 26 = 47</td>
<td></td>
</tr>
<tr>
<td>84 - 37 = 47</td>
<td></td>
</tr>
<tr>
<td>95 - 46 = 49</td>
<td></td>
</tr>
</tbody>
</table>

Jana suspects the calculations to be wrong. She comments: “2 - 6 aren’t 6 that are 0”. First she crosses out the 46 than the 47 of the third task.

(4) not worked on
First the results of the paper-and-pencil-test and the interviews were quantitatively analysed whether the task was worked on or not. In the second step the solutions offered were categorised as shown above. The video documents were also qualitatively analysed with special emphasis on level II and III.

Results of the Research Studies

The main results of the paper-and-pencil-tests are in summary:

(1) The percentage of children whose answers belonged to category 1 or 2 averaged 60 % (i.e. the results of the type C – tasks see fig. below).
(2) Category 4 (not worked on) was more often found in solutions of older children.
(3) A genetic or continuous increase of category 1 and 2 solutions across ages could not be found.

The paper-and-pencil-test showed a great acceptance of number pattern tasks. The design of the following interview study allowed the children to show all three levels of understanding (recognising & continuing, describing, and explaining).

The main quantitative results of the interview study can be summarised as follows:

(1) The percentage of category 1 and 2 solutions varied from type to type. A continuous increase with advancing age could not be found (type C – results).
(2) The percentage of category 4 (not worked on) solutions showed no uniform tendency across ages and types.

![Type C Paper-Pencil-Test Interview Study](image)

<table>
<thead>
<tr>
<th>Not worked on</th>
<th>solved without an apparent connection with the pattern</th>
<th>solved with aspects of the pattern having been considered</th>
<th>solved with solution which suggests itself</th>
</tr>
</thead>
<tbody>
<tr>
<td>6/7 year-olds</td>
<td>7/8 year-olds</td>
<td>8/9 year-olds</td>
<td>9/10 year-olds</td>
</tr>
</tbody>
</table>

The qualitative results have shown i.a. that

(1) the older children were more able to describe the pattern more generally. The younger ones often referred to examples in their descriptions.
(2) with advancing age the students were more able to recognise different patterns that simultaneously occurred in one complex structure, e.g. patterns of the sequence of addends and the one of the sums.
(3) calculation skills were useful in solving number pattern tasks.
(4) the children showed no spontaneous need to explain the structures and occurring patterns (level III).
Conclusions

The research project gained insight into the children’s understanding of number patterns. The results should not be overestimated. The shown and assessed solutions only mirror the present strategy the individual student regarded suitable, and do not give any information about the ability to use alternatives (cf. Litherland, 1997, p. 13). As a tendency the results of the studies are evident, because “... every particular is also a sample of a larger class. In this sense, what has been learned about a particular can have relevance for the class to which it belongs” (Eisner, 1998, p. 103). The tendency “provides us with a guide, not a guarantee” (Eisner, 1998, p. 105).

The research gave answers to the two questions posed in the beginning.

I  How do children across ages react to the given number patterns, which are unfamiliar to them?

The children do not have any reservations about the unfamiliar tasks. 60 to 88% of the solutions offered in the paper-and-pencil-test and 40 to 94% of the reactions in the interviews could be categorised as 1 or 2. The number patterns were fully accepted by the students and did not need any extrinsic motivation.

II  To what extent can a kind of natural or genetic development of understanding of number patterns with advancing age be found?

A genetic development of understanding with advancing age could not be found on principle, even though some of the older children have shown a qualitatively better insight into complex structures and were more able to describe patterns generally. Other researches, i.e. the pattern researches in Leeds, came to similar results: “It could not be expected to occur ‘naturally’ in all classrooms, and would have to be taught more actively” (Threlfall 1999, p. 27). The understanding of number patterns has to be motivated by the teacher in school lessons. The active thinking approach, the SLEs (cf. Wittmann, Chapter 1 and Steinbring, Chapter 5), and the patterns offered in the textbooks of the maths 2000 project provide the settings in which the teacher and the children can unaffectedly access mathematics as the science of patterns.

CHAPTER 4: MATHEMATICAL KNOWLEDGE AND PROGRESS IN THE
MATHEMATICAL LEARNING OF CHILDREN WITH SPECIAL NEEDS IN THEIR FIRST
YEAR OF SCHOOL

Elisabeth Moser Opitz, Institute for Special Education, University of Freiburg/CH

The paper is a summary of an empirical study which showed that the “mathe 2000”
approach is feasible also for children with special needs.

A research project conducted by the Institute for Special Education at the University
of Freiburg, Switzerland, has evaluated the mathematical knowledge of children
with special needs at the start of their school education. One definition of “special
needs” is children with learning disabilities. In Switzerland, these children are assigned to
special classes where, as a criterion, an intelligence quotient between 75 and 90 is
employed. Alternatively, so-called “introductory classes” are common in
Switzerland. This kind of class is meant for children with partial delay in their
development and, in some cases, when the maturity level required for entering the
first class is questionable. Here, the subject matter of the first class is extended over
two years. The children then enter either the second year of the mainstream class, or a
special class for children with learning disabilities.

Current approaches to initial mathematical teaching are strongly marked by an
understanding of the concept of numbers developed by Piaget. It recommends
introducing numbers step-by-step after a lengthy pre-numerical practice (several
months, up to one year). Classification, seriation and number-conservation are
considered as prerequisites for understanding numbers. However, the “mathe 2000”
approach (Wittmann; Müller, 2000) offers the sphere of numbers between one and
twenty simultaneously. Exercises, which precede concrete calculation, are completely
lacking. In addition, the emphasis lies on working with images of quantities with a
given structure. The reasons for this are as follows:

There are many studies showing that the numerical knowledge of first-grade children
in mainstream classes is much higher than traditional schoolbooks assume. Lengthy
pre-numerical practice, based on the concept of number by Piaget, is ignored because
such an approach to mathematical learning is under question. For example, many
studies show that number-conservation is not a prerequisite for the development of
mathematical abilities (Wember, 1989; 1998; Moser Opitz, 2001, p. 486). Nowadays,
it is known that children acquire mathematical knowledge by solving meaningful
mathematical problems and not by solving tasks like conservation and class-
inclusion. Furthermore, it is important to present the sphere of numbers from 1-10 or
1-20 immediately. A separate number can only be understood as a part of a whole, in
the context of a larger area of numbers. A step-by-step introduction of numbers
hinders such an overview and, consequently, understanding. To help children to
represent numerical quantities, it is important to use sets with a given structure of five
or ten. This structure should help them to internalise the concept of numerical quantities.

In the practice of special education, some critical questions about this new approach have arisen. It is doubtful if children in special classes have the prerequisites necessary to work in the sphere of numbers from one to ten or one to twenty immediately. In addition, it is difficult for teachers to accept that pre-numerical practice, which used to and still does characterise the teaching of mathematics in special education, is questionable. Furthermore, there are doubts over whether children in special classes are actually able to acquire the concept of numerical quantities from one to twenty. This situation has led to the questions the intended research project seeks to address:

- What kind of numerical knowledge do children in special classes bring into school?
- Do children in the first year of a special class, who are taught according to the “mathe 2000” approach, make more, less or similar progress in mathematical knowledge than children taught according to current (special education) methods?
- What conclusions can be drawn from this information for initial mathematics teaching?

Method

The subjects of the study were 162 children (59 female, 103 male), schooled in special classes at the start of their school education. The average age was 6 years 9 months. The test comprised two parts, “prerequisites” (pre-numerical practice; comprehension of quantities; grasp of numerical quantities; counting; number words and writing of numbers) and “calculation” (addition and subtraction from 1-20 with and without counting aid). The test was given in the form of a gold coin game and the children were tested individually (cf. Moser Opitz, 2001; 126f).

Results

The results are given as percentages. Where a percentage range is given, different scores were given for different tasks.

The results show that the children's numerical knowledge at the start of their school education is higher than current approaches to special education presuppose (table 1). Most of children managed the pre-numerical tasks and had a comprehension of quantities from 1 to 6. More than half of them knew the number words from 1 to 10 and a similar number were able to write numbers from 1 to 5 (cf. Moser Opitz, 2001; 1999a; 1999b). The addition tasks, with the possibility of counting within the first ten, were completed by 43-66% of the children, the subtraction tasks by 32-40%. It shows that the ability of children with learning disabilities is lower than in mainstream classes, where the score for the addition is 80% and for the subtraction 40%. Only a few children were able to solve addition and subtraction without counting aids.

Table 1: Numerical knowledge of children with special needs at the start of their school education

The second part of the research project examined the improvement in mathematical knowledge in the first year of school. Based on written reports by the teachers, three different groups were matched. One group was taught according to the current approaches to mathematical teaching with lengthy pre-numerical practice, the second group by the “mathe 2000” approach (including working in the sphere of numbers from 1-20 and laying emphasis on the recognition of sets with a given structure) from the beginning of their school education and the third group started working with the “mathe 2000” approach during the first year of school. Eight months after the start of their school education, the children were tested again.

The scores of the second and third group were, in some areas (number words, writing of numbers, recognising sets with a given structure) but not overall, significantly better than those of the first group. Interestingly, the group which has worked with images of quantities with a given structure from the beginning of their school education used (finger) counting strategies significantly less in addition and subtraction than the other groups. This is an important finding because it is known that one symptom of children with learning disabilities in mathematics is the frequent use of finger counting strategies (Geary; Brown; Samaramayake, 1991).
The results of the study presented here show that the numerical knowledge of children with special needs at the beginning of their school education is much higher than current approaches in special education presuppose. These common teaching materials, which prescribe pre-numerical practice during several months or a whole year without using numbers, can be considered questionable. Moreover there are good reasons to conclude that working with the "mathe 2000" approach helps children to develop their concept of number. Particularly, working with sets with a given structure seems to supply number representation and the practice of addition and subtraction. Early mathematical teaching for children with special needs should take these results into account and adapt its methods.

In addition, interviews carried out with special education teachers (Moser Opitz, 1999c, 172) show that they lack knowledge as to how to adapt the "mathe 2000" approach to children with special needs (e.g. with regard to perception, spatial organisation, memory problems). This should be taken into consideration. More guidance to special education teachers for teaching the "mathe 2000" approach is necessary.

CHAPTER 5: ANALYSES OF MATHEMATICAL INTERACTION IN TEACHING PROCESSES

Heinz Steinbring, IEEM, University of Dortmund

About the Epistemological Nature of Substantial Learning Environments

Mathematical concepts are no empirical things, but represent relations. "... there is an important gap between mathematical knowledge and knowledge in other sciences such as astronomy, physics, biology, or botany. We do not have any perceptive or instrumental access to mathematical objects, even the most elementary ... The only way of gaining access to them is using signs, words or symbols, expressions or drawings. But, at the same time, mathematical objects must not be confused with the used semiotic representations." (Duval, 2000, p.61). With regard to this epistemological position, mathematical knowledge is not simply a finished product. The (open) concept-relations make up mathematical knowledge, and these relations are constructed actively by the student in social processes of teaching and learning.

Mathematical learning environments concern the particular character of mathematical knowledge in the following way: On the one hand, it is a matter of concrete mathematical problems which are given in a situative - not formalized - context as immediate learning offers (cf. Wittmann, 2000 & chap. 1). On the other hand, it also becomes obvious that it is not only a matter of concrete mathematical activity, but with the exemplary treatment, something should be learned at the same time, something which is not directly visible, e.g. a mathematical relation or a generalized structure. Essentially, mathematical learning environments develop only in the active construction by the learner. Also, one is not dealing with concrete objects which one could touch, but with embodiments of mathematical structures.

The Role of Learning Environments in the Analysis of Classroom Interaction

Mathematical learning environments essentially represent an open, structural system which was constructed according to didactic and epistemological design criteria, and which can then become an environment filled with life only in classroom interaction through the students' activities and the teacher's interventions. The wired structure of learning environments is illustrated in the following diagram:

When interactively treating a learning environment, a similar problem arises in communication: The fact that the invisible mathematical relations in learning environments cannot be directly communicated by naming visible attributes means
that the students have to construct relevant mathematical relations in the present exemplary learning environment with their own mathematical conceptions. This construction by the students is not directly readable in their descriptive statements; one has to analyse the intentions meant in the children's descriptions, and to discover which general mathematical relations the children aim at with their exemplary words.

In the interaction, the children have to deal with the not directly palpable mathematical knowledge and with the hidden relations by means of exemplary, partly direct interpretations - and not by means of abstract descriptions, notations, and definitions. By means of epistemological analysis (cf. Steinbring, 2000a; 2000b) it is to be found out whether the exemplary description used in the documented statement aims at a generalizing knowledge construction or whether it is a statement in the frame of the old, familiar knowledge facts.

Exemplary Analysis of a Classroom Interaction in a Learning Environment

On the basis of the following short interaction scene, the joint and situative construction of an "invisible" mathematical relation in a learning environment about number walls (in a 4th grade class) shall be illustrated exemplarily. The children are working on four-stage number walls; the four base stones 35, 45, 55, and 65 have been interchanged several times, which led to number walls - written on the board - with different top stones. The teacher asks about particularities, whereupon the children give descriptions and first reasons for big or small top stones. The student Timo explains his reasons first:

| 102 | Timo | The reason is also that if the sixty-five is in the middle, it is counted twice. Once with the outmost and once with the one next to, that is with both next to it. If it is at the edge, it is only counted once. |

For the time being, Timo stays at his seat; he talks about the base number 65 "in the middle". This is not a mere description, but Timo develops linguistic-conceptual designations: "in the middle", "the outmost", "both next to it", "at the edge". These are not names for the objects ("stones" or "numbers"), but relations between these number-places which are important for the application of the rules for number walls.

| 103 | Timo, I would like you to come up to the board and to show that to the other children |

| 104 | Timo goes to the board, talks, and shows: |

| 105 | Timo | Here, (points at the first stone "65" of the lower number wall with the top stone "380") when the sixty-five is here, it is counted only once. (points at the first and second stone, "65" and "35") Here. One moment, plus thirty-five. |

| 106 | Timo | 100 90 100 35 55 65 380 190 190 |

Now, Timo does not continue using his "concepts" constructed before; he points at the stones and talks about the numbers. Thereby, his description becomes more concrete and tied to the example. The importance of the attribute "count a base number once" can only become clear to other students through additional, active allusions by Timo, who points at the stone "65" and designates an edge stone at the same time.
Timo constructs new "mathematical signs" and symbolic relations with the sequence of designating numbers and showing stones in a wall.

105 T | # Please show the children where you are counting to!#

After the teacher’s request, Timo points at the calculated "result", the number "100" in the 1st stone of the second stage of the wall.

| 106 | Timo | # Yes, there (points at the first stone "65") is the sixty-five, there (points at the second stone "35") plus that are a hundred. (points at the stone "100") But if the sixty-five stands here, (points at the second stone "35") that one there and there the thirty-five, (points at the first and second stone, "65" and "35") this one here plus thirty-five and there plus fifty-five (points at the third stone "55") is counted once more.

In the second step of his argumentation, Timo refers to the 2nd stone - a middle stone - of the same number wall. He uses the same number wall, but varies the position of the "65": he moves it mentally from the left edge stone to the middle stone next to it. This is what he intends by pointing at the corresponding stones. By means of the possibility that "65" and "35" could switch positions, Timo stresses that it is mainly a matter of the different positions (edge or middle stone); in this way the example contains aspects of a general interpretation. Furthermore, Timo emphasizes that this number now has to be added twice: "... counted once more." The teacher asks Timo to show this possibility for "65" as a number in the middle in an appropriate example.

107 T | Great. But now, please, choose an example where the sixty-five really is in the middle, then we can imagine even more easily how you mean that. (Timo points at the second stone "65" of the lower number wall with the top stone "440") yes. Mhm.

Timo points at the lower wall with top number "440":

| 108 | Timo | Plus fifty-five (points at the second and third stone "65" and "55") and plus thirty-five. (points at the first and second stone "35" and "65")

Here, the rather "general" interpretation "if the 65 stands here" (on the 2nd stone) is concretized. Timo now only names the readable addition tasks. The possibility that, not only the concrete calculations and results are meant hereby, but that e.g. the middle number "65" is counted twice, cannot be inferred from the statement, but has to be constructed actively by the other participants.

Timo begins a partially general interpretation of the relations between the positions of the base stones, which affect the number of calculations and therefore the size of the top stones, and which could lead to a mathematically full reasoning in the frame of the exemplary environment. The teacher requests Timo to concretize his considerations several times in the progress of the interaction. Timo follows this request, also where he in thoughts flexibly places the "65" instead of the "35", by now taking a number wall with the appropriate numbers. The span between the original exemplary conceptual generality in Timo’s description and the teacher’s request for concretiza-
tion is narrowed down reciprocally until the general description has been substituted by concrete numbers. Timo's declaration seemed too abstract and therefore incomprehensible - although the teacher aimed at the just not directly visible structural relation in the environment "number walls", which cannot be described directly. In contrast to this, the designation of calculations with the given, concrete numbers and the written results, as they follow according to the construction rules of number walls, could, in tendency, only have led to a simply verifying confirmation of mathematical facts, without offering insights to the invisible relations. The "complementarity" of intended generality - in Timo's first description - and reducing concretization to the given numbers and examples - as requested by the teacher - seem to lead to an optimum of constructive interpretation and communicative understanding in this classroom interaction.

**The Specific Social Epistemology of Interactively Constituted Mathematical Learning Environments**

The particular epistemological character of mathematical knowledge consists in the concentration on relations which are neither openly visible nor directly palpable. (Duval, 2000). In order to develop these relations and to be able to operate with them, they have to be represented by signs, symbols, words, diagrams, and references to reference contexts (Steinbring, 2000c), learning environments, or experiment fields. Thereby, the scientific status of the mathematical knowledge does not depend on the choice or the abstractness of the means of representation; neither are there any universal means of illustration distinguished a priori which would automatically guarantee the epistemological quality of the mathematical knowledge (cf. Ruthven, 2000). The development of mathematical knowledge always occurs - be it in the academic discipline or in classroom learning processes - in social contexts which can, however, differ concerning their objectives and particular constraints (Steinbring, 1998).

Mathematical, substantial learning environments - the core element of the research project "mathe 2000" - represent such experiment fields which are suitable for interactive, social learning and developing processes in different situations of learning and acquiring mathematical and didactic knowledge in the classroom or in the training and in-service training of teachers. Which epistemological conception of mathematical knowledge becomes relevant is not simply determined beforehand and objectively, but this is subject to the active construction in the communication and in the proceeding interactive processes. Exemplary, epistemological analyses show that conceptions of the knowledge of the following kind can be constituted at this point: Mathematical knowledge as a collection of single facts, or mathematical knowledge as isolated, formal structures (cf. Steinbring, 2000b).

In the exemplary episode, a third and essential epistemological attribute of mathematical knowledge appears: A situatively tied form of describing and constituting the relations of mathematical knowledge in the frame of the exemplary learning environment; using exemplary, independent descriptions and words, but with the intentions - identifiable in the analysis - of generalizing exemplary attributes of the situation to the invisible general mathematical relations. In this regard, substantial learning
environments represent a productive base for the interactive acquisition of knowledge, on which knowledge about mathematical knowledge can be acquired through the interaction at the same time, i.e., in the interaction, a specific, partly situation-bound, social epistemology of mathematical knowledge constitutes itself - which is not given by an independent authority from the outside.

This particular social epistemology constitutes itself in the proceeding of the according situation, for example during the treatment of a learning environment, and for this purpose, it needs situative, exemplary context conditions as well as words and relations already known and familiar for communication. In order to understand how relations in mathematical knowledge - which are not directly, empirically palpable - can actually be expressed and communicated in this way, a thorough epistemological analysis is required (Steinbring, 2000b). Such qualitative analyses of different situative epistemological interpretations of mathematical knowledge in interactive treatments of learning environments have different objectives and react upon the perspective of mathematical knowledge taken in the different chapters. So, feedback to the design and construction of learning environments, especially such modifications which make these environments become living systems, occur; furthermore, testing analyses of environments by teachers or students can increase the awareness (Selter, 1995) concerning the complex (professional) application conditions as well as the classroom interaction with mathematical learning environments.

REACTION 1: BETWEEN PSYCHOLOGISING AND MATHEMATISING

Kenneth Ruthven, University of Cambridge School of Education

This necessarily brief response will focus on the central idea informing the rich body of work developed within the Mathe 2000 project: that of ‘substantial learning environments’ as organising systems for mathematical and didactical transactions between students and teachers, and between teachers and teacher educators.

As Wittmann illustrates, while common epistemological, psychological and pedagogical principles underpin these environments, what characterises each of them is a distinctive flexible mathematical artefact around which classroom activity can be organised. Steinbring and Selter variously show how such environments are brought to life through classroom activity in which mathematical structure latent in an artefact is actively (re)constructed by learners with assistance from their tutor. Underpinning successful learning through this co-operative and communicative activity are the complementary processes by which codified mathematical knowledge and reasoning are -in Dewey’s term- ‘psychologised’ to recast them in forms more accessible to, and usable by, students; and through which student experience is -in Freudenthal’s term- ‘mathematised’ to recast it in disciplinary terms. Evident too, in the design principles and exemplary environments, is an orientation towards -in Bartlett’s terms- ‘simplification by integration’ over ‘simplification by isolation’. Indeed, Moser Opitz conceives her study in this way, and provides some empirical support for the integrative position through evidence of successful pre-school learning as well as of distinctive trends in the development of student competence and strategy over the first year of schooling.

Some of the complexities of these processes emerge from Steinweg’s study which explores -and largely rejects- the conjecture of ‘natural or genetic’ development in understanding of number patterns ‘with advancing age’. Intriguingly, an important socio-cultural dimension is suggested by the illustrative student responses to the unfamiliar type of ‘beautiful package’ task. When Jana ‘suspects the calculations to be wrong’, she seems to be interpreting the task simply as one of checking the solutions to a conventional school exercise. From the way in which Réne ‘repairs’ the exercise, he appears to be interpreting it as a puzzle devised so that the answers form some pattern (somewhat analogous to the picture pattern formed by the arithmetic domino illustrated by Selter). Finally, Kim forms the ‘epistemologically evident’ interpretation that not only the answers but the problems themselves are intended to conform to an overarching mathematical pattern. Arguably, then, Jana, Réne and Kim were not tackling the ‘same’ task, and only Kim was tackling the task as envisaged by the designer. ‘Success’ in the task seems to depend on students’ anticipation of new didactical norms as much as their grasp of mathematical structures. While over half the spontaneous responses fitted the maximally mathematically formatted interpretation of the task, one suspects that further analysis would reveal some troubling relationships between social position and task interpretation. Considerations of equity in making these (new) rules of the classroom mathematics game explicit lend further support to Steinweg’s suggestion that such ideas may need to be taught more actively.
Nevertheless, the idea that teacher and students are working on 'the same task' and seeing 'the same structure' is a useful strategic fiction where classroom participants are seeking to co-ordinate and articulate their interpretations of a task and their resulting constructions. Steinbring’s microgenetic analysis of the production of a public explanation shows such processes in operation. Through interaction between teacher and student, the focus of this episode of classroom communication shifts from the articulation of a generic mathematical structure which the student perceives as fundamental to an artefact, towards the concretisation of this idea in specific examples inscribed on the board. Far from the front of the classroom, Timo uses positional language to evoke the common structure he perceives in number walls. But as he moves closer to the board and starts physically pointing, 'the outmost' becomes 'here', and his account becomes more tied to a designated example. In response to teacher solicitations to concretize his ideas, his accounts become progressively more focused on the manifest content of specific number walls. As Steinbring notes, this layered explanation casts latent structure into a form of relief, making it more readily accessible to other participants.

These accounts lead one to appreciate the considerable demands of managing these forms of classroom activity so as to promote effective learning, and both Moser Opitz and Selter emphasise the change and challenge this presents for many teachers. In this respect, one admires the sense and subtlety with which substantial learning environments seem to extend and reshape the familiar didactical form of the exercise rather than wholly rejecting it. An important aspect of this is the way in which tasks seek to 'combine the practice of skills with higher mathematical activities'. Correspondingly, Selter emphasises the potential of substantial learning environments as organising structures within teacher education around which concerns to develop the mathematical, psychological, didactical and practical expertise of primary teachers can be co-ordinated.

One crucial question is how to conceive mathematical expertise for primary teaching. For the honourable tradition of 'elementary mathematics from an advanced standpoint' may lead to an over-extension of a single-minded idea of progression. Take the treatment of a generalised form of arithmogon in terms of the theory of systems of linear equations. Whilst appreciating that the theory is developed 'just as far as is necessary to frame a certain class of problems', and noting student teachers interest 'to see how abstract algebra applies to concrete numbers', it is not clear how such ideas estimable in their own right- might readily be brought to bear in shaping children's mathematical enquiry and argumentation. There, the teacher is required to operate with great ingenuity, flexibility and fluency within the construction zone of the students. So, while a matrix representation neatly captures the relationship between 'inner' and 'outer' values of the Rechendreiecke, a more didactically pertinent representation might highlight the complementary arithmetic relationship between each 'inner' value and its spatially opposite 'outer' counterpart, and between 'inner' and 'outer' sums. In short, the question is one of finding a sound balance between 'psychologising' and 'mathematising' in professional education.
REACTION 2: DESIGN AND USE OF SUBSTANTIAL LEARNING ENVIRONMENTS IN MATHE 2000

Lieven Verschaffel, University of Leuven, Belgium

This short reaction is organized around the four principles at the heart of the MATHE 2000 project that are listed in Wittmann's introduction to the Research Forum. However, I want to begin by expressing my admiration for the project, which entails a unique, provocative and successful concept of how to organize and do research in the field of mathematics education. The decision to place substantial learning environments (SLE) at the core of the research and the developmental work and to use these SLE as the common starting point for the design of curricula and textbooks, empirical studies into children's thinking and communication, and teacher education, has proven to be a very valuable and effective strategy both from a theoretical and a practical point of view. Although the project has many similarities with other projects, such as the Realistic Mathematics Education (RME) project in The Netherlands, there seem to be some differences with these other approaches in terms of aims, content and research strategy, -- some of which will be pointed out below.

Fundamental ideas of mathematics as guidelines. As stressed and illustrated in all papers, SLE are at the very heart of the MATHE 2000 project. Throughout the papers it is shown how the design of SLE -- both for pupils and for student-teachers -- is based upon the progressive elaboration of the epistemological structure of elementary mathematics. Major characteristics of SLE are that they represent central objectives and contents at a certain level of instruction, and that they are related to significant mathematical objectives and contents beyond that level. Quite strikingly, almost all examples of SLE relate to pattern finding (see, e.g., Wittmann's "rechendreiecke", Selter's "number chains", Steinweg's "series of beautiful calculation tasks", and Steinbring's "number walls"). I consider this as one of the clearest manifestations of taking the (quintessens of the) subject of mathematics as a "science of patterns" -- already from the very first years of elementary mathematics education on -- very seriously. Equally strikingly, these pattern-finding tasks are given in a purely symbolic format and not embedded in a real-life context. Although it should be acknowledged that some of these pattern-finding tasks are briefly introduced through a realistic or fantasy context and that these symbolically presented pattern-findings activities are complemented with more "applied" kinds of problem-solving activities in the textbook series "Das Zahlenbuch", the early and frequent recurrence of these context-lean pattern-finding activities -- is remarkable. Interestingly, Steinweg's study of 6-10-year old children's understanding of patterns reveals that these children do not have any reservations against such unfamiliar, context-lean tasks, that they fully accept them, and do not need any extrinsic motivation.
Learning as a constructive and a social process. The view of learning that lies at the basis of the MATHE 2000 project is in line with current conceptions in instructional psychology in general, and in the psychology of mathematics education in particular, wherein learning is considered an active, constructive, cumulative, self-regulated, goal-oriented, situated and social process of knowledge building and meaning construction. Throughout the papers, it becomes clear that in the MATHE 2000 project not only the subject (i.e., mathematics) but also the learner -- with his or her own constructions, interpretations, beliefs and goals -- is taken very seriously. The documentation that this process of knowledge building and meaning construction is fundamentally social in nature and that it is shaped by the norms, rules and agreements that constitute the culture of the mathematics classroom (especially in Steinbring's paper) fits with recent analyses by others (e.g., Brousseau, Cobb).

Teaching as organizing learning processes. Complementary to the above view of learning, teaching is conceived in the MATHE 2000 project as inducing and supporting children's active process of knowledge building and meaning construction, rather than providing them with the necessary knowledge and skills to pass the next test. As in most other countries where similar new conceptions of teaching and learning mathematics are being developed and implemented, MATHE 2000 risks of being criticized for giving children too much freedom in developing their own strategies, for paying too less attention at the basic skills, for not progressing quickly enough towards abstraction and formalisation... For many reasons, these criticisms do not hold to the MATHE 2000 project. The carefully designed SLE, grounded in a thorough epistemological and historical analysis of the domain and supported by empirical research on pupils' reactions to the materials, provide ample opportunities for the well-balanced combination of the practice of skills with higher mathematical activities. Moser-Opitz's evaluation study of children with special needs provides some empirical support for this claim, -- even among those children for whom this new approach is deemed to be most detrimental.

Cooperation with teachers. Finally, in the MATHE 2000 project, not only the subject and the child, but also the teacher is taken very seriously. This is evidenced, among other things, by the great attention given to teacher pre-service and in-service education and to cooperation with teachers. Selter's approach to pre-service teacher education, with its multi-dimensional view of the components of teacher professionality, its emphasis on "de-constructing" student-teachers' erroneous beliefs about and negative attitudes towards mathematics (education), and its focus on the development of teachers' background knowledge and awareness rather than of their executive skills, convincingly demonstrates the value of SLE as the keystone, not only for elementary mathematics education, but also for teacher education.
RESEARCH FORUM 5

Theme
Realistic Mathematics Education Research:
Leen Streefland’s work continues

Coordinator
Norma Presmeg

Session 1
• Introduction by Norma Presmeg
• Presentation 1
  “A focus on experiences—my experiences with Leen” Willibald Dörfler
• Presentation 2
  “Social interaction as reflection: Leen Streefland as a teacher of primary school children” Ed Elbers
• Presentation 3
  “Learning from history to solve equations” Barbara van Amerom
• Synthesis by Norma Presmeg
• Audience discussion

Session 2
• Introduction by Norma Presmeg
• Three simultaneous Round Tables based on
  “Didactising: Continuing the work of Leen Streefland”
  Erna Yackel, Diana Underwood, Michelle Stephan, Chris Rasmussen
  Round Table 1: Diana Underwood
    Theme: Roles of symbolizing (Activity: Stacked cubes task)
  Round Table 2: Chris Rasmussen
    Theme: Models of students’ thinking (Activity: Tangents task)
  Round Table 3: Michelle Stephan
    Theme: Arguments and discourse (Activity: Analysis of video clip)
• Short presentation by the round table leaders
• Reaction by Koeno Gravemeijer and Marja van den Heuvel-Panhuizen
• Audience discussion
• Synthesis by Norma Presmeg
REALISTIC MATHEMATICS EDUCATION RESEARCH:
LEEPEN STREEFLAND'S WORK CONTINUES

Leen Streefland

Introduction: A focus on experiences — my experience with Leen. Willi Dörfler

It has been very good luck for me to have the opportunity for enjoying a close cooperation with Leen Streefland. We got to know and appreciate each other in the context of PME. When I was entrusted with editing Educational Studies of Mathematics (ESM) I decided to share this demanding task. It was absolutely clear to me that Leen had to be my first choice and I was very happy that he agreed. Thus we had six years from 1990 until 1995 jointly dedicated to the journal and to the enhancement of maths education research. Over this time, of course partly together with Gila Hanna as the third editor and with the members of the editorial board, Leen and I had a fruitful and productive exchange of ideas and opinions about questions like: main issues of mathematics education research, basic orientations, criteria for quality of research, role of theories in maths education, policy of the journal. Mostly these questions and issues were discussed with respect to submitted papers and thus they were not just esoteric deliberations but had a strong relevance for concrete action.

It is against this background of shared experiences that I will now turn to some traits of the personality of Leen which could be found in his personal life, in his academic life and in his so highly valuable work in mathematics education. Leen’s interest in and concern for people had a strong influence on what he did, what he said, what he wrote, in short on how he lived his life. Foremost there was the feeling that you really matter as a person and a human being which you had when sharing your time with Leen. This was never an abstract or detached interest, say, just in your academic work but it took into account the complex living conditions, the emotions, fears and wishes of the respective other. One can read this general attitude from many letters by Leen to authors of papers submitted to ESM. In those he tried to establish a communicative basis on which to
negotiate about the content, style or quality of the paper. Leen never forgot that it always is a concrete person who writes and that a judgement on a paper implies a judgement on the author. This should not be misinterpreted as a tendency to lowering standards. Quite to the contrary, it was the struggle to guide authors in matching high standards.

The concern for people be they pupils, authors, colleagues or friends in my view most prominently resides in Leen’s own work in mathematics education. This research in the context of Realistic Mathematics Education (RME) genuinely and seriously puts the learner into the center. And again it is not an abstract or epistemological subject from which maths education is stipulated to start. The subjective, individual and personal experience of the learner is on the one hand the background and the basis for all (mathematical) learning. On the other hand learning mathematics according to RME is to be organized by making new experiences possible, by engaging students in reflections on their personal experiences in mathematical ways of thinking. This reflects a deep respect for the individual student and his or her faculty for building up mathematical meaning provided adequate experiential situations are offered. It also expresses a view on mathematics as originating out of human experiences and their description, organization, structuring and planning. That this nowadays is a broadly accepted stance can be attributed to the insistence with which Leen and other representatives of this school of thought have expounded their position: mathematics is relevant for the future lives of our students and can be experienced as being meaningful by them. But for this to occur the widespread separation and isolation of school mathematics have to be overcome. Leen’s work impressively shows us a way to attain that goal and convinces us that it really is attainable. The related demands Leen did not only impose on his own work, but he always tried to urge the authors of papers submitted to ESM to think about consequences of their work for the students in the classroom and how it relates to their struggles with making their mathematics meaningful to themselves. When admitting that there is a multitude of possibilities for approaching that goal this could and should mean a basic guiding framework and orientation for future research in mathematics education: to make the mathematics experientially real to the learner.

A related feature of Leen’s thinking about research and scientific theories in general and specifically in maths education is the following one: As the learning of mathematics itself, also the development of theories about it has to be experientially grounded. This attitude of Leen’s showed itself in a kind of doubtfulness and suspicion of what he sometimes called a jargon. By this he labeled texts that used vague or opaque concepts too much detached from the concrete realities of the mathematical classrooms to have any sensible implications for the organization of the latter. In other words the basic tenets of RME in Leen’s view have also to be applied to maths education research. As the teaching of mathematics in school has to be
rooted in prior or current experiences of the learner, a valuable piece of research and its presentation in a paper has to be related to the experiences of the readers. It must make sense by making clear the meaning of used notions and terms and should have the potential to change the experience of the reader. As the relevance of most mathematical concepts and methods resides in their potential to structure and organize the experience and activity of the learner, research and theories in mathematics education should have analogous implications for the practice of school mathematics. I remember various vivid discussions on this issue that showed us both that such general tenets have to be substantiated in each single case, such as a specific contribution to ESM. It also became clear that experience is not a given which passively is imposed on the individual but that it is something that is actively constructed and developed by the latter in his/her social context. This inherent indeterminacy of individual experience, be it by the pupil in the classroom or by the reader of a journal article, brings in notions such as affordances and constraints. Whatever a teacher does in the class or an author writes in a paper establishes affordances and constraints for the thinking and understanding on the part of the students or of the readers. This might make teaching and writing a daunting endeavour; but only if one believes in fixed and absolute meanings (in mathematics and mathematics education), which have to be acquired and transmitted adequately. Contrary to that, Leen's conception of RME and of mathematics education research is that of a developmental process that leaves room for interpretations, negotiations, inventions, deviations and the like, which yet constantly and consciously is devoted to sense-making. And in this framework a jargon is a way of teaching, speaking or writing which inhibits or even prevents the above cognitive and communicative processes. And I take it as a kind of legacy from Leen to avoid jargon in this sense because it acts against the interest in people as learners, readers and researchers.

**Social interaction as reflection: Leen Streefland as a teacher of primary school children.** Ed Elbers

Leen Streefland did pioneer work in creating a community of inquiry in the mathematics classroom. He encouraged students to “do research” and to adopt the attitude of researchers. The task of the teacher was to guide and assist students who had been given considerable responsibility for their own learning. Streefland was convinced that creating a learning community in which students had ample opportunity to produce and discuss ideas would allow their mathematical creativity to blossom. Interaction and
collaborative learning would stimulate children to make their own mathematical constructions and to discuss them in what amounted to a social process of reflection. Streefland was involved not only as a researcher but also as a teacher. He worked with the primary school teacher Rob Gertsen for about 15 years.

I shall present a case study of a lesson co-taught by Leen Streefland and Rob Gertsen. In this lesson Streefland alternated whole class discussions with individual or group work. I want to use this particular case as an illustration of Streefland's ideas about mathematics education. Moreover, I shall analyse the relationship between whole class discussions and learning processes of individual students and the tension between teacher's guidance and students' invention.

Three principles of realistic mathematics education form the basis of this lesson. Firstly, the starting point is the problem instead of the mathematical strategy or solution. The teacher introduces a meaningful problem, which the students use as a source for constructing mathematical understanding. Secondly, a basic element in realistic mathematics education is to motivate students to 'mathematize', to turn everyday issues into mathematical problems and use the mathematics resulting from these activities to solve other problems. Thirdly, the students do not depend on the teacher to find out whether their ideas are correct. Part of their task is to develop good arguments to support their approach and solutions.

Streefland's lessons had a basic format (Elbers & Streefland, 2000a, b). They started with a statement of the principle of a community of inquiry: "We are researchers, let us do research." The students were given a topic or problem as the subject of their research (often with reference to some example from everyday life, a newspaper clipping, a photograph, etc.). After the introduction of the topic, the students were invited to formulate research questions and develop answers to these questions. Work in small groups of 4 or 5 students, and sometimes individual work, alternated with class discussions in which the results were made available for discussion in the whole class. Leen Streefland and Rob Gertsen worked as a team. They introduced themselves not as teachers, but as senior researchers. This role allowed them to participate in the discussion themselves. The students knew, of course, that they could expect assistance and guidance by their teachers. However, by acting as they did the teachers gave the students responsibility for their work and made it clear that the validation of their solutions comes from mathematical argument and not from the teacher's authority.

The case study

The lesson was taught in a combined seventh and eighth grade class at a primary
school in the Netherlands (children between 11 and 13 years of age). It was part of a short series of lessons in June, at the end of the school term, when the students had already completed their regular mathematics curriculum for that year. An activity sheet was used with the problem and its variations printed on it, leaving space for the students to write down their own solutions. My presentation is based on an analysis of the video recording of this lesson, a transcript and a short Dutch article Leen Streefland wrote about this lesson in 1997. The case is divided into a number of Episodes. The problem introduced in the classroom was set in a pharmacy and involved calculating the number of tablets prescribed by a physician.

“Elisa works at a pharmacist’s. She is preparing medicines prescribed by Doctor Sterk for Mrs. Jansen.

For Mrs. Jansen: 40 falderal tablets.
6 tablets a day for 2 days;
then 5 tablets a day for 2 days;
then 4 tablets a day for 2 days;
then 3 tablets a day for 2 days;
then 2 tablets a day for 2 days;
then 1 tablet a day for 2 days.

Elisa thinks: ‘This isn’t right! The doctor has made a mistake.’

What do you think? Is Elisa right?”

During the lesson variations on the original problem were given which amounted to changes in the number of tablets. The students, first, had to solve the original version of the problem (starting with 6 tablets), next they had to calculate the number of tablets in a prescription starting with 8 tablets (8 tablets for the first two days, 7 for the next two days, etc.) and then the number of tablets in a prescription starting with 10 tablets. For reasons of space, I shall restrict my presentation here to Episodes 5, 6 and 7. In the preceding Episodes 1 to 4, the students, in order to solve the problem in its original form, had developed two approaches: (1) multiplying the various numbers of tablets (2x6; 2x5; etc.) and adding them up (12 + 10 + etc.), and (2) adding up the numbers (6 + 5 + etc) before multiplying them (2 x 21). In Episode 4, which consisted of individual and group work, students worked on the version of the problem starting with 8 tablets. Episode 5 is a class discussion immediately following Episode 4.
Episode 5. One of the children showed his solution to the whole class. He used the solution to the original version (starting with 6 tablets) as a starting point for solving the new problem (starting with 8 tablets): $42 + 2 \times 7 + 2 \times 8$. After this, the teachers asked who had applied a different approach. One of the children showed that she had made combinations of tens ($8+2=10, 7+3=10$ etc.) in order to add up quickly: “I took out the tens”. In the ensuing discussion about this approach, Streefland asked: “What shall we call this approach? Can we invent a name for it?” The children proposed expressions such as “making tens”, “jumping to tens” and “bridges of ten”. Leen Streefland concluded this discussion by suggesting they call this method: “making combinations” and “making clever combinations”.

The third variant of the problem was then introduced, starting with 10 tablets. But before the students started their work on the activity sheets, the teachers presented a challenge:

Sequence 1.

Gertsen: You can solve the next problem. Just try to solve it: if I start with 10 tablets, how many do I need? The children who have found the answer quickly, then think about this extra question: can I find the answer without making the calculation? I’ll give you a hint: compare the three numbers. When I start with 6 tablets..., when I start with 8..., when I start with 10... When you compare, you may come to a conclusion, a discovery. After all, you are researchers, aren’t you?

Streefland: I would like to add that it may be fun to try out other combinations. Try to experiment with combinations. Maybe you’ll discover something surprising. If you discover that, the problem is a piece of cake.

Episode 6. In this Episode, some students invented a new solution to the problem. Their invention was the result of a discussion in a group of four boys.

Episode 7. In the subsequent class discussion, these boys’ solution was presented by one of them in the following way:

Sequence 2.

Gertsen: Researcher Tom, show your solution on the blackboard.
Tom: If you start with 42, it is 6x7. If you look at 72, that is 9x8. Beginning with 10, that is 10x11. (He writes these numbers on the blackboard).(...)

Streefland: Be consistent: 6x7, 8x9, 10x11.

Gertsen: Put the smaller number first.

Streefland: It is very nice to do it this way.

Gertsen: I can know the next one, too, because, look, (pointing at the numbers on the blackboard) here is 6, 8, 10, and the next one should be: 12x13. (...)

Streefland: That is very good, but I think that he should show it by writing it out in full. Because it does not appear out of the blue, of course!

Gertsen (addressing Tom): Show it, prove it.

With some help Tom succeeded in showing on the blackboard that 6+5+4+3+2+1 = 3x7 (6+1, 5+2, etc.), and because the numbers should be doubled, the result is 6x7. Next, Gertsen demonstrated this way of calculating for other variants of the problem. The prescription starting with 8 tablets can be solved by making combinations of 9. With many students participating, the teachers demonstrated the outcome of the problem starting with 12 and with 14 tablets.

Analysis of the activity sheets demonstrates a clear and direct influence of the solutions discussed in the whole class on the individual work. The majority of students adjusted their solutions on their activity sheets and adopted the strategies developed just before in the whole class. The sheets show that, in three episodes of individual work, 26, 19 and 16 (of 28) students appropriated the strategies discussed in the whole class. The activity sheets also show that students did not stick to one strategy once they had invented it and found it to be correct. They acted in line with the teachers' encouragement to continue finding other, more efficient and clever, solutions.

Discussion.

At first sight the results would seem to fit into a two level approach (suggested by Inagaki et al., 1998): understandings are first constructed collectively, and then appropriated by individual students. This theory would seem to apply here, since the case study showed that the majority of students accommodated their solutions on the worksheets to the previous collective argumentation in the whole classroom. The difficulty with an account in terms of a two level approach is that it is not so easy to tell where the collective work ends and individual learning begins. Both collective argumentation and individual work took place within a discursive structure with rules
such as: find out for yourself, choose a practical solution, present it understandably. These rules structured the students’ work, both in the whole class discussions and during their work on the activity sheets. In their individual work, students applied the same kind of arguments which they had to use in the class discussions. Students’ achievements are best understood by referring to this discursive structure. Individual work is to be considered as an anticipation of a class discussion or a reconstruction of it. Given this discursive structure, there is no priority for individual or collective work; they are two sides of the same coin.

Students did not just internalize or incorporate the outcomes of the class discussion, they had to reconstruct them (cf. Elbers, Maier, Hoekstra & Hoogsteder, 1992). Even the use of the outcomes of class discussions for writing an answer on their sheets was not a reproduction, but demanded creativity. Students’ creation of novel solutions, as in Episodes 6 and 7, can illustrate this. The discursive structure of the interaction was the outcome of the teachers’ transformation of the mathematics class into a community of inquiry. At the beginning of the lesson Streefland told the students: “I am convinced that, if you have the courage to figure out something, you can do much better than you thought you could!” Addressing the class as a learning and researching community created roles and responsibilities for the teachers and the students which differed from a conventional classroom (Ben-Chaim et al, 1998; Elbers and Streefland, 2000b).

Because of the students’ contribution to the class, the teachers faced a problem originating from their double role. On the one hand, they were in charge and responsible for the students’ activities. They decided what topics would be worked on and they had their ideas of what knowledge students should acquire during the lessons. On the other hand, they wanted the students to find out for themselves: to invent solutions to problems and to prove their validity. They did not want to frustrate children’s creativity by using their authority for supporting certain answers instead of others. For solving the problem originating from this double role, the teachers used three strategies to channel the discussion. Firstly, the teachers selected students to give a presentation in front of the whole class. During the parts of the lesson in which students worked on their worksheets the teachers walked around and sometimes asked individual students to show and explain their work. During these episodes, the teachers observed what solutions the students were trying to work out and they singled out students with novel solutions rather than with familiar ones to present their work to the whole class. Secondly, the teachers stimulated variation in solutions. Students trying to discover a different solution from one already found were rewarded with compliments and enthusiasm by the teachers. Thirdly, the teachers made general suggestions to help students to view the problem from a different
perspective. An example of this can be seen in Episode 5 above. The children, who at this stage had only made combinations of ten, proposed calling this procedure: taking out tens, etc. Streefland taught them to use the term: making combinations. In this way he paved the way for students to find out that they could make combinations which add up to numbers other than ten. Using these strategies, the teachers could direct the discussion and at the same time leave the students ample freedom to find out and make inventions. After having worked out a correct solution, there was no reason for students to stop, since there was always an even more efficient solution to be found.

The case demonstrates how students in an atmosphere of collaboration and interaction contributed to their learning and how the teachers exploited the various productions and constructions made by the students to structure the learning process.

**Learning from history to solve equations.** Barbara van Amerom

Several research projects of recent years report on learning difficulties related to algebraic equation solving (Kieran 1989, 1992; Filloy & Rojano 1989; Sfard 1991, 1996; Herscovics and Linchevski,1994, 1996; Bednarz et al. 1996). These difficulties include constructing equations from arithmetical word problems, as well as interpreting, rewriting and simplifying algebraic expressions. According to some researchers part of the problem is caused by fundamental differences between arithmetic and algebra. A good starting point for an investigation into this issue could be a return to the roots. By looking into the past we shall try to gain insight into the differences and similarities between arithmetic and algebra and learn from the experiences of others. Streefland emphasized the value of ‘reciprocal shifting’: changing one’s point of view, looking back at the origins in order to anticipate (Streefland 1996). Such a change of perspective can propel the learning process of the researcher, the teacher and the student alike.

**Algebra and arithmetic**

A closer look at the similarities and differences between algebra and arithmetic can help us understand some of the problems that students have with the early learning of algebra. Arithmetic deals with straightforward calculations with known numbers, while algebra requires reasoning about unknown or variable quantities and recognizing the difference between specific and general situations. There are differences regarding the interpretation of letters, symbols, expressions and the concept of equality. For instance, in arithmetic letters are usually abbreviations or
units, whereas algebraic letters are stand-ins for variable or unknown numbers. According to Freudenthal (1962), the difficulty of algebraic language is often underestimated and certainly not self-explanatory: ‘Its syntax consists of a large number of rules based on principles which, partially, contradict those of everyday language and of the language of arithmetic, and which are even mutually contradictory’ (p. 35). He continues:

The most striking divergence of algebra from arithmetic in linguistic habits is a semantical one with far-reaching syntactic implications. In arithmetic $3 + 4$ means a problem. It has to be interpreted as a command: add 4 to 3. In algebra $3 + 4$ means a number, viz. 7. This is a switch which proves essential as letters occur in the formulae. $a + b$ cannot easily be interpreted as a problem” (Freudenthal 1962, p. 35).

Several researchers (Kieran 1989; Sfard 1991) have studied problems related to the recognition of mathematical structures in algebraic expressions. Kieran speaks of two conceptions of mathematical expressions: procedural (concerned with operations on numbers, working towards an outcome) and structural (concerned with operations on mathematical objects). But despite the contrasting natures of algebra and arithmetic, they also have definite interfaces. For example, algebra relies heavily on arithmetical operations and arithmetical expressions are sometimes treated algebraically. Arithmetical activities like solving open sentences and inverting chains of operations prepare the studying of linear relations. Furthermore, the historical development of algebra shows that word problems have always been a part of mathematics that brings together algebraic and arithmetical reasoning.

Cognitive obstacles of learning algebra

An enormous increase in research during the last decade has produced an abundance of new conjectures on the difficult transition from arithmetic to algebra. For instance, with regard to equation solving there is claimed to be a discrepancy known as cognitive gap (Herscovics & Linchevski 1994) or didactic cut (Filloy & Rojano 1989). They point out a break in the development of operating on the unknown in an equation. Operating on an unknown requires a new notion of equality. In the transfer from a word problem (arithmetic) to an equation (algebraic), the meaning of the equal sign changes from announcing a result to stating equivalence. And when the unknown appears on both sides of the equality sign instead of one side, the equation can no longer be solved arithmetically (by inverting the operations one by one). Sfard (1996) has compared discontinuities in student conceptions of algebra with the historical development of algebra. She writes that rhetoric (in words) and syncopated algebra (involving abbreviated notations) is linked to an operational (or
procedural) conception of algebra, whereas symbolic algebra corresponds with a
structural conception of algebra. Da Rocha Falcaô (1995) suggests that the disruption
between arithmetic and algebra is contained in the approach to problem-solving.
Arithmetical problems can be solved directly, possibly with intermediate answers if
necessary. Algebraic problems, on the other hand, need to be translated and written in
formal representations first, after which they can be solved. Mason (1996, p.23)
formulates the problem as follows: ‘Arithmetic proceeds directly from the known to
the unknown using known computations; algebra proceeds indirectly from the
unknown, via the known, to equations and inequalities which can then be solved
using established techniques.’

‘Reinvention of algebra’

Recent research on the advantages and possibilities of using and implementing
history of mathematics in the classroom has led to a growing interest in the role of
history of mathematics in the learning and teaching of mathematics. Inspired by
Streefland’s work as well as the HIMED (History in Mathematics Education)
movement, a developmental research project called ‘Reinvention of Algebra’ was
started at the Freudenthal Institute in 1995 to investigate which didactical means
enable students to make a smooth transition from arithmetic to early algebra.
Specifically, the ‘invention’ of algebra from a historical perspective will be compared
with possibilities of ‘re-invention’ by the students. The historical development of
algebra indicates certain courses of evolution that the individual learner can reinvent.
Word or story-problems offer ample opportunity for mathematizing activities.
Babylonian, Egyptian, Chinese and early Western algebra was primarily concerned
with the solving problems situated in every day life, although they also showed
interest in mathematical riddles and recreational problems. Fair exchange, money,
mathematical riddles and recreational puzzles have shown to be rich contexts for
developing handy solution methods and notation systems and are also appealing and
meaningful for students. Another possible access is based on notation use, for
instance comparing the historical progress in symbolization and schematization with
the contemporary one.

The learning strand: pre-algebra as a link between arithmetic and equation solving

The barter context in particular appears to be a natural, suitable setting to develop
(pre-)algebraic notations and tools such as a good understanding of the basic
operations and their inverses, an open mind to what letters and symbols mean in
different situations, and the ability to reason about (un)known quantities. The
following Chinese barter problem from the ‘Nine Chapters on the Mathematical Art’
has inspired Streefland (1995a, 1996a) and the author to use the context of barter as a natural and historically-founded starting point for the teaching of linear equations:

By selling 2 buffaloes and 5 wethers and buying 13 pigs, 1000 qian remains. One can buy 9 wethers by selling 3 buffaloes and 3 pigs. By selling 6 wethers and 8 pigs one can buy 5 buffaloes and is short of 600 qian. How much do a buffalo, a wether and a pig cost?

In modern notation we can write the following system:

\[2b + 5w = 13p + 1000\]  \hspace{1cm} (1)
\[3b + 3p = 9w\]  \hspace{1cm} (2)
\[6w + 8p + 600 = 5b\]  \hspace{1cm} (3)

where the unknowns b, w and p stand for the price of a buffalo, a whether and a pig respectively. The example is interesting especially when looking at the second equation, where no number of 'qian' is present. In this ‘barter' equation the unknowns b, w and p can also represent the animals themselves, instead of their money value. The introduction of an isolated number in the equations (1) and (3) therefore changes not only the medium of the equation (from number of animals to money) but also the meaning of the unknowns (from object-related to quality-of-object-related). Streefland (1995) has found in his teaching experiment on candy that the meaning of literal symbols is an important constituent of the vertical mathematizing process (progressive formalization) of the pupils. “The changes of meaning that letters undergo, need to be observed and made aware very carefully during the learning process. In this way the children’s level of mathematical thinking evolves.” (Streefland 1995, p 36, transl.).

We also intend to investigate how notation and mathematical abstraction are related. The categorization rhetoric – syncopated – symbolic is the result of our modern conception of how algebra developed, and for this reason it is often mistaken for a gradation of mathematical abstraction (Radford 1997). When the development of algebra is seen from a socio-cultural perspective, instead, syncopated algebra was not an intermediate stage of maturation but it was merely a technical matter. As Radford explains, the limitations of writing and lack of book printing quite naturally led to abbreviations and contractions of words. Perhaps our students will reveal
similar needs for efficiency when they develop their own notations (from context-bound notation to an independent, general mathematical language), but this may or may not coincide with the conceptual development of letter use.

Classroom examples

The first version of the experimental learning strand for primary level was tried out in 1997-1998 in two primary school classes grade 5-6 pupils (combined). The general topic of the primary school lesson series is recognizing and describing relations between quantities using different representations: tables, sums, rhetoric descriptions and (word) equations. No prior knowledge was required apart from the basic operations and ratio tables. The study is based on data collected through the observation and analysis of classroom work and the evaluation of a written assessment test taken by the students after the last lesson.

Shortened notations form one of the spear points in the learning strand. One of the units for grade 5-6 is centered on the context of a game of cards. In one of the lessons children suggested what could be the meaning of the expression ‘pA = 3 x pJ’. Our decision to use this kind of symbolism is based on other pupils’ free productions in a preliminary try-out. The letter combination maintains the link with the context: the letter p stands for ‘number of points belonging to’ and the capital letter stands for the person in question, in this case Ann and Jerry. In the expression, such a letter combination behaves like a variable for which numbers can be substituted. When the score of one of the players is given, the expression becomes an equation which can be solved. The teacher asked the children for an example that will illustrate that the relation between the variables pA and pJ is ‘3 times as much’:

Teacher: ‘If we think of points, what would be possible? You have to write it down in a handy way, just like in Pocket Money, which numbers are possible.’
Yvette: ‘3 and 9’.
Teacher: ‘Who has 3 and who has 9?’
Yvette: ‘Annelies has 9’.
Teacher: ‘How would you write it down? Why don’t you show us on the blackboard.’
Yvette writes: A - 9 p j - 3 p
Sanne: ‘I would write an equal sign, not a line.’

Figure 1: inconsistent symbolizing

Figure 1 illustrates three samples of inconvenient symbolizing: Yvette’s choice to write a capital letter A and then a small letter j, her use of the letter p as a unit even though it is already part of the variable, and Sanne’s suggestion at the end. Apparently it was not a problem to the children that letters mean different things at
the same time. As long as the pupils and the teacher are all conscious of this fact, the development and refinement of notations is a natural process. On the other hand, it is not our intention to cause unnecessary confusion regarding the meaning of letters. It was decided that if children have a natural tendency to use the letter p as a unit, p should not be included in the expressions and formulas.

The lesson materials were adjusted and tested again in 1999. The dual character of the learning strand – to develop reasoning and symbolizing skills in the study of relations – was maintained but placed in a more problem-oriented setting and with a more explicit historical component. We have selected two examples of student work from the final classroom experiment to demonstrate that (pre-)algebraic symbolizing tends to be more difficult for students than reasoning.

**Symbolizing versus reasoning**

The project’s final experiment was conducted in three primary schools (grade 6) and two secondary schools (grade 7). Encouraged by the ideas and results of the classroom experiment on candy by Streefland (1995), a grade 7 unit on equation solving was designed based on the mathematization of fancy fair attractions into equations. One of the tasks in the written test was:

*Sacha wants to make two bouquets using roses and phloxes. The florist replies: ‘Uhm ... 10 rozes and 5 phloxes for f15.75, and 5 roses and 10 phloxes for 14.25; that will be 30 guilders altogether please.’

*What is the price of one rose? And one phlox? Show your calculations.*

One of the outcomes of the experiment is that algebraic equation solving need not necessarily develop synchronously with algebraic symbolization. For instance, we have observed student work where a correct symbolic system of equations was followed by an incorrect or lower order strategy, or where the student proceeded with the solution process rhetorically. The student in figure 2 mathematizes the problem by constructing a system of equations, and then applies an informal, pre-algebraic exchange strategy which is developed in the unit. Below the equations she writes: ‘We get 5 roses more and 5 phloxes less, the difference is 1.50. We get 1 rose more and 1 phlox less, the difference is 0.30.’ The calculations show that she continues the pattern to get 15 roses for the price of 17.25 guilders, and then she determines the price of 1 rose and 1 phlox. The level of symbolizing may appear to be high at first.
due to the presence of symbolic equations, but the student does not operate on the equations. The equations may have helped her structurize the problem but they are not a part of the solution process. And even though the unknown numbers of flowers are an integral part of her reasoning, the letters representing them are not needed in the calculations. There is a parallel here with the historical development of symbolizing the solution. In the rhetoric and syncopated stages of algebra the unknown was mentioned only at the start and at the end of the problem; the calculations were done using only the coefficients.

Alternatively the solution in figure 3 illustrates how the level of reasoning can be higher than the level of symbolizing. This student solves the system of equations

\[
\begin{align*}
2x + 2k &= 66 \\
3x + 4k &= 114
\end{align*}
\]

by doubling the first equation and then subtracting the second from it. First he deals with the right hand sides of the equations (66 x 2 and 132 - 114). In between the two horizontal lines we observe how he multiplies the terms with the unknowns. Then he writes 'but the task says 3h so 18 is 1 h'. Finally he substitutes the value 18 to solve for k. A remarkable contrast presents itself. This student successfully applies a formal algebraic strategy of eliminating one unknown by operating on the equations, while his symbolizing is still at a very informal level. Again the unknown is only partially included in the solution process; it appears only where necessary. In other words, both examples of equation solving illustrate that competence of reasoning and symbolizing are separate issues.
Conclusion

Difficulties in the learning of algebra can be partially ascribed to ontological differences between arithmetic and algebra. The project ‘Reinvention of algebra’ uses informal, pre-algebraic methods of reasoning and symbolizing as a way to facilitate the transition from an arithmetical to an algebraic mode of problem solving. We have shown some examples where informal notations deviate from conventional algebra syntax, such as inconsequent symbolizing and the pseudo-absence of the unknown in solving systems of equations. These side effects bring new considerations for teaching: how can we bridge the gap between students’ intuitive, meaningful notations and the more formal level of conventional symbolism. The observation that symbolizing and reasoning competencies are not necessarily developed at the same pace – neither in ancient nor in modern times – also has pedagogical implications. It appears that equation solving does not depend on a structural perception of equations, nor does it rely on correct manipulations of the equation. In retrospect we can say that knowledge of the historical development of algebra has led to a sharper analysis of student work and the discovery of certain parallels between contemporary and historical methods of symbolizing. Streefland’s notice to look back at the origins in order to anticipate has turned out to be a valuable piece of his legacy.

Didactising: Continuing the work of Leen Streefland

Erna Yackel, Diana Underwood, Michelle Stephan, & Chris Rasmussen

When we think of the work of Leen Streefland we think of his seminal work in developing prototypical courses and instructional sequences (fractions, negative numbers and algebraic expressions and equations). In developing these courses and sequences Streefland was not only putting into practice the general principles of Realistic Mathematics Education (RME) that had been set forth by Freudenthal and Treffers but he was demonstrating how these principles might be realized in practice over an extended period of instructional time. In doing so, he went beyond earlier work that demonstrated one or more of the principles for individual problems, such as the van Gogh sunflower problem (Treffers, 1993). However, Streefland viewed his work as much more than the development of prototypical courses and sequences. In the abstract of his paper, The Design of a Mathematics Course, A Theoretical Reflection, Streefland (1993) pointed to what he saw as the major contribution of this work, namely operationalizing RME instructional design theory and thereby raising it

PME25 2001
to a higher level. As the title of the paper indicates, Streefland’s purpose was to reflect on the development process and identify strategies used in the design of the exemplary materials. To this end, he analyzed his fractions course and other examples of prototypical instructional sequences that were developed following the principles of RME. As Streefland noted,

In consequence an important theoretical change of perspective looms ahead. Where the theory was first an after-image, it can now act as a pre-image, i.e., as a model for realistic mathematics education in advance (p. 109).

The activity of developing such after-images that then can be used as pre-images in future work is what Streefland called didactising.

In one sense, the work of our research group might be thought of as applying the model that Streefland has articulated since we are developing prototypical courses in mathematics for various audiences, including university students. However, the intention of our work extends beyond applying Streefland’s model. We prefer to view our work as having the same character as Streefland’s in that as we engage in the process of the developmental research that is required to develop prototypical courses, we are continually analyzing aspects of our own activity for potential after-images that might be useful as pre-images in other situations. In this sense, we, too, are engaged in didactising.

Each of the researchers in this session will describe their didactising activities within the context of their respective research. First, Underwood will discuss designing instructional sequences so that students’ mathematical understanding grows out of their development of symbolic representations while at the same time contributes to the development of those representations. Next, Stephan argues that argumentation analyses are useful not only for analyzing students’ learning as they engage in prototypical courses, but also as a tool for the designer in her attempts to anticipate the quality of the social interaction and discourse associated with the instructional sequences under development. Stephan’s work is a form of didactising in the sense that she is using argumentation theory as a tool for describing how the conditions for learning the desired mathematics can be created and sustained in social interaction (Streefland, 1993). Rasmussen uses different modes of "listening" as a conceptual tool for describing aspects of the activity of analysing the vast amounts of data collected from developmental research for the purposes of informing and revising the development of instructional sequences. As an after-image, these different modes of listening have the potential to be useful pre-images for others engaged in RME-based instructional design.
Thus, each of the three researchers demonstrates a form of didactising. In doing so, each goes beyond treating the development of prototypical courses for various mathematical content areas and various audiences as a simple matter of applying Streefland’s model. In each case, the researcher gives explicit attention to reflecting on critical aspects and strategies of the design process which includes: developing means of recording and notating that can describe informal activity and that have the potential to lead to formal and/or conventional mathematical notation, anticipating the classroom discourse that can emerge as students solve problems, and selecting or designing "realistic" contexts that have the potential to lead to formal mathematizing.

**Emergent Models in a Context of Linear Equations**

The purpose of this section is to illustrate how mathematics instruction might be designed to facilitate the emergence of conventional symbolism for linear equations from students’ ways of representing and notating their reasoning in situations of linear change. This approach is in contrast to much of the recent reform curricula concerning linear functions that focus on facilitating students' ability to move flexibly within and across tabular, symbolic, and graphical representations. While it is important that students are able to interpret linear functions in a variety of ways, a problem with this approach is that the student still needs to integrate them. For example, even when students are able to describe slope graphically as "rise over run" and are provided opportunities to “discover” that the number representing the slope is the coefficient of x in the equation for a line, they usually cannot explain a basis for this relationship.

One explanation for this difficulty is that students are asked to create and use the graphs of functions on a Cartesian plane as a *model for reasoning about quantities* without first facilitating development of the plane as a *model of anything*. The Cartesian plane is a symbol system used in creating a visual (dynamic) representation of the relationship among quantities. According to the principles of RME, this symbolism should emerge from students' mathematical activity (Gravemeijer, 1994) rather than be given to them prepackaged.

The Stacking Cubes instructional sequence attempts to promote students' understanding of a coordinate system while simultaneously facilitating their understanding of linear relationships. Our inspiration for creating this sequence grew out of noting students’ solutions to a data recording and graphing activity. In this activity from the Connected Mathematics series (Lappan, Fey, Fitzgerald, Friel, & Phillips, 1998), students were asked to flip a coin for 90 seconds, record the cumulative number of flips at 10-second intervals, and make a graph of the data. Many students generated bar graphs to represent their data. In an earlier instructional
sequence adapted from the Mathematics in Context series (Wijers, Roodhardt, van Reeuwijk, Burri, Cole, & Pligge, 1997), students had successfully developed formulas for growing spatial patterns. By combining the idea of writing formulas for growing patterns with the idea of bar graphs, our goal was to design an instructional sequence that would help students develop a conceptually-based understanding of linear relationships, thereby enabling the symbolic representation of a linear function to grow naturally out of graphical representations.

The instructional design was based on the tenets of RME emphasizing that through engaging in realistic tasks, students create models of/for their mathematical activity (Gravemeijer, 1994). In the initial activity students were presented with a sequence of “towers,” asked to draw the next few towers in the sequence, and figure out the number of cubes that would be in the 100th tower in the sequence (see Figure A). The spatial arrangement of the towers resembled the bar graphs that students had drawn in their prior data recording and graphing activity. As the instructional sequence progressed, students were asked similar questions, but were given less information to answer them. At the same time, the notation used to represent the stacking cubes evolved to look more like ordered pairs. For example, towers were first replaced by "sticks" and the sticks were ultimately replaced by points on the Cartesian grid:

The students' descriptions of the spatial patterns also evolved. Initially they gave detailed verbal descriptions such as, *I figured out that the change between the towers was 2 and then I counted back to the zero building, which is one. So I know that the 100th building is 2 times 100 plus 1, or 201 cubes high.* Later, this type of description was generalized to *height of the nth building = zero building + pattern number * change.* Eventually students developed the symbolic notation $H = a + bP$ to represent the relationship that was illustrated in the graph.
While the bar graphs/towers initially served as models of students’ thinking in the graphing activity, the sticks/points became models for their reasoning about the relationship between height and pattern number. This symbolic progression can be thought of as a \textit{chain of signification} (Cobb et. al, 1997; Gravemeijer, 1999):

\[
\text{pictures of cubes} \rightarrow \text{pictures of sticks} \rightarrow \text{graphs of points}
\]

In a similar way, the verbal/symbolic descriptions of the patterns that the students developed were models of their reasoning about the graphical representations of the patterns. Here again, the progression from an extended verbal description to a verbal formula to a symbolic formula can also be viewed as a second chain of signification.

The two chains of signification are intertwined in the sense that the symbolic representation of the relationship grew out of the students’ thinking about the different graphical representations (towers of cubes, sticks, points) while at the same time the graphical representations enabled students to develop meaning for the different components of the equation \(H = a + bP\). In contrast to the multi-representational approach, the two chains of signification are not two separate ways to represent a linear relationship. Instead, the instructional goal is that students' concept of a linear relationship will grow out of their development of symbolic representations while at the same time contributing to the development of those representations. That is, they evolved together as a dynamic, interactive system.

Under the guidance of the RME emergent models heuristic, we designed the Stacking Cubes sequence to support students’ moving beyond using symbolic descriptions as models of patterns in towers to using them as models for reasoning about linear relationships. We believe that the approach that we take can be viewed more broadly as a \textit{pre}-image for designing instruction that provides students with opportunities to create and reason with conventional symbols.

**Argumentation as a Tool for Didactising**

The purpose of this section is to show how analyzing students' argumentations impacts the design of instructional activities within a broader instructional sequence. Generally, argumentation has been used to analyze students' learning (e.g., Krummheuer, 1995; Yackel, 1997). In addition to this function, we will argue that argumentation analyses can serve to provide feedback to the RME designer by informing her of the nature of the justifications that students provide as they engage in the designed activities. The justifications may not be those that are anticipated by the designer and thus, she can revise the sequence by constructing tasks that better
provide students the opportunity to construct mathematical justifications that are more in keeping with the overall mathematical goals for the instructional sequence. To begin this conversation, we first describe Toulmin's (1969) scheme for analyzing argumentation.

For Toulmin, an argument consists of at least four parts: the data, claim, warrant and backing. In any argument, the speaker makes a claim and, usually presents evidence or data to support that claim. Even so, a listener may not understand what the data presented has to do with the conclusion that was drawn and, therefore, challenges the presenter to clarify the role of the data in making a claim, a warrant. Perhaps the listener understands why the data supports the conclusion but does not agree with the mathematical content of the warrant used. The authority of the warrant can be challenged and the presenter must provide a backing to justify why the warrant, and therefore the entire argument, is valid mathematically.

In general we have found that students' warrants consist of further elaboration of their methods for solving a problem and that backings involve justifying why their method or interpretation should be mathematically acceptable in the classroom. In this section we would like to explore the usefulness of Toulmin's model of argumentation from a design perspective. In other words, what kinds of reasoning might the designer/teacher find useful to capitalize on in whole class discussions and what warrants and backings for a particular type of task are productive for learning? Do the instructional tasks she has designed provide the opportunity for such justifications to arise? Anticipating the nature of the warrants and backings that we think could be useful for supporting the classroom argumentation can aid in the development of mathematically productive instructional tasks. We will illustrate this with an example from the Stacking Cubes sequence. On the first day that students engaged in the Stacking Cubes sequence, the diagram shown in Figure D was drawn.

![Figure D](image)

The teacher explained that the picture showed a series of buildings constructed by a company and asked, "How many more little blocks do I need to make the 13th building?" While some students attempted to count how many increases of two there

1 - 244

PME25 2001
would be to get to the 13th building, one student explained that she found a formula for finding the number of floors in any building.

Abby: I tried to figure out how many blocks would zero have. And it would be 1. Each building as you go down is decreasing by 2, so I just subtract the 2 [to get the 1]...2P + 1.

Teacher: How did you get the 2P + 1 part of it though? That's the part I don't understand.

Abby: They are each increasing by 2. So I just figured we're going to multiply by 2. And I know there is just 1, because the zero. That one has 1. So, 1 is already there. So you would be adding 1.

Teacher: She's going to be adding 1. Do you know what she means when she says that she is going to be adding 1? Do you know? Do you want to say something about that, Terry?

Terry: She is adding the 1 because it is...[inaudible]...you still have to add the 1 that was like the odd man out...1 times 2 is 2, but you have to add that 1 man in building 2 because of the one block in the zero building. 2 times 2 is four, plus 1 which is 5 in building 2.

Analyzing the structure of the argumentation above, we see that Abby provided a claim that consisted of her formula, 2P + 1. She provided data for her claim when she explained, "I tried to figure out how many blocks would zero have." Once Abby explained her claim, the teacher challenged Abby to explain how finding the plus one led her to the formula 2P + 1. In other words, she was asking for Abby to make the warrant, how the data "+1 leads to the formula 2P + 1," more explicit. Abby responded by explaining the origin and necessity of each term in the formula. In Toulmin's terms, Terry provided a backing regarding why multiplying by 2 and adding the "odd man out" each time led to the desired results in each pattern ("2 times 2 is four, plus 1 which is 5 in building 2").

This type of argumentation for generating a formula was typical early in the instructional activity. The backing provided justification for the origin of the formula, but it was grounded in the specific example of the first and second buildings. As students' understanding becomes more general, we would expect that the backings to become more general in nature, i.e., the buildings are increasing by 2 floors per pattern number (a rate) from the original pattern (the "zero building"). However, this type of backing never arose in the course of instruction. As a consequence, we created two new tasks designed to provide students the opportunity to construct justifications for the formula that were based more explicitly on rates of change.
Task 1: Show students a picture of a building pattern that increases by 2 floors per day and starts at 4 floors. Only show the first three days. On which day will you have 14 more floors than the original? The teacher can draw a horizontal line on top of the 0 building and also notate each jump of two as pictured:

<table>
<thead>
<tr>
<th>Day</th>
<th>Floors</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>4</td>
</tr>
<tr>
<td>1</td>
<td>6</td>
</tr>
<tr>
<td>2</td>
<td>8</td>
</tr>
</tbody>
</table>

Task 2: Some construction workers get paid by the day but the foreman lost the record of how many days the company has worked since they started building onto the original. He knows that the current building is 32 floors tall at the end of the day and that they've been putting 3 floors on per day from the original building that was two floors tall. How many days has the crew been working?

In new Task 1, students may either draw subsequent buildings, counting the extra floors each time until they have 14 more floors than the original, or they might double count, keeping track of the number of twos and the number of days increased until they have counted 14. Double counting in this manner might allow students to draw attention to the 2 floors per day justification. The dashed line might support students constructing the backing described above: a rate of change of 2 floors per day added onto the original 4 floors. The dashed line might also support students seeing the original building as nested in each subsequent building.

In Task 2, some students might actually draw every building between the original and the last day while others may simply double count again to find how many counts of size three can be found between the last day and the original. The teacher might even symbolize those double counts by circling 10 groups of three blocks on the last day only (see figure accompanying Task 1). She might also ask students to explain what each number means as they double count. In this case, the intent again is to bring attention to the constant rate of change as it goes on from the original number of floors.
The point of this short excerpt is to bring attention to the role of argumentation in the designer's activities. By examining students' argumentations as they engage in tasks, we can discover the nature of the students' current justifications and the range of potentially productive justifications. This type of examination can lead to revisions in the instructional activities within a sequence.

Listening as a Conceptual Tool

The purpose of this section is to describe how the construct of "listening" to data can be used as a conceptual tool for the purposes of instructional design. As Streefland's work demonstrated, paying close attention to students' reasoning has always been a fundamental characteristic of RME based instructional design work. Using our developmental research efforts in differential equations as an example, we use different modes of "listening" as a lens to reflect on our retrospective analysis of the data collected during a semester-long classroom teaching experiment. In particular, a mode of listening that we call generative listening helps shape and clarify our thinking about realistic starting points for instruction that are mathematical in nature.

Within the theory of RME, realistic starting points for instruction refer to situational contexts that can serve as a building block for students' mathematical development. For example, Streefland (1990) discussed how distribution situations, like sharing 3 candy bars among 4 friends, can serve as a realistic starting point for students' learning the concept of fraction. Although this example of a realistic starting point is characterized by a real-world situation, the term "realistic" is intended to be broad enough to include mathematical situations that are experientially real for students. Relatively few examples, however, of realistic starting points that are themselves mathematical currently exist.

As researchers begin to explore ways in which the theory of RME can inform instructional design at the university level, it will be useful to have images of strategies that others find useful in locating realistic starting points that are mathematical. To begin to address this need, we use the notion of generative listening as a means to bring to light aspects of our developmental research activity that has yielded mathematical starting points that are experientially real for students.

Generative listening is intended to reflect the negotiated and participatory nature of interacting with data. This type of listening, which Davis (1997) called hermeneutic, is "an imaginative participation in the formation and transformation of experience" (p. 369). The notion of generative listening can be clarified by comparing it with what Davis calls interpretive listening and evaluative listening. In comparison with generative listening, where the purpose is to learn something new
about one’s own thinking, interpretive listening is to decipher the sense that students appear to be making of the mathematics under discussion. Davis posits that within interpretive listening, mathematics is still about constructing conventional associations between signifiers. Finally, evaluative listening is characterized by the fact that the listener is listening for something in particular. The motivation for evaluative listening is to evaluate the correctness of the contribution by judging it against a preconceived standard (Davis, 1997).

During the spring of 2000, we conducted a 15-week classroom teaching experiment in differential equations. At the commencement of the teaching experiment, we conjectured that population situations would serve as an experientially-real starting point for the development of students’ concept of the solution space for differential equations, where solutions to these differential equations are functions of time. Note that the nature of this starting point has the same real-world character as Streefland’s distribution situations for fractions. After engaging in extensive retrospective listening to the data collected during this teaching experiment, what students had to say transformed our thinking about what we could take as an experientially-real starting point.

To illustrate the notion of listening generatively to data, we use an excerpt from an end-of-the-semester interview with Marta, one of the students in the class. In the excerpt that follows, we asked Marta if she now thinks about the concept of function differently than she did before taking the differential equations course. We asked her this question because we take the viewpoint that solutions to differential equations are functions and thus the study of differential equations may provide opportunities for students’ to deepen their notions of function. At the time of the interview, we were curious about students’ evolving notions of function through their study of differential equations. That is, our listening was more interpretive and evaluative. Only later, upon retrospective analysis, did we listen generatively to this piece of data.

Marta: I can think of it more as, when you say this function, I can think of it more as instead of three x squared, I can think of it more as a motion, more as some kind of change. More as something that’s actually going on opposed to, yeah, these are some numbers and this is what it looks like on a piece of paper...when I say 3 x squared, what I’m really talking about is, I’m talking about this marble moving from here to here and how it got there, you know?

Although we think it is useful for developmental researchers to listen evaluatively and interpretively to data, we restrict the discussion to generative listening because when we listened generatively to this piece of data, we began to think differently.
about the possibilities for starting points in differential equations. In particular, our own thinking was transformed by engaging imaginatively in Marta’s description of motion and of a “marble moving from here to here.” We began to think about how the movement from “here to here” stems from conceptualizing rate of change and how solution functions can, for students, grow out of their mental and bodily experiences with rate of change. That is, the mathematical construct of rate of change, when coupled with population situations, can serve as an experientially-real starting point.

To take rate of change as an integral component of an experientially-real starting point is not to say that all students have a full conception of rate of change that is in line with expert notions. It is to say, however, that students’ at this level have some way to conceptualize rate of change as a mathematical construct so that they can proceed with a problem situation. For example, students might conceptualize rate of change as an intensive quantity by which a different quantity changes over time or they might view rate of change as a ratio of two co-varying quantities that gives rise to motion or movement and involves directionality. Although beyond the scope of this paper, we should note that the transformation in our thinking about taking rate of change as an experientially-real starting point has also led to revisions in the sequence of instructional activities.

The intention of this short example was to describe how we can use listening as a conceptual tool for reflecting on our developmental research efforts at the university level. Although we used the construct of listening to crystallize our efforts at locating experientially-real starting points that are mathematical in nature, the different modes of listening, generative, interpretive, and evaluative, may serve as a broader image for others engaged in developmental research.

Conclusion

As these three examples show, didactising can take a variety of forms depending on the mathematical content, on the student audience for the prototypical courses or instructional sequences, and on the interests of the researcher. At the same time, the researchers’ interests evolve as the developmental research progresses. In this way there is an evolution of the nature of the after-images that researchers develop that then become pre-images for future work. Thus, in a sense Leen Streefland’s work has set in motion a cyclic process that has the potential to move the field of mathematics education forward in substantive ways.
Reaction Koen Gravemeijer

The work on RME at the Freudenthal Institute constitutes the heart of what people at the institute call, "educational development". The term educational development has been introduced to indicate an all-embracing process of educational innovation, encompassing both the actual enactment of the innovation in the classroom and an open dialogue between researchers and practitioners. Developmental research is conceived of as a catalyst of innovation. The results of developmental research are meant to function as a source of inspiration for practitioners. What we aim for is re-enactment of instructional sequences in various situations, adapted to those situations, and shaped according to the insights and preferences of the practitioners involved. This then is seen as an extension of the original developmental research, which produces feedback that will contribute to an enrichment of the original findings. Leen Streefland would be pleased to see how efforts to explicate the RME design theory with help of exemplary materials have led to a similar process in the mathematics education research community. To see that other researchers are inspired, experiment with, and expand RME theory. In this respect, the Purdue-Calumet research group has much to offer. Moreover, they address issues that were near to Leen Streefland’s heart: - the perspective of a reflexive relation between the development of symbols/models and meaning, which fits so well with the quotation of Leen Streefland on page 1; - the focus on the role of argumentation within whole-class discussion, which is in line with Leen Streefland’s research activities on the basis of the idea of a community of researchers; - the proposal to integrate generative listening as a conceptual tool in developmental research, which he would have welcomed as a valuable contribution to his effort to bring the RME design theory to a higher level. In conclusion, we may truly say: Leen Streefland's work continues.

Epilogue Marja van den Heuvel-Panhuizen

As Freudenthal stressed once, it was Leen Streefland who opened our eyes to the anticipatory learning of concepts that will develop in full at a later time. From the very beginning of his work in the field of mathematics education Leen was focused on where and how education can anticipate the learning process that is coming into view in the distance. This anticipatory perspective was not only true for Leen’s ideas about how to teach mathematics to students, but is as true for Leen’s role within our
research group at Utrecht University and the international community of researchers of mathematics education. The concepts, the language, the way of thinking with which Leen provided us, turned out to be strong and continuing guides for deepening our understanding of the learning and teaching of mathematics. The contributions to this PME Research Forum prove this.

Imagery and Affect in Mathematical Learning

Coordinators:
Lyn English, Queensland University of Technology (Australia)
Gerald A. Goldin, Rutgers University (USA).

Representation in learning mathematics includes not only external structured physical configurations, but also internal systems that encode, interpret, and operate on mathematical image and symbol configurations (Goldin & Janvier, 1998). Continuing the discussion begun at PME-24 in Hiroshima, we focus on imagery, affect, and their interplay with natural language, formal notations, heuristics, beliefs, and especially with each other. Traditional views of mathematics as an abstract, formal discipline have tended to relegate visualization, metaphor and metonymy, emotions, and the relation between feeling and mathematical imagination to incidental status. Yet we have a case for the centrality of imagistic reasoning, analogies, metaphors, and images in mathematical learning (English, 1997; Presmeg, 1998). Lakoff and Nunez (2000) even aim to recast the foundations of mathematics in terms of metaphorical image schemas. The essential role of affect, encoding information and influencing learning and performance, has also been stressed (McLeod, 1992, Goldin, 2000). It may even be the most fundamental system in powerful mathematical learning and problem solving (DeBellis & Goldin, 1997; Gomez-Chacon, 2000).

Our general purpose is to explore the nature and role of affective and imagistic representational systems in mathematical learning and problem solving. The first session will begin with brief presentations by the coordinators, focusing on: analogies, metaphors, images, affect, meta-affect, and beliefs in mathematical reasoning and problem solving, including highlights of last year’s discussion. Participants are encouraged to cite examples of imagery, affect, and their interplay in children and adults doing mathematics, for group discussion and interpretation. We shall discuss some of the difficult issues in the empirical investigation of these topics through classroom observation and structured clinical interviews; identify key research issues, and shape plans for future development of these ideas.

DISCUSSION GROUP:
STOCHASTICAL THINKING, LEARNING AND TEACHING

Coordinators:  Kath Truran, University of South Australia
               Brian Greer, University of San Diego, USA
               John Truran, Private Practice, Adelaide, Australia

The group’s discussions will be on the relationship between stochastical and mathematical thinking, learning, and teaching. We consider that there is more on this theme which can usefully be discussed. It is our intention to approach this theme from multiple perspectives, including:

- Philosophical, in terms of the perceived boundaries of the disciplines.
- Historical, in terms of the developments of the disciplines.
- Educational, in terms of the positioning and implementation of the teaching and learning of stochastics within school and tertiary curricula, including such fundamental issues as teacher development, assessment, and technology.
- Psychological, in terms of the specific cognitive and sociocultural processes involved in the teaching and learning of stochastics.
- Research, in terms of cross-fertilisation of theoretical frameworks and methodologies.

The following members will present a short contribution which will be followed by discussion, questions and feedback from the other participants.

- Angustias Vallecillos Jiménez (Spain) who will speak about her work in statistical inference learning.
- Rene Ritson (Northern Ireland) who will speak about her current research study into possible relationships between young children’s understanding of probability and their understanding of fractions.
- John Truran (Australia) whose subject is “The Place of Probability in Stochastical Thinking Learning and Teaching”
DISCUSSION GROUP
SEMIOTICS IN MATHEMATICS EDUCATION

Coordinators: Adalira Sáenz-Ludlow, University of North Carolina, USA.
   sae@email.uncc.edu
Norma C. Presmeg, Illinois State University, USA,
npresmeg@email.msn.com

Mathematics Education is a unique field in which philosophy, psychology, anthropology, sociology, and numerous other fields find a place alongside education and mathematics. Each of these fields provides a different perspective on teaching and learning of the subject matter. A recent addition to this interdisciplinary list is semiotics, which is the science of signs, signification, and sense-making. Mathematics and the teaching and learning of mathematics make use of different sign systems to encode and decode concepts. It is through a constant interpretation of conventional and non-conventional signs that one comes to construct personal mathematical meanings. Researchers in mathematics education, all over the world, are trying to incorporate semiotic perspectives to shed light on classroom teaching-learning processes and learners’ interpretations of mathematical concepts.

The purpose of the group is threefold: (a) to foster interaction among researchers using or wanting to use semiotics in the analysis of classroom data; (b) to share and discuss different semiotic perspectives; and (c) to share papers and analysis of data. The following contributions will be presented in the meetings to stimulate discussion and interaction.

First session
I) Mathematical epistemology from a semiotic point of view, Michael Otte, Germany. (20 minutes)
II) Euclid’s signs: A cultural-semiotic analysis of the theory of even and odd numbers, Luis Radford, Canada. (20 minutes)
III) Cognitive analysis of comprehension problems in the learning of mathematics, Raymond Duval, France. (20 minutes)
IV) General audience participation and discussion. (30 minutes)

Second session
I) Summary of the first session. (20 minutes)
II) Progressive mathematizing using semiotic chaining, Norma Presmeg, USA. (20 minutes)
III) Classroom discourse as an evolving interpreting game, Adalira Sáenz-Ludlow, USA. (20 minutes)
IV) General audience participation and discussion. (30 minutes)

Presentations will be both theoretical and empirical in nature, and will include examples to elucidate semiotic perspectives. Participants are also invited to bring classroom episodes and share their work with the group. Each session will end with a discussion about the advantages of semiotics as a theoretical framework, its potential for analysis of data, outlets for dissemination, and partnerships for research.
Culture and Mathematical Cognition

Coordinators: Yeping Li, University of New Hampshire, USA
Tad Watanabe, Towson University, USA

Although there is no universal agreement as to whether mathematics is a culturally bound subject, few would disagree that the teaching and learning of mathematics is a cultural activity. The view of mathematics teaching and learning as a socio-cultural activity is reflected in and supported by various studies (e.g., Boaler, 2000; Stigler & Hiebert, 1999). Although researchers with different research perspectives tend to agree that both socio-cultural factors and individual cognition are two inseparable parts in the development of students' mathematical cognition, the nature of culture and mathematics cognition and the relationships between them are far more complicated than we may think of. As one further step towards a better understanding of culture and mathematical cognition, this discussion group is proposed to use cross-system studies as examples to examine relevant issues.

The discussion group will be organized as a two-section activity. During the first section, two researchers will present brief (10 minutes each) overviews and/or examples of relevant research on two issues: (1) the ways of assessing students' mathematics thinking, and (2) the nature and quality of mathematics curriculum and teaching in different settings. After the presentations, the participants will be organized to join small group discussions that will constitute the second section. Based on cross-system studies that have been discussed in the first section, the discussion in small groups will center on the following four questions:
1. Can mathematical cognition be examined cross-culturally?
2. Are cultural variations in context, tools, and practices (e.g., curriculum, teaching practices) related to the development of students' mathematical cognition?
3. Can a cultural practice be adapted in a different setting?
4. What similarities and differences may exist between cross-system studies and multi-cultural studies within an education system in understanding the issues relevant to culture and mathematical cognition?

After small group discussions, all participants will come together to generate a collective summary and synthesis of the small group discussions. A list of potential research questions will be generated/selected and interested participants will be organized to develop further research activities on this topic after the meeting.

References
Mathematics education which seeks to promote inclusion has a number of different but interrelated facets. Firstly, there is the development of a critical content in the curriculum: this seeks to use mathematics as a means to help learners understand the world they live in. Secondly, drawing on some aspects of ethno-mathematics and situated cognition, the informal mathematics practices of various groups in society can be examined. This reminds us that the reality that the accepted curriculum content reflects is that of the dominant cultures and groups in society and is not the only model of mathematics available. More importantly, the gap between these informal mathematics practices and school mathematics helps to reveal the mechanisms by which the mathematics curriculum acts to disadvantage certain groups. Thirdly, building on concepts of communities of practice, we see the development of critical pedagogies that seek to democratise the mathematics classroom.

Against this background, we wish question what it means to conduct research into inclusion in mathematics education. Our inquiry will include the following.

The choice of what to research. Choices about what to research are inevitably ethical and political.

Our decisions about what to research ... are, at root, value-based decisions which we expect to have to defend. (Wiliam 2000, p124f)

The purpose of research. Whether or not research is critical or promotes inclusion is bound up with its potential to be used in transformative ways. This might be the purpose for which it is intended: could it also be the purpose to which it is put?

The methodology of the research. Are there essentially critical research methodologies or can research based on traditional methodologies promote inclusion? Are there types of research questions which can only be addressed through critical research methodologies and that cannot be answered by traditional methodologies?

The practice of the research. What can the relationship between/amongst research participants be like? How do different research relationships allow us to uncover different truths?

The discussion group will take as an initial focus a paper dealing with some of these issues.

SEARCHING LINKS BETWEEN CONCEPTUAL AND PROCEDURAL MATHEMATICAL KNOWLEDGE

Co-ordinators

Prof. Lenni Haapasalo, University of Joensuu (FIN)
leppa.haapasalo@joensuu.fi http://www.joensuu.fi/lenni

Prof. Bernd Zimmermann, University of Jena (GER)
bezi@mathematik.uni-jena.de http://www.minet.uni-jena.de/~schmitzmimidida/mitarbeiter/chef/bzhome.html

The aim
is to discuss and share perspectives on the relation between conceptual knowledge and procedural knowledge. Research in this important domain seems to be neglected or at least eclectic, e.g. restricting mainly on terminological level. To what extent it can be revitalised and enhanced to develop a relevant overarching research paradigm - or even help to produce theories for concrete teaching?

Sessions
The first of the two 90-minute sessions is aimed to give an overview of researcher's views. The distinction between procedural knowledge and conceptual knowledge seems to be possible at a theoretical, epistemological and terminological level. However, many kinds of problems begin when this distinction is to be operationalized by acceptable tasks, and the relation between the two knowledge types is to be clarified.

The second session tries to share perspectives for resolving some of these problems by use of different mathematical content, age cohort to be taught, from historical perspective or other concrete contributions. The focus of the discussions is to search for links between the two knowledge types, and to check, whether research in this domain might have some relevant implications for teaching.

Preparation
for the discussion will be made via Internet. Potential participants are invited to send possible contribution for discussions via e-mail to the co-ordinators. This discussion within the next 2-3 months should offer a thorough warm-up for the group activities during the conference, as collecting theoretical studies on the topic. An example is the recent Haapasalo/Kadijevich paper in JMD 21 (2), 139-157.

Outcomes
Evaluation of the relevance of the topic will be made for the PME activities to come. Furthermore, a summary of the discussions will be made.
The words "mathematical modeling" cover a broad range of theoretical and practical orientations to the teaching and learning of mathematics. Equally broad are the approaches researchers have taken to understand the role of technology in the teaching and learning of mathematics. In this session, we propose to bring these two major strands of work together by examining some of the issues and some of the approaches that have emerged over recent years. The main purpose of this group will be to discuss the nature of the learning activity when students engage in modeling with various technological tools. The discussion group will begin by discussing some epistemological and psychological perspectives on modeling. Then we will shift the discussion to examine the issues that are raised by some examples of research on modeling and technology.

**Epistemological and Psychological Perspectives:** There are two epistemological underpinnings to mathematical modeling: first, the model is separate from the world to be modeled and, second, modeling is a cyclic, iterative process. The essence of this epistemological stance is that the world of phenomena and the model world co-construct each other. A psychological perspective on modeling and technology more directly addresses issues related to the role of the learner and learning. A distinction we have found useful is that between the learner’s activity in using existing model created by an expert and in building a model that reflects the learner’s own emerging understandings of the phenomena. In the first case, the learner’s task is to explore the consequences of actions taken within the boundaries of a content domain model. In the second case, the learner’s task is to express their own concepts by making explicit the relationships among objects and variables and then to examine, interpret and validate the consequences of their idea.

**Exploratory modeling through microworlds:** Environments such as Cabri Geometry, probability microworlds and spreadsheets have all been used to provide environments for students to explore models that have been designed by experts. After presenting a brief example of some work by students in a probabilistic microworld, we will engage in discussion on questions such as: How do such tools mediate between reality and mathematics? How is it that learners come to understand the explored world?

**Expressive modeling through function toolkits:** Tools such as graphing calculators, spreadsheets, and qualitative function graphers have all been used to provide students with the opportunity to express their understandings of some experienced phenomena. Again, we will present a brief example from the Visual Mathematics project showing some work done by students as they strive to make sense of experience. We will discuss such questions as: How do the available tools support or constrain the expression of students’ ideas? What is the nature of effective modeling tasks with particular tools? What is the role of the teacher in such expressive environments?
The crucial idea in the conceptual change is the radical reconstruction of prior knowledge which is not very well observed in traditional teaching. The theories of conceptual change (see Vosniadou 1999; Duit 1999; Reiner, Slotta, Chi & Resnick, 2000) define two levels of difficulty in the learning process. The easier level of conceptual change means enrichment of one’s prior knowledge structure. In this case the prior knowledge is sufficient for accepting the new specific information. The student needs only to add the new information to the existing knowledge. The more difficult conceptual change is needed when the prior knowledge is incompatible with the new information but needs a reconstruction. There seems to be at least two basic kinds of directions for problems in conceptual change. The one is the knowledge and operations which are relevant on a certain domain, but need to be revised on the other. This is the case with the mistaken transfer from natural numbers to the rational numbers. For example the students seem to face considerable difficulties in trying or struggling to sort fractions (Hartnett & Gelman 1998) because of their spontaneous use of the logic of natural numbers. The other kind of problems are the beliefs and conceptions caused by experiences with mathematics (see Verschaffel, DeCorte & Lasure 1999). The need to make drastic changes to the prior thinking may not even occur to the students unless the needed change is made very explicit in the teaching.

The purpose of the discussion group is to explore the nature of conceptual change in mathematics concept formation, to discuss about the role of prior thinking and to find the principles that govern the facilitation of the conceptual change.

Discussion Group on

Work-related Mathematics Education

(Coordinators: R. Straesser, Univ. of Bielefeld & J. Williams, Univ. of Manchester)

The Discussion Group will continue the discussion begun at PME 23 in 1999 (see the PME News of November 1999, pp.5-7) by briefly recalling this activity and then looking into aspects of “Work-related Mathematics Education” not treated at PME 23. An additional reference will be the papers of a one day conference in Manchester in February 2001 on “Maths into Work” (for information on this conference’s papers see http://www.man.ac.uk/CME/conferences/index.htm).

At PME 25, we start from a dictionary definition of work as "exertion directed to produce or accomplish something, productive or operative activity, employment, a job, esp. that by which one earns a living", and look into the role of mathematics in this type of human activity and the teaching/learning of work related Mathematics - not forgetting activities like “community services“. As a salient feature of maths related to work we take the fact that the goal of the activity is not to produce or learn mathematics, but to use it for different purposes outside maths.

Keeping in mind that we discussed “current use of maths at the workplace” and “current ways to teach work-related maths” at PME 23, work at PME 25 will focus on three additional issues:

- the role of old and new technologies ("artefacts")
- theoretical perspectives on discourse and activity in work, college and research
- research methodologies.

The importance of artefacts is based on the use of technology (old as in Geometry, charts as in administration, technical languages ... and/or new as computers, software and programming languages) in workplace activities and teaching/learning for it. Discussions in the group should aim at better understanding the contradictory trends of hiding or revealing workplace maths by means of artefacts and discourses, and identify problems and potentials for teaching and learning work related mathematics.

Current research into the use of mathematics at work (with the spectrum from traditional statistics to ethnomet hodology) seems to favour case studies in a participatory style, while different ways of “stimulated recall” are also in use. After discussing research perspectives and methodologies, the Discussion Group should decide on the feasibility and necessity of continuing the Discussion Group in future PME conferences and between conferences.

PME-delegates who want to actively participate in the Discussion Group are asked to contact the coordinators via email as soon as possible at rudolf.straesser@uni-bielefeld.de or julian.williams@man.ac.uk

---

Discussion Group:
Psychology of Computer Science Education

Coordinators: Dan Aharoni, Technion, Israel Institute of Technology, Haifa, Israel
Chronis Kynigos, Univ. of Athens and Computer Technology Institute, Patra, Greece
Tami Lapidot, Technion, Israel Institute of Technology, Haifa, Israel

Compared to Mathematics Education research, Computer Science Education (CSE) research is still in its infancy. Especially, the domain of Psychology of Computer Science Education (PCSE) lacks enough research; hence no specific community has been formed yet. But many domains of CS are mathematical in nature (e.g. the computational ones), and thinking in these domains is mathematically oriented. In fact, these domains of CS originated in mathematics. Thus it has been a few years now that PME is also the community of PCSE researchers. It has already been shown that PME theoretical and research background is adequate for PCSE (e.g. Aharoni & Leron, 1997). PCSE researches use PME theories like the Actions-Process-Object model (Sfard, 1991), theories on the role of affect (McLeod, 1989) etc., to name just a few. Papers on PCSE were presented in several conferences including PME (e.g. Aharoni, in press; Kynigos, 1995; Levy & Lapidot, 2000).

From past PME conferences we know that there were other PME members interested in the mathematical aspects of the PCSE domain. We would like this discussion group to be an opportunity for these people to share their experience in PCSE research, and discuss issues like:

- What is mathematical about learning computer science?
- Which PME theories were found adequate for PCSE?
- Which theories or parts of theories are specific to PCSE, beyond the scope of PME?
- What are the questions and issues PCSE should address?
- What are the CS domains or sub-domains that are adequate for PCSE research?
- What PCSE studies were done up to now?
- What PCSE studies should be done in the future?

The Importance of Matching Research Questions and Methodology to the Reality of Researchers' Lives

*Coordinators: K. Hart and P. Sullivan*

One focus of the Discussion Group is the training of students studying for a doctorate in Mathematics Education, their expectations and their needs. The doctorate is the highest academic qualification we offer. But the nature of the preparation doctoral students receive raises several questions: Is it an adequate preparation for a lifetime of research, supervision of students and leading a University department? Should we consider what use the student is likely to make of the research degree? What courses or readings do we think essential for any person studying for this higher degree? What level of mathematics should we require before a student is accepted, or should we provide tuition in mathematics as part of the degree course?

Another issue has to do with the nature of the thesis. Typically, the student submits a thesis, which is examined by external moderators. Does the supervisor have a responsibility to advise his or her students on a choice of subject that reflects the work they will probably do when they have graduated? If the future occupation is likely to be dealing with teachers should the student work on topics that are likely to appeal to teachers? On what criteria should the submitted thesis be judged?

These questions form the basis of our debate.
Symbolic Cognition in Advanced Mathematics
Stephen Hegedus, University of Massachusetts, USA (Convenor)
David Tall, University of Warwick, UK.
Ted Eisenberg, Ben-Gurion University, Israel

The main aim in establishing a group for the discussion of Symbolic Cognition in Advanced Mathematics would be to enable a forum for international debate and exchange in a field which has received much attention recently at PME in a variety of formats (e.g. Tall, 1999)

We would aim to facilitate discussion of new ideas emerging in the field and to distinguish between research in undergraduate mathematics education and inquiry into more general psychological aspects of mathematical thinking.

The role of symbol and cognitive processes relating to the representation and manipulation of mathematical signs and symbols is a popular topic (e.g. Dehaene, 1997; Deacon, 1997). The discussion group would aim to discuss such works and related aspects of pedagogy as well as present technological appreciation of symbolic cognition. In discussing the role of symbol in advanced mathematical work we would aim to discuss the process of symbolic manipulation from a psychological perspective where one would investigate in more depth the transitional processes from elementary mathematical thinking to advanced mathematical thinking.

Agenda: Research in following areas for possible discussion
1. The role of symbol in mathematical thought and meaning making;
2. Syntactic progression from the evolution of signs into symbols;
3. The historic consequence of sociological devices which enable constructive meaning for symbolic development;
4. Emerging theories of symbolic cognition in the fields of mathematical psychology and neuroscience;
5. Discussion of symbolic processing with reference to specific mathematical topics, i.e. in addition to limits, functions, calculus, analysis, linear algebra develop topics in abstract algebra, topology, probability/statistics, etc.

Allen Lane: Penguin Press.
WORKING SESSIONS
EXPANDING RESEARCHERS’ ABILITY TO STUDY STUDENT EXPERIENCES

Markku S. Hannula, University of Helsinki, Finland
Chris Breen, University of Cape Town, South Africa

ACTIVITIES

In this working session we will be involved in role play where participants will be asked to engage in learning situations where emotions are engaged. From these activities, implications for mathematics education researchers wanting to explore the emotions of learners will be discussed.

AIMS

Increasing interest has been devoted to students’ experiences in the mathematics classroom, including the emotions they have during mathematics-related activities. In qualitative research, the researcher is the main instrument of data analysis. While trying to understand the experiences of students, the researcher is always reflecting upon their own experiences to interpret and understand the student’s behaviour. While the researcher’s own experiences provide the basis for interpreting any data, they also are a source of bias. The researcher can best interpret experiences similar to his/her own and easily ignores or misinterprets other kinds of experiences. The aim of this working session is to expand the participants’ ability to identify and interpret different experiences that student’s might have.
FOCUSSING ON MENTAL ARITHMETIC
Coordinators: Kees Buys & Dagmar Neuman

Description of the topic
Today, there are some interesting tendencies to be observed in primary school mathematics education in many countries. First of all there is a growing tendency to postpone or even abolish the teaching of standard written algorithms. Instead, there is a growing focus on the establishment of early number sense and on the development of mental strategies (mental arithmetic) as central topics for the mathematics curriculum. This is not only taking place within the field of numbers up to 100, but also within the field of numbers up to 1000 and, with ‘nice numbers’, above 1000. Secondly, there is growing attention for estimation and the development of estimating strategies as a vital part of the curriculum. And thirdly, the use of pocket calculators, especially with larger numbers and decimal numbers, is becoming more and more common in the higher grades of primary school. Altogether this means that developing number sense and mental strategies are becoming more and more the heart of the curriculum.

Activities
In this working session we focus on mental arithmetic and work on important characteristics of the learning and teaching of mental arithmetic as an essential part of the new mathematics curriculum in primary school. During the two 90 minutes slots of the session the participants will do several activities, including:
-- Analyzing and discussing typical mental arithmetic problems as they occur in recent textbook series from various countries
-- Analyzing and comparing students’ work and assessment results in the field of mental arithmetic in various countries
-- Analyzing and discussing videotapes and interview protocols of the learning and teaching of mental arithmetic
-- Mapping the changing place of mental arithmetic in the primary school mathematics curriculum in different countries
-- Analyzing and constructing games that can stimulate the development and flexible use of mental strategies

People from several countries will inform the participants of the working session about the ‘state of the art’ in their country and will provide the participants with recent materials from their country. The aim is to analyse and compare developments in different countries, to reflect upon these developments and to envisage possibilities to stimulate and coordinate these developments.
Embodiment, Gesture, and Mathematics Education

Coordinators:
Janete Bolte Frant, CEDERJ, Rio de Janeiro
Jan Draisma, Catholic University of Mozambique, Nampula
Laurie Edwards, St. Mary's College of California

The study of mathematical thinking and learning has, for the most part, focused on how learners and teachers reason and communicate about mathematics using language and symbols. Data may include written inscriptions, diagrams, and/or verbalizations between teacher and learner, or among learners. However, the utilization of gesture for both the construction and communication of mathematical understanding has received much less attention in the research community. The purpose of this working group is to investigate the nature of the use of gesture in mathematical learning and knowledge. This focus will be situated within the context of recent work in cognitive science, including the theory of embodied mathematics (Lakoff & Nunez, 2000), research on gesture and thought (McNeill, 1992) and perspectives on number from cognitive neuroscience (Dehaene, 1997). In addition, specific research on gesture and number (Draisma, 2000; Gerdes & Cherinda, 1993; Fuson & Kwon, 1992) will be summarized to provide a background for the work that will take place within the two sessions.

In accordance with the purposes of a Working Session, the sessions will provide opportunities to participate in developing a research perspective and engaging in analysis of data within this perspective. The first portion of the initial session will be devoted to preparing a theoretical and practical grounding for the work. We will then present two video case studies, one focused on young children and gesture arithmetic (Draisma), and the other on motion graphics (Frant). A preliminary analysis of each case will be presented by the researchers, followed by an opportunity for participants to further analyze each case in small groups, as well as to engage, for example, in learning gesture arithmetic themselves. The groups will then present their analyses within the whole forum for further discussion. The session will conclude by considering possible ways to move forward in this area of investigation.

PME25 2001 314 1 - 273
OBSERVING SYSTEMS
David A Reid, Acadia University, Canada
Laurinda Brown, Alf Coles, University of Bristol, Graduate School of Education, UK

AIMS
As researchers we observe the dynamics of learners and groups of learners in communication with one another. Learners in communication can be said to form a social system. We will explore the differences and similarities in the three perspectives on the observation of social systems of Bateson, Maturana and Varela and Luhmann. In a reading which participants will get before meeting the author states:

Gregory Bateson defines information, or the basic unit of information in communicational and mental processes, as "a difference which makes a difference" (e.g. Bateson, 1972:453). And in Niklas Luhmann's terminology, observation means nothing more than handling distinctions - making a difference in this context involves an observing system (Alroe, 2000).

Maturana and Varela deal with the issue of observers making distinctions within systems of which they are a part. All three perspectives bring a systems view to the making of distinctions and cognition. The aim of this working session is for us to understand more fully the differences in these approaches, and their use in observing cognition in individuals and in social systems.

ACTIVITIES
The work of the session will revolve around analysis of a video-tape segment and associated transcript. Relevant selections from the literature will be distributed ahead of time to prospective participants, to establish a basis for our work. Multiple viewings of the video, small and whole group discussion of it from perspectives guided by the three approaches, and sharing interpretations of the data seen from these perspectives will be the main activities during the two 90 minute programme slots. Participants will be invited to continue our collaboration via email after PME25.

REFERENCES
WORKING WITH TRANSCRIPTS

Co-ordinator: Janet Ainley

As researchers in mathematics education, many of us make extensive use of transcripts, made from audio or video recordings of interviews, discussions and classroom interactions. We analyse these in many ways, to look at both the content and the social organisation of dialogue. We use them for many purposes, and yet we generally use a very small range of ways of presenting transcripts to serve all of these needs.

This Working session will be based around the exploration of some different styles of presenting transcripts, and how these might support different kinds of analysis and interpretation. I hope that we shall get into discussion of some important research issues, such as the notion of the ‘truth’ of a transcript, or whether more (detail) is necessarily better. However, the primary purpose of the session is to do some work together, and this will be organised as follows.

In the first session, I shall introduce some models for presenting transcripts, and invite any participants who are familiar with other models to add to these. Then we shall work in small groups, each taking a section of dialogue from an existing transcript, or better still from an audio tape, and transcribing this in different ways.

At some point in the second session, we shall come back together and invite groups to present what they have done, and their views about what may gained or lost in each of the styles. I am confident that this will lead us into valuable discussion of the sorts of general issues indicated earlier.

If you wish to participate in this working session you are encouraged to bring along your own data to work on. There will also be some examples of different kinds of dialogue provided. If you have a small audio recorder which could you used for the working session, please bring this as well.
HOW ICT AFFORDS THE REINVENTION OF MATHEMATICS: TWO EXAMPLES

Pijls, M. H. J.

Graduate School of Teaching and Learning, University of Amsterdam, The Netherlands

Doorman, M.

Freudenthal Institute, Utrecht University, The Netherlands

In reform mathematics education in general, and in the case of realistic mathematics education (RME) especially, the constructing activity of students plays an important role. In contrast with the traditional view in which teaching mathematics was seen as a process of teaching partial skills according to a pre-designed hierarchy, mathematics teaching in the reform view is seen as guiding students to let them reinvent mathematical knowledge.

The Dutch research program 'Mathematics and ICT' is concerned with the question how ICT can be utilized to facilitate the learning of mathematics according to the principles of 'guided reinvention'. This is elaborated in five projects with an emphasis on developmental research, a cyclical process of thought experiments, developing educational materials and classroom experiments.

In this working session we want to elucidate how ICT is used in experimental educational materials to both support a reinvention process by the students, and to ensure that formal mathematics is firmly rooted in the students' understanding of common sense knowledge. We like to discuss this usage of ICT and we want to discuss how we try to understand how ICT can be utilized for mathematics education.

The materials of two projects concerning upper secondary education, 16-year-old students will be presented. In one project a computer program is used as a tool in the process of modeling movement for the learning of calculus. It is expected that the affordances of the software elicit students to invent the concept of derivative. The other project concerns the learning of probability theory. Here the role of the software is to create an environment for explorations on the visual level that links up with students' experiences.

Participants of the working session get the opportunity to work with the learning materials of both research projects. Subsequently, student's answers will be analyzed on indications for reinvention. Finally, we will debate on the aims of the software, the experiments, the experiences and what we learnt from it.
Working Session
What Counts as Multiplicative Thinking in Younger Students?

Coordinators: Anne Reynolds, University of Oklahoma, USA
Tad Watanabe, Towson University, USA
Gard Brekke, Telemarksforsking-Notodden, Norway

When the Project Group, Understanding of Multiplicative Concepts met in Hiroshima, Japan last year the following questions emerged as in need of further study:

- If repeated addition is not multiplicative thinking, when does a child’s understanding of multiplication operation become multiplicative?
- Where is the line between additive and multiplicative reasoning?

This working session will provide an opportunity for mathematics education researchers who are interested in these questions to develop criteria for identifying a child’s actions as multiplicative rather than additive.

The group will examine data from student interviews focused on multiplicative reasoning and discuss how the data does or does not support an interpretation of multiplicative thinking. The coordinators will provide transcripts, interview protocols, and samples of written responses from their research with younger students for the group to consider. Participants are also encouraged to share episodes from their research into multiplicative thinking with the group to further extend our thinking on the topic.

Based on our analysis it is proposed to redesign the tasks to better probe young students multiplicative thinking. Participants who are interested will be invited to use these tasks with students in their various locations over the coming year and collaborate on further analysis of young students’ multiplicative thinking from different countries and cultures to highlight similarities and differences.
The Ferris Wheel problem
Ricardo Nemirovsky and Jesse Solomon
TERC and City on a Hill

This working session will focus on a problem that is part of the Interactive Mathematics Program for the senior year in high school. Imagine a Ferris Wheel and a train travelling underneath. A diver is in one of the ferris wheel's cart waiting for the right time to jump in order to land safely on a cart full of water that is part of the train. The problem is when he should jump. The unit was conducted by Jesse Solomon in his class at City on a Hill public charter school in Boston, Massachusetts. In order to investigate new ways to work with the Ferris Wheel problem, we constructed a physical device that includes all the components (a ferris wheel, an electric train, a diver jumping at a pre-set time, etc.) although in a reduced scale to allow for its classroom use. The speed of the ferris wheel and of the train can be changed by turning two knobs on the controllers. The time at which the diver is going to jump is set by positioning a magnet on the train track, so that the jump will take place whenever the train goes over the magnet. Students worked on this unit for six weeks.

The working session will be divided in two parts. During the first half the participants will work on different mathematical aspects of the Ferris Wheel problem and on ways to connect it to the behavior of the Ferris Wheel device. During the second half the participants will analyze selected episodes filmed in Mr. Solomon's class. The coordinators will set up the ferris wheel device and bring videotapes and transcriptions for the selected episodes.

The research question for the session will be about the roles of physical experiences in mathematics learning. This question will be explored through the participants' engagement with the ferris wheel problem as well as through the analysis of classroom interactions.
In this paper I want to show how one teacher’s tests changed over a period of four years. This case study is part of my doctorate, in which I wanted to show that if elementary school mathematics teachers were provided with good assessment tasks and were taught how to analyze their students’ work on such tasks, then their mathematics teaching would improve. (Albert, 1999) I collected data on their teaching by questionnaires, interviews, and samples of assignments and tests.

This teacher was involved in an in-service project which put emphasis on changing the teachers’ vision of mathematics. Mathematics assessment was not a part of this project. I had decided that School-based Assessment would be introduced first to the principals, and then to all mathematics teachers - not just the leading ones participating in the weekly workshops. In December, 1996 a workshop was held for the elementary school principals where they solved a mathematics investigation task, discussed its characteristics, and were introduced to other tasks and samples of student work. They were shown how these tasks enable teachers to assess students' mathematical achievements in a broader way than is possible with single-answer tests. During the spring term, I ran three workshops for all fourth through sixth grade mathematics teachers.

On the first questionnaire of this workshop, this teacher who I will call Sarah gave an example of an assignment which required students to explore fractions and use manipulatives to do this. Compared to other teachers not participating in the project, this task showed Sarah was teaching more in the direction of reform mathematics. Yet the test I collected from her that spring was extremely conventional, with twenty-six short exercises and two standard word problems. Thus there was no correlation between the way she was teaching and the way she was testing.

Four years later, the test Sarah brought me was radically different. It included different types of mathematical processes, not just calculations. It not just permitted the students to use manipulatives, but encouraged their use, and required generalizations based on this use. There were also questions requiring verbalizations and justifications. The way Sarah talked was different too. Her explanations of the test questions showed understandings she had not previously applied in her assessment tasks.

TYPES OF REPRESENTATION USED IN THE PRESENTATION OF TRIGONOMETRY IN A TEXTBOOK

Kristin Amundsen, Telemarksforsknings-Notodden, Norway

This study reports on how representations are used in the presentation of trigonometry in a textbook written for upper secondary school. It is an analysis of how a tripartite use of representation is used in the presentation of the topic.

Representation is a complex concept used in different contexts. In proportion to learning and teaching there is a main partition between external and internal representations (Goldin & Kaput, 1996). In my work the focus was on external representations. One motivation for applying a tripartite view on mathematical topics came from the introduction of “The Rule of Three” in an American calculus reform in the 1990’s. The main idea here was to emphasise a balance between numeric, algebraic and graphic representations in the teaching and learning of calculus (Hughes Hallet, 1991). Lesh (1999) uses a model for transfer between five types of representation in the learning situation, which is an extension of Bruner’s enactive, iconic and symbolic representation forms.

The main aim of my study was to explore how concrete, visual and symbolic representations were used in the presentation of trigonometry. Part of the work was to adjust and define the difference between concrete, visual and symbolic representation, and especially what concrete representation is in the context of a textbook. My research questions were: What kinds of representations are used; in which order do they occur; and what connections are found between and within the different representations.

Visual and symbolic representation dominated. When concrete representation was used, it was so strongly connected to visual representation that it was difficult to separate them. Even if the three representations were used, pairs of representation forms appeared simultaneously. Generally there was a bipartite approach and not a tripartite approach to the topic that dominated. The order of the representation was mainly from visual to symbolic except from the graphic representation of the functions.

THE COMPUTER AS MEDIATOR IN THE DEVELOPMENT OF MATHEMATICAL CONCEPTS

Charlotte Krog Andersen
IMFUFA, Roskilde University, Denmark

To motivate my ideas, I present an episode from observations of mathematics university students using a computer software package consisting of pre-programmed Maple procedures. These procedures may be used to create dynamical and interactive illustrations of central spatial concepts of differential geometry. In the episode, the students explore geodesics on an ellipsoid. They manipulate the parameters and create an ellipsoid with a curve running from the north “pole” to the south crossing itself on the equator and making a small circle at each pole. Subsequently, the students come up with a preliminary description of the curve as Ribbon on an Easter egg in order to formulate and anchor their experiences with this ellipsoid.

With the aim of investigating the role of such preliminary descriptions for mathematical concepts formation theoretically, I draw on Vygotsky’s work on the development of scientific and spontaneous (everyday) concepts. A similar distinction proves valuable also in relation to university mathematics. Scientific concepts (here mathematical) are according to Vygotsky initially introduced through their verbal definitions but based on a relatively mature development of spontaneous concepts formed in an out-of-school context. This emphasises the importance of everyday concepts as they mediate meaning to the mathematical ones. However, in an educational context students form semi-spontaneous concepts originating in intuitive reactions and empirical experiences as evidenced by the episode. These are valued by their illustrative and sense making potential in relation to the mathematical concepts, and I shall call them preliminary intuitive mathematical concepts.

In conclusion, I suggest that the use of computer software may play a mediating role in the acquisition of mathematical concepts. This is so at least if the software is rich in interactive, dynamic visualisations that enable the students to form preliminary intuitive mathematical concepts.

STUDENTS' UNDERSTANDING OF GRAPHICAL ASPECTS OF DERIVATIVE AND OF SOME OF ITS UNDERLYING CONCEPTS

Jan Bezuidenhout
University of Stellenbosch, South Africa

The purpose of the study, on which this paper is based, was to examine university students' understanding of fundamental calculus concepts, after the concepts concerned had been dealt with in first-year calculus courses. 630 students were subjected to the diagnostic tests (a pre-test and a post-test) pertaining to this study. Fifteen of these students also participated in individual interviews. The analysis of students' written and verbal responses to test items revealed a great deal of detail about the nature and characteristics of students' understanding of key calculus concepts and their symbolic representations (Bezuidenhout, 1998; Bezuidenhout and Olivier, 2000; Bezuidenhout, in press). This paper focuses on students' understanding of graphical aspects of the derivative and of some of its underlying concepts, including the derivative as a rate of change.

The following three kinds of function representations were most commonly used in the diagnostic tests: tabular and graphical representations and the function defined in algebraic symbols. The main reason for the utilization of different representations of functions, was to examine students' understanding of concepts within different modes of representation. Concerning this paper the graph of a non-linear function provides the graphical context for examining students' "graphical" understanding of aspects relating to derivative or rate of change. These aspects include the following: increase/decrease of a function at a point; rate of increase/decrease; increase/decrease at the greatest rate; the average rate of change over a small interval of the independent variable as an approximate value of the derivative at a point; slope of a secant line; slope of a tangent line; increase/decrease of the rate of change.

The interview format served to reveal the nature of some misconceptions of students. One such misconception suggests that "the average rate of change over an interval corresponds to the average of the rates of change at the two endpoints of the interval". Knowledge associated with the arithmetic mean was identified as a key source of this misconception.

Theoretical Framework

The status of error in the teaching and learning process has been analysed from several points of view depending on the epistemological bent from which different authors stand. Within a constructivist perspective, the error produced by a subject when performing a task is not an ill to eliminate and forget, but a behaviour worthy of analysis and interpretation. (Inhelder et al., 1974, Vinh-Bang, 1990, Astolfi, 1997).

This research has the goal of analysing errors committed by pupils, from kindergarten, first and second grades, on solving different kinds of addition arithmetic problems (e.g. composition and transformation) (see G. Vergnaud, 1981).

We intend to answer to three issues: firstly to determine if the error produced by the child results from a lack of structural mechanisms to solve the question or if it is only a functional difficulty. The second issue is to determine if the pattern of errors is connected with the child’s psychogenetic development. The third issue is to determine the relationship between the additive problem proposed and the type of errors committed.

Methodology

In this investigation 30 pupils where questioned in four sessions and qualitative methodology formed the basis of data collection. After a operatory diagnosis being done with three Piaget’s tasks (number’s conservation, seriation of length and class inclusion), nine additive verbal problems were be presented at which the child shall answer using manipulative materials, followed by iconographic representation and finally symbolic representation (calculus) to determine the kind of errors produced.

Results and Conclusion

The first results analysed until now shows:
1. In general, pupils committed more errors in additive problems involving transformation.
2. These errors seem to be at the root of a lack of structural mechanisms of knowledge; in fact pupils with low results in Piagetian tasks, independently of their educational level, are those who commit more errors.
3. Errors coming out from functional difficulties, like computational errors, are not connected with psychogenetic development, but with the educational level of the pupil.

The TIMSS study found significant gender differences in achievement only in a few of the participating countries (grades 7 and 8). In general attitudes towards mathematics were positive for most countries, however gender differences in favour of boys were found in 31 out of the 40 participating countries (Beaton et al 1996). Norway was one of countries with the largest gender difference (Lie et al 1997). The largest gender difference in achievement in the mathematics test in TIMSS’ population 3 (grade 13) was found in the Norwegian population.

Leder and Forgasz (2000) have presented a rational and methods which they used to develop a scale for investigating to what extent mathematics continues to be considered as a gender domain. The study presented here concerns issues from a large-scale project could offer another to this discussion.

Since 1995 the project has collected national data on students’ understanding of key concepts in the national mathematics curriculum. A questionnaire that contained a wide range of issues related to the teaching and learning of mathematics (125 items) was administered to 1482 students in grad 6 (11.5 y) and 1183 students in grade 9 (14.5). Forty-two of the items were related to students’ beliefs about mathematics, mathematics teaching and self, as well as attitudes towards the subject. A factor analysis of the 42 items formed five groups, Interest, Usefulness, Self-confidence, Diligence and Security.

In another eight items the students were asked to consider assertions such as: “To enjoy asking questions in the mathematics lessons is most typical for: boys, girls, equal. The responses to these items gave important information on how such gender stereotypes develop in different age groups.

A subgroup of the students, respectively 273 and 243, responded to a test which investigated students’ conceptions of measurements and units. This made it possible to study relationships between scales above and gender, and in addition to investigate relations between students’ performances to these scales.

In whose interest are we working when we construct mathematical curriculums for schools? How does mathematics as a discipline lend itself to being categorised within curriculum documentation? Our attempts to describe the world always result in formulations that at best approximate the world we seek to describe. But we are always governed by specific purposes in trying to create such descriptions. Governments, mathematicians, teachers, economists would all have different motivations as to how mathematics should be described. The attempt to describe mathematics in a curriculum inevitably results in a caricature of traditional understandings of mathematics as a discipline. Should this sort of formulation be seen as a simplification, a misunderstanding or as an ideological distortion? The formulation can be viewed variously, for example, as a serious but imperfect attempt to describe mathematics to guide school instruction or as a cynical ploy to make teachers and children more accountable according to a particular institutionalised account of mathematics or a reconfiguration of the discipline itself to meet contemporary needs. Ricoeur (1981) would downplay intent in the construction of the formulation and see it more as a matter of subsequent interpretation, and action on the basis of this, as to how the formulation is viewed.

This presentation will review new work (Brown, 2001) discussing the social construction of mathematics for school instruction and how progress in learning mathematics might be viewed as a function of particular learning theories or evaluation strategies, and the particular characteristics they value. It will also consider strategies for enabling teachers to address such concerns within professional development programmes (Brown and Jones, 2001).

At the Pedagogical University in Beira, teachers of mathematics for secondary schools are being trained since 1996 under BLEM Programme (Bacharelato e Licenciatura em Ensino de Matemática). In the programme, I am lecturer of Didactics of Mathematics and my main aims are: a) to discuss secondary school mathematics topics with prospective teachers and find best ways of teaching them; b) to provide prospective teachers with basic knowledge for scientific research in mathematics education.

The first topic that we studied in 1998 was Negative Numbers because it is the first topic of the syllabus for secondary schools (grades 8 – 10), and because "Negative numbers have intrigued and confused some of the greatest mathematicians who have ever lived" (Davis and Maher, 1993).

Firstly, the prospective teachers answered a questionnaire with simple addition and subtraction tasks in which they were asked to explain how to calculate and to explain how they would explain these tasks to pupils. They were asked to indicate, which everyday life situations they could use to explain the tasks. After that, the prospective teachers conducted interviews in secondary schools to verify how pupils work with negative numbers.

In the study we wanted to find out which specific problems the pupils in school have with negative numbers and identify their origins, in order to find an approach which may help pupils and teachers.

With this topic we found that prospective teachers had many difficulties in formulating questions which could help the pupils to reflect on their own words, ideas and solutions. There were some very positive examples, where the students succeeded in conducting an interesting dialogue with a pupil and making a good report of the discussions. During the activities we required that the students learned to analyze the ways of thinking of pupils. They became conscious that in teaching mathematics, teachers should teach in the direction of what pupils think instead of what the teachers think.

THE ROLE OF FIGURATIVE CONTEXT IN REALISTIC TASKS

Andreas Busse
Institut für Lehrerfortbildung Hamburg

The real context a realistic task is embedded in is called figurative context (Clarke & Helme 1996).

Previous studies covered the role of figurative context in certain aspects: familiarity (Papastravidis et al. 1999), gender (Kaiser-Messmer 1993), involvement (Stillman 1998), individuality (Clarke & Helme 1996).

There is no comprehensive theory covering the role of figurative context. Especially questions concerning the subjective reception of figurative contexts have not been answered and not been investigated empirically yet.

Quantitative approaches to theses questions would not lead to a sufficient understanding of the students' individual processes. On the contrary, these questions require a qualitative approach.

The aspect of the subjective reception of figurative context was, among others, investigated in a qualitative-orientated case-study. Students were asked to solve different realistic tasks. Their solution-process was recorded on video. Afterwards the students watched the recordings and expressed their thoughts concerning the figurative context they had had during the solution-process (method of stimulated recall). In following interviews the students were asked additional questions.

First analyses allow, among others, the following conjectures:

- Figurative contexts given in the tasks can internally be represented in very different ways.
- Depending on the individual and the situation the role of figurative context can vary considerably
- In different phases of the solution-process the figurative context can have various functions

All mathematicians concern themselves with mathematics, and most scientists and engineers concern themselves with mathematical applications. Some psychologists concern themselves with mathematical cognition, and a few neuroscientists have recently begun to concern themselves with the physiology supporting mathematical thinking. This broad spectrum of study comes to a focus in mathematics education. It would seem appropriate therefore, that mathematics educators and researchers in mathematics education concern themselves with how these studies interrelate.

Understanding the relation between mathematics and the material world has long been a classical problem in the history of the philosophy of mathematics. More recently, the potential roles of psychology and physiology have been added into this equation. Can recent psychological developments in cognitive science, or recent physiological findings in the neurosciences shed light on this problem, or do they complicate the matter further? This talk is concerned with identifying and explicating some central issues that are emerging in understanding research in mathematics education at the nexus of math, mind, brain, and world.

What, for instance, are the implications for teaching and learning mathematics of limiting or defining mathematics and/or mathematical cognition in neural terms? Can, or should we try to extend our understanding of mathematical cognition downwards into the very fabric of the world out of which the human organism has emerged? In terms of mind-brain identity and interaction theories, how and at what level(s) do categorical structures of cognition relate to physiological structures?

At a more functional level, what mathematical operations are primitive and which are derived or adapted? What operations are innate, if any, and which result from the conscription of preexisting neural processes that may have evolved for different purposes? In terms of mathematical applications, what aspects of mathematical understanding, if any, are unconsciously embodied in the evolutionary past of human development (e.g., numerosity)? What aspects are normative? That is to say, what aspects may have been consciously developed solely on the basis of more recent human motivations and purposes (e.g., cryptology)?

The emerging need to address such issues requires critical evaluation the ability of our existing conceptual frameworks to do so. Some basic philosophical assumptions may need to be reevaluated, and some consideration of new ones may be warranted. Attempting to develop new roadmaps for navigating through these kinds of issues poses many new interesting questions and challenges for teaching and learning mathematics, and promising new directions for research in mathematics education.
FROM GEOMETRICAL FIGURES TO LINGUISTIC RIGOR:
VAN HIELE’S MODEL AND THE GROWING OF TEACHERS AWARENESS.

L. Canizzaro, M. Menghini
Dipartimento di Matematica, Università Roma 1, Roma,

The work takes off from a curriculum design elaborated within a school-university working group for students aged 14-16. The observational study focused on how teachers manage the project in order to lead students to the full understanding of the significance of the definition meant as the expression of the minimal of a figure, i.e. as the nucleus of the idea of necessary and sufficient condition. We used van Hiele’s Theory in order to encourage expert teachers to reflect on a curriculum previously implemented and on their own practise. We registered with evidence that teachers’ awareness of the van Hiele’s level has a positive influence on students’ learning.

The itinerary has been developed through individual worksheets alternated with slots of collective discussion and of reorganization guided by the teachers. We considered that in a teaching prospective the scope for a correct definition is to develop awareness of what a definition is better than to explain what an object is; i.e. we undertook the difference between descriptive definition and prescriptive definition.

Exemples from the project materials, teachers’ observations on students’s written work, collective discussion and behaviour will be illustrated in the oral communication.

Observations. 1. a good homogeneity was reached in all the eight classes; 2. teachers recognized in the learning process many actions, i.e., in van Hiele’ conception, the essence of geometry; 3. teachers declared to feel they have learned to adapt themselves better to the students; 4. we observed the two different registers into which action research methods leads to be active: the register of practitioners’ reflections on their own action and the register into which researchers in Mathematics Education are active.

Two remarks on the way in which the idea of inclusion and the set schemata are used arose from students and teachers observation and will be briefly outlined in connection with an analysis of some Euclid’s proposition.

IN-SERVICE CALCULUS COURSE: WHAT DO STUDENTS AND TEACHERS WISH?¹

Elaine Cristina Catapani
Miriam Godoy Penteado
Tânia Cristina Baptista Cabral

UNIVERSIDADE ESTADUAL PAULISTA, SP, BRAZIL

Mathematics has penetrated into several areas of knowledge, seeking to comply the demands of professional formation and technical assistance. However, students and teachers of these technical areas complain that mathematics courses do not generally offer them what they need. According to Howson et al (1988) the problems arising from the so-called "courses in service" have been poorly understood and insufficiently analyzed by mathematics educators and researchers.

During 1999, we used a questionnaire and semi-structured interviews in order to determine the profile of the students' expectations in a freshmen calculus course for a Geology Program. Our leading question was: what do they wish? It turned out that their basic complain, as well as of other teachers in the Program, was the lack of applied problems whose importance for the subsequent professional courses could be recognized as relevant. We designed and carried out a freshmen calculus course for geologists attempting to fulfil this demand. Here we shall report on the outcomes of such attempt.

As soon as the applied exercises were introduced into the classroom, the students started complaining about their “complexity”, about their unfamiliarity with the concepts involved, about the length of the problem statements. Some asked us to go back to the routine exercises in the textbook. A polemical situation was installed in the classroom. From this point on, our research focused on what was happening. We expected to appease the students' complaints, but our action only made them worse. Based on the psychoanalytical theoretical framework of Slavoj Zizek [3] and Tânia Cabral [1] we identified the students' contradictory behavior as apparently hysterical: this is what we ask you but it is not that we want you to give us. The theoretical framework led us to consider two concepts, the symbolic and the imaginary identifications that frame one's desire. We inquired the social models that the institution (university) offers to teachers and students of in-service calculus courses: to which gaze do the actors play their roles? From what point of view do they look at themselves?

In trying to answer these questions we finally discovered that our own speech had also been contradictory. With the applied exercises we expected that the students would recognize the importance of the operations of differentiation and integration that we were trying to teach them, but we failed to stimulate the discussion about the meaning of these problems for their future courses and profession.

INCLUSIVE SCHOOLING: FROM POSSIBLE TO UNDELAYABLE
César, Margarida, Rijo, Catarina & Loureiro, Marta
Centro de Investigação em Educação da Faculdade de Ciências da Universidade de Lisboa

In the past decade, the broadening of compulsory schooling in Portugal to 9 years and the inherent principles of inclusive schooling, defending a school for all – therefore, Mathematics for All – forced the educational community to look at a set of problems for which it (still) had no answers but which at the same time demanded the urgent discovery of forms of action. But the change processes are slow and not without contradictions and they only work if the different actors of the educational scenario are involved in this change process, feeling they can actively contribute towards what is happening.

Defending the principles of inclusive schooling (Ainscow, 1994, 1997; Porter, 1997; Ware, 1997) means believing in the educationability of all and in the educators’ capacity to promote the full development of their pupils. It necessarily means believing that every child learns – albeit with different rhythms – that each one can develop his/her socialising skills, be able to build a life project and that the teacher must discover the best way to get him/her to achieve all this.

The case study we undertook refers to a class (8th grade) that integrates several pupils either with special educational needs or from socio-cultural minorities and whose teacher is taking part in an action-research project that has existed for seven years and studies and promotes peer work as a way of enhancing pupils’ self-esteem, promoting their socio-cognitive development and their mathematical performances. We shall highlight the cases of two pupils since we feel them to be paradigmatic and clearly show how the classroom practices, working instructions and the didactic contract that is established may contribute to go from the ideals of inclusive schooling to classroom practices that really take them into account, thus contributing towards Mathematics for All and preparation for full citizenship as a reality in our schools.

Students' Concept Images for Period Doublings as Embodied Objects in Chaos Theory

Soo D. Chae and David Tall

Mathematics Education Research Centre, University of Warwick, U.K.

The aim of this research is to study how visualisation using dynamic computer software helps students construct conceptual knowledge in a context where symbolic proofs are difficult or unknown and numerical computation offers insightful data. We focus on the study of period doubling in chaos theory, situating our analysis in process-concept theory (Tall et al, 2000), relating this to the embodied theory of Lakoff and Nunez (2000).

The results presented here will reveal in what ways able mathematics undergraduates interpret visual pictures of the eventual behaviour of the iteration of \( x = \lambda x (1-x) \) for various values of \( \lambda \) starting at \( x \in (0, 1) \). For \( 1 < \lambda \leq 3 \) the iterations home in on a limit which bifurcates to an iteration of period 2 after \( \lambda_0 = 3 \), then to periods 4, 8, \ldots at a sequence of increasing values \( \lambda_1, \lambda_2, \ldots \) which seem to approach a limit \( \lambda_\infty \) (the Feigenbaum limit). After this point the behaviour is chaotic and graphing the set of limit points against the corresponding value of \( \lambda \) gives a picture termed the Feigenbaum tree.

The investigation is performed with a second experiment that involves period doubling of a closed loops on an oscilloscope. (See Chae & Tall, 2001 for details.)

In this paper we focus on students' responses to the following post-test questions:

What first comes to your mind when you think about 'period doubling'?

Please draw/make an example of a period doubling in your mind's eye.

The pictures were diverse, including sketches of both of \( x = f(x) \) iteration and loop doubling, which we analysed in terms of a new perspective of 'base object'–'process'–'concept'. We found most of the 20 students focused on the pictures as base objects; 7 drew a single picture representing the base object after bifurcation, 12 drew 'before and after' representing the process of bifurcation and only one drew a Feigenbaum diagram which we interpret as moving towards an overall view of the concept of bifurcation. Further analysis reveals that of the 8 students drawing loops, 7 concentrate on the move from a single loop to a double loop, but of the 10 students using \( x = f(x) \) iteration only one draws the shift from a point to a period 2-orbit and only one draws a period 2-orbit. We will discuss how this intimates that students focus more on visual concepts as embodied objects than on symbolic/numeric representations at this stage of their investigation.

THE TAIWANESE TEACHERS’ BELIEFS AND VALUES IN
MATHEMATICS EDUCATION

Ching-Kuch Chang, Graduate Institute of Science (Math) Education,
National Changhua University of Education, Taiwan, R.O.C.

This article reports the pedagogical values of two Taiwanese
teachers, Ms. White and Ms. Wang. They have been teaching
mathematics in a junior high school for 16 years. They went back to the
university and learned constructivism and constructivist teaching six
years ago. However, as time went on, their teaching began to return to
traditional teaching. Why did this happen? We suppose that they value
something in traditional teaching rather than in constructivist teaching.
This study was designed to reveal the teachers’ beliefs and values in their
teaching. We took the teachers interviews, observed their teaching in
class, made discussions with them after class, and encouraged them to
change their teaching. The findings show that White and Wang value
differently above the surface, but they tend to have a few core or deep
beliefs and values in common such as: score-ism in education, specialism
in mathematics education, and absolutism in mathematics. Taiwanese
teachers’ score-ism was reported (Chang, 2000). This article focuses on
the latter, Taiwanese teachers’ specialism and absolutism.

School Based Inservice Improvement as an Effective Instrument to Change Mode of Mathematics Teaching

Jing Chung
Department of Mathematics Education
National Taipei Teachers College, Taiwan, R.O.C.

The national mathematical curriculum of Taiwan stressed that the learner should actively construct and understand mathematical concepts from his own experience; that the learner should understand, evaluate and respect his classmates' ways of problem solving and his viewpoints and the viewpoints of others. In addition, the teaching should inspire each student to communicate, discuss and debate. Since the curriculum changed so greatly, the change of the teachers needs support. At present, the inservice improvement programs are mainly lectures and rely on experts. This is not effective. The school is responsible for the realization of the curriculum, so the school has to push and carry out the reform.

I raise my six years action research in National Taipei Teachers College (NTTC) laboratory school as a focal case of “school-based” inservice improvement program (Chung, 2000). What was done in NTTC lab school in the reform of mathematics teaching, though it is a unique case (Hsiau, 1998), it realize the resocialization preached. From the beginning, I made the pedagogic study meeting on mathematics into pedagogic discourse session (PDS) which was the nucleus of the model. A stable model appeared with four aspects: workshops, newly transferred teachers, inter-grade growth group, daily interactions. This model carried several characteristics. The key word are culture, education, humanization, duality, momentum, spotlight.

Yet, from the success of the NTTC laboratory school with the new mathematical curriculum, I believe that setting up many school-based inservice improvement programs could be an effective measure to implement the new curriculum, but the following key points should be observed: 1. The functioning of the old pedagogic study meeting should contain reflective professional discourse to induce the teachers to participate actively. 2. The principal should be the action leader of the curriculum reform and teaching mode change. 3. The frequency and quality of the professional discourse should improve considerably as days going by. 4. The improvement activities should gain the consent of the teachers and be effective. 5. The administration staff should make wise planning so that the environment is supportive and safe. Competent expert or subject leader should be present when needed.

References
As part of a research project aimed at establishing and analyzing links between “home mathematics” and “school mathematics,” we developed a teaching innovation centered on a garden theme in a fourth-fifth grade classroom (9-10 year-olds). This theme was chosen based on the students’ and their families’ knowledge and experiences with gardening. Our goal is to engage children in sociocultural activities that are personally meaningful to them and “recognized as 'real' by the mathematical community” (van Oers, 1996, p. 106). The gardening context allowed us to explore students’ informal understandings of area and perimeter as they faced authentic problems. For example, the need to cover their enclosed gardens with plastic led to finding the areas of these irregularly shaped gardens. The need to make their enclosed gardens bigger, yet using the same amount of chicken wire, led to an optimization problem. The discussion of these real life situations was followed by in-class tasks to further probe the children’s understanding of area and perimeter. As Hoyles (1991) writes, “it is pedagogic intervention which imposes the mathematical structuring and provokes the pupils' awareness of the underlying mathematical ideas” (p. 149).

This presentation will focus on four children’s thinking about area and perimeter as they worked on a series of tasks which included finding the area of a miniature garden (tools available were transparent grid paper, rulers, tiles and cubes) and exploring what shape would give the maximum area (for a fixed perimeter). Each child was individually interviewed and each interview was videotaped and audiotaped. Analyses of the interviews shed light on at least four areas: 1) the interplay between everyday knowledge and school mathematics; 2) the influence of tools (e.g., rulers vs. tiles) on the children’s approaches (Nunes, 1996); 3) the effect of prior kinesthetic experiences on shaping a child’s thinking about perimeter (the children had explored perimeter by making shapes with their bodies as units of length); 4) the use of “academic” approaches to the tasks (in terms of methods and language).

PREFERENCE OF DIRECTIONS IN 3-D SPACE

Nitsa Cohen
The David Yellin College of Education, Jerusalem
Ministry of Education, the Israeli Curriculum Center

In the course of research dealing with misconceptions in 3-D geometry basic concepts, I could clearly see that students tend to prefer particular and typical directions, and disregard other directions. These preferred directions are not necessarily the obvious ones – the horizontal and the vertical. They may be other directions, which are chosen relatively to the directions given in the problem.

For example:
- Given a line \( a \) situated in a plane \( P \), the students are asked to place another line \( b \), perpendicular to \( a \). Most of them choose \( b \) to be perpendicular both to \( a \) and to the plane \( P \).

For some of the students the preferred directions are their “first choice”, but they have no difficulties to see other directions as well. However, there are students who focus only on those preferred directions and are not able to see other options. For those students, awareness of their choices and of the possible reasons for these choices can improve considerably their visual ability and flexibility in 3-D space.

This study is an attempt to locate and to analyze those preferred directions among prospective teachers in a college of education. It is a part of broader research, which I presented last year in Japan: “Misconceptions in 3-D Geometry Basic Concepts”.

Over a period of 8 years, I watched most of the 272 students who participated in the research. During their discussions (some of which were video or audio taped), I noticed very clearly that they almost always choose typical and predictable directions when they illustrate interrelations in 3-D space. Then I interviewed some of them in order to try to analyze more carefully my assumptions about the preferred directions.

In general, we can see three types of preferences of directions:

1. Preference of gravitational directions: horizontal or vertical.
2. Preference of “convenient” directions, in which there are no conflicts between different concepts related to the same terms: “perpendicular”, “parallel” or “angle”. (For instance: in the example above, we can notice a choice of direction that avoids the conflict of being perpendicular to the line but not to the plane.)
3. Preference of directions which are perpendicular to one another (like the axes \( x, y, z \)), or directions which have a “balance” (internal or gravitational).

In the oral presentation some of the findings will be presented and analyzed, with examples of episodes that took place during the interviews or the discussions.
A problematic issue in research on understanding the arithmetic mean has been to develop a satisfactory conceptual and instructional definition. My research in the area of statistics education has brought me to distinguish between three different uses of the arithmetic mean in statistics, each of which requires different sophisticated understandings of statistical analysis. Hence, I believe each of these uses should be introduced at a different time in the curriculum.

1) Measure of the aggregate. The mean is used to measure the aggregate of a group when the total becomes inadequate because of differences in group size. The salient property of the mean in this usage is that of addressing the multiplicative relation between total accumulation in a group, and the number of units that generated that accumulation. This way of using the mean is common in science and in social sciences to construct normalized units of measure (e.g. kilometers per liter). My research shows that 12 and 13-year-old students with limited exposure to statistics, can make sense of this way of using the mean (cf. Cortina et al., 2001).

2) Measure of the center. The mean is used to characterize a distribution. Its salient property becomes the indication of the point of symmetry (or balance) of the deviations of values in a data set. The mean in this case is used in combination with other measures to characterize a distribution. To use the mean in this way, students need to at least understand "center" as a stable characteristic of a data set. Recent research suggests that even after 6 months of instruction, many 13 and 14-year-old students do not easily develop this understanding of center (cf. Cobb et al, in press). Hence, relatively long exposure to statistical instruction might be necessary in order for students to develop an understanding of the mean as a center.

3) Inferential tool. In this case the mean is used to infer, from a sample, characteristics of the aggregate and/or distribution of a population (i.e. central tendency). This use is based on the Law of Large Numbers, and requires relatively sophisticated understandings of sampling and probability. Hence, this use should be addressed in a rather advanced stage of statistical instruction.

Attainment and Potential: Procedures, Cognitive Kit-Bags and Cognitive Units

Lillie Crowley
Lexington Community College
Kentucky, USA
Lillie@pop.uky.edu
Http://www.uky.edu/LCC/MATH/Crowley/Papers

David Tall
Institute of Education
University of Warwick, UK
David.Tall@warwick.ac.uk

Why do two students, both of whom did well in one course, have vastly different experiences in the subsequent course? Does the successful student merely have more available procedures, or is there a fundamental difference in his or her cognitive activities?

Nancy and Kathy both earned a “B” in college algebra, and both enrolled in pre-calculus the following semester. Nancy had little difficulty in pre-calculus, but Kathy had a great deal. The course is a degree requirement, so she needed to pass it; she dropped once, re-enrolled and eventually passed, but with much work and anguish. Why do “so many of the population fail to understand what a small minority regard as being almost trivially simple?” (Gray & Tall, 1994). Why do two students with apparently similar attainment go on to perform so differently?

To seek insight into these questions, we explored the cognitive structure demonstrated by the two students working problems involving graphs of lines from the first algebra course, and compared their problem solving approaches. We have previously studied the diffuse cognitive structure of a less successful algebra student (Crowley & Tall, 1999). This study compares and contrasts the work of a similar student—who struggled with very straightforward algebra concepts—with that of a student who proved to be more successful in the succeeding course.

Barnard and Tall (1997) introduced the idea of “cognitive unit” as “a piece of cognitive structure that can be held in the focus of attention all at one time.” We see cognitive units as forming the nodes of a cognitive structure linked to other units using the web metaphor of Hiebert and Carpenter, incorporating the varifocal element of Skemp. If various elements are not connected securely, the individual may not be able to consider the totality as a cognitive unit. Links are not made to a flexible conceptual entity, but to one procedure from a collection, the student’s “cognitive kit bag”. Interviews revealed quite different cognitive structures. The successful student had a variety of approaches to problems, checking mechanisms, and an overall grasp of linear equations as if it were a cognitive unit. The other student had a cognitive kit-bag of procedural techniques with no flexibility or checking mechanisms. She had the same attainment but very different potential to cope with the ensuing course.
PLEA FOR A SIMPLE CALCULATOR IN PRIMARY SCHOOLS  
Ed de Moor (e.demoor.fi.uu.nl)

One of the goals in Dutch primary education (age 12) is about the electronic calculator: "Students are able to use a calculator with understanding". The additional description "with understanding" means that the teaching should be focussed on developing such an attitude that the students can decide theirselves about the help of using the calculator in a specific arithmetical problem. The calculator is a very helpful tool in applications with difficult numberdata (decimals, percentages), but it is not useful if the student doesn't know how to organise a method of calculation. There are also lots of problems in which the use of a calculator could work in a counterproductive way (The train leaves A at 10.37. Arrival in B at 12.11. How long does this trip last?). At last, the students should not use the calculator for simple problems like 12,3 x 100 and 1002 - 999. Mental computation and estimation activities are highly recommended in the Dutch curriculum (age 6 -12). These abilities are important conditions for a sensible use of the calculator.

At the moment calculators with very specific functions have come into the market. Texas Instruments now recommends for primary education a calculator with more than 50 functions. We think that this is a too sophisticated and too complicated apparatus with respect to the goal, mentioned before. What we need for the Dutch situation is a simple four-function calculator, but with a display that represents the formula that has been typed in.

That is why Van den Brink, Moerlands, De Moor and Vermeulen have written a report, in which they state their arguments and make a proposal for a very simple model, as represented in the picture below (Vermeulen 2001). During this oral communication I will explain this report in some detail.

Literature
LEARNING TRAJECTORIES BASED ON PROTOCOLS
Willi Dörfler
University of Klagenfurt

A learning trajectory according to Simon (1995) is a theoretical design for a possible way of concept development of an intended learner. Using the notion of protocol as espoused in Dörfler (2000) such trajectories are designed for the concepts of permutation and discrete function or mapping. This is done by telling a narrative about a hypothetical student in an appropriate learning environment. A protocol of an action (actual or imagined) carried out by the learner is conceived of as a cognitive process which takes note of relevant steps, stages, conditions or outcomes of that very action. This is achieved by the learner through developing or applying graphic, diagrammatic or symbolic inscriptions which denote the aspects of interest of the action. Depending on the experience and available knowledge of the learner many different ways of producing a protocol and its inscriptions are possible. The guidance of a teacher will be helpful for arising interest in and focusing attention on the intended aspects and relationships created by the actions.

In the current case as actions are chosen the placing of books on different places and the rearranging of books on numbered places. This context can be enriched by asking how many ways there are in both cases for carrying out those actions. The learning trajectory now proceeds along the development of protocols and their inscriptions in a process of stepwise refinement and change of the means of the inscriptions. They are conceived to develop from verbal reports to lists of places and books, to tables and to arrow diagrams in both action contexts. The arrow diagrams can be seen by the learner as expressing an association of elements of one sort with elements of another or in the second case as describing a kind of movement on a set of elements. The focus of attention gradually shifts to the inscriptions themselves and their properties. Thereby the diagrams and symbolic expressions and the operations on them become the objects of investigation instead of the original objects and the actions upon them. The operations by the learner on these inscriptions constitute the core of the notion of a mapping between two sets or within one set. By this process the notion of a mapping gets related to the learner’s own activity thus avoiding the more common alienation of mathematics.

The usefulness of mathematics studies through the eyes of electronics college teachers.

David Feilchenfeld
The Hebrew University of Jerusalem

There is a wide consensus about the necessity of studying mathematics in favor of engineering and hi-tech. It is clear that understanding and implementing electronics, for example, are based upon conceptual understanding of mathematics, and the ability to contextualize it. This explains why electronics practical-engineers take some calculus topics as an essential component of their training. It is interesting to examine to what extent the mathematics course supports the electronics studies in a practical manner.

Learning mathematics without a cognitive commitment results in pseudo-conceptual or pseudo-analytical modes of behavior rather than in true conceptual understanding (Vinner, 1997). These modes of behavior resemble the behavior that results from true understanding so accurately that most people do not distinguish between them. They are characterized by two elements. In pseudo-conceptual behavior, actions are mainly based on association of words with other words, rather than on association of words with ideas. In pseudo-conceptual behavior words are used and actions are taken without going through any reflective procedure, or self-critique.

The mathematics is contextualized if data is processed with an orientation to an external phenomenon (Janvier, 1996). This is expressed when a decision made how to solve a problem can be based both on the algebraic and numeral content of an expression, as well as on the external-concrete content.

Five Israeli college electronics teachers were interviewed, and opened a window to the ways they see mathematics education as part of electronics practical engineering training. They compared the students’ knowledge with the knowledge needed, and pointed at the gap between them. They also pointed at the degree of instrumental behavior when solving problems. They argued against the lack of contextualization to their subject matter, and described the students’ anxiety when calling on an advanced mathematical topic. The poverty of mathematical knowledge was described as a consequence of pseudo-conceptual and pseudo-analytical modes of behavior. These modes of behavior led to anxiety related to advanced mathematical topics, to non-conceptual understanding, and above all, to uselessness of these studies regarding a large portion of the students.

References.

The work reported in this communication is part of a research project whose main objective is the building up of a local theoretical model of ratio, proportion and proportionality which enables the organization of the teaching of those mathematics contents from the first grades of primary school up. Such construction requires the characterization and integration of four main components: the formal competence component, the cognitive component, the communication component and the teaching component (Filloy, 1999). Freudenthal’s (1983) phenomenological analyses of the mathematical ratio concept has been taken as a starting point for structuring a formal competence model.

A didactical phenomenology has shown that an important role is played in the track towards the constitution of the ratio and proportion mental object by mental objects precursors of this mental object. A number of those mental object precursors have a qualitative character and involve ratio comparison as the context in which the equality of ratios, that is, the proportion can be given sense. A particularly important one is the mental object called “relatively” by Freudenthal which has been used by Fernández (2001) to design parts of a teaching model. The didactical sequences structured about the density concept emphasizing ratio unities, as well as its experimentation by means of two teaching interviews that constitute case studies is the theme of this communication.

The performances in a paper and pencil test of both primary students, a forth and a sixth graders, were characterized by a classification scheme (see for example Fernández and Figueras, 1999). That characterization enabled us to identify a performance tendency: the use of qualitative compensations (according to Lammon, 1993). The teaching model improved children’s knowledge in both cases. However, the fraction knowledge better mastery of the elder pupil provided a further understanding of density tasks as well as a more appropriate use of ratio unities.

How to teach (secondary) mathematics is a question of increasingly problematic nature. Appropriate methods courses and the student teaching phase of teacher education programs can provide prospective teachers with opportunities to face numerous challenges, such as becoming reflective practitioners and skillful questioners, listeners, and respondents to their students as well as diminishing their anxiety about mathematics teaching and improving their sense of self-efficacy in teaching mathematics. This study intends to analyze the extent of the impact of the methods courses at a large Midwestern university on student teachers': propensity for reflective thinking; questioning, listening, and responding skills; and perceived anxiety and self-efficacy towards teaching mathematics. Initial data suggested that, in general, the student teachers, whose conceptions about mathematics and its teaching and learning conform to the recommendations of the NCTM, hold a high sense of self-efficacy as well as a high anxiety level towards teaching mathematics. However, they have disparate opinions regarding the usefulness of their methods courses for their student teaching and their future life as teachers. Based on the analysis of the initial data, three student teachers will be selected to be observed in their classrooms and interviewed afterwards.

Selected bibliography:

WHERE TO WITH HIGH SCHOOL GEOMETRY?

Mariana Fourie & Hercules D. Nieuwoudt

School for Science, Mathematics and Technology Education, Potchefstroom University, Potchefstroom. 2520, South-Africa

E-mail: nwtmf@puknet.puk.ac.za

In South-African high schools where the emphasis is on formal Euclidean geometry, one often hears complaints from teachers and learners that geometry is difficult, boring and irrelevant, i.e. has no real-life application (Glencross, 1998). This is not just the trend in South Africa, but also part of a much-talked about topic worldwide, and researchers are constantly searching for solutions to the problems surrounding the teaching and learning of geometry. It seems that in most countries geometry education has entered a period of low tide. Even in those countries where geometry still maintains its former central position in school curricula, this seems to be owing more to the persistence of tradition, than to a careful analysis of the impact of formalist Euclidean style geometry teaching on the “mathematical culture” of contemporary learners (Mammana, 1998). Hansen (1998:20) believes that when selecting geometry content in the secondary school mathematics curriculum, it will become increasingly important to choose units of geometry that foster the “right” skills, abilities and attitudes for meaningful and useful (further) education. The question that needs to be addressed then is: What should be the aims and outcomes of geometry education in primary and secondary grades?

In an attempt to address this question, an investigation in the form of an email enquiry among identified international experts in the field (n=30) was done to determine what kind of geometry, and geometry teaching and learning should be done in the high school mathematics curriculum? From this, key perspectives emerged, which will be discussed in the presentation. For instance, transformation geometry must definitely be included in the curriculum (e.g. Glencross, 1998; Bartels, 1998; Mariotti, 1998); formal proof must have a place in the curriculum (e.g. Carroll, 1998); in countries where Euclidean geometry had to make place for transformation geometry, it was not always exactly the right thing to do (e.g. Pressmeg, 1998).

In view of the outcomes of the email survey, a field survey followed among selected teachers (n=147) in the Northwest Province of South-Africa to determine the extent to which current classroom practices were in compliance with the identified perspectives. Results, which will be discussed too, suggest that, due to inappropriate teacher training, little else than traditional practices were prevailing. As a change of a curriculum has to start at the teacher-level (Mammana, 1998), the question about appropriate school geometry-related training for teachers needs to be, and will be accounted for, again, in view of the gained perspectives.
A COMPARATIVE STUDY ON THE INFLUENCE OF DYNAMIC GEOMETRY SOFTWARE ON THE ACQUISITION OF BASIC GEOMETRIC NOTIONS

Thomas Gawlick, Hochschule Vechta, D-49377 Vechta, Germany

Background Dynamic Geometry (DGS) increasingly makes its way to the classroom. It is widely believed that its capabilities help learners to gain insights and develop heuristics. But one must also account for a computational transposition\(^1\) – for instance, Hölzl\(^2\) reports epistemological shiftings and increased cognitive demands as side effects of DGS usage. But his case studies have been criticized for being too demanding and not representative. Therefore it seems appropriate to investigate on a broader basis the impact of a more retentive DGS application on students' achievements in regular classroom situations.

Method At 3 senior high schools (one being a private school for girls), 12 lessons were taught in grade 7, developing basic notions like perpendicular or angular bisector from "real life" problem contexts. This was done either based on paper (P classes) or, by the same teacher, exploring "electronic worksheets" with DGS (C classes). In the control classes (V), ordinary lessons were given by the regular teacher.

Results Mean posttest achievements (adjusted by pretest) were about equal in P and C (and considerably higher than in V)\(^3\), but we found some distinctive features:
- in C, higher achievers profited more than lower achievers – vice versa in P,
- P was (significantly) superior to C for girls at the private school,
- C was somewhat more effective than P for girls at public schools, but considerably less effective for lower achieving boys, so C lay slightly behind in totals.

Also, differences in achievements and strategies between P and C occurred with "dynamic" problems, but surprisingly also with some "static" ones.

Discussion It seems that when dealing with standard examples, the benefits of dynamic exploration can easily be outweighed by the extra costs of DGS, so we confirm that dynamics is not a didactical advantage per se (Hölzl). The use of DGS should therefore be preceded by thorough consideration – it will be most favorable when an objective requirement for the tool meets an advanced mathematical experience.

The interplay of environment and gender with the effect of DGS seems new and deserves further attention. In coeducative classes, girls can profit from DGS treatment, but special care should be taken of lower achieving boys, especially to prevent them from using DGS just as a plaything.

\(^{3}\) This could have been expected, if one considers DGS just as media, as treatment is commonly believed to matter more than media, see e.g. Clark, R. (1983): Reconsidering research on learning from media. Rev. Educ. Res., vol. 53, p. 445-459.
Mathematics is a kind of language with its symbols, relations, and grammar. This language is perfect, abstract, universal and is used not only in the exact and the natural sciences. Mathematics is a very powerful tool in social sciences, liberal arts, arts and many activities of every day life. The aim of this paper is to show an humanistic approach to mathematics education as to increase motivation, satisfaction, interest and to reduce anxiety from learning this subject. Poetry uses also symbol systems, relations and grammar to express feelings, ideas and sometimes... axioms, theorems. A poem, like mathematics theorem, condense in few symbols - words, a whole idea. Omar Khayyam, the Persian mathematician, astronomer, philosopher and poet, wrote his "Rubidat" to express in four lines his opinion about meaning of life. In parallel he confront with the parallel postulate as with the third order equations, the binomial coefficients and with a new sun calendar (Franceschetti, 1999). Omar Khayam is one of some mathematicians that were involved in creative writing rather than in mathematics language. Hardy declared (1940) that mathematician's product is like the product of poet or painter. Russel (1903) wrote about the feeling of being more than human being, that can be found in mathematics as in poetry.

Ebn Ezra, Bachet, Dodgson ("Lewis Carroll"), Hamilton, Weistrass, Leibnitz, Kowalevsky and the P.M.E. member Shlomo Vinner are examples to the duality rather than dichotomy, between mathematics and poetry. Joining poems and historical background with features of the mathematicians-poets may introduce some interest, color, esthetic and also fun to the almost, but not always, monotonous, dull lessons. Demonstrations of poems will be presented during the short oral communication.

IMPROVING TEACHERS' CRITICAL THINKING IN A "ON LINE" GEOMETRY COURSE

Joaquim Giménez Rodriguez\textsuperscript{1} \hspace{1cm} Marcelo Almeida Bairral\textsuperscript{2}
Universitat de Barcelona, Spain \hspace{1cm} U. Federal Rural do Rio de Janeiro, Brasil

Introduction

The ability of teachers to develop better professional understanding is an evolving process presenting multiple faces and it's usually an "incomplete activity" (Ponte 1994). Professional development in a teacher practice is necessary for increasing metacognitive understanding about mathematical processes but other components will appear. Thus, in a research process, we want to analyze critical aspects (Smith 1991) of the situated (distributed) professional knowledge (Llinares 1998), and evolution of a critical thinking process (Kuhn 1999).

Developmental design.

Our developmental "on line" research framework and activity (Bairral, Giménez e Togashi 2000) is a part of a greater project for improving teacher training in geometry (for 11-14 years old students) developed since 2000 as a cooperation project by the Federal Rural University of Rio de Janeiro (Brasil) and Barcelona University (Spain). A group of teachers followed a distance-telematic learning course of about 50 hours in sixth months by using a diversity of teleinteractive tools: email, discussion list and collaborative chats.

A case study is conducted with two of the teachers in order to (1) characterize some specific issues in this "on line" activity and (2) proposing a model for the critical component of a professional knowledge by means of an internet training experience.

Rationale and results

The initial, intermediate and final slots of the course were considered as data. We observed all registrated teachers' communications in the course tasks, collaborative lists, narratives and self-regulation enquiries at the end of each lesson. Two semi-structured interviews and text writings were also used and videotaped experiences of their classroom activity has been analyzed in order to recognize their changes-in-action.

The study reveals the importance of meta-strategic, metacognitive components (Kuhn 1999). In fact, semantic text analysis shows (i) affective influences as an important issue for development of professional critical thinking and (ii) specificity on the epistemological geometrical perspective. Eventhough just descriptive level was a starting point for many teachers, some of them could exhibit through the course, pseudoepistemological view when confronting geometrical situations in the on line environment.

COMPUTABLE REPRESENTATION OF CONTINUOUS MOTION IN
DYNAMIC GEOMETRY ENVIRONMENTS

María José González-López
University of Cantabria (Spain)
glopez@matesco.unican.es

In compulsory education, geometry is presented as a model to organise the physical environment, including considerations on the motion of objects in space (through the geometric transformations). Besides, we use drawings to represent, at the same time, geometrical concepts and physical objects, and the dynamic geometry environments give us the possibility of moving the drawings on the screen. This feature is used to promote in students the construction of geometrical knowledge from exploration and conjecture activities (Laborde, 1998) and has consequences on the behaviour of the users and their reasoning style (Hölzl, 1996).

In this work we analyse to what extent the computational model of the geometry implemented in a dynamic geometry environment provides models for continuous physical motion. In particular, we go over the utility of dynamic geometry environments to simulate the motion of mechanical linkages, as this activity allows us to compare, by means of dynamic drawings, the computable representation of geometric properties with the real motion of a mechanism.

Analysing a simple example, we provide foundations for the particular behaviours observed in the motion of a picture on the screen, which require a subtle interpretation to be understood in a purely physical context. This approach allows us to go deeply into the particular relations existing between the different contexts that come into play: physical, geometrical and computational. In this way, we reflect on the new epistemological and didactic questions derived from the computable representation of the knowledge (Balacheff, 1994).

We consider this work to be a previous step to deduce didactic consequences on the students’ perceptions of the moving drawings; in particular those concerning the uses of the dragging mode as a tool not only for automatic drawing of many instances of the same construction, but also to produce continuous motion.

REFLECTIONS FROM TWO-DAYS SEMINAR/WORKSHOP ON USING CALCULATORS IN TEACHING OF ELEMENTARY SCHOOL MATHEMATICS

Hulya Gur, Gozde Comlekoglu, Yasar Ersoy

The result of many studies point out that the hand-held personal technology such as calculators are the cognitive tools that must be used in mathematics classes. To have the widespread use of technology and effective mathematics learning, the teachers should be aware of the recent development, e.g. I^4 (introduction, integration, implementation and issues on using information and communication technology) in mathematics education (Ersoy, 1997). Therefore, a two-day teacher training seminar and workshop for pre-service and in-service teachers were organised with the participation of various groups of people at Balikesir University in Turkey. This activity is, in fact, a part of an ongoing project, which was conducted and coordinated by the director of the project, and namely Technology Supported Mathematics Teaching, and by local Directory of Ministry of Education.

In the present study, a group of teachers’ and teacher trainees’ perceptions of using calculators in mathematics instruction is searched, and their views were reflected to some extent. The planned activities were programmed and scheduled as seminar and workshop for the participation to teachers of maths. In the seminar part, information on the integration of calculators in mathematics instruction and the recent developments in the implementation were summarised and discussed. After the seminar, workshops on elementary school level mathematics were organised, and various topics in four sessions studied and discussed. At the end of the workshop a questionnaire about the use of calculators and teaching/learning mathematics was conducted by the sample of 90 teachers and 120 teacher trainees. Then a panel was organised in which the teacher and teacher trainees reflected their ideas, beliefs about calculators, mathematics education and the main issues.

The statistical analysis of the designed questionnaire is in the process, and some results have been obtained. The first result shows that although the teachers and teacher trainees had negative opinions about the use of calculators in mathematics instruction and student-centred activities at the beginning of the seminar and workshop, their attitudes and beliefs were changed towards positive at the end. The detail of two-days seminar and workshop will be reported, and teachers’ and teacher trainees’ perception and views will be reflected in presentation of the paper.
The graphing calculator with its multi-line screen served as a tool of exploration in a week-long sequence of activities developed around the "Five steps to Zero" problem.

"Take any whole number from 1 to 900 and try to get it down to zero in five steps or less, using only the numbers 1 to 9 and the four basic operations +, -, x, ÷. You may use the same number more than once."

The classes of Secondary 1, 2, and 3 students, aged 13-16 years, participated. The analysis focused on the interaction between the epistemological power of the technology and the emergence of mathematical strategies. In all three classes, the main initial strategies observed were S1: Decrease or increase the number so that it ends in 0 or 5, and then divide by 5, and S2: Decrease or increase the number to bring it to the form abc such that one can identify a divisor of abc, either from ab or from bc. For Secondary 1, S2 gained in importance over the study. For Secondary 2, S2 became more complex; furthermore, many students moved toward S3: Decrease or increase the number to make it divisible by 9. For Secondary 3, S3 became the dominant strategy.

The multi-line-screen calculator, with its suppression of calculation details, thus keeping a proximity--physical as well as temporal--between the numbers and results of the operations, served to heighten students' number sense along several important dimensions. But it played a different role at each grade level. For Secondary 1 and 2, the calculator was used as a tool for calculating and as a medium favoring the formulation of conjectures. Reasoning in a local manner, these pupils based their judgments on an analysis of the form of the numbers. In contrast, for Secondary 3 pupils, who reasoned in a global manner, it also served as a search tool. This allowed them to develop more powerful algorithms than were seen in Secondary 1 and 2.

LEARNING MATHETMICS IN SMALL GROUPS: CASE STUDIES FROM PAKISTAN

Anjum Halai
Aga Khan University, Karachi, Pakistan

As part of my D. Phil. research, I investigated the role of social interactions in students’ learning of mathematics. The research methodology was qualitative in nature. Over a period of nine months I observed two small groups of students as they did mathematics in their respective classrooms in Karachi, and recorded the social interactions on videotapes. To follow up on issues arising from the classroom observations, students were interviewed under stimulated recall. During these interviews students were also set mathematics tasks similar to the ones used in the classroom. Grounded theory procedures (Strauss & Corbin, 1998) were used in analysis of data.

Preliminary findings from one case, indicate that the socio cultural norms being constituted and stabilised in the classroom, in turn constituted and stabilised mathematical norms where mathematical norms were criteria of values for mathematics activities. For example, the classroom organisation of working at mathematics tasks in small groups, preceded by some introductory work by the teacher and followed by presentations to whole class, was very consistent across the lessons observed. The social norms were that students were expected to explain their solutions to others, give reasons for their thinking, and make sense of other’s explanation. As different groups presented their work using varied approaches to the solution, a mathematical norm being stabilised was that there could be more than one solution to a mathematics problem. This had implications for mathematics development in the classroom community.

Moreover, the teacher’s effort to ensure individual accountability in group work led to qualitatively different patterns of interaction in the group with further implications for students’ learning.

The study also revealed that students’ responses were different to mathematics tasks with the same content but given under different social settings that of the classroom and of the interview. Thus raising deep and intangible questions about the processes involved in learning.

MATHEMATICS ANXIETY IN ACTION
Markku S. Hannula
University of Helsinki, Department of Teacher Education

Anxiety is an unpleasant emotional state of fear. It is directed toward an unwanted possible future outcome, and is typically out of all proportion to the threat. Mathematics anxiety is anxiety in mathematical situations. It is related to general anxiety and its sub-constructs (e.g. test anxiety). (Hembree, 1990)

Experimental psychology has concluded that anxiety biases cognitive processing. Attention is biased towards threatening information, and judgments towards more threatening alternatives. There may be also memory bias towards threatening information. All this leads to impaired performance in cognitive tasks. (MacLeod, 1999)

I shall present a case study of one classroom interaction that illustrates the role of anxiety in the interaction between teacher and student. The student was an exceptionally well-behaved girl and rather quiet in the class. She was a diligent worker, yet she achieved below average in tests. For Helena, mathematics was characterized by strong negative emotions. She did not, however, express these emotions in the classroom. The severity of her negative affect became apparent first in an interview.

Helena: Mathematics makes me at least so quite anxious ... and agonized and distressed. ... mood goes really down or you start ((to think)), depressed, that 'I don't understand this again'. Then just wait for the next exam horrified ... For me, that ((problem solving)) is exactly what makes me feel anxious, and then sort of, like, in a way, somewhat unpleasant feeling that sort of: 'Am I stupid or what - or feeble-minded?' - 'coz everyone else can solve this. So, why can't I?

I shall present and analyze in detail a teaching interaction between Helena and her teacher. During one class, the teacher spent 15 minutes helping Helena. When teacher and Helena had finished the task, Helena had not learned to do the task. Instead she was feeling incompetent and frustrated.

The case study is a good example of unsuccessful interaction. Interaction with anxious pupils is more difficult than with normal pupils because of their biased attention and judgments. Anxious pupils need a learning environment where they can feel safe.

Instruction to use a graphic calculator to solve problems in a context of secondary vocational education

Dirk J. Hoek & Gerard Seegers
Leiden University, The Netherlands

Mathematics education is gradually changing from teacher oriented instruction towards student self-regulated learning. Co-operative and collaborative learning are increasingly emphasised as effective learning environments. This means that both the learning context and the didactics for teaching mathematics are changing, emphasising that students have to plan, to discuss and construct their own knowledge.

Beside the context of the learning situation the content of mathematics is also changing. In the Netherlands a new mathematics curriculum has been implemented, in which the use of a graphic calculator is more or less integrated in the booklets. The graphic calculator is integrated in the new mathematics curriculum because it is expected that the use of a graphic calculator in a setting of co-operative, small group work will improve students’ flexibility in solving mathematical problems in an engineering context.

To investigate this hypothesis teachers of four schools of secondary vocational education are being supported in using the graphic calculator as a problem solving and learning tool and for applying mathematics as well as in guiding small group work. We try to describe the possibilities and obstacles of instruction in this learning environment. Students’ discourses are analysed while they are working collaboratively. Videotapes are used to write down verbatim protocols. Preliminary qualitative analyses of verbatim protocols and observations show that students mostly use their graphic calculator as a computational tool. However, during a whole class instruction and discussion the graphic calculator stimulates discussion between students. Especially when the teacher asks challenging questions about different mathematical phenomena.

On the basis of the protocols, the interviews and the field notes conclusions are drawn and recommendations are formulated. Finally we will discuss some implications for the use of the graphic calculator as an integral part of mathematics education.
COMPUTER SIMULATIONS IN MATHEMATICS EDUCATION
Ronit Hoffmann
Kibbutzim College of Education, Israel

Many educators agree that a more extensive use of computers in school in general, and in mathematical education in particular, is desirable. The NCTM standards (1989) recommended this over 10 years ago.

In this presentation, I will present a teaching module (Hoffmann, 1996), meant for teachers intending to teach in the higher grades of elementary school and/or the upper grades in high-school.

To demonstrate the teaching module I will describe The Monte Carlo simulation for area approximation, focusing on the computation of the area of a unit circle (a topic taught in the 6th grade in Israel), which leads to the approximation of the number \( \pi \). (Hoffmann, 2000). The term “Monte Carlo method” is general in nature. It refers to numerical methods based on probabilistic or randomized algorithms, which use elementary statistical methods, allowing rapid approximate solutions for problems for which computational solutions are either not known or are inefficient (Harel, 1992). Monte Carlo methods are used in various fields of computational science: economics, statistics, nuclear physics, chemistry, biology, mathematics, and the like.

In my talk I will show how modern day technology enables embedding this topic within the school curriculum. I will review our experience in teaching the topic to a variety of populations in teacher education. The following data will be presented: (a) algorithms written by students; (b) the numerical output received using the Excel spreadsheet; (c) a mathematical graphic presentation of the convergence to the approximate area; (d) a visual presentation clarifying the process as a whole; (e) the “Buffon’s needle” simulation (Breuer & Zwas, 1993); (f) some simulations in basic probability.

The students in all the classes engaged in this module with great enthusiasm and interest. The topic created opportunities to discuss important mathematical concepts such as: area; probability; the use of simulation; approximations. In addition, the students were introduced to yet another facet of computer use in mathematics, and were lead to experience mathematical studies from a new perspective.

CONSTRUCTING PROCEDURES AND CONCEPTS IN THE CLASSROOM – ADDITION AND SUBTRACTION UP TO 100

ALENA HOŠPESOVÁ, UNIVERSITY OF SOUTH BOHEMIA, CZECH REPUBLIC

Children learning in mathematics can be taken as a specific activity constructing cognitive structures (various relationships between real situations, their models, and mathematical notations etc.) in children’s minds (Ku ina, F. [2]). Various interpretations of concepts, models and visual aids support the understanding of the concepts and processes in a determined way. For illustration this idea an introduction of addition and subtraction up to 100 will be used. The nature of children strategies will be described in the framework of theory of procept (Gray, Tall [1]).

The organisation and framework of the study:
We conducted an experimental education in 4 classes (children aged 7) where different teaching materials were used. Starting points for the study:
- in teaching children the teacher usually come out from the textbook – it means they use the same representations;
- children will be given the opportunity to create and use their own strategies, because they are able to introduce new procedure of addition and subtraction up to 100 without any explanation of the teacher. This promotes understanding and creation of procepts.

Questions of the study: What strategies do children use in mentally adding and subtracting up to 100 in respect to the aids used mainly in the classroom?

What nature have these strategies from the point of view of creation the procept?

Conclusions:
- Pupils are better motivated to learn when teaching builds on their own strategies.
- Paying attention to relation between the learning aid, procedure and concept is necessary. Various tools are essential to carry out activities but they do not lead direct to creation of the processes, concepts or procepts.
- When pupils learn to co-ordinate systems of signs, with their activity, their reasoning system becomes more powerful (more efficient, faster, less subject to distraction).

PME25 2001
Several years ago Shaughessy (1992) emphasised the close ties between the two areas of research I consider here, stochastics (probability and statistics) and problem solving. He also pointed out the unfortunate situation of teaching probability and statistics in primary and secondary schools, citing one of the possible issue that hinder the effective teaching of stochastics the preparation of the mathematics teachers.

The Cave problem is a problem I used as a context in teaching and learning probability and statistics in training primary and secondary teachers. The problem-situation talks about 27 explorers that are into the cave in a randomise situation. There are three paths into the cave but only one let a explorer to leave the cave in one hour walking, but not the other two paths, coming back to cave inside after 2 days and 3 days walking. Each explorer has meals for 6 days as maximum. The question is how many explorers will leave the cave?

As we know, problem solving can be situated in several worlds (Puig, 1996). One of them considers problems in relation to the mathematical sign systems (MSS) (Filloy, 2001) with which they are solved. In this context, learning probability and statistics is seen as a process to gain competence in continuos strata of the MSS that solve this problem or others. Teaching probability and statistics, consequently, will organise the step from a stratum of the MSS to a new stratum of the MSS from which the first is seen as more concrete and with which what was previously describe as separated or unconnected is described the same way, and therefore, are produced as new concepts and new signs.

In solving Cave Problem I identify three strata of the MSS mentioned. The more concrete one uses signs from the play that solves the problem. The intermediate one uses signs from the representation systems and associated rules and, finally, the more abstract one uses signs from the more formal representation in mathematics. The use of each stratum can be associated to learning process at different school levels: primary school, secondary school and college.

There is a national policy in Zimbabwe to address all the issues of gender equity. However in the education field, national statistics still show that more girls than boys drop mathematics, before completing secondary school (Dhliwayo et al 1996). This study investigated the extent to which the attitudes of girls and boys towards mathematics differ at primary (Grade Seven) and secondary (Form Four) school levels in Harare. In his research on gender-related and achievement-related beliefs in mathematics, Risnes (1998) found that boys displayed more positive motivating and achievement-related beliefs girls.

Two primary and two secondary schools were randomly selected in Harare. In each school, one Grade Seven class (primary school) and one Form Four class (secondary school) participated in the study. Two questionnaires were administered to Grade pupils and to Form Four pupils respectively. The questionnaires were used to survey the students' attitudes towards mathematics. The results showed that more Form Four male and Grade Seven female pupils find mathematics enjoyable and interesting than the Form Four female pupils. Similar results were observed about the level of participation in mathematics lessons and not fearing the subject. It was observed that more Form Four boys and Grade Seven girls indicated that they are good at mathematics and denied being poor at mathematics than did their Form Four female counterparts. In another set of results more Form Four male and Grade Seven female pupils claimed that mathematics was their favourite subject than the Form Four female pupils. In contrast fewer Form Four male and Grade Seven pupils indicated that mathematics was their most difficult subject than the Form Four female pupils. In all the cases Grade Seven male and female pupils gave similar responses.

The study concluded that there was evidence that more Form Four male and Grade Seven female pupils have a more positive attitude towards mathematics than the Form Four female pupils. However this difference was not apparent between Grade Seven female and male pupils. My conjecture is that in the Zimbabwean culture, maturation and gender socialisation may contribute to the decline of positive attitude towards mathematics observed in senior girls. For example, girls do more household chores than boys and this may reduce their preparation time for lessons. Further research should investigate this conjecture since it may not be true in other cultures.

There are many teaching/learning problems surrounding the concept of function. These are bound up in the complexity of its history which are reflected in the partial or distorted views of the concept held by students as well as in the difficulties they meet as shown in various studies on the matter (we cannot give here any reference). We believe that in order to develop a true knowledge of a subject, it is necessary for the student to distinguish between mathematical concepts and their representations. Our hypothesis is that only through the co-ordination of different representative registers (verbal, tabular, algebraic, graphic) of a function the pupils can move flexibly and consistently between variational/qualitative and pointwise approaches to the function, even if the graphic level clearly plays a fundamental role.

What we shall present is a fragment of a wide research developed in this frame. We shall concentrate on the results of some experiments, carried out mainly in 7th and 8th grade, which concern the recognition and the qualitative interpretation of graphs relating to physical phenomena not associated to formalised rules, for what they express compared to the variability of the magnitudes in question. In particular, we shall look at the main concepts and difficulties encountered by pupils by analysing their work on the co-ordination of the graphic representation of a given phenomenon and the character of the same phenomenon when expressed verbally or which derives from the relative interpretation. An example of these activities is below.

The following table refers to a parachutist’s free falling jump from an aeroplane:

<table>
<thead>
<tr>
<th>time (s)</th>
<th>0</th>
<th>5</th>
<th>10</th>
<th>15</th>
<th>20</th>
</tr>
</thead>
<tbody>
<tr>
<td>height (m)</td>
<td>3000</td>
<td>2875</td>
<td>2500</td>
<td>1875</td>
<td>1000</td>
</tr>
</tbody>
</table>

a) how high is the plane the moment you start the drop?  
b) how many meters lower was the parachuter after the first 5 seconds?  
c) one of these drops describes the drop. Which? Why?

The results about the pupils’ real understanding of the meaning of a given graph, from the observation of its tendency, confirm the foreseen difficulties of reading if not preceded by activities of effective construction. In particular, pupils confuse increasing and decreasing development patterns, especially in the case of non-straight lined graphs. As far as we have been able to observe in the course of their studies, these difficulties persist substantially into the third year of middle school, even when the pupils have been introduced to further graph-drawing activities starting from functions given to them in the form of algebraic formulation.
RECOVERING A POSITIVE ATTITUDE TOWARD MATHEMATICS IN 
FUTURE ELEMENTARY TEACHERS 

Donatella Iannece - Roberto Tortora

Dipartimento di Matematica e Applicazioni - Università Federico II di Napoli - Italy

For the first time, in Italy, future elementary teachers follow universitary courses, where, however, the mathematical and scientific formation is confined in a few terms. Moreover their mathematics is usually badly structured and felt as extraneous. So, we believe that the crucial task is to help students to recover a sense in doing mathematics, namely, to radically modify their conception of this discipline and to transform their initial hostility into motivation and interest.

History tells us that mathematical notions were invented and gradually sharpened in order to give sense and structure to reality. There is a continuous link among the observation of phenomena in the physical world, their representation in mathematical form, the development of mathematical structures and of scientific language, and again an outcome in the comprehension of real world (Israel, 1996). Moreover the two processes of mathematical abstraction and formalization and of physical modelization appear as different sides of the same coin.

Our teaching activity utilizes this relationship between mathematics and physics, as a powerful didactical resource, both from the cognitive and the motivational points of view. So, the abstraction process comes from two problematic contexts: the first one concerns mathematical “objects”, their properties and behaviours, as for example in (Tall, 1992) and (Arcavi, 1994); the second one starts from everyday experience or simple physical phenomena (Polya, 1954). In both cases special attention is devoted to the development of mathematical language, which expresses and supports the development of scientific knowledge.

This strategy naturally brings to view mathematics as an activity (Freudenthal, 1991), and moreover makes the abstraction process from reality to mathematics resonant with natural cognitive processes (Guidoni, 1985).

A special metacognitive tool is what we call the “logbook”: in this personal diary each student records her/his individual understanding percourse (exercises, achievements, personal comments, etc.). The awareness of the growth in knowledge turns out to be a source of intrinsic satisfaction (Bruner, 1996).

In the communication, we will report some examples of our activity and of the achievements of our students (in our opinion, quite satisfactory).

Flexible Spaces of Language
Marit Johnsen Høines, Bergen University College, Norway

'Flexible Spaces of Language' reflects
- dialogical concept of knowledge
- perspective on learning
- reflections on interaction according to the dialogisity.

The background for my study has been earlier work done on the richness and variation in children's use of language when solving problems in school and in their 'daily-life'. By use of Vygotsky's theory I focused on the function of language in the learning processes. The translation link was seen as a tool for making "new languages", as mathematical symbolistic language, as a tool for thinking. When I focused on the manifold of children's 'own language' it became clear that it is an educational challenge to facilitate the learning process by making it natural for the children to use 'their languages' in the processes of leaning more mathematics. This was seen as a background into which we could introduce or offer formal and 'authorised' languages, in order to obtain students developing ownership of the formal language. (Johnsen Høines 1998, Mellin-Olsen 1987)

The data in my present study emerge from a learning situation where teacher students are working on calculus. Analysing the data and reading Bakhtin widened my concepts of texts, utterances, voices and dialogisity. It helped me to get insight into a field of learning characterised by manifold, complexity and movement. The multiplicity of voices in utterances that are written, drawn, said or uttered in other ways by students or by other, got visible. The different voices are, however, not enough to create meaning in this respect. According to Bakhtin, it is the tension and struggle between them that create understanding. (Dysthe 1999:76). It is about how our understanding is constituted by understandings and how it is a consequence that there would not be an explanation without interactive explanations, without multiplicity of voices.

I got, by focusing on one situation, insight into a Bakhtinian concept of knowledge. I have arguments I would not have had without this insight: It is about dialogisity knowing. It is about intentional and dialogisity learning.

As an outcome of this presentation I would like a focus on:
- How do we see the educational challenge represented by 'flexible spaces of language'?
- How do we see interaction according to the dialogisity?
- And - how to interact with the teachers practice?

FIRST RESULTS OF A STUDY IN DIFFERENT MATHEMATICAL THINKING STYLES OF SCHOOL CHILDREN

GABRIELE KAISER, RITA BORROMEO FERRI

UNIVERSITY OF HAMBURG

First results of an empirical Study of different styles of mathematical thinking of teenagers (9th and 10th class) will be represented. In connection with the empirical Studies by Leone Burton (1997) on practising mathematicians by means of a classification attempt by Felix Klein (1892), the following thinking styles are distinguished: • Visual thinking style • Analytic thinking style • Conceptual thinking style. Single mathematicians change between several thinking styles, but nevertheless one style is dominant.

It shall be investigated, how far the recognised styles of mathematical thinking of the practising mathematicians can be reconstructed with school children or, how far other thinking styles can be distinguished. This study is laid out as a quality oriented case study based on the following design: Pairs of female or male pupils will be video-taped while working on mathematical problems. Then the problem solving processes carried out by the pupils and the underlying thinking style will be documented by means of the method of stimulated recall and an interview which will be recorded by audio-tape. In the following the video and audio recordings will be transcribed and analysed by categories which still have to be developed. A central point of this design are the problems itself, originating from different mathematical topics which need different problem-solving strategies (e.g. graphic-visual strategies, numeric strategies, algebraic-algorithmic strategies, trial-and-error methods.). By this the use of different thinking styles shall be stimulated.

Within the framework of school teaching this study is of highly explosive nature: Generally, a teacher has his own dominant style of mathematical thinking, that normally he is not conscious of, and this style is underlying his school lessons and simultaneously structuring it. School children and teenagers, using other thinking styles than a teacher, have – this must be expected – clearly more difficulties with the lessons than those using thinking styles which are similar to those of their teachers. In order to provide all teenagers the same proportion of participation in the lessons, and to give them the same chances, those different thinking styles must be made conscious, so that one can handle them in a conscious way.

EFFECTS OF TEACHING FOR DEVELOPMENT OF METACOGNITIVE ABILITY — CLASSROOM SESSIONS —

Hisae Kato
Hyogo University of Teacher Education, Japan

SUMMARY
The purpose of this paper is to investigate the effects of teaching for developing of metacognitive ability. This experiment involved fourth grade 2 classrooms (experimental classroom and control classroom). Classroom sessions were carried out for the both by same teacher used same problems. But it was the differences of both classrooms’ situations that were the teacher’s activities and the work-sheets used on the sessions. In the experimental classroom the teacher promoted the children to do metacognitive activities through the framework of teaching for development of metacognitive ability (Table 1). Instead, a pretest and posttest were carried out for all children.

The main findings of this investigation are the followings :
- Both metacognitive and cognitive growth of the experimental classroom are higher than those of the control classroom
- In the posttest, some children in the experimental classroom did some metacognitive activities that they had not done in the pretest

METHOD

Classroom Session Table 1 is the framework of the teaching of the experimental classroom. It is based on Schoenfeld (1987) and others.

Pretest and Posttest In the tests, each child was asked to solve the problem on the work-sheet and to answer the stimulated recall questionnaire. The work-sheet was used to analyze his/her problem solving process, and the stimulated recall questionnaire was used to represent his/her metacognitive activities.

Analysis These problems of the pretest and posttest were the same. Then from the tests, children's metacognitive growths and cognitive growths were respectively identified as followings.

Metacognitive growth is defined as
\[ \text{[the number of his/her metacognitive activities on the posttest]} - \star \text{[the number of his/her metacognitive activities on the pretest].} \]

Cognitive growth is defined as
\[ \text{[the marks at his/her work-sheet on the posttest]} - \star \text{[the marks at his/her work-sheet on the pretest].} \]

The results of teaching will be reported in this presentation.

DIRECT OR INVERSE RATIO PROBLEMS- DOES IT REALLY MATTER?

Ronith Klein
Kibbutzim College of Education, Israel

In recent PME papers we described a workshop that was specifically designed for enhancing teachers' knowledge of students' ways of thinking. This workshop focused on students' misconceptions, possible incorrect responses and their sources and presented theories and research findings concerning students' ways of thinking (e.g. Klein & Tirosh, 2000).

During the workshop it became obvious that teachers were using and teaching almost only mapping tables as means for solving specific word problems, without considering the appropriateness of such a procedure. They believed that such a technical and automatic way always works well. We challenged the automatic use of mapping tables by presenting participants with both direct and inverse ratio problems. Most teachers did not identify inverse ratio problems as such and consequently arrived at incorrect solutions when using mapping tables. We used the teaching by conflict method (Swan, 1983) in order to raise teachers' awareness of the correct use of the mapping tables procedure.

In the short oral presentation we will describe the problems we used during the workshop, teachers' responses and their beliefs. Our data supports research findings that change in teachers' knowledge without change in teachers' beliefs is not significant. After the workshop teachers beliefs were only slightly changed and they still supported the automatic use of mapping tables. These findings are in line with former research demonstrating inflexibility in teachers' understanding of ratio concepts (Klemer & Peled, 1998).

COUNTER EXAMPLES AND CONFLICTS AS A REMEDY TO ELIMINATE MISCONCEPTIONS AND MISTAKES: A CASE STUDY

Sergiy Klymchuk
Auckland University of Technology, New Zealand

This case study deals with typical students' misconceptions in first-year university engineering mathematics courses. Unfortunately sometimes those misconceptions were caused by mistakes and mathematical inaccuracies in textbooks. In order to eliminate misconceptions and correct mistakes counter examples were used. The students were given the extracts from their textbook containing mistakes and were asked to give counter examples. They had enough knowledge to do that. However, for most of the students that kind of activity was very challenging and even created psychological discomfort and conflict for a number of reasons. Some of the reasons were consistent with findings from another study of the author (Klymchuk S, 1999).

In this study, practice was selected as the basis for the research framework and, it was decided 'to follow conventional wisdom as understood by the people who are stakeholders in the practice' (Zevenbergen R, Begg A, 1999). The theoretical framework was based on Piaget's notion of cognitive conflict (Piaget, 1985).

Below are some examples of bad mistakes from the textbook (Bolton W, 2000) that were used in the study:

- 'With a continuous function, i.e. a function which has values of y which smoothly and continuously change for all values of x, we have derivatives for all values of x' (p.332).
- 'If \( \frac{dy}{dx} = 0 \) then y is neither increasing nor decreasing' (p.353).
- 'At a maximum \( \frac{d^2y}{dx^2} \) is negative and at a minimum positive' (p.353).

Eighty students were questioned regarding their attitudes towards the method of using counter examples to eliminate misconceptions. The majority of the students reported that the method was strong, effective and successful.

A THEORETICAL FRAMEWORK FOR EXAMINING DISCOURSE IN MATHEMATICS CLASSROOMS

Eric Knuth, University of Wisconsin-Madison
Dominic Peressini, University of Colorado-Boulder

The purpose of this session is to present a theoretical framework for examining discourse in mathematics classrooms that draws upon work from outside the body of mainstream mathematics education literature. Specifically, we draw upon Mikhail Bakhtin's notions of speech genre and voice (see Knuth & Peressini, in press). Bakhtin (1986) posited that discourse can be characterized—in terms of speech genres—by the nature of its utterances: "A speech genre is not a form of language, but a typical form of utterance.... Genres correspond to typical situations of speech communication, typical themes and, consequently, also to particular contacts between the meanings of words" (p. 87). Bakhtin differentiated between different types of speech genres in terms of the degree to which one voice can come into contact with and interanimate another (Wertsch, 1991). According to Bakhtin, true understanding results only when the voice of a listener comes into contact with and confronts the voice of the speaker, that is, through the interanimation of voices. Yet, the degree of interanimation of voices—and thus the understanding developed—may differ depending upon the nature of discourse in which the interlocutors engage.

Using this framework, we explore the theoretical underpinnings of discourse and how discourse actually functions in mathematics classrooms. We then address possible ramifications of these different functions of discourse in mathematics classrooms. In conclusion, we discuss a variety of issues that have arisen as we have used this theoretical framework as well as considerations for future research.

TEACHING MATHEMATICS METHODS COURSES TO PROSPECTIVE ELEMENTARY SCHOOL TEACHERS: FIVE YEARS OF REFLECTION

Hari P. Koirala
Eastern Connecticut State University, USA

In the last decade, researchers have shown a great deal of interest in the study of learning to teach prospective elementary school teachers. They have reported that there is often a conflict between what the university teacher educators want to teach in their methods courses and what prospective teachers want to learn (Katz & Raths, 1992; Nicol, 1999; Wineburg, 1991). Mathematics teacher educators usually want to engage prospective teachers in theory-based teaching approaches. Prospective teachers, on the other hand, usually want to be told "best practices" of teaching. These conflicts create dilemmas and complexities in classrooms. This presentation describes such a conflict that this author has consistently experienced in the teaching of mathematics methods courses to prospective elementary school teachers.

This study was carried out within a framework of case study research. The data for this study were collected from seven groups of elementary mathematics methods courses that I taught over a period of five years. In order to prepare this presentation I reviewed my course materials and analyzed them using a qualitative approach.

The data indicate that prospective teachers often wanted a collection of activities, lessons, and units in order to use them in their future classrooms. They wanted to make sure that I cover the curriculum by giving them enough activities from each content area. However, my feeling was that the carrying out of activities without proper philosophy is superficial and cannot get prospective teachers into inquiry and analysis. I wanted to cover only a fewer topics with appropriate theories and philosophies while prospective teachers wanted to cover more topics eliminating the time for theories. Basically I wanted to emphasize the depth and the prospective teachers wanted a breadth of activities.

DETECTING VISUAL CHARACTER OF THE ISOSCELES-TRIANGLE SCHEMA
Eugenia Koleza, Elisabeth Kambani
Department of Primary Education, University of Ioannina

The purpose of this research is to investigate the relation between a perceptive and an interpretive treatment of a simple geometric figure. A figure is more than what is initially stated in the building instructions and the surplus is not immediately visible but requires a mental reconfiguration. This heuristic approach permits the connection of different concepts under the cognitive construction of a geometric schema, in our case: the Isosceles-Triangle Schema (ITS).

A concept-understanding schema combines information about concept-image and concept-usage (Moore 1994, Chinnappan 1998). This information follows from a treatment of a geometric figure in two levels: The level of gestalt-apprehension and the one of operational apprehension (Duval 1995). Both treatments may be analyzed in the wider context of visual imagery. Our study aims to trace the 10-grade students' ITS on the basis of their responses to recognition and construction activities demanding different types of imagery as these are defined by Owens and Clements (1998).

The participants were 63 students (31 high achievers and 32 low achievers) who, according to curricula, had been taught geometry in a deductive level for a year.

The language used by the students in order to explain the way of acting was used as a tool of analysis of their conceptual schemata. The analysis of students' responses showed that a successful mathematical treatment of a geometric problem does not assure that students are also capable for a successful conceptual treatment. We have observed a tendency for overgeneralization of the application field of some basic mathematical concepts, but also a tendency for limitation of the operational treatment of the geometric figure on the base of quantitative relations at the expense of qualitative ones.

References
- Duval, R:1995, Semiosis et pensée humaine, Peter Lang
The purpose of the present study is three fold: (a) to investigate the effects of metacognitive instruction versus worked-out examples on students’ mathematical reasoning and mathematical communication; (b) to examine the extend to which the two methods exert different effects on group problem-solving behaviors; and (c) to compare the long-term effects of the two methods on students’ mathematical achievement. Both the metacognitive instruction as well as the worked-out examples were embedded within cooperative learning settings.

Worked-out examples specified all the steps needed to solve the problem and provided complete explanation regarding the sequence of actions required. The metacognitive instruction was based on the IMPROVE method (Mevarech & Kramarski, 1997) implementing metacognitive questioning in small groups. The metacognitive questions focus on: (a) the nature of the problem/task (b) the construction of relationships between previous and new knowledge; and (c) the use of strategies appropriate for solving the problem/task.

The study was conducted in two academic years. Participants for the first year of the study were 122 eighth-grade Israeli students who studied algebra in five heterogeneous classrooms with no tracking. In addition, problem-solving behaviors of eight groups (N=32) were videotaped and analyzed. A year later, when these participants were ninth graders, they were re-examined using the same test as the one administered in eighth grade. Within cooperative settings, students who were exposed to metacognitive instruction outperformed students who were exposed to worked-out examples on both the immediate and delayed posttests. In particular, the differences between the two conditions were observed on students’ ability to explain their mathematical reasoning during the discourse and in writing.

REFERENCES
Mistakes by pupils and teachers/researchers are often treated as crime in the case of pupils and not even recognised in the case of teachers/researchers. In this research we attempt to show that 'everyone can learn by their mistakes'. If the teacher/researcher undertakes self-reflection critically of the work they have done with students then this will show where mistakes occur, which might hamper the student’s thinking.

Research

We will present examples of self-critical reflections of our own experimental work. The theoretical framework for this study is based on the constructivist view of teaching. Analysing our experiments we have found that the researchers have made various types of mistakes:
1. The researcher does not react to the indirect information given by a student.
2. The researcher is not sensitive on the ambiguity in the interpretation of some statements.
3. The researcher is not sensitive enough for the important moments.
4. The researcher is engaged by his/her own idea and cannot follow the pupil’s way.

We have tried to determine what is fundamental about different mistake. Our incomplete classification of mistakes describes phenomena which show that mistakes do not depend on the types of problems given nor on the level of pupils’ development.

We have concentrated on the different ways of interactive mathematical and social communication: questions, sentences, and non-verbal expressions. We have also observed the social aspect of pedagogical interaction. Following this we have tried to evaluate our interpretations and reactions in the directions of the sensitivities on special “sense” and meaning that emerged during the discourse and on our skills in understanding correctly the speakers’ intentions.

Every researcher has his/her own mental model of a concept or of a solving process and this model is autonomous for each researcher. Sometimes it is impossible to foresee what kind of obstacles and restrictions this individual model brings into the observed situation. The examples of mistakes presented will show that the researcher occupied by his/her model is not sufficiently sensitive to perceive the student’s model and hence causes communication difficulties between researcher and student.

We will show that the interaction between the researcher and the student could be detrimental to the student’s thinking process. In the theoretical model of research it is the researcher’s role to be objective during his/her work, to create confidence and accept fully everything that a student says and does during the experiment. But reality shows that it is not easy to work according to this rule. The self-critical reflections on experimental work can help avoid the same mistakes in future work. In addition this reflection increases the sensitivities of researchers and develops a wider perspective when analysing research results.

DYNAMIC MODEL OF MATHEMATICS TEACHER TRAINING
Marie Kubínová, Jarmila Novotná, Charles University, Prague

"The purpose of education can be seen in the learners’ cultivation, particularly in the cultivation of their mental world.”
(Hejňý & Kuřina, Pedagogika 2000)

In mathematics teacher training, we put emphasis on the support of constructivist approaches to mathematics education; not only verbally, but mainly in changes in actual teaching. In (Kubínová, Mareš, Novotná, 2000) we showed attempts to present constructivist teaching even in cases where detailed analysis showed that teaching by means of transmissive or instructive methods were used.

Our research
Large scale research done in 1999-2000 showed that:
• In mathematics, teacher training was conducted mainly by frontal and receptive methods. A static approach prevails (Kubínová - Novotná, 2000).
• From their own experience at school, students training to become teachers - our undergraduates - come to us with believing all teaching is transmissive.

If we want to change the nature of education we have to influence, above all, future teachers. We need to develop and cultivate their feelings about the functions and purposes of mathematical education. This implies a total change in the nature of existing teacher training concepts in the following directions:
• To create new schemas of transformation of scientific disciplines forming theoretical basis of pre-graduate mathematics teacher training.
• To move from a static, frontal teaching strategy and faculty based environment to a dynamic one, characterised by constructivist methods of teaching and learning taught both at the faculty and in faculty schools.
• To train future teachers in concrete activities using modern forms of didactical interpretation rather than traditional ones.

We prepared a new model of mathematics teacher training and from Autumn 2000 we have been teaching it. The model is “dynamic” because it makes use of constructivist approaches in teacher training, including breaking the isolation of individual subjects. There are strong links between the faculty and faculty school environments and these together with the creative approach to teaching profession become a permanent part of the teachers’ future work.

Concrete examples of the proposed changes will illustrate the results of our research.

Meaning-making processes based on the use of dynamic exploratory mathematical software in the classroom is attracting prolonged research interest (Noss & Hoyles, 1997). It is suggested that the enrichment of representation, functionality and feedback achieved with computer based learning environments could enable more focus on the ways by which medium resources within specially designed activities support the emergence of mathematical meanings. We report research aiming to explore how children construct meanings around the concept of curvature while working with software which combines symbolic notation (through a programming language) to construct geometrical figures with dynamic manipulation of variable values. “Turtleworld” enables constructions with variable Logo procedures and dynamic manipulation of these constructions using the “variation tool” (Kynigos et al. 1997) to sequentially and continually change variable values. The students were engaged in trying to construct the arcs of bridges of different sizes and shapes. We investigated emerging meanings about the notions of curvature, arcs and angles and how these were constructed with the use of the variation tool. The analysis of pupil’s interactions suggests that vivid interplay between symbolic and graphical representation was an integral part of the process by which they expressed “theorems” (Vergnaud, 1987) on length of arc, length of corresponding chord and the tilt of the arc as they were trying to create horizontal bridge arcs. Unexpected levels of abstraction emerged within these situations (Noss and Hoyles, 1996) and formalisation in quasi-algebraic terms became a means of thinking about and expressing relationships in a notational form. The dynamic manipulation and continuity effect of the variation tool facilitated pupil’s spontaneous conceptions of arcs as well as their hypotheses drawn from pencil and paper calculations. Further research is suggested on the entanglement of symbolic expression in mathematical activity with dynamic manipulation software.

Curriculum change in South Africa requires that students engage with culturally oriented activities related to space and shape. Curriculum guidelines provide for assessment in 6 levels in a space and shape strand over grades 1 to 9. The particular specific outcome being addressed by the research reads as follows: “Analyse natural forms, cultural products and processes as representations of shape, space and time” (National Department of Education, 1997: 4). No guidelines are however provided for judging the developmental level at which the learner is engaging with such activities in terms of the mathematics embedded in the culturally oriented activities suggested.

The RADMASTE Centre has been engaged in developmental research (Gravemeijer, 1994) related to the implementation of an ethnomathematical approach in classrooms in South Africa for a number of years. An educative assessment framework (Wiggins, 1998) has been adopted in the development of tasks arising out of this research. These tasks were given to grade 7 and 8 students in well resourced suburban schools as well as in disadvantaged township (e.g., Soweto) schools.

This paper reports on a preliminary analysis of the responses of a sample of students on three of these tasks: Ndebele designs, house designs and map symbolism. The approach to the analysis was similar to that adopted by Sproule (1999) on culturally-based counting practices. The analysis has resulted in a tentative rubric involving performance indices and related assessment criteria. Learner performance in symmetry, scale, notation, symbolism, was identified in the tasks as a basis for the assessment criteria.

References
According to Kuhn (in Wood, 1999), "argument is central to thought and the construction of knowledge". Students could be disadvantaged in a problem-centred classroom if they lack the confidence to explain their own methods or to challenge other methods with which they do not agree with or do not understand. This paper suggests that this can be overcome if small group interaction is sensitively facilitated.

Classroom observations were made as part of a project to investigate the role of argumentation and articulation in students' conceptions of fractions. Students worked in heterogeneous groups. How discourse should be conducted was addressed by the teacher and the researchers in whole-class and small-group discussions. Some 'weaker' students did not appear to participate in heterogeneous group discourse, although the expected kind of discourse was demonstrated by others in the group.

After assessment of the concepts formed, students were regrouped into relatively homogeneous groups for remedial purposes. Two of the apparently disadvantaged students, Riyah and Lindile, were in a group whose assessment showed that the relevant concepts were not yet evident. The two girls were allowed to work together, on their own, in the hope that facilitation and support could help them to make sense of the mathematics and to participate in discourse where methods and solutions were explained, challenged and justified. A deliberate effort was made to illustrate the role of the listener by asking questions like Why do you say that? and Do you agree with what she said? and by requiring the students to verbalize their ideas - If you want to [do something], what do you have to do?

Although the two students did not make major conceptual gains in the first few sessions, they were soon able to participate in discourse that was characterised by reasoning and thinking. Riyah consistently demonstrated that she was willing to grapple with a problem for a length of time and try out various strategies. This type of behaviour is regarded as necessary for the construction of understanding (Hiebert et al., 1996). Lindile still tended to act irrationally, for example, adding the numerator and denominator of a fraction. But Riyah challenged her every time, genuinely interested in the reasons for her actions and trying to convince her to a different view. Assessment at the end of the year indicated an improvement in Riyah's conceptions and her ability to work abstractly.

Mathematics Pedagogical Value System centering on mathematics knowledge acquisition in elementary school

*Yuh-Chyn Leu  **Chao-Jung Wu

* Department of Mathematics Education,
National Taipei Teachers College, Taiwan, R. O. C.
* *Department of Educational Psychology & Counseling,
National Taipei Teachers College, Taiwan, R. O. C.

The paper investigated the pedagogical values presented in the mathematics teaching of a fifth grader elementary school teacher. Based on the valuing theory of Raths, Harmin and Simon (1987), the study defined a value as any belief or attitude or other similarity which meets the three criteria of choosing, prizing and acting. The criteria have different methods of examination.

The methodology of the research was classroom observation and interviews. The time for research was one year. Ten lessons were observed and 18 interviewed were conducted. The research subject was a teacher, Ms. Lin, who has been teaching in elementary school for nine years.

The purpose of classroom observation was to look for the repeated behavioral patterns of Ms. Lin, such as the demand for previews, the raise of testing questions, the neglect of student’s wrong solution, and the repetition of reviews.

Furthermore, interviews were used to examine if Ms. Lin’s value indicator met the criteria of choosing and prizing. For example, after considering the pros and cons of teacher-centered and student-centered teaching, Ms. Lin still chose to teach in former teaching style. Ms. Lin said, “going over them three times is better than going over them twice; twice is better than once.” These words revealed that she stressed that students must learn the knowledge from the textbooks well.

Therefore it was concluded that the purpose of mathematics teaching is to teach student to learn the knowledge in the textbooks is a mathematics pedagogical value of Ms. Lin.

In addition to the mathematics pedagogical value stated, two more values of Ms. Lin were defined. But these values were not equally important. In the educating of teachers, the relationship among the values must be clarified and the core values must be found first. Then we further examine whether the core values accord with the current education policies. If not, in modifying teachers’ mathematics pedagogical values, the change of core values will be the underlying solution. Of course, how to change teachers’ mathematics pedagogical values is a new subject for research.

References
The importance of developing reflective skills has gained acceptance in mathematics teacher education in recent years. To gain insights into the teaching, critical reflection is an essential skill for teachers to develop (Krainer, 1999). Cobb and his colleagues (1997) suggest that if reflection becomes a regular part of the process, teaching and learning will improve. Therefore, this study was intended to provide teachers with opportunities for reflecting on their teaching and learning mathematics experience.

Eight teachers with different teaching experience were asked to share their knowledge and experience in weekly meetings. They piloted journal-writing efforts by reflecting on what was discussed in the meeting. The researcher also responded with written comments to the questions teachers posed in their journals. The teachers were asked to reread their own journal entries in order to promote in-depth reflection rather than simply replicate others' ideas.

The reflective journals of the teachers were analyzed according to the parameters of a three-dimensional diagram that emerged in the course of the present study. "Perspective" describes the ways teachers organized and reviewed their teaching and learning experiences; focusing on mathematics content (M), pedagogy (N), or student learning (P). "View" describes whether participants reflected on themselves (E) or others (S). "Level" indicating the degree of reflection was separated into five levels: descriptive (1), illustrative (2), reflective (3), critical (4), and meta-grow (5). These three dimensions are represented as a 2x3x5 matrix by means of a three dimensional solid. This matrix is illustrated in Figure 1.

It is found that perspective of reflection was determined by concerns that depend on teachers' professional background. The pedagogical aspects of teaching were reflected on more frequently than mathematical content or student learning.

This study found that reflective writing was an effective tool in promoting conceptual change. The longer the participants took part on the development program, which emphasized a learner-centered approach, the better they understood how their students learned. However, the novice teachers focused more on their own teaching skills than students' cognitive processes in their reflections.

TOWARDS AN ANTI-ESSENTIALIST VIEW OF TECHNOLOGY IN MATHEMATICS EDUCATION: THE CASE OF CABRI-GÉOMÈTRE

Bibi Lins
University of Bristol

In this paper both theoretical and empirical support to a view on secondary mathematics teachers' use of Cabri-Géomètre is presented. In particular, I argue that the use of a software package for teaching is not only linked to the school curriculum but also strongly linked to what a teacher sees in such a software package. By treating software packages as texts and secondary mathematics teachers as readers of such texts from an anti-essentialist viewpoint of technology (Grint and Woolgar, 1997), this paper discusses a preliminary analysis of two of the case studies -The Cabri of Anthony and The Cabri of Camilla - of my ongoing PhD.

Anthony and Camilla, two secondary mathematics teachers from a state school in Bristol (UK), were interviewed both in front of and away from a computer, talking about and describing her/his Cabri. They also had two of their lessons within a Cabri environment observed. Methodological issues on how the research had been designed will be given in the talk.

The research project aims to look at what is actually being said by secondary mathematics teachers about Cabri, and to investigate to what extent this is linked to the teachers' use of Cabri in the classroom, in their teaching.

Here, to look at 'what is actually being said' means to look at what meanings are being produced by teachers for Cabri. One of my assumptions is that the software package which reaches the classroom environment is not the software that once had been designed but rather a software: the one that the teacher has constituted. The Cabri presented in a classroom is a Cabri: the Cabri of the teacher.

One of the said powerful features of Cabri-Géomètre is drag-mode that allows deformation of figures, which brings dynamism, where ideas of dependence and independence can be explored by establishing relationships among points on geometrical figures. From the two case studies, seeing and treating Cabri as such has shown not to be the case. The drag-mode has nothing to do with the Cabri of Anthony and the Cabri of Camilla at the time they were interviewed. This does not imply that it will never be. New meanings can be or will be produced by each teacher for Cabri, as meaning production is to be viewed and understood as a process rather than something static and fixed. The point is the importance of such awareness of the Cabri of the teacher in order to understand how and why Cabri is being taken and used in a classroom in a certain way.

THE ROLE OF TECHNOLOGY IN THE STUDY OF SEMIOTIC REPRESENTATIONS IN MATHEMATICS

Jose Luis Lupiáñez Gómez
University of Cantabria, Spain
lupi@matesco.unican.es

We assume that, in the realm of mathematics, a representation is a symbolic, graphic or verbal notation to express concepts and procedures, as well as their more relevant characteristics and properties. According to these properties, representations can be classified in semiotic registers of representation (Duval, 1999). In this work, we reflect on the role that technology plays into cognitive processes, and its relation with the semiotic systems of representation, which constitute the key point to understand the way in which students construct mathematical knowledge. We will consider the calculator as a mediating tool in that knowledge construction process.

A repeated argument against the use of technology in mathematics teaching is that student forget and drop what they do with paper and pencil, and that this fact is considered as a damage for the quality of their education. But in the same way that the writing is not an obstacle for mental calculus, neither the calculator is. Instead, the representations supported by this tool have features which makes them especially productive for the learning of mathematics. They are executable representations, that is, they can simulate cognitive actions independently of user of calculator.

The power of technology is mainly epistemological, as its impact is based in a reification of mathematical objects and relations (Balacheff & Kaput, 1996, p.469): the calculator allows them to be regarded as "manipulable" objects, and gives us the possibility of working "about" them. A calculator as the TI-89 or TI-92, supply a big number of representations of mathematical objects in different registers, and they allow making conversions between registers, and this is a valuable tool in mathematics education. In the environment supplied by this technology, we can obtain mathematical properties very different of those possible with paper and pencil.

This comes to emphasise the notion of executable representations. The abstract ideas and concepts of mathematics become to be real with use of calculator: they can are mathematically manipulated and transformed, as we will whit many examples.

RATIO COMPARISON: PERFORMANCE ON RATIO IN SIMILARITY TASKS

Juan Margarit
Bernardo Gómez
Universitat de València, Spain
Juan.Margarit@uv.es
Bernardo.Gomez@uv.es

Olimpia Figueras
Centro de Investigación y de Estudios Avanzados del IPN, Mexico
dfiguera@mailer.main.conacyt.mx

Since 1996 a study about ratio, proportion and proportionality learning and teaching has been carried out at Valencia (see for example, Fernández and Figueras, 1999; Fernández et al, 1998). As part of this research an investigation to identify the ways in which secondary pupils —13 to 16 years old— solve Σ-construct tasks (Freudenthal, 1983) was made. These tasks comprise problem situations related to similarity, scale, the use of Thales theorem and the graphic of linear functions.

Students' answers to ratio comparison problems of a paper and pencil test in which similarity criteria play an important role were analysed using a classification scheme built up for other parts of the aforementioned global research. In search of elements which could serve as a framework to further understand pupils' answers a study with mathematics teachers was done. Interviews were made individually in a group setting, where teachers were asked to solve the pupils tasks, to describe their strategies and to compare them with those of their colleagues, to assess students answers and to discuss their characterisation.

The purpose of this communication is to describe cognitive tendencies in students' and teachers' ways of reasoning. Characterisation of pupils and teachers performance took into account criteria for preservation of ratio in similarities such as: preservation of equality of lengths, of angles, of congruence, of internal ratios and constancy of external ratios. Two differentiated types of reasoning were identified. One called "formal" was characterised by the use individuals do of necessary and sufficient criteria to sustain their answers. The other type named "qualitative performance" due to the use of visual reasoning which considers aspects that are necessary but not sufficient. These aspects are based fundamentally on the perception of form and relations that can be identify in a visual inspection of figures. Among the relevant results it can be mentioned the identification of similar behaviours between students and teachers. The qualitative performance of some of the teachers shows that it is necessary to design a teaching model (in the sense of Filloy, 1999) based on visual reasoning which favours the construction of mental objets closer related to the ratio in similarity mathematical concept.

RESEARCH ON EMOTION IN MATHEMATICS EDUCATION — THEORIES AND METHODOLOGIES

João Filipe Matos, University of Lisbon
Jeff Evans, Middlesex University

Within the Project Mathematical Thinking the research team has developed ways of looking at key issues in mathematics education research, namely emotion, transfer and assessment, through the lenses of four theoretical perspectives current in mathematics education and in social research more broadly: theories of symbolic control; situated learning; discursive practices; and semiotic mediation.

In our work on emotion, as with much recent work in mathematics education, we tried to move beyond a narrowly psychological approach and, influenced by cultural, sociological and psychoanalytic approaches, developed new ways of addressing how emotion permeates mathematical activity in the classroom.

Drawing from earlier work of Evans (2000) who used textual analysis of interview transcripts based on a discursive practice framework and a psychoanalytic basis for the methodology we then applied a range of methodological tools, including emotion metaphors (Kovecses, 2000; Lakoff, 1987), cognitive scenarios and scripts (Wierzbicka, 1999) to analyse classroom episodes. Through the analysis of transcripts of problem-solving interviews and classroom episodes it was possible to notice how emotions apparently attached to mathematical activity nevertheless draw on the experience and beliefs related to schooling more broadly and to non-school contexts rather than to narrowly school mathematical issues. Emotion is seen as integral with cognition and, whether it manifests itself as enjoyment or aversion, a relevant issue in the development and sustaining of mathematical activity in the classroom.

In this presentation we will discuss the methodologies used to address the corpus of data.

The Construction of Objects as a Crucial Phase for the Articulation of Registers in Tridimensional Situations *:

A.L. Mesquita (U. de Lille/IUFMNPdC, France)

The study presented here concerns a longitudinal project which privileges space and action in the learning of geometry at school; the project is being implemented in a primary school of the northern of France, since 1997/1998, with about fifty pupils, from six to eleven years old, during their school-attendance.

Activities of modelization of space are decisive to our approach (Mesquita, 2000). These activities are linked to the construction of tridimensional objects and other actions of manipulation (Berthoz, 1997). Along these activities, we give a special attention to the articulation of the different registers (the semiotical systems of presentation of knowledge considered by Duval, 2000) which can be used in tridimensional situations with children.

In this presentation we will focus on a particular moment of the study, where 8 to 9 years-old pupils were asked to construct a relief map of a part of the school quarter (including buildings, streets and hills). We will show how the construction of a maquette enables the coordination between the real objects and their tridimensional representation. This coordination is essential to the articulation among the representations used in this phase of the study: the tridimensional representation (the relief map, a non-semiotical representation, in the sense of Duval, 1999) and the different forms of bidimensional representations used by pupils: orthogonal projections (a land-register map, a semiotical representation) and perspective views (air views, non-semiotical representations). Actions of manipulation have a major role on this coordination.

EXPLORATORY STUDY ON INFERENTIALS CONCEPTS 'S LEARNING IN SECONDARY LEVEL IN SPAIN

Antonio Moreno
I.E.S. “Trevenque”, Granada. antoniomore@wanadoo.es
Angustias Vallecillos
University of Granada. avalleci@ugr.es

SUMMARY
In this paper we in summary communicate the first results obtained in an exploratory study on the learning of statistical inference basic concepts for Spanish students in secondary level. This is a part of an ongoing research project, with the aim to determine problematic areas, the students' difficulties, favourable learning environments or methodological questions that can serve like base to improve the teaching of the statistical inference in the secondary level. The taking of data has been carried out in two courses of secondary level, in total 49 students of different age and previous statistical formation. The students have answered a written questionnaire whose content refers to inferential basic concepts as those of population and samples, the influence of the type and size of the sample in the realisation of inferences, the different sampling types role in the inferential process as well as the implications of the possible biases in the obtaining of data. The enunciates are posed in three different contexts, concrete, narrative and numeric. The analysis of the answers has been, fundamentally, of qualitative type. First, each one of the items separately; later, each researched conceptual nucleus, grouping for it all the results of the items that refer to the same one. As it is an exploratory study we intend especially to determine the open questions and to formulate queries to research later more than to reach accelerated conclusions. Nevertheless, we have obtained some first interesting results: a categorisation of answers about concepts, only seemingly easy, as those of population and samples; differences among the students' conceptions about the sampling process in connection with the age and the context in that the question it posed; appreciation lack about the importance of the randomness in the taking of data or the influence of the sampling type. All these questions have a certain social importance, given their incidence in the taking of decisions in situation of uncertainty for all the citizens, therefore, the improvement in the basic education in these aspects is so much an obligation of the educational system as of the teachers and the educational research.

CONCEPTIONS AND BELIEFS OF MATHEMATICS UNIVERSITY PROFESSORS ABOUT THE TEACHING OF DIFFERENTIAL EQUATIONS

Mar Moreno and Carmen Azcárate
Department of Mathematics (University of Lleida)

The present research is an approach to the conceptions and beliefs of mathematics university professors related to the teaching of differential equations within the first years of scientific and experimental studies (Moreno, 2001). The teaching objectives are twofold: on the one side, to discern the most relevant characteristics of present way of teaching differential equations ant to explain the persistence of traditional teaching methods; an secondly, categorise each professor under study in terms of his conceptions and beliefs about the subject matter itself, about the teaching and learning of it, and also to establish the level of coherence and consistency or permeability of such conceptions and beliefs.

The theoretical elements on which the conceptual framework is built on comprehend aspects related to the knowledge each professor has of the subject matter and his relations with the elements of the teaching practices and with his conceptions and beliefs (Brophy, 1991). Furthermore, we resort to epistemology as a bridge to link the subject matter and the teaching and learning process with the conceptions and beliefs. The study is a qualitative one, involving six mathematics university professors, all specialised in practical mathematics. An ad hoc designed questionnaire and a recorded interview are used for data collection. The data analysis includes eight phases, during which the corresponding tables, layouts, descriptor lists and the like are produced.

The analysis results corroborate the predominance of teaching approaches encouraging algorithmic and algebraic practices towards differential equations (Artigue, 1998; Yusof and Tall, 1999), also signaling some asymmetry and a certain lack of transparency as far as the teaching objectives are concerned. In addition, we explain: the professors persistence in their conception and belief of the conceptual difficulty of this mathematical subject, the personal conception each professor has about this equations, within mathematics in general, their fear to lose the mathematical contents considered as "real mathematics" and the ease and simplicity implied in a way of teachings based on mechanical solving.

The differences when categorising each professor arise from coherence between his conceptions and his beliefs, and they allow us to set up three groups of professors (I, II and III). Group I consist of the most incoherent holding the most permeable beliefs; group II includes the most coherent and consistent; and finally, professor of group III is fairly incoherent though consistent in his beliefs about teaching differential equations.

ANALYZING "MORE THAN" AND "n TIMES AS MANY AS"
IN MOZAMBICAN BANTU LANGUAGES

Adelino Evaristo Murimo
Universidade Pedagógica, Beira Campus – Mozambique

In English, comparative relations are often described using more than and n times as many as (MacGregor, 1991). The former is used to describe a linear difference (e.g. 5 more apples than) and the latter, a proportional comparison (e.g. 3 times as many apples as). MacGregor analyzing these expressions in English and in other languages found that difficulties pupils have in understanding them may vary from language to language. "In some languages, the logical form of a relation matches the grammatical form used to express it. In others, including English, grammatical form obscures logical form. Some languages offer no way of translating certain English expressions until their logical form is revealed by paraphrasing (MacGregor, 1991)."

Misinterpretations of more than and n times as many as in mathematics are also reported by Zepp (1989), Dickson, Brown and Gibson (1984).

An ongoing study carried out among Mozambican Bantu language speakers, representing three different communities (Nyungwe: 8 participants, Changana: 12 participants and Makuwuva: 17 participants), showed that in local languages people may better state and understand simple linear difference problems and proportional comparison problems than in Portuguese, the language of instruction in schools.

For the research, the following verbal problem was used: Paulo has 7 apples. Maria has 5 more apples than Paulo. Rita has 3 times as many apples as Paulo. How many apples does Maria have? How many apples does Rita have? The problem was given to participants (unschooled adults and children) in Portuguese. The statement Rita has 3 times as many apples as Paulo is translated into Portuguese as A Rita tem três vezes mais maçãs do que o Paulo (Rita has 3 times more apples than Paulo). MacGregor observes this statement as being seen by some pupils as a complex relation that combines difference and proportion.

The participants were asked to solve the problems in Portuguese and then, to translate into their Bantu language as clear as possible. Their statements were collected and confronted with other speakers of the same language. Preliminary results showed that people understand these relations better than in Portuguese.

The German addition to the OECD-PISA mathematics assessment: Framework for the supplementary test and its connection to the international framework.

Michael Neubrand
University of Flensburg, Germany

The OECD-PISA assessment in 2000 (PISA = Programme for International Student Assessment) included two parts in Germany: the international test and national supplementary tests. These two parts are intended to complement each other. In this presentation, the reasons for the German national option are described and the framework for the test is explained. We will demonstrate how the national framework relates to, refines, and supplements the international framework for PISA-mathematics.

The basis the national framework is based upon is the international PISA framework (OECD 1999). There are essential differences between former international studies like TIMSS and the general aims of PISA. The most valuable point from a mathematics education viewpoint is that PISA aims to evaluate "mathematical literacy", mathematization being the central instance. One is therefore forced to define this conception, and the international framework does it while pointing to the competencies necessary for doing mathematics. However, those competencies never occur as single capabilities. They occur in bundles when specific tasks are worked out. So, items should be classified in competency classes which indicate some qualitative distinction between different modes of mathematical thinking:

Class 1: reproduction, definitions, and computations;
Class 2: connections and integration for problem solving;
Class 3: mathematical thinking, generalisation and insight. (OECD 1999)

The German national framework takes the three classes as a starting point, but differentiates it for the reason to describe in more detail the achievements of German students. There were formed five classes, two for each, Class 1 and 2, and Class 3 leaving unchanged. The classification follows what in the German discussion was called "mathematische Grundbildung" (Winter 1995). The differentiated classes allow to distinct between the mastering of purely technical tasks and the various steps towards mathematization, which can be both, intra- and extra-mathematical modelling.

In South Africa consensus is growing among researchers, as well as teachers that mathematics teachers’ preparation to fulfil their role as learning facilitators needs to be improved (Taylor & Vinjevold, 1999). The results of the TIMSS and other surveys indicate that a disturbing number of school teachers are incompetent, especially with respect to domain specific conceptual and pedagogical knowledge in critical areas of mathematics, like geometry (Howie, 1997; Strauss, 1999; Van der Kooy, 1996). Taylor and Vinjevold (1999) found that South African mathematics learners, as well as their teachers performed very poorly with regards to conceptual knowledge, while a substantial number of the teachers did not outperform their learners by much, if at all, when completing exactly the same test. As teaching behaviour is fundamentally influenced by teachers’ domain-specific conceptual knowledge (Koehler & Grouws, 1992), Kennedy (1998) rightfully appeals for concrete evidence of what prospective and practising teachers do in fact know and understand about the content they learn or teach.

The current project primarily aims to reveal further evidence to this effect, and to explore some ways of tackling the problematic situation. The project, undertaken in the Northwest Province of South Africa, involves selected Grade 7 mathematics teachers, their learners and the final-year mathematics student teachers (primary school) at all training institutions. Teachers teaching at schools with supposedly good track records regarding mathematics performance were specifically selected for the purpose of the study. Initially five selected "good" teachers and their learners (n=142) were subjected to the same Mayberry-type Van Hiele Test, set on the topics in the Grade 7 geometry syllabus, as to determine and compare (relate) their conceptual competence. The teachers also participated in a survey about their beliefs, attitudes and practices regarding the teaching and learning of mathematics, particularly geometry. Afterwards an additional twenty “good” teachers and their learners were involved. Results suggest that even "good" teachers are not much, if at all, above the level of geometry acquisition of their learners. They also suggest the existence of a seemingly intricate relationship between teaching success, and teachers' beliefs, conceptual competence and relevant own school experiences.

The results of the student teachers (n=102) do not seem to reveal a clear pattern, suggesting that even "good" hands-on geometry training programmes are not yet specific or focused enough to make a marked difference. However, as with teachers, own school experiences, and positive beliefs and attitudes about teaching and learning seem to be significant factors to be accounted for in the relevant teacher training.
LEARNING SCHOOL MATHEMATICS IN THE ABSENCE OF A TEACHER IN CLASS: REALLY?

Susan Nieuwoudt

College of Education, Potchefstroom University, Potchefstroom, 2520 South Africa

E-mail: poksmn@puknet.puk.ac.za

In South Africa, as in many developing countries, poorly trained teachers, absenteeism and lack of financial resources pose serious problems for school education, particularly in mathematics. In this time and age, it seems logical to ask whether relatively accessible and affordable technologies, such as TV and video, can contribute towards addressing problems like these. Huge (1990) reports on the use of video recordings of mathematics lessons to successfully compensate for the absence of teachers. In addition, there is evidence that the use of a “video class system” (VCS) does not impair the learning and teaching of school mathematics (Lowry & Thorkildsen, 1991). In the current project the influence of a VCS on learning variables and achievement in mathematics was investigated in a pretest-posttest experimental setting; qualitative analyses of observations were noted too.

Three groups of classes participated in this project over a period of six months. The mathematics lessons of experimental group 1 (E1) were videotaped, which were then played back to experimental group 2 (E2) in the absence of a teacher. A third group of classes acted as a control group (C), taught by the same teacher in the “conventional” way. Although the experiment was conducted in two suburban state schools, this presentation focuses mainly on the observations and results obtained in a multicultural high school for girls, involving grade 9 learners (n=100). The instrumentation used comprised a version of the LASSI-HS (Weinstein & Palmer, 1990), adapted for mathematics, which was used to measure variables influencing classroom learning (e.g. attention, motivation, etc.), as well as a series of self-constructed mathematics tests, which were used to measure achievement.

Overall, the results seem to support the claim that the use of a VCS does not impair learning performance in classes E1 and E2, as no significant differences occurred between the achievement of the learners in the respective groups. Surprisingly significant differences (p<0.05) occurred concerning the learning variables: Compared to E1, E2-learners’ attention, use of main ideas and use of test strategies improved with medium effect (d≥0.5), however, their anxiety also raised markedly (d=0.6). Compared to E1 and C, E2-learners’ learning motivation differed with medium effect to almost practically significance (d=0.7; d=0.5), while their concentration (d=0.5) improved with medium effect. Finally, these results can, and will be connected to mostly “positive” qualitative changes observed in learning behaviour, especially in E2, as well as with marked mostly “positive” adaptations of teacher behaviour.
SOME NOTES ON REFLEXIVE WRITING ACTIVITIES

Hiro Ninomiya
Hiroshima Univ. Graduate School, Japan

There have been a lot of discussions on the importance of either metacognition, reflective thinking, or affective issues in mathematics learning. On the other hand, there have been lots of reports on the writing activities in mathematics education, such as Journal writing, Reflective writing, etc. In this paper, a kind of writing activity which refers to the reflective and reflexive nature of mathematics learning is defined, and the example of “Reflexive Writing” is presented.

A kind of statement which is written in mathematical notation, such as numbers, expressions, proofs, is one kind of writing. In this paper, such kind of writing is called “Objective Writing”, which means such writing is the object of mathematics learning. On the other hand, a kind of writing which express the students’ metacognition, reflective thinking, or affective issues should be in another category of writing in mathematics education. Considering the importance of these mental activities in students’ learning, such writing is also crucial in mathematics education. In this paper, this is called “Reflexive Writing”, because there might be reflections or reflexions between the object of learning (Objective Writing) and Reflexive Writing.

Finally, the Fig.1 is an example of Reflexive Writing.

Development of Naïve Algebraic Ideas during Solving Problems and Explaining the Solution Processes

Masakazu OKAZAKI
Joetsu University of Education

Our concern is to rethink mathematical learning from a holistic perspective, especially Japanese 7th grade's unit "letters and algebraic expressions" in which the teaching is likely to be atomistic, since most students don't feel the need to learn algebraic methods.

Bednarz & Janvier (1996) discussed students' approaches in solving the algebraic type of problems in their research of the transition from arithmetic to algebra, and suggested some gaps between their approaches and the algebraic method. We think their problems are good situations as a starting point for learning algebra in that they offer a picture of linear equation to students, and for our study it is important to understand how they overcome the gaps and develop their naïve ideas towards algebra.

The aim of this paper is to analyze several case studies and to suggest how students who haven't learned the contents of letters and algebraic expressions can construct and develop some algebraic ideas through solving problems and explaining the solutions. The following are suggestions resulting from the analysis.

1. The interplay between using trial-and-error methods and setting up expressions could help them to understand local relationships and to create algebraic ideas.
2. The naïve idea of uniting several terms emerged in two situations. One was the situation of simplifying the numerical calculation and the other was that of understanding the structure of the parts in the expression that they set up.
3. It was effective for the emergence of the naïve idea of distributive law that they conceived the problem situation and the numerical computations structurally. The idea became explicit when the explanation was shifted from numerical calculation to algebraic expression using letters and when they found the number of uses of the letter in the expression.
4. Students could create a feeling of necessity and appreciation of using letters through solving problems in the context of linear equation before they learned algebraic expressions.

References
In this paper we study the attitudes of a group of eight mathematics students following a preservice teacher training Program, based on the use of the graphic calculator in the process of teaching and learning mathematics. This Program was implemented by means of a course-workshop. We considered it important to elicit the attitudes of the participants involved in the Program both at the beginning and the end of the Program. In order to do so, a Likert-style attitude questionnaire was designed, the aim of which was to record the attitudinal changes in the mathematics students arising from the development of the Program which incorporates modeling and the graphic calculator in the context of linear algebra. This scale was set up from a matrix structure supported on a system of categories taking two variables into account. The first variable was defined by means of the specific objectives stated for the Program: i.e. mastery of the graphic calculator (O1), knowledge of linear algebra and problem-solving strategies (O2), modeling of real-world problems (O3) and the design of teaching units (O4). The second variable was defined by means of the components of the curriculum concept: i.e. student (C1), teacher (C2), mathematical content (C3) and social use (C4). From these two variables, a bidimensional variable OiCj was built with 16 values, from the combinations of the previous variables. The reliability of the instrument was measured, by applying the Spearman rho (rs) coefficient.

The scale of attitudes allows favorable changes to be appreciated in the student’s attitude towards modeling (O3C1), the teacher’s attitude towards modeling (O3C2), the attitude towards solving algebraic problems concerning evaluation (O2C4), and the student’s attitude towards the graphic calculator (O1C1). However, in view of the log-linear analysis, these were not statistically significant. Similarly, attitudes were detected which did not increase after the application of the Program, as is the case in O4C1, O4C4, O3C4, and O4C2, which suggests that some aspects should be revised. These aspects include practical and theoretical activities, teaching tasks and activities which involve evaluation with a calculator and modeling.

Short Oral Communication

Title: Initial Mathematics teachers training at the Ecole Normale Supérieure of Nouakchott
Author: Mohamed Ahmed Ould Sidaty

Abstract
The Mauritanian educational system reform, recently decided by the government, aims first of all to improve the quality of scientific teaching, especially teaching Mathematics. The Ecole Normale Supérieure (Teacher Training College) of Nouakchott, the only institution in the country in charge of training secondary school teachers, is aware of the fact that the success of such a reform depends mainly on the teachers responsible for putting it into practice. Therefore the E.N.S. took a certain number of measures aiming to improve the quality of mathematics teachers' training.

These measures consist of:
Deepening vocational guidance of training programs.
Making trainees more responsible to be able to monitor their own training.

The objective of this communication is
- to give a short overview of the new training programs and their modes of application.
- to precise the impact of these measures on the course of Mathematics, the course of didactic of Mathematics, the supervision (follow up) of teaching practice in high schools, the attitude of trainees when they become responsible for their own training.

Finally, we shall talk about obstacles met when applying these measures.
Exploring the Link between Preservice Teachers' Conception of Proof and the Use of Dynamic Geometry Software

Eric A. Pandiscio
University of Maine, USA

This study seeks to connect two well-established research strands. One is the role of proof in geometry, and the other is the link between teachers' subject matter knowledge and pedagogical content knowledge. Of particular interest is how secondary preservice teachers perceive the need for, and benefits of, formal proof when given geometric tasks in the context of dynamic geometry software.

Building on the work of Eves (1972), who conjectured that mathematicians determine truth by methods that are originally intuitive and empirical, and Lakatos (1976), who suggested the deductive format in which proofs are presented is misleading, Battista and Clements (1995) suggested that students should learn the meaningful use of proof by avoiding formal proof and focusing instead on justifying ideas and building visual and empirical foundations for later work. One way to do this is with dynamic geometry software, such as Cabri and Geometer's Sketchpad, which facilitate the making and testing of conjectures. Bershadsky and Zaslavsky (1999) also investigated how such dynamic environments impacted students' awareness of the intuitive, visual aspects of geometric situations, and described how this in turn was reflected in students' understanding of the ideas under study. Crisan (1999) suggests that the use of mathematical software both challenges and enriches teachers' subject matter knowledge as well as pedagogical content knowledge.

This report presents results of a case study of four preservice teachers as they solve two geometric problems posed in the form of questions, and then attempt to create formal proofs that generalize their results. The problems were chosen to be unfamiliar in their specifics, yet based on traditional Euclidean concepts. Thus, the preservice teachers were faced with issues of proof in areas that challenged their subject matter knowledge, and were asked to do so in a software environment that also challenged their pedagogical content knowledge. Preliminary results indicate that students see dynamic software as tool to make sense of proofs, but not necessarily helpful as a tool to create proofs.

SYMBOLIC EXPRESSIONS ADOPTED BY PUPILS
ANSWERING TO A WORD PROBLEM

Tasos Patronis and Kallia Pavlopoulou
University of Patras, Department of Mathematics
Athens University of Economics and Business, Department of Informatics

In this article we study the answers to a word problem given to 69 pupils of 7th grade of a “multicultural” school in Greece. This problem was an adapted version of a problem proposed, among others, in several research projects by Sowder (1988), and by Lester et al (1989). The adapted version reads as follows: “A teacher plays the following game with her pupils. Each pupil would exchange a teacher's one hundred drachmas coin with lower value coins, excluding the one drachma coin. How many pupils could play this game if each exchange should be made in a unique way?”

Greek language was not the mother tongue for 12 of the pupils. Although there was, partly, some misunderstanding of the problem (some pupils constructed questions of their own in a way similar to that described in Lean et al (1990)), it seems that being part of a linguistic or ethnic minority (e.g. albanian, russian, gipsy etc.) does not seem to be a significant factor, that affected the understanding of the problem.

Of particular interest are the symbolic-arithmetic expressions (or forms) adopted by pupils in their answers, in order to represent the various ways of exchanging a 100 drachmas coin. A large part of the symbolic-arithmetic forms we refer to sometimes resemble arithmetic «mononyms» and «polynomials», where the structural units represent the «basis» elements (50, 20, 10, 5 and 2 drachmas). For example: «5(2) + 2(5) + 1(10) + 1(20) + 1(50) = 100» or «100 = [ 10+ 10 + 10 + 10 + 10 ] · 2» or even in «exponential» (!) form «5^10 + 2^20 + 2^5 = 100». We would like to emphasize that a variety of symbolic forms as above could not probably be achieved without the particular verbal context of the problem. It has been argued that only the development of non-verbal mathematical activities can support cognitive activation and “integration” of pupils who are socially isolated due to linguistic problems. Our research provides some evidence that this claim does not seem to be fully justified.

TOWARDS A COMMON CHARACTERIZATION
OF BELIEFS AND CONCEPTIONS

Erkki Pehkonen
University of Turku, Finland

Fulvia Furinghetti
University of Genoa, Italy

The purpose of this paper is to draw attention to theoretical deficiencies of belief research (cf. Furinghetti & Pehkonen 1999). The concept of belief (and other related concepts) are often left undefined or researchers give their own definitions which might be even in contradiction with each.

On the ground of the previous considerations we have worked out a questionnaire in which we listed from the recent literature (1987-98) nine belief characterizations which focus on one or more terms of the triad in question (beliefs-conceptions-knowledge). In March 1999 we sent via e-mail our questionnaire to the 22 specialists invited to the international meeting "Mathematical Beliefs and their Impact on Teaching and Learning of Mathematics" (see Pehkonen & Törner 1999).

Our first observation was that in the responses of the specialists, there was no clear pattern to be observed. But in some points, one can find some regularity. The answers were most unified in one characterization ("Beliefs and conceptions are regarded as part of knowledge. Beliefs are the incontrovertible personal 'truths' held by everyone, deriving from experience or from fantasy, with a strong affective and evaluative component.") in which 15 specialists (83 %) disagreed with the statement. Then we have single out quite clearly two central features determining the disagreement: the adjective incontrovertible and the relation between beliefs and knowledge. In gathering the criticisms and the constructive parts of the answers that we had at disposal we realized that there are points on which future research may be based.

In summarizing the results, we propose for studying beliefs and the related terms a list of basic recommendations, which should be used flexibly according to the situation, analyzed. They are, as follows: to consider two types of knowledge (objective and subjective); to consider that beliefs belong to subjective knowledge; to include affective factors in the belief systems, and distinguish affective and cognitive beliefs, if needed; to consider degrees of stability, and to leave beliefs open to change; to take care of the context (e.g. population, subject, etc.) and the research goal in which beliefs are considered.

THE MATTER OF CHANGE - BEING RESPECTABLE

Leila Pehkonen
University of Helsinki, Finland

In the last decade, studies on teacher change (e.g., Clark and Peterson 1986) have presented many aspects of the change process. One of the main interests has been to find out the conditions for change. Recent studies have suggested the complex nature of teacher change (e.g., Senger 1999). In Finland all teachers are educated at universities. Anyway, also to these well educated teachers, it seems hard to meet changes in curriculum and education (Pehkonen, E. 1993). The aim of this paper is to understand the difficult question of change from the perspective of stability. What constitutes the good and stable elements in school mathematics teaching and learning in the minds of teachers?

The data consists of theme interviews of nine competent elementary school teachers. They had teaching experiences from one year to seventeen years. The themes in interviews were: 1) The teacher's personal conception about the state of mathematics teaching; 2) The good and proper elements in mathematics teaching; 3) The elements in mathematics teaching which should not be changed in the case of any change. The data was analyzed qualitatively. The aim was to find out the stable key elements most important to teachers and to interprete the prerequisites of change. The interpretation was later negotiated with the involved teachers.

Three key elements found in maths teaching were: the math book, basic counting skills and teacher-centred classroom teaching. These were the elements most frequently mentioned in every theme. They were also seen as the main elements not be changed in case of any change. Teachers do not object the changes, but they want to do their job properly. Teachers know the curriculum, text books, learning materials, teaching methods. They argumentate their action by explaining that they use best possible text books. Pupils seem to achieve what they are expected to achieve according to official standards and tests. Teachers could be satisfied.

But - however all teachers express their feelings of guiltiness. They know the trends of modern mathematics education, but they are not sure how to be able meet them. They are afraid that they have given up a part of their professional competence to the text books. Teachers are busy and teaching groups are very heterogenous.

Teachers want be respectable. They do not want to take too serious risks. They have experience-based evidence that their teaching meets well enough the set standards. But they do not have any evidence what happens, if they will spend their time on something else - for example on problem-solving.

A COMPUTER GAME FOR MATHEMATICAL LEVEL RAISING

Pijls, M. H. J., Dekker, R., Van Joolingen, W. R.,

Graduate school of Teaching and Learning, University of Amsterdam, The Netherlands

Aim of this research project is to use ICT to attain level raising in the learning of mathematics. We define level raising as the transition from a visual or perceptual approach of a problem towards a conceptual approach. The assumption is that students attain level raising by executing the so-called key activities from the process model of Dekker and Elshout-Mohr (Dekker & Elshout-Mohr, 1998): to show, to explain, to justify and to reconstruct one's work. The expectation is that the use of computer simulations and working in pairs on investigations tasks will promote the occurrence of key activities.

A computer game is the starting-point for a couple of investigation tasks on the subject of probability theory in upper secondary education with 16-year-old students. Students are working in pairs on these tasks and the teacher is giving minimal help. The mathematical model underlying this game is the model for binomial chances. The research question of the first experimental study in this project is the question on which moment in the learning process working with investigation tasks is most effective. Executing mathematical investigation tasks can have different functions in the learning process. At first, they can activate prior knowledge and make students curious. Secondly, their function can be to give students the opportunity to apply and to process what they have learned. Thirdly, the investigations tasks can support the process of reinvention of the model for binomial chances. These three functions occur in this research project in three conditions. The question that we want to answer is in which condition the students attain most level raising. Besides, we want to know if there is an difference in the occurrence of key activities.

In January 2001 an experiment was executed in which 68 students were working on the investigation tasks in the three conditions. The data set consists of a pre- and posttest, audiotapes of 9 pairs, log files of all students and written tasks. These data will be analyzed on the occurrence of key activities and indications for level raising.

In the presentation we will make explicit the concept level raising and explain how in the process model of Dekker and Elshout-Mohr the occurrence of key activities involves level raising. We will show how this model is applied and the preliminary results of the experimental study will be presented.

IMAGERY AND VISUALIZATION WITHIN PRE-SCHOOL AND ELEMENTARY NUMBER: A 2-YEAR CASE STUDY OF 11 SCHOOLS

Adrian J Pinel, Jenifer M Pinel
University College Chichester, Freelance Researcher

For two school years from Autumn 1998, 11 schools teaching 4-9 year old students adopted and pursued a number curriculum with a strong emphasis on progressively building imagery and visualization. Both authors studied this by visiting the schools, discussing developments with teachers, and observing lessons.

Research questions identified were:
- Will the initial commitment of teachers to the more visual curriculum be sustained? (1. we assert that there is not a culture of persistence in English elementary education; 2. the 2-year period included, from Autumn 1999, the introduction of the English National Numeracy Strategy);
- Will the students show themselves as in a different relationship to numbers – e.g. as having a greater ‘at-homeness’ with numbers – after 1 year, after 2 years of the visual curriculum;
- Will the students’ achievements with numbers be enhanced: specifically their number location, ordering, counting, complement-finding, calculating and calculation-adjustment abilities.

The oral presentation will:
- Identify key features of the responses of teachers and their students, including gains in ‘at-homeness’ with numbers;
- Illustrate these with respect to one of the teachers and her class;
- Present evidence of increased abilities to use imagery and to visualize when dealing with number problems;
- Present evidence of increased achievement levels within the aspects specified above;
- Outline how these schools reacted to the English National Numeracy Strategy;
- Relate this study to the ideas of Freudenthal, Gattegno, Wittmann and others.

Klein A S (1998) Flexibilization of Mental Arithmetic Strategies on a Different Knowledge Base. Freudenthal Institute
Treffers A (1991) Didactical Background of a Mathematics Program for Primary Education. In Realistic Mathematics Education in Primary School, L Streefland (ed.) Freudenthal Institute

1 - 358

PME25 2001
Within New Zealand there is a “growing awareness of the special needs of gifted and talented students and of the importance of providing them with an educational environment that offers maximum opportunities to develop their special abilities” (Ministry of Education, 2000, p. 6). However, despite National Education Goals that charge schools with the task of providing programmes that enable all students to realise their full potential, many (32%) secondary schools have no school-wide policy on gifted education.

This paper combines the findings of two related research projects in order to provide an overview of the types and frequency of programmes offered to secondary gifted and talented mathematics students and examines both teacher and student perceptions of accelerated programmes in mathematics.

While mathematics is the subject that is most commonly targeted for special attention for gifted and talented secondary school students, there exists a great variation in the types of programmes available. Factors such as school size, decile (SES) rating, proximity to competing schools, and school culture appear to influence both the availability and the scope and nature of programmes. Many schools that offer accelerated programmes reported problems in timetabling, parental pressure, and student achievement in subsequent years. However, 25% of respondent schools reported no problems.

In contrast, students’ perceptions of accelerated programmes (4 case study schools) were very favourable. Contrary to fears identified in the literature the students perceived that inclusion in the accelerated programme had not affected their friendship base; they believed that they had a normal adolescent social and emotional development. Participant students felt that the accelerate programmes enhanced their learning and they identified no significant problems with compaction of the curriculum or gaps in knowledge. Issues of selection into accelerate programmes and reasons for students wanting to be accelerated in mathematics were often influenced by school culture.

While acceleration is currently one way to provide for gifted and talent mathematics students in New Zealand, this research suggests the need for schools to develop more cohesive and flexible programmes, with clearly identified goals, in order to best meet the needs of talented and gifted mathematics students.

PROOF, PROOFS, PROVING AND PROBING:
RESEARCH RELATED TO PROOF

David A Reid
Acadia University

Research on proof and proving in mathematics education makes use of several
different meanings for the words “proof” and “proving”. In some cases this can lead
to seeming contradictions in research findings. This paper identifies four current
usages.

The concept of proof: Most professional mathematicians would say a proof of a
statement confers absolute certainty on it. Some research has concluded that many
secondary students do not understand proof in this way (see, e.g., Healy & Hoyles
2000). On the other hand, unpublished data (Zack 2000) suggests that some younger
students may understand this concept of proof. For example, one Grade 5 student
stated: “I think proving means showing that your answer is correct and it can’t be
wrong.”

Proofs: There are sections of writing in mathematics textbooks and journals, which
are called “proofs”. They are characterized by a particular form and style. Writing
proofs is a goal of recent reform documents but further research in this area is
needed.

Proving: “Proving” is usually connected with deductive reasoning. Quite young
children have been observed to be reasoning deductively (see, e.g., Zack 1997) but
their reasoning seems to depend strongly on context. Additional research on the
contexts in which children find deductive reasoning useful is needed.

Probing: Lakatos (1976) describes a process of “proof-analysis” in which “proving”
is probing, testing the truth of a statement. Lakatos claims that his version of the
nature of proving is incompatible with the concept of proof described above, which
implies that researchers working from either perspective need to be careful they are
not misunderstood as working from the other.

Note: A longer version of this paper is available at

A TEACHING PROPOSAL ABOUT RATIO AND PROPORTION WORKED WITH STUDENTS OF ELEMENTARY SCHOOL

Elena Fabiola Ruiz Ledesma
Marta Elena Valdemoros Álvarez
CINVESTAV-IPN. MÉXICO

The present document is the report of a research that deals with the topics of ratio and proportion whose great importance nowadays has been shown on the studies that the researchers of different countries have made during various decades. The problem of research consists in reviewing the strategies used by the Mexican students of 6th grade of Elementary Education when they solve problems involving ratio and simple and direct proportions, in order to identify qualitative and quantitative components of though linked to these topics and their diverse modes of representation; which is the base of the design and the application of a teaching proposal about, that was adapted to the school’s program.

The theoretical and empirical antecedents include a revision the cognitive aspect as a part of a disciplinary development, as well as didactic and psychopedagogic aspects, which was taking from Freudenthal (1983), Streefland (1993) and Coll (1998); respectively. It was pretended to do a conjunction between the mathematical reflection about ratio and proportion and the didactic aspects. Teaching proposal was conformed by six teaching models, considering the definition that Figueras, O.; Filloy, E. and Valdemoros, M. (1987) give of teaching model, which were retaken in different sessions as they were required by the advance of the teaching process, which is similar to what Streefland (1990) points out in his Realistic Theory, referring to the strategy of change in perspective. The elaboration of different tasks shows a progression, starting with the review of qualitative aspects for reaching the quantitative because the recognition of ratio as a relationship between quantities and proportion as the relationship between ratios.

Two phases manifested, interconnected, of the progression of the methodological instruments. The first one was the exploration phase, this was done through the observations and the initial questionnaire, the second phase, that was the one of enhancement, it took place with the teaching proposal and the interviews. The observation as well as the Questionnaires gave a light for designing the teaching proposal which was constructivism-didactic; it allowed the students to give sense and meaning to the concepts of ratio and proportion. The validation of the methodological instruments was carried out through a process of piloting by a triangulation of different sources of register and of crossed controls. As a way of evaluating this proposal, a final questionnaire was used and after this one the interviews were designed. The interviews had two intentions: evaluation and feedback.

SURPRISE AND HUMOUR IN TEACHING UNDERGRADUATE MATHEMATICS

Ildar Safuanov, Pedagogical Institute of Naberezhnye Chelny

Nobody doubts that undergraduate mathematics teaching should be interesting. The elements of surprise and humour can help to solve this problem.

In our view, the most effective and useful surprises are of three types: 1) when the concepts and elements, familiar to students from one mathematical context, appear in another mathematical context, resulting in new contents - new properties of these elements, or other mathematical results; 2) unexpected interpretation (geometrical, graphic, or, on the contrary, algebraic interpretation of the geometrical facts), allowing to look at things from a new viewpoint and to receive, unexpectedly and effectively, new mathematical contents; 3) unexpected applications of mathematical concepts and results in new areas outside mathematics.

As well as in art, the surprises are more effective when they are well prepared. Any concept intended to be considered in a new, unexpected context, earlier should be imprinted on the minds of the students, so that they really could recall it in a new situation. Lecturers might imitate authors of detective stories: the keys to the disclosure of a crime or mystery usually are distributed in different parts of a story, so that the reader, even after overlooking these moments, at once recollects them in a final scene. In mathematics it means that the lecturer, introducing a new concept, should make it unusual, connect it with an interesting example, method or application.

The humour is connected to surprises: to a paradoxicality of the phenomena, unexpected connections of serious with ridiculous. If the purpose of elements of unexpected is to make learning interesting, the purpose of humour is to give ease to the process of learning.

The humour is proper both for oral teaching and for textbooks. Certainly, the elements of humour in oral teaching have features, quite different from those in the textbooks. In oral teaching there is a place to the improvisation, it is possible to use peculiarities of an audience, moment, external circumstances, of a lecturer's own mood. However, in oral teaching the humour frequently is of the external (w.r. to mathematical contents) character, being not related to mathematics and aiming only to create a respite or pause for switching or refreshing attention.

In the textbooks the humour, as a rule, is in greater extent related to elements of the mathematical contents, connecting this contents with non-mathematical (e.g., everyday) things or pushing it together with other intellectual contents (e.g., humanities or other manifestations of the spiritual life), giving birth to paradoxes and amusing contradictions.
An Approach to Teachers’ Knowledge about the Mathematical Concept of Volume

Mariana Saiz
msaiz@upn.mx
Universidad Pedagógica Nacional, México

In Mexico, the study of the concept of volume forms part of the program of studies for primary education. In accordance with Freudenthal (1983) the objective of mathematical education should be the forming of rich, well founded mental objects, related with the concepts of mathematics, nevertheless, experience in workshops with teachers of elementary school indicate that on occasion these “mental objects” of teachers are very limited. On the other hand, the participants in these workshops have pointed out volume as one of the thematic contents in which they found more difficulties for the learning of the children.

These considerations motivated an investigation project whose principal objectives to characterize beliefs and knowledge of the teachers related with the concept of volume and its teaching. The theoretical and methodological frameworks, as well as some preliminary results, have been commented on Saiz & Figueras (1999 and 2000).

Evidences that teacher beliefs and knowledge affect the way they teach have been obtained in different studies (Thompson, 1992). The work reported herein fits in this line of investigation, now that it focuses attention on the beliefs with respect to a mathematical concept and its teaching. A group of elementary school teachers were video and audio taped during a workshop designed to permit teachers spontaneously comment and share their ideas with their peers when working with tasks related to the concept of volume.

Some segments of these tapes’ transcriptions have been analyzed. Until now, some results related to the teachers’ subject-matter knowledge have been obtained: a) Teachers define volume as the place occupied by a body in space; nevertheless they themselves use this term, at times, as a synonym of capacity. b) They relate the raising in the level of liquid upon submerging an object to the weight, not to the volume. c) They believe that the lateral area is directly related to volume, that is, they believe that the greater the lateral area, greater volume and vice-versa. d) They have problems with the conversions between distinct units. e) They believe that enlarging the linear dimensions of a solid in k times gives place to k times enlargement in volume.

As collateral results of this investigation some are found that point toward the formation and actual circumstances of the teachers. When they work in groups and confront designed didactic situations—with the purpose that they themselves discover misconceptions and erroneous beliefs—they reconsider their own knowledge. They think over the difficulties that the children can confront, which will cause them to reflect about their role in the classroom, as it has been the situation in the workshop herein commented.

The understanding and handling of inequalities by pupils is analysed into the general framework of algebra initiation. The transition from arithmetic to algebra is a deep qualitative step, which is, often assumed by pupils as an introduction of a set of rules that constitute an aim in their selves (Sfard & Linchevski, 1999). It is within this theoretical framework that this present study intends to identify the related factors that influence, in secondary schools in Mozambique, the pupils' skills and understanding of the concept of inequality and its solution. It is a correlated research where we intend to explain a phenomenon(a), relating some variables such as the institution, the teachers, and the pupils.

In terms of institution we analysed the syllabi, textbooks, and final exams. Moreover, 20 teachers of grade 10 answered a questionnaire which aimed to collect data from the teachers themselves about inequalities so as their opinions about the performance of pupils in this topic.

These activities had as the start point the following hypotheses: (1) It seems that there is some confusion between the concepts of equation and inequality; (2) in solving inequalities, the relation between the numerical, algebraic and graphical methods, if it is done, is very incipient and (3) the resolution of inequalities seems to be assumed as a "game of mathematical symbols" without any relation to reality, losing the sense of what one is really looking for.

The findings corroborate the hypotheses assumed beforehand. At the institutional level it seems that the inequalities are handled in a disorganized and discontinuous way as follows: (1) Different types of inequalities are treated in different ways. Some are treated as algebraic and others as function inequalities; (2) some grades inbetween do not handle inequalities; (3) Questions formulation in most of final exams allows rigidity instead of flexibility of resolution methods and (4) the syllabi and textbooks seem to reinforce the similarities between equations and inequalities. According to the results of the questionnaire, teachers are faithful implementers of what the institution sets up and pupils face a lot of difficulties when solving inequalities. This study recommends curriculum changes that help a (smooth) transition from arithmetic to algebra (Gimenez,) taking into account what Banzini says: "the passage from natural to symbolic language is a key point in the development of algebraic thinking and asks for special attention" (Banzini, 1999).

---

TEACHERS’ PRACTICE AS A PROBLEM SOLVING ACTIVITY

Leonor Santos
University of Lisbon

This presentation, based in a larger investigation (Santos, 2000), focuses on the professional problems posed by mathematics teachers in a process of curricular change. Many authors have proposed to regard professional practice as a problem solving activity. Dewey (1910/1997), associated thinking to problem solving, Schön (1991), spoke about professional problems and their ill-structured nature. In this study, I tried to understand more deeply the characteristics of the problems that teachers daily face and solve in individual and collaborative contexts of practice.

The study methodology stands on an interpretative approach, using case studies. A secondary school was selected where three teachers planned to work collaboratively, applying for the first time a new mathematics program in their 11th grade classes. Data was gathered by observing collaborative work and each teacher's classes, carrying out reflective sessions concerning these classes and in interviews.

Results strongly suggest that professional problems are ill-formulated and ill-defined. They are progressively reconstructed and understood by teachers along their work. In the collaborative context, the problems range over a great variety of contents (mathematics; didactics, organizational) and are marked by their global character — normalization is valued. Their starting point is the curriculum and the end point is the practice; some of them enter in the public domain. In the individual context we find that problems are centered on the didactical knowledge. They are very specific and particular — singularity is valued —, starting and ending in practice, while curriculum has a guiding role, and they belong to the private domain. The main processes used are analysis, consultation and “living with the problem”. The extent to which problems identified in the collective working context are solved much greater than that found regarding the individual context.

References

McLeod (1992) has emphasised the central role of affects for the learning of mathematics and characterised the affective domain in mathematics education by three types of affect "beliefs", "attitudes" and "emotions". The latter are ranked in order of increasing intensity and decreasing stability. There are many approaches to linking affect and cognition and these were characterised by Evans (2000) according to four types of models. The aim of this paper is to analyse the relationship between affect and cognition on the level of the individual learner. The concept of "affect logic" (due to Ciompi (1982)), which combines the psychoanalysis of Freud with the genetic epistemology of Piaget, were employed. Within this concept, the psyche is understood as a complex hierarchical structure consisting of affective-cognitive schemata. These are the result of maturation and learning processes which are based on assimilatory/accomodatory interactions with reality. The entirety of affective-cognitive schemata form at each moment the "world view" of an individual and control further learning processes. If we regard affect and cognition as two inseparable components of a mental unit, we are in a position to understand why we can know anything about our feelings. This type of knowledge is used in the research of beliefs and attitudes.

Roth (1996) sees the role of affects as an assessment system for thinking and acting. This aspect allows us to understand the importance of social factors for the learning process.

THE QUALITY OF INSTRUCTION IN THE CONTEXT OF REFORM
MARY C. SHAFER, UNIVERSITY OF WISCONSIN–MADISON, USA

Research has identified elements of U.S. school capacity that directly affect instruction, sociomathematical norms that affect the learning environment, factors that support students' reasoning, ways to judge the intellectual quality of class work, and ways to examine cross-national differences in instruction. Remaining to be developed, however, are research methodologies that characterize instruction in ways that examine the impact of standards-based curricula on student achievement. This report focuses on the results of the development and use of a composite index that characterized and described the variation in instruction among teachers in a longitudinal/cross-sectional study using the reform curriculum Mathematics in Context (MiC; NCRMSE & Freudenthal Institute, 1997–1998).

Standards-based curricula present mathematics in ways often unfamiliar to U.S. teachers and require more planning for successful instruction than generally perceived necessary for teaching via traditional methods. In MiC, topics traditionally reserved for high school are introduced in middle school using real-world contexts, with an emphasis on student reasoning rather than on memorization of procedures, providing challenges to U.S. teachers, who are often accustomed to teaching mathematics as isolated pieces of knowledge (Romberg, 1997).

The index used to examine instruction discriminated differences in instruction among study teachers in two districts who used either standards-based or conventional curricula. Variation was found by grade level, curriculum, and district. These results confirmed (a) the significance of integrating assessment practice into instruction, with the content corresponding to content standards and emulating what it means to know and do mathematics; and (b) the need to develop instruction that emphasizes teaching mathematics for understanding, that is, developing classroom norms in which students value and participate in discussion, providing meaningful tasks, creating opportunities for students to articulate their thinking orally and in writing, and seeking multiple forms of evidence of understanding from each student in class.

The results also suggest that even in classrooms using reform materials, students are rarely given opportunities to reflect on and express their own mathematical ideas or to listen to the reasoning of other students. Teachers' own understanding of the mathematics, the ways the mathematics is presented, and their developing pedagogical content knowledge related to the units have a significant impact on classroom instruction and on student achievement.

The findings in this study underline the need to take into account such variation in instruction in any interpretation of the impact of reform curricula on student achievement.

References

This study reports a way to help students to organize their strategies to write mathematics proofs. The purpose of this is to justify why argumentation is important as a pedagogic strategy to facilitate the study of mathematics proof. In Brazil the taught of proofs follows a traditional deductive approach, where students try to repeat what their teachers wrote before. These students are engaged in a course with emphasis on deduction and proof but they are, in general, unable to understand logical deductions and consequently cannot write their own demonstrations. The researcher concluded that there is a necessity of develop a rhetoric argumentative thinking as mentioned by Perelman at the theory of the Argument or New Rhetoric. For him the New Rhetoric can be involved in the context of discussions about relationship between formal language and natural language. For that students are asked to talk aloud about their reflections. The purpose is for them organize their own reflections about their study and understanding deeply their strategies. They try to convince others about their thinking wishing to have others to affirm their statements. They make observations and conjectures, keep a record off all decisions made by the class, while use prior statements to validate or support new conjectures. After this students are asked to write logically their conclusions based on their according and register their observations producing a text to explain these conclusions. On this way the teacher is able to identify some of the organizing strategies students used for constructing their proof while students write informal proof naturally and with sense for them.

The focus of this paper is to examine teachers' beliefs about the differences of boys and girls (aged 13-15 years) as learners of mathematics. For this purpose we developed a questionnaire with a new answering scale. A sample of Finnish teachers of mathematics, 110 female and 94 male, answered to this questionnaire in February 2000. They classified a list of characteristics as being more frequent among girls or among boys in their mathematics classes.

Research on affect and mathematics has focused on the affective responses of students rather than those of teachers (McLeod, 1994; Li, 1999). Teachers' knowledge of, and beliefs about, mathematics have been studied from the perspective of cognitive science, but this perspective is less used in studies concerned with gender (Fennema & Hart, 1994). Studies that deal with mental processes of teachers might give insight into why teachers interact with boys and girls the way they do.

Table 1. Alternatives and scores for X.

Our questionnaire consisted of 55 items of the type: "X finds mathematics difficult." For each statement, teachers had to select the subject X out of the five alternatives: G, g, ±, b, and B. In the analysis the neutral alternative was scored as 0, the direction "girls more often" was scored negative and the direction "boys more often" positive as presented in Table 1.

The results indicated that a great majority of teachers held different beliefs about girls and boys as mathematics learners. Factor analysis revealed six main factors in the structure of beliefs about gender differences: Avoid using intelligence, Talent, Lack of equity, Work-orientation, Expectations of success, and Teacher attention. The two most common beliefs stated girls avoid using intelligence and boys attain most of teacher attention. Beliefs are gathered as parts of a belief system (Green 1971, p.42). Correlations between the six belief dimensions will be discussed in the presentation.

The atomic analysis of the conceptual field: similarity

Ewa Swoboda, Pedagogical University, Rzeszow, Poland

My work was related to the very large research problem: structuralisation. Filip, a junior-secondary student, was subjected to a series of tests and observations. As the 10 years old boy, at the end of 1996 he took part in the experiment in which he was taught how to understand the statement: "figures have the same shape". Three years later I met him again. During the investigation I tried to describe the actual level of his competence by using an informal idea of similarity.

The first part of the investigation was related to the former experiences of Filip. His reaction to the task which he solved in 1996, and tools used, gave me a possibility to describe the actual structure of his field concerned transformations. It contained three almost separate conceptual fields: deformation, isometries, and similar figures. The differences between concept derived mainly from their epistemological nature.

During the second part of the investigation Filip solved a new series of tasks related to similar figures. After that he was asked to describe that concept. The atomic analysis showed how the solving process changed the scheme of similarity. I isolated 14 phenomena which described the mathematical activities connected to his work on the task. The analysis showed also the new linkage created between the concept "similar figure" and the concept "isometry". New capacity of the concept treated gave Filip a chance to build the new meaning for the statement: "figures have the same shape".

LITERATURE:
EFFECTS OF PRE-SERVICE TEACHING PRACTICE ON TEACHER-STUDENTS' EVALUATION OF PROBLEM SOLVING STRATEGIES

Julianna Szendrei, Budapest Teacher Training Institute

In Hungary primary teachers' preparation includes about 500 hours of teaching practice, with more than 400 hours of teamwork concerning classroom experiences. My presentation will deal with the following question: How does the teaching practice influence the teacher-students' evaluation of pupils' problem solving strategies? In order to tackle this question, an experimental study was planned. Two samples of 25 second year (before teaching practice) and fourth year (after t. p.) students were chosen. Ten primary school pupils' solutions to the same problem were analysed by the teacher-students, according to the following guidelines:

A) Try to describe the ways of thinking of this pupil.
B) Evaluate the solution, if the maximum score is 7.
C) Evaluate what this particular pupil knows, and what are the necessary elements in his or her knowledge to be acquired in the direction of solving this problem.

The problem was:

With 32 forints for stamps one can mail a letter weighing no more than 250 grams. Eva has an envelop weighing 14 grams. How many drawing sheets, weighing 16 grams each, may she put in the envelop in order not to exceed (with the envelop) the weight of 250 grams?

It was chosen because it is a true 'word problem' (not an usual 'exercise' in Hungary!) and, according to precedent studies (see Boero and Shapiro, 1992) it allows different strategies (in particular, trial and error strategies and pre-algebraic strategies). The ten solutions were chosen amongst 300 solutions produced by fourth grade Hungarian pupils. The chosen solutions contained: different strategies; different mistakes (in particular, ineffective calculation or notation mistakes); correct numerical answers with evident loss of meaning, or wrong but reasonable numerical answers; etc.

Some preliminary analyses of student-teachers' protocols show: an overall stability of evaluation (mainly centred on formal correctness) across two years of teaching practice (and attended courses), especially as concerns item B; and (especially for items A and C) some changes as concerns the depth of analyses, the mastery of professional-technical expressions and the security in performing the task. This study raises interesting questions about the reasons for stability, and how to change the student-teachers' deep attitudes towards pupils' ways of thinking.

SOME CHARACTERISTICS OF STUDENTS’ INNER WORLD IN LEARNING SCHOOL MATHEMATICS

Hitoshi Takahashi
Joetsu University of Education

Takahashi(2000) proposed that students had internal frames of reference which were their own grounds to view something, to perceive something and to reason in learning school mathematics. Four participants were interviewed two times in grade six and two times in grade seven. Eight modalities of the participants' inner worlds, which make up their internal frames of reference, were found. They were their view of mathematics, attitude/affection towards mathematics, objectifying knowledge, influence of significant others, ways of learning, relating mathematics with daily life, relating mathematics with other subjects, and formalized mathematical knowledge.

This research was extension of Takahashi(2000). The purpose of this research was to explore some of the characteristics of modalities of internal frames of reference in students’ learning mathematics through additional two interviews.

This research was based on Polanyi’s theory of knowledge. Polanyi (1958) proposed that scientific knowledge doesn’t exist as an impersonal universally established. Mathematical knowledge of a society also consists of relationships between personal knowledge and includes a tacit dimension. Owing to the tacit dimension we can try to know actively through intellectual passion, images, and the belief in the existence of mathematical answers to problems.

Knowing depends on a conceptual framework which either assimilates new experiences or ideas, or adapts to them. The framework includes a tacit dimension which supports and fosters the activity of the framework. The tacit dimension is key domain to form internal frames of reference. Polanyi’s theory proposes that knowing constructs metaphorical relationships in our mind. The theory has the same standpoints as Lakoff, Johnson and Núñez’.

Three of four participants were interviewed six times and one was interviewed five times. At fifth and sixth interviews the participants were eighth graders.

As results there were remarkable changes in two participants’ modalities. One student changed her way of learning based on the change in her view of mathematics. Another student changed his way of learning based on the relationship with his friends. There weren’t remarkable change in the other two participants.

STUDENT’S TRANSLATIONS BETWEEN MODES OF REPRESENTATIONS AND ITS UTILISATION IN DIDACTICAL RESEARCH

Marie Tichá, Academy of Sciences of the Czech Republic, Mathematical Institute, Prague

Results of many investigations confirm great significance of the development of representations for the process of education. Halford (1993) noted agreement between theorists "... that understanding means having an internal representation or mental model that corresponds to a concept, task or phenomena (p. 9)." Bills and Gray (1999) pointed out the relationship and connections between internal and external representations. Lesh, Post and Behr (1987) identified five types of representation relevant for the teaching of mathematics. Janvier (1987) stressed that the level of understanding is related to the continuous enrichment of a set of various modes of representation and Bönig (1994) emphasised the development of student’s capability of translation between modes of representation.

These works inspired the present research that follows the previous investigation (Tichá, 2000). This contribution focuses on the study of possibilities for utilising the students’ translations between modes of representations (a) as a diagnostic means in the course of study of images and understanding, misunderstandings and obstacles for understanding of the notion of fraction, and (b) as a re-educational method that helps to eliminate students’ difficulties, insufficiency and obstacles for understanding.

Sample: 10 - 13 years old students from 15 classes at various places in the Czech Republic. Classes were in no manner specialised. In one of classes the students worked in groups since we wanted to observe communications.

Background: Students’ formulations of word problems with fractions to the given calculation or to the given pictorial representation.

Method: Analysis of written work. Students were asked to write only on the sheet with printed problem, without erasing anything. With some of them, we discussed “their problems” after they submitted the test.

It is widely agreed that students’ ways of thinking, their correct and incorrect ideas, should play a role in teaching (e.g., NCTM, 2000). This paper illustrates a way to base instruction on students’ reactions to mathematical tasks.

A class of elementary school mathematics prospective teachers was asked to solve \(200 \div 50 \div 10\) as part of a weekly home assignment. An examination of their solutions revealed a variety of correct as well as incorrect methods that led to different results. The correct solutions included, \(200 \div 50 \div 10 = \frac{200}{50} = \frac{20}{5} = 4\), and \(200 + 50 + 10 = 200 + (50 \times 10) = 200 + 500 = 700\).

The incorrect solutions included, for example, \(200 \div 50 \div 10 = 200 \div 50 \div 10 = \frac{200}{50} \times 10 = 4\), and \(200 + 50 + 10 = 200 + (50 + 10) = 200 + 60 = 260\).

In order to trigger the prospective teachers to reflect on their own and on their peers’ solutions, a class assignment was designed, consisting of their correct and incorrect solutions for the above task. In a 90 minutes class session, the prospective teachers were first asked to work individually and decide whether each suggested solution was correct or not, and why. Later in this session they formed small working groups, and had to discuss their ideas and come up with an agreed response to each suggested solution. Finally, each group presented its decisions to the entire class, followed by further discussions.

In the written responses and in the class discussion the prospective teachers exhibited a rule-based mathematical approach. For instance, several students claimed that “In division one can reduce the elements by cancellation” as a justification for \(200 \div 50 \div 10 = \frac{200}{50} \times 10\). Some others stated that “there is no commutative law for division, hence \(200 \div 50 \div 10\) cannot be computed as \(200 \div 10 \div 50\)” (see also Tirosh, Hadass & Movshovitz-Hadar, 1991).

Additional findings regarding the prospective teachers’ criteria for accepting or rejecting the suggested solutions, and regarding the consistency of their solutions will be provided in the oral presentation.

Teacher behaviours in computer based mathematics – gender implications

Colleen Vale, School of Education, Victoria University, Australia

Mathematics curriculum policy in Australia requires teachers to use information technology as a focus and aid to students' learning and understanding of mathematics. However it is unclear how the use of technology will impact on the participation, engagement and outcomes of girls and boys (Burton & Jaworski, 1995).

In the study reported in this short oral communication the behaviours of two secondary mathematics teachers, who used computers as a resource in their mathematics lessons, were explored. The study was part of a larger ethnographic study concerning the culture of computer based mathematics in secondary coeducational classrooms. Two mathematics teachers, a year 8 and year 9 mathematics class from an urban school participated in the study. The year 8 class used computers in a laboratory for two of their five mathematics lessons each week. During the period of the study they were learning to solve multi-step equations and used Microsoft PowerPoint to display their understanding. The students in the year 9 classed owned laptop computers and used Geometers' Sketchpad to investigate and demonstrate properties of particular shapes during the period of observation.

Six computer based mathematics lessons for each class were video taped, documents collected and four students from each class and the two teachers were interviewed. Data were analysed qualitatively. Teacher behaviours were coded for the content and cognitive nature of interactions (Geiger & Goos, 1996), the attitudes and feelings about people conveyed in their behaviour (Lee, 1993), the methods used to teach with computers and ways of solving problems. Teacher behaviours were compared for interactions with girls and boys and with high and low achieving mathematics students.

Data that illustrates the way that teachers’ behaviours contributed to the culture of these classrooms will be presented. Whilst each classroom was culturally different, and influenced by other factors in addition to teacher behaviour, they advantaged the learning of high achievers and boys.

THE ROLE OF COMMUNITY IN LEARNING TO TEACH MATHEMATICS
Laura R. Van Zoest
Western Michigan University

The current environment of reform in the United States, prompted in great part by calls published by the National Council of Teachers of Mathematics, has created the opportunity for those who are learning to become teachers for the first time to partner with experienced teachers who are learning to teach in a new way. For the past four years, the Learning to Teach in a Reform Environment (LTRE) project has been investigating this learning process for six secondary school mathematics teacher education students from Western Michigan University. During their two-semester pre-intern and one-semester intern teaching experiences, these students partnered with teachers from a school that was implementing the Core-Plus Mathematics Project (CPMP) curricular materials. They also attended two week-long summer workshops with teachers from the school to learn more about teaching the CPMP curriculum effectively. The partnership was designed to provide three key benefits beyond a traditional field experience: 1) including the preservice teachers in a community of learners that had made a commitment to continually improve their teaching to meet the challenge of current calls for reform; 2) putting the preservice teachers in classrooms with teachers who were learning to teach an innovative mathematics curriculum; and 3) ensuring that the field experience was consistent with the teacher education coursework at the university.

Extensive interview and observation data was collected from the participants during their pre-intern and intern teaching experiences and follow-up data was collected through their second year as full-time teachers. In this short oral presentation, results of the analysis around the issues of community will be discussed. These issues include: the effect of participating in a community that is in the process of redefining itself, the different nature of discussions depending on which members of the community are present, and aspects of the community that the interns sought out or tried to recreate in their permanent teaching positions. Looking at these issues leads to a better understanding of the role of community in optimizing the benefits of field experiences.

This paper is based upon work supported by the National Science Foundation under grant No. ESI-9618896. Any opinions, findings, and conclusions or recommendations expressed in this paper are those of the author and do not necessarily reflect the views of the National Science Foundation.
Mitchelmore & White (2000) have recently advanced a developmental theory, based on the theory of abstraction, which attempts to explain the formation of a single concept for angle which results from recognising the underlying similarity between a variety of angle contexts which all involve two lines meeting at a point with some meaning (often "turning") attached to the opening between them. An angle diagram represents the common features of all the different angle contexts.

The authors have shown conclusively that children rarely recognise the dynamic similarity (turning) between two angle situations and more easily recognise the static similarity (two lines meeting at a point), the facility depending on the salience of the two lines which form the angle (over 90% of Grade 2 children where the two lines are obvious in situations such as tile corners and scissors; but only about 40% of Grade 6 children where one or both lines has to be imagined in situations such as hills, doors, and wheels). Based on their findings the authors tested a method for teaching angles which focused on the lines (in particular), vertex and opening in paired situations where one situation had both arms of the angle visible and one situation did not.

The data showed that focusing students’ attention to the individual attributes of an angle helped them to make appropriate matches, to identify the critical features of an angle, to recognise irrelevant matches, and to draw abstract angle diagrams. However, it was not as effective as hoped because it sometimes seems to have led to an angle being viewed just as a line, a vertex, or an opening, and not as a single mental object integrating all three. The data also showed that focusing on these features in a 2-line situation often did little to help students recognise angles in 1-line situations or 0-line situations. The data on drawing abstract angle diagrams at first seems paradoxical because even though students could not match the angles in a pairs of situation, they easily learnt to make an abstract drawing of an angle. This finding can be regarded as a non-transitivity effect: Being able to match a drawing to two angle situations does not imply being able to match the two situations.

In hindsight, we realise that we failed to correctly interpret our own research findings and in fact used an approach which is the exact opposite to that suggested by the theory of abstraction. Hence, taken overall, the teaching sequence suggested is supported, but with a specific focus on the three critical features of an angle occurring after the appropriate similarity has been recognised, not before. Further teaching experiments are currently being undertaken to test the revised approach.

Reference
A collaborative group of senior secondary calculus students sustained a high level of engagement with an unfamiliar challenging problem and progressively developed concepts new to all group members. This is explained using a schematic representation that connects aspects of the zone of proximal development (Vygotsky, 1978) with flow (Csikszentmihalyi & Csikszentmihalyi, 1992) and discovered complexity (Williams, 2000). Discovered complexity occurs during task completion if a problem solver or a group of problem solvers perceive intellectual and conceptual complexities (Williams & Clarke, 1997) not evident at the commencement of the task. This altered perception arises when the group spontaneously formulate a question (intellectual challenge) that is resolved as they all work with unfamiliar mathematical ideas. Discovered complexity meets the conditions for flow; students work just above their present skill level to meet a challenge almost out of reach. Even though the group members are progressing through their individual ZPDs, the expert other (Vygotsky, 1978) is not apparent. Evidence of the group’s interaction pattern (Figure 1) and a profile of each student’s individual ability to solve unfamiliar challenging problems (Krutetskii, 1976) are used to explain how the composition of the group facilitated concept creation.

A Community of Practice associated with Graphics Calculators

Peter Winbourne, South Bank University, UK; Bill Barton, Auckland University, NZ; Megan Clark, Victoria University, NZ; Gerri Shorter, St Cuthberts College, NZ

This report will present some results of a collaborative research project exploring the way secondary school students use graphics calculators. It builds on and complements the work of other colleagues involved in the project (Graham and Thomas, 2000). Here we will discuss how graphics calculators have affected the lives of some senior students: how the technology has helped or hindered their learning; how it has affected the mathematics they learn in mathematics classrooms and how they see the mathematics they are required to learn in other classroom contexts.

The report will be framed by theories of situated cognition (Lave 1996, Lave and Wenger, 1991, Wenger 1998) and adopt the perspective derived from this (Winbourne and Watson, 1998, Winbourne, 1999) where mathematics classrooms are seen as multiple intersections of practices and developing identities.

Students in the study attended schools in England (London) and New Zealand (Auckland). The schools were chosen for their support for graphics calculators in senior classes and for the general and systematic use of ICT in teaching and learning. Student interviews revealed a wide range of student use of graphics calculators. In particular, they revealed students' predisposition to 'see' uses for the technology in their non-mathematics lessons. This predisposition, varying slightly between the schools, was seen to be practically significant. For example, it allowed students to engage in spontaneous graphics calculator-based mathematical discussion in 'non-mathematical' contexts. It was also seen to be theoretically significant; from our perspective, we see this kind of spontaneous discussion as signifying the growing and developing mathematical practices participation in which is central to the success of these students. Such 'predispositions' then, are taken to indicate a community of practice associated with graphics calculators. We will suggest that they are thus desirable as outcomes of teaching and discuss how teachers might aim to achieve them.

WHY AND HOW TO PROVE:
THE PYTHAGORAS’ THEOREM IN TWO CLASSROOMS

Ka-Lok Wong

School of Education and Languages, The Open University of Hong Kong

We have long recognised the pedagogical significance of proofs, even informal proofs, in the mathematics classroom. The teaching of proof concerns itself more with meaning and understanding than validity. Wittmann (1996), in his case with the teaching of the Pythagoras’ Theorem, has suggested that those diagrammatic proofs are conducive to students’ construction of conceptual relationships.

Despite such theoretical concerns, however, we have been increasingly aware that for mathematics learning in the classroom context, a wide range of factors, intertwining with each other, are impinging on students’ understanding of what purposes a ‘proof’ serves and how it constitutes a mathematical proof (e.g. Sekiguchi (1992)). Taking on board the significant shaping effect of everyday classroom practice, analyses of teacher-student interaction (mainly found in recent German mathematics-education research) from the sociological interactionist position look closely into the communication and negotiation process occurring in the mathematics classroom.

Against this general background and following the method of analysis proposed by Steinbring (1998), teaching episodes are taken from two classrooms (at Secondary 2 level in Hong Kong) during the teaching and learning of the Pythagoras’ Theorem. Attempts in using Steinbring’s conceptual tool, the epistemological triangle, open a window on our understanding of how students conceptualise the Pythagorean formula (i.e. the symbolic representation $a^2 + b^2 = c^2$) in relation to certain reference contexts.

Although the teachers took more or less the same approach (i.e. started from a few examples and then went through the same ‘dissection proof’ to reach the general theorem), results of analysis reveal that the development of the mathematical arguments and explanations in the classrooms unfolded in their own self-referential ways, qualitatively different from each other. Among others, the difference lies in why the proof was perceived as needed, and also in how the proof was done. These two aspects are particularly considered as regards the possible meaning of proof conjointly constructed and emerged amidst the teacher-student interaction.

STATISTICAL MINITOOLS IN A LEARNING TRAJECTORY

ARTHUR BAKKER, FREUDENTHAL INSTITUTE

The three demonstrated statistical minitools are Java applets that can run via the Internet (e.g. www.fi.uu.nl/~arthur), but are also available as stand-alone applications. They have been designed for teaching experiments in grade 7 and 8 for Cobb, McClain and Gravemeijer of the Vanderbilt University (USA), and are now used for Dutch experiments of Bakker in grade 7.

At first sight, user-friendly data-analysis software packages seem to be the self-evident accessories for exploratory data analysis. However, working with such packages rather signifies an end point of the intended instructional sequence than a means of supporting it. Instead of using ready-made statistical tools, the present minitool sequence incorporates software tools that can be used for *learning* exploratory data analysis.

The point of departure is a bottom-up approach in which the minitools are perceived by the students as sensible tools that are compatible with their actual conception of analyzing data. For the students, the primary function of the minitools is to help them structure and describe data sets in order to make a decision or judgement. In this process, notions such as mean, mode, median, skewness, spreadoutness, and frequency may emerge as ways of describing how specific data are distributed within this space of values. Further in this approach, various statistical representations or inscriptions like histogram and box plot may emerge as means of structuring or describing distributions. In fact, the minitools are so designed, that they can support a process of progressive mathematization by which conventional statistical concepts and representations are reinvented.

![Figure. Minitool 1 and 2: value bar graph and stacked dot plot.](image)

In minitool 1 every measurement is displayed as a bar. The data can be sorted and investigated with several tools. While working on problems with the simple bar representations, the students learn to relate characteristics of the graphs to the meaning within the context of the problem. If this relationship is consolidated, a more advanced representation is used: not bars but dots in a stacked dot plot are used, the representation of minitool 2. The data in minitool 2 can be organized in several ways, e.g. make your own groups, fixed interval width, two and four equal groups. The last three are useful precursors to histogram, median and box plot. Later, the students can go on with minitool 3, which offers a multi-dimensional scatter plot with several grouping options.
The years from 1936 to 1939 were a time of Civil War in Spain. The conflict brought to an end the progressivist ideas of the Second Republic, and cut off any impulse for innovation in the different regions of the country.

Concerning mathematics and education, proposals coming from foreign authors such as Decroly and Montessory had profoundly influenced teacher training during the years before the war. English textbooks were translated into Spanish to modernize the learning of mathematics, and interesting proposals written by Spanish authors became broadly diffused in the form of textbooks. It was a moment of change and renovation for the whole of Europe, but abruptly stopped in Spain because of the war.

New perspectives opened up during the sixties when old teachers -those plenty of enthusiasm before the war-worked, hand with hand, with young recently graduated teachers. It was again a moment of change and eagerness for recuperating their history, which we also wanted to recuperate by consulting their textbooks and their class notes; by chatting with those young teachers, the grandpas and grandmas of today. The result of this experience permits us to value many things we do today in our school with a different perspective: mental calculations; manipulation of different materials and use of drawing tools; sequence for presenting contents, etc. And the most beautiful thing that this experience permits us is to gather so many grandpa's hopes about teaching mathematics, so many histories of life!

The presentation shows some examples extracted from the books we consulted and from the interviews we made.
PHYSICS AND MATHEMATICS AS INTERRELATED FIELDS OF THOUGHT DEVELOPMENT

Ilsa Basson* and Retha van Niekerk#
*Department of Physics, University of South Africa (bassoi@unisa.ac.za)
#Crawford Teacher Centre, Pretoria, South Africa (retha@uskonet.com)

Students of all ages struggle with Physics not only due to the complexities of the subject, but also due to inadequacies with their skills and knowledge of Mathematics. Mathematics is the “language” of Physics and it is clear that the learning problems of students in Mathematics are transferred to the learning environment in Physics. Lecturers and teachers in Physics consume hours of teaching/learning time to “redo” the Mathematics required to describe physical phenomena. Internationally it is common to find courses such as “Mathematics for Scientists and Engineers” as part of curricula in Physics, since Physics teachers feel that they are in a better position to teach the Mathematics required for their courses. It is proposed that the learning environment in Physics in particular and Science in general, could be much more effectively structured when Physics/Science and Mathematics are considered as interrelated fields of thought development.

Concept formation in the physical sciences depend heavily on two aspects namely a (1) suitable context in which the physical phenomenon takes place and (2) an accessible language in which to comprehend and express these physical phenomenon. One of the criteria for a suitable context would have to be that it is accessible from the real world in which the child/student finds him or herself at that moment as well as that the concepts (e.g. length) within the context, adhere to the psychological (cognitive) structures which the child/student has available at that moment. The context must also be utilised in such a way so that the child/student is exposed to a multitude of interactions in order to prevent him/her from forming so called limiting constructions. The teaching of the physical sciences at school level (secondary or primary) presupposes that some basic building blocks (e.g. position, length, direction, etc.) are in place. By the time the child reaches high school the endeavour is to develop scientific concepts that are already a combination (e.g. velocity, acceleration, etc) of the basic building blocks. The majority of these scientific concepts have their foundation in mathematical sub-structures (magnitude, space, time etc) that the child encounters from his first day of formal schooling (and long before that from birth).

We would like to propose a model that reflects the complexity of this interaction between mathematics and physics with the endeavour to assist in the design of appropriate materials and activities for the development of specific scientific concepts using acceleration as an example.
PROFESSIONAL DEVELOPMENT OF MATHEMATICS TEACHERS: TWO RESEARCH PROJECTS

Ana Maria Boavida, Escola Superior de Educação de Setúbal
Fátima Alonso Guimarães, Escola 2,3 do E. B. de Telheiras

Today's world, characterised by sudden, complex, diverse and uncertain changes that profoundly influence the social practices, is obliged to rethink the concept of professional development in the educational context by associating it to a personal, continuous, dynamic, unlimited and situated process.

This poster will present, schematically, two ongoing research projects focused on teacher professional development. These projects are integrated into DIF, a research group of the University of Lisbon, whose study object is the mathematics teacher.

The poster will include a diagram organised in three parts (A, B, C): A will be a DIF’s characterising schema, while B e C will present, with more detail, the research projects P1, Professional development of mathematics teachers: two life stories and P2, Professional development of mathematics teachers and the teaching of mathematical argumentation, showing the relationships between them and DIF’s work.

Both P1 and P2 have in common the fact that they aim to describe and understand professional development processes of elementary mathematics teachers, adopting, in methodological terms, an interpretative approach of phenomenological inspiration. P1 is included as a biographical approach, using life stories (Pineau, G. & Jorbert, G., 1989) and P2 frames in the paradigm of the co-operative research proposed by Reason (1988). In order to understand the processes and dimensions of the professional development – both in its more broad aspects and in the ones more connected to mathematics teaching – the perspective transformation theory (Mezirow, 1991) and the concept of project (Boutinet, 1996) will be applied in P1. P2, which focus on teachers’ knowledge, competences and dilemmas, will be developed in a context of a collaborative work organised around the teaching of mathematical argumentation. Concerning this last aspect, the concepts of argumentation (Toulmin, 1993; Perelman, 1993) and speech genre (Bakthin, 1986) will be applied, as well as the relationships between proof and argumentation in mathematical activity.

The Departments of Mathematics and Linguistics at Unisa have been investigating the relationship between reading difficulties and mathematics learning, with a group of foundation level students. Some issues involved are the following.

- Potential problems when the primary language is oral rather than written.
- Relationship between bilingualism and the ability to learn mathematics. (Bain & Yu, 1980; Ben-Zeev, 1977; Clarkson, 1991; Cummins and Gulutsan, 1974; Dawe, 1983; Duran, 1988; Hakuta & Diaz, 1984; Prins, 1997; Secada, 1988; Zepp, 1989)
- Specialised academic and mathematical vocabulary and skills; technical terms.
- Specialised semantic and syntactic structure of mathematical discourse.
- Special symbols which denote processes and concepts.
- A variety of ways in which the same operation can be indicated.
- The use of passive voice.
- Visualisation of problems or concepts.
- Lack of equivalent words in the mother tongue.
- The redundancy of words in ordinary language
- Reading rate adjustment; eye movement patterns.

The Unisa team postulated that a strategy for effective reading and learning of mathematics, initially using a volunteer group of foundation level students, and applying the SLAMS (Second Language Approach to Mathematics Skills) (Dale & Cuevas, 1987) method, should take into account

- level of difficulty of text, in particular: general vocabulary and language proficiency; academic vocabulary and mathematical vocabulary; identification of ordinary, mathematical or multiple meanings of words
- syntactic structures specific to mathematics
- semantic/logical relations specific to mathematics
- reading rates
- trialing the PQ4R technique: (P) preview, (Q) question, (R) read detail, (R) reflect, (R) rewrite, (R) review
- verbalisation of mathematical notation
- anaphoric references within the text.

We plan to generalise the results into a strategy we can use with an entire cohort of similar students in 2002. We hope to determine whether the reading enhancement programme has any significant impact on the extent to which these students can meaningfully read, and hence learn, mathematics.

The above information will be more comprehensively available at the conference, as well as details of the references on which this paper is based.
WHAT STRATEGIES DO PRIMARY SCHOOL CHILDREN USE IN MEASUREMENT ESTIMATION PROBLEMS?

Dagmar Bönig
University of Bremen, Germany

In mathematics instruction at school frequently the search for a precise answer is dominant. In every-day life however, we often base our decisions on estimations, sometimes because it takes less time or effort, sometimes because it is the only suitable method to solve a problem. In addition, (measurement) estimation competencies play an essential role in the development of number sense (Dehaene 1997; Greeno 1991). Nevertheless, currently little attention is given to this topic both in education research and classroom instruction (e.g. Sowder 1992).

The poster presents the estimation problems and findings of a large scale empirical study involving over 100 primary school children (grade 3 and 4), who were asked to solve a variety of estimation problems in an interview setting. Since the main research interest was concerned with the qualitative analysis of the estimation process, the key findings relate to the estimation strategies the children used in these contexts. The poster will display photographs of several problems used in the clinical interviews and illustrate the observed student strategies. In conclusion, a system of major categories which has been developed on the basis of these results as well as under consideration of models discussed in the research literature (Forrester et al. 1990, Hildreth 1983, Siegel et al. 1982) will be proposed. In this connection, special attention is given to the relationship between task demands and the observed strategies as well as to the role of spatial structuring in measurement estimation situations (Battista et al. 1998).

A NEW METHOD FOR RESEARCH IN
COMPUTER-BASED LEARNING ENVIRONMENTS

Stephen R. Campbell
University of California, Irvine

Instructional designers are becoming much more attuned to the importance of user-centred design, the wide variety of experiential modalities associated with human-computer interfacing, and various relations between instructional design and cognition. As a result, computer-based learning environments (CBLEs) for mathematics education now typically involve multiple representations of subject matter content in ways that attempt to accommodate different learning styles. Typically, human-system interaction research has relied on monitoring user activity via computer tabulation of keystrokes and mouse clicks. Advances in digital video and telecommunications technology have now provided the means to develop a new method for dynamically tracking teaching and learning in these environments. Some empirical results demonstrating this method of dynamic tracking are presented.

Dynamic tracking presents teachers, learners, researchers and instructional designers alike with more intuitively accessible opportunities for investigating symbiotic cognitive development in CBLEs. Dynamic tracking allows teachers to conduct action research on the effectiveness of their teaching with CBLEs, and learners with the opportunity to reflect on their own learning. What researchers can discover about various factors that promote or inhibit learning in CBLEs using this method can also serve to inform instructional design. On the other hand, instructional designers, through the CBLEs they have developed, provide researchers with a variety of different constrained conditions in which to investigate factors that promote or inhibit learning with respect to a variety of different learning styles.

This presentation will demonstrate dynamic tracking using familiar protocols (such as “talking aloud”) as well as new ones that were simply not possible using previous methods (such as “keeping your mouse where your mind is”). The method of dynamic tracking will be demonstrated in both teaching and learning situations, as well as in classroom and clinical contexts. Once data have been collected, they can also be analysed using digital video processing software. Thus, various action sequences and meta-cognitive factors can be identified and used for data interpretation. Using this method, CBLEs can be analysed to help identify potential systemic constraints placed on the learner, as well as the kinds and effectiveness of the scaffolds for learning that they offer. Dynamic tracking thus provides a variety of avenues for investigating various modalities of mathematical cognition and how they are interconnected, for ways in which CBLEs can be improved, and for ways in which teaching and learning with them can be more effective.
Purposes and basis for the proposal: Our intention is to design environments for children to use the math they learn in the classroom for their lives, to learn it through their lives and during their whole lives; a mathematic knowledge that supports the upbringing/raising of integer human beings and improves the society’s life quality.

For this reason, we take UNESCO principles as a basis, and we propose that the process to construct mathematic notions, to practice and apply them should be the basis for:

- Learn to be: Development of creativity, attitudes, values, conscious decision taking.
- Learn “to live together“: Enhance respect for learning styles diversity, intelligence, cultures, preferences, sex, perceptions,...as a guide to find common elements to make grow the unity.
- Learn to do and to learn: Development of skills of thinking, mathematics, designing plans, project participation, competitions.
- Learn to know: Construction of math notions departing from dialectic processes which suppose that learning is mediated, among other things, by the individual maturity level, social historic experience and technology; given through approximations; which is the product of individual interaction and social collaboration, and that is meaningful when gradually, the consciousness levels of reality increase while participating in environments with projects related to the knowledge of oneself, the family, the school, the place where one lives, the country, the world, the universe, the present, the past, the future....combined with actions on didactic situations requiring descriptions of surroundings, solving problems, games, construction, organisation, research....(Vigotsky, Piaget, Freire, Papert).

The experience: Departing from the observations made with 20 children for 10 years where they were building the mathematic notions during their daily activities, related to their family-life and outside school; later, a test phase was carried out with 10 children for 3 years (1997-1999) in which, the practice of values, attitudes and decisions-making were proposed, together with learning maths and using computers. Beside this we worked with 200 in service primary teachers (1998 - 2000) and 20 pre-service teachers from the Benemérita Escuela Nacional de Maestros (2000) to promote the study about UNESCO Principles as a synthesis of different theories of education philosophy, and important data was got on the human being’s potentials, his creativity, attitude, will and responsibility in making decisions, the diversity of learning styles and the diversity of reactions over difficult situations, the skills and the learning foundations, based on which we designed didactic strategies as well as the creation of environments in which mathematic knowledge is integrated with learning to be, to “live together“, to do and to learn.

Produced materials and applications: To make concrete this proposal we have elaborated text books for basic school children with the sections Monthly Game (recreational exercise), For Thinking (skill development), Giving Opinion (respecting the diversity and recognising the unity), Deciding (decision making and attitude recognition); Suggestion on Didactic Planning in which the activities gather the concepts and procedures with skills, attention to diversity – unity, creativity, decision making, values and attitudes; CD with math games, courses and workshops designed for teachers and future teachers. A Web site has been set with the didactic planning.

Future actions: During the year 2001 we will keep working on didactic planning with in service and pre-service teachers in order to let them learn about the proposal and collect relevant feedback for evaluation.
MATHEMATICS TEACHERS’ DIDACTICAL DEVELOPMENT AND THE QUADRATIC FUNCTION

Cristina Carulla, Pedro Gómez

University of los Andes, Colombia • Universidad de Granada, Spain

In this study, mathematics teachers’ didactical development was explored on the basis of a series of conceptual maps that they produced while working on small groups. The teachers participated in a one-year long in-service training program in which they were asked to produce content, instruction and cognitive analysis of the quadratic function. The training program methodology was based on the presentation and discussion of the groups progressive productions for each analysis. The notion of representation system was the organizing idea for the teachers’ conceptual maps. These maps were codified using a series of attributes for identifying what the teachers saw as the essential characteristics of the mathematical object and the type of representations they used to describe it. Using these attributes, a characterization of all possible maps based was produced and used to analyze the results of the codification process. The results show that this in-service training program, designed using the notions of didactical analysis and representation systems as conceptual structure, using conceptual maps as communicating tool for the teachers, and promoting small group work and whole class discussion, induced a didactical development of the participants that expressed itself in the increasing complexity with which the teachers represented the mathematical object at hand.

We describe briefly the methodology used to codify and analyze the nine conceptual maps produced by each of the five groups of teachers. The attributes considered were the following: whether the map is based on representation systems or not; number of structured representation systems present; number of connections between representation systems; number symbolic forms of the quadratic function present; whether there are connections among these symbolic forms; whether the map is centered on the quadratic equation; and whether the symbolic manipulation techniques were presented as objects or as relationships. On the basis of these attributes some conceptual maps are possible and others are not (i.e., one cannot talk of connections between representation systems if the map is not organized on them). These produced four different structures of the evolution of the possible maps and the paths the maps of a group of teachers can follow while improving them. In this way, we were able to characterize the development of the productions of each group of teachers.

All groups showed significant differences between the first and last conceptual maps produced. However, while some groups were able to make steady progress, other groups showed that there are obstacles to this development, related mainly to the use of structured representation systems and the connections among them. Furthermore, while some groups productions evolved using always the same basic structure, others groups changed that structure at least once along the program.
A Model of Teaching Integrated Theories of Teaching and Learning

Ching-Kuch Chang, Graduate Institute of Science (Math) Education, National Changhua University of Education, Taiwan, R.O.C.

In 1992 the Taiwanese National Science Council began funding a two-year project which had the goals of: (a) investigating the practicality of implementing problem-centered instruction (Wheatley, 1991) in Taiwan, (b) increasing the possibilities for effective mathematics teaching through teaching strategies change, (c) developing a new model of teaching for Taiwanese teachers. The research results of (a) and (b) have been reported (Chang, 1995, 2000). This paper reports the research results of (c), a new model of teaching (Figure 1).

Figure 1. Problem-Centered with Double Cycles (PCDC) Teaching Model

1. The difficulties and questions arising from the implementation of single-discipline programs in educational institutions have led to the search for a different approach to teaching. In France, the Ministry of National Education has set up interdisciplinary studies at various levels of secondary education in order to bring about this new approach.

2. MAG7 (Paris 7 IREM), a multidisciplinary group consisting of seven teachers and researchers in education, directs its efforts toward elucidating the relationship with space as it appears both specifically within the three disciplines taught (maths, plastic arts, and geography), and in ordinary communication. MAG7 uses the results of its work to construct a common training program on the subject of the relationship with space for teachers in these disciplines at the middle-school level (years six through nine of compulsory education).

3. The objectives of the program are the following:
   • to promote awareness of the ways each discipline approaches the concept of space
   • to compare and articulate the various points of view, and attempt to define an axis of communication and collaboration among the disciplines.

4. This training program consists of eight three-hour sessions.
   • The goals of the course are presented, followed by an interactive introduction to ordinary communication and the analysis of images (diagrams, photos, multimedia) that are considered to be inter- or trans-disciplinary. • Each of the disciplines is introduced by means of a case study concerning learning about space. Although placed in a specific context, it can prompt an exchange of ideas from the points of view of the various disciplines. • Activities involving the collaboration of teachers from at least two disciplines are proposed, carried out, analyzed, and evaluated.

5. Is it possible to join different sorts of knowledge together, and to build bridges between the disciplines involved in learning about space? If so, how? Herein lies the heart of the debate on interdisciplinarity in education.

This poster presents some results of Project AMECC (Learning in Mathematics: A study on the construction of concepts\(^1\)), focused on the topic of functions taught in the 10th grade. This study intended to characterize the concept of function and of graph of function developed by pupils in a situation of formal learning. More specifically we intended:

- to identify the nature and the use of pupils' own conceptual models
- to understand how these models are changed through education.

The methodology, of qualitative nature, was based on semi-structured interviews of 6 pupils at 3 different moments: before the beginning of the formal study of the topic, immediately after this study, and about 3 months later.

The results presented are centred on the performance of pupils in the accomplishment of two tasks that involved the translation between different representations of the concept of function, namely, a two-way translation between a written representation of a real-life situation and a graphical representation. This type of translation posed some difficulties to the pupils who engaged in the tasks using their intuitive knowledge and who gave less relevance to the variables involved and to the functional relationship among them. Some graphics constructed by the pupils showing these types of difficulties and usually related to special kinds of pictorial representations will be shown. Although in general accordance to previous works, (Janvier, Dreyfus, Kaput, Vinner), some variations will be presented.

Promoting children's number sense

GINSHIMA, Fumi    Kanazawa University, JAPAN

Number sense has been a focus of the mathematics education in about ten years. And, in recent years, instructions have focused on promoting number sense in the domain of numbers and calculations at elementary schools in Japan. These instructions have reflected on old instructions for the acquisition of formal calculation skills. Performing calculations quickly and correctly is completely different from performing calculations using many kinds of methods flexibly or seeing numbers in various ways. If the instructional aim is one of these, the other one can not be achieved automatically. In other words, we have to aim at qualitative improvements in such capabilities so that children can utilize meaningfully numbers and operations and can solve problems effectively.

Children come to treat numbers in various contexts before entering school, and have naive knowledge concerning numbers. In school, they are expected to develop rich knowledge about numbers, to perform well with numbers or calculations in mathematics. A rich number sense can not develop only within a certain one domain or in a fixed time period. Such a sense is developed gradually and refined in various activities involving numbers and calculations. Furthermore, a rich number sense cannot be directly taught as a certain fixed procedure. The number sense of children can only be developed after they recognize the merits of calculation methods or the necessity of using them. For example, the following important points can be mentioned in calculation instructions.

- Do not focus only on performing calculations quickly and correctly.
- Do not focus only on whether calculation results are correct or not.
- Have children develop their own calculation methods.
- Put a child's original way of thinking as the basis of the instructions.
- Provide a lot of opportunities for children to experience and compare various calculation methods.
- Provide a lot of opportunities for children to apply trial-and-error methods using various calculation methods.
- Provide the opportunity for children to recognize the necessity of examining calculation results.

Each of the above-mentioned important points is apparently very common. In spite of this, it is very difficult to implement these points in daily classrooms or everyday life. The amount of daily activities has a serious influence, making it difficult to promote such a number sense.
SPATIAL ABILITY & GEOMETRY LEARNING

Meike Grüßing, Frank Hellmich
Department of Mathematics, Carl von Ossietzky University Oldenburg, Germany

Spatial ability is regarded to be an important part of mathematical competence. In particular, research studies have shown that spatial ability is positively related to achievement in mathematics (e.g. Fennema & Sherman 1977). Other studies gave evidence of transfer effects between a training of spatial ability and problem solving competence (e.g. Souvignier 2000). Moreover, transfer effects between spatial ability training and the enhancement of mathematical skills is discussed.

Our research contributes to the role of spatial ability in geometry problem solving processes. We present two studies concerning
(1) the effects of computer presented spatial geometry problems on spatial ability,
(2) the influence of spatial ability on geometry performance, and
(3) the differences between low-achievement and high-achievement students with respect to the training effects.

The sample comprised 63 elementary school children (study I) and 110 students in special education (study II). The students were assigned to one of two groups. Students of the experimental group took part in a computer-based training of spatial ability. All students took part in a series of regular geometry lessons. Both groups were presented questionnaires with items concerning their spatial abilities and their geometry performance as pre-test and as post-test.

Our results show that spatial ability can be enhanced in particular with respect to specific items closely related to the training environment (study I: Mann-Whitney-U-Test p= .000, Cohen’s effect size d= 1.1; study II: p= .014, d= .404). We did not identify a significant effect concerning the influence of spatial ability on geometry performance. These results confirm results of former studies with secondary school students (Hartmann & Reiss 1999).

Our study-in-progress aims at refining the results of previous studies: In particular, we will consider content, environment and duration of training as important components influencing the effectiveness of training.

A NEW COURSE FOR PRE-SERVICE MATHEMATICS TEACHERS

Valery A. Gusev
Moscow State Pedagogical University

We will consider the new approaches to pre-service teacher education in a leading pedagogical university in Russia – in the Moscow State Pedagogical University. For the last few years here the problems connected to the realization of the complex approach to mathematical, psychological, pedagogical and methodical preparation of the mathematics teacher have been studied.

In particular, the program of a course “Psychological and pedagogical foundations of mathematics teaching” is elaborated. In the following we describe some features of the structure and contents of the course.

Essentially, the traditional general methods duplicate didactics, not concerning at all psychology of teaching. On the other hand, the particular methods consist of exact prescriptions for teaching certain themes of school mathematics, sometimes simply describing the school course. Necessity of the intermediate course, that would serve for a bridge between psychology, pedagogics and mathematics, on the one hand, and methods of teaching of mathematics, on the other hand, is obvious. This necessity is caused by the impossibility to effectively refer to general psychology and pedagogy. It is assumed that the course “Psychological and pedagogical foundations of mathematics teaching” will be studied by the students, that have already learnt psychology, pedagogics and some part of mathematics, before the course of methods of teaching mathematics (see the scheme below):

PSYCHOLOGY   PEDAGOGY   MATHEMATICS

PSYCHOLOGICAL AND PEDAGOGICAL FOUNDATIONS OF MATHEMATICS TEACHING

METHODS OF TEACHING MATHEMATICS
```

The brief description of the contents of the course “Psychological and pedagogical foundations of mathematics teaching” follows:

MATHEMATICAL UNDERSTANDING OF GRADE 8 STUDENTS

Aiso Heinze, Jeeyi Kwak
Department of Mathematics, Carl von Ossietzky University Oldenburg, Germany

We will report on a survey in four classes of 8th grade at a secondary modern school (German Realschule). Overall 106 pupils were asked to answer ten exercises which mainly dealt with school geometry. The survey aims to investigate the pupils' knowledge on five general mathematical concepts, which are not taught explicitly in mathematics classroom. We want to find out: (1) Are grade 8 students able to give definitions; (2) Are they able to identify equivalent descriptions of a simple geometrical object; (3) Do they have an understanding of a mathematical proof; (4) Do they know that in general the converse of a logical implication is not true; (5) Are they familiar with the concept “proof by a counterexample”.

First results indicates the pupils understanding of a mathematical proof. We gave the students three “proofs” for the statement that the vertical angles are equal. We asked the students a) to select the “proof” which they would choose as own approach and b) to select the “proof(s)” which are correct. It turns out that more than 50% of the pupils preferred the proof with the empirical arguments as own approach but only 39% chose this approach as right answer. This result corresponds to those of Healy and Hoyles (1998). In contrast to the results of Healy and Hoyles in our study more students preferred empirical arguments. This difference seems to base on different age groups and different mathematical skills of the populations.

With respect to logical implication, we presented a daily life problem and a mathematical problem. Most of the pupils answered correctly to the problem of daily life: More than 65% stated that the converse of the implication “If it rains, then the street is wet.” is not true. Around 45% of this correct answers were given by a counterexample. However, in the case of the converse of the mathematical implication “If a square is a rectangle, then the opposite lines are parallel.”, only 10% offered a correct answer. These results show similar tendency as those of Douek (1999) and Duval (1991).

Description of Doctoral Project

I have been working with teacher education in mathematics for 25 years. Through this work I have gained some experience and have made a number of reflections about the learning of mathematics.

My doctoral project will be based on my experiences and thoughts connected with my work as a teacher educator. This will cause me to choose a philosophic analysis of mathematical content and/or of the process of learning. In order to restrict myself to something accessible, but still relevant to all learning of mathematics, I will concentrate on the formation of concepts. The problem I will pose is therefore this:

How do human beings form mathematical concepts?

This problem leads straight to the core of the epistemology of mathematics. The most important sub-problem here is:

- What is a mathematical concept?

To answer this, we must answer something even more fundamental:

- What is a concept?

Then we must consider the process of acquiring knowledge:

- How do human beings form concepts?

If we combine these points, we will closer to answering the question I have posed.

In order to say what mathematical concepts are, one has to consider the philosophy of mathematics. As a result, one has to pose the didactical question:

- How does the teacher's philosophical view on mathematics influence the teaching?

Then I have to cope with the very difficult task of separating mathematical concepts from all other concepts. This is about finding criteria describing a clearly defined hierarchy of concepts. These criteria shall fit concepts that are so different as circle, addition and topological space. I am not sure what the result of this analysis will be, but a doctoral dissertation must find some new paths. I think part of this is definable, but I imagine some concepts must be considered as mathematical by cultural tradition.

Constructivism as a philosophy of learning holds a strong position today. Recently, it has been claimed that this philosophy has no didactical influence, because the theory does not incorporate guidelines for good teaching. I will thoroughly investigate the importance of discriminating between on the one hand the philosophy of how mathematics is learned and on the other hand methodological recommendations. At the same time I want to show how philosophical insight combined with didactical goals may influence teaching.

The real core in my project is to use philosophy not only to understand, but as guidance for practice.
The understanding of the environmental questions supposes an interdisciplinary work in which Mathematics is inserted. The quantification of involved aspects in environmental problems favors its clearer vision, helping in making the decisions and permitting the needed interventions (recycling and reutilization of materials, for example). This project is part of an investigation in which the line of research is Mathematics and Society, of the Master’s Program in Mathematics Education of the Institute of Mathematics Education of Santa Úrsula University. This project was elaborated and implanted during the year of 1999 in three classes of the Sixth year of the Fundamental Course, totaling 80 students of a private school in the south zone of Rio de Janeiro Country. The investigated problem was how to avoid the waste of water, since the missing of hydric resources in one of the most present day concerns of humanity, The project had as its targets - development of peoples' capacity to approach questions in the environment - environmental and ethical consciousness. The study implied the disciplines Geography, Portuguese, Mathematics and Sciences. At the beginning, the students and the teachers of the cited disciplines visited the State Company for Waters and Sewers - CEDAE - where they received an explanatory video and participated of activities that gave information about the origin, supplying, treatment and reutilization of the water in the city of Rio de Janeiro. The classes were divided in groups of three or four students; each group was held responsible for a specific theme related to one of the disciplines implied in the project. The groups in charge of the mathematical part chose as their theme: the quantity of water wasted in homes. It was asked to the students and each group was held responsible for the data collection in the following actions: dishwashing, teethbrushing, taking a bath, washing the sidewalk and washing a car. The students made tables that indicated the quantity of water spent in the action leaving the tap always open or closing it when flowing water was not needed. They calculated arithmetic means, ratios, percentages and, using EXCEL, made a graphic of sections where there appeared intuitively an idea of angle and its measures. Each group showed a synthesis of its investigation to all the students. The students took conscience of the environmental and ethical question of water economy with the aim of having a sustainable development. They influenced their families in this respectful attitude of preservation of the ecosystems.

CONTEXTUALIZED MODELS FOR SLOPE AND LINEAR EQUATIONS
LAURA B. KENT
UNIVERSITY OF SOUTH CAROLINA, USA

This poster presentation will describe and illustrate photos and products of student work from the results of a classroom-based case study involving 10 eighth grade students' use of visual and tactile models during instruction of a unit involving the topics of slope, graphing, and equations. The models were derived from the Mathematics in Context curriculum unit Graphing Equations (Kindt, et al., 1998). Samples of student work from pre- and post-unit interviews and classroom work will be used to illustrate the impact of various models on their ability to determine the slope of a line and solve a linear equation for an unknown.

Pre-unit tasks were used to assess students' informal and prior knowledge of slope and solving linear equations. Most of the informal/prior knowledge consisted of recognizing slope as "something slanted". Several students related the word to skiing and drew a diagonal line to represent a ski slope. In addition, four of the ten students were able to use the slope of a line within a context to determine an unknown quantity. None of the students, prior to the study, used any formulas or symbols to describe slope when asked to do so in their own words. During the study, compass cards and graphing calculators were used to locate points, draw lines, and determine the slope of a line. The results of post-unit interviews revealed that these activities enhanced eight out of the ten students' abilities to conceptually describe slope in their own words and determine the slope of a line using a variety of informal and symbolic strategies.

Prior to instruction, none of the students were able to solve linear equations for an unknown. A frog jump context and linear (visual and tactile) models were used during instruction to connect their knowledge of modifying "equal lengths" to the steps involved in solving a linear equation for an unknown. The results on post-unit tasks showed that eight out of the ten students were able to solve multi-step linear equations for an unknown.

We will present the design, and discuss the mid-project findings, of a one-year project that is examining how mathematical ideas and techniques are used in the practice of engineering, based on case studies of professional engineers working on design projects in several large civil engineering consulting firms. We are especially concerned with the observation of mathematics as used in workplace activities, rather than merely asking people to describe what they think they do. This is because we want to look beyond those elements of work conventionally described as mathematical (such as techniques learnt in school or university) to try to observe situations in which a more general, and harder to specify, "mathematical literacy" is involved. These situations are made complex by the fact that engineering design is done by teams of people, made up of different kinds of specialists, where mathematical work may be the principle responsibility of only a small part of the team. We have a particular interest in the role of digital technologies in this collective design process: is mathematics becoming an ever more specialist realm, where non-specialists are increasingly the consumers of "pre-cooked" mathematics hidden behind the interfaces of software packages? We believe that this question is not as clear cut as it seems, if we admit a broader definition of mathematisation than the visible application of mathematical techniques.

The methodology and theoretical basis of this project are derived from a previous project carried out several years ago at the Institute of Education, which examined the mathematical practices involved in nursing, commercial aeroplane piloting, and investment banking (Hoyles, Noss & Pozzi 2001). We found that the various professional groups employed a variety of mathematical strategies which were finely tuned to their practice, yet simultaneously retained the notion of invariance that typifies abstract knowledge. We have begun to explain this phenomenon in terms of a theory of "situated abstraction" (Noss & Hoyles 1996), and the current project is developing this theory by carrying out research in a domain of practice where we can see sophisticated kinds of mathematics (geometry, algebra, calculus) that entail complex structures of abstractions in their practical application.

References

Students often find the concept of zero difficult to understand. The linguistic of zero is confusing even for university students, including many elementary school preservice teachers (Ball, 1990; Blake & Verhelle, 1985). The purpose of this poster is to highlight some of the difficulties that the elementary school preservice teachers face in understanding zero and its concepts. This poster will depict some dilemmas of teaching these concepts.

The current study primarily focused on two questions. First, what do prospective teachers understand about zero in general? For example, do they consider zero a number? What do they know about the development of zero in various civilizations? Second, what is preservice teachers' understanding of division by zero? For example what is 5/0? 0/0? These questions lead to a discussion on their ability to convey the meaning of zero to their future students.

The data for this study were collected from a course entitled "Mathematics for Elementary School Teachers" for the last five years. Approximately, 200 students have participated in this study. This poster will draw data related to zero from their quizzes, exams, and personal interviews conducted by this researcher at the end of each course.

In all the courses, prospective teachers had difficulty understanding zero and its concepts. Before introducing zero in the class, more than 90% of the preservice teachers thought that a number divided by zero is zero. Even after the concepts of zero were taught for an entire session of one hour, only about 60% of the preservice teachers stated that 5/0 cannot be determined. The other 40% stated that 5/0 was zero. The percentage of correct response did not increase substantially in the final examination when basically the same question was asked. In the personal interviews, many students were confused and even indicated that they would avoid teaching the concept of zero to their future students. The author of this proposal finds it alarming and hopes that it will generate some discussion in the PME poster session.

A STUDY OF STUDENTS' SPATIAL ABILITIES WITH THE USE OF VIRTUAL ENVIRONMENTS

E. Koleza, I. Dimitriadou and T. A. Mikropoulos
Department of Primary Education
University of Ioannina, Ioannina, Greece

Children move, interact, perceive, recall and represent the natural world space and its attributes. (Osberg 1997) The geometrical study of space leads to its reference systems, namely the Euclidean, topological and projective. An interesting research question is the way primary school children perceive and exploit these, intentionally or unintentionally.

The understanding of space and its attributes, the relations and rules govern them, allow children not only to act, but also to conceptualize complicate concepts allowing them to adapt and face similar spaces and learning situations, to develop spatial skills (Wilson 1997, Doorman, L.M., Kooij, H v.d. :2001)

The present research concerns the study of spatial skills of children of ages 10 – 12 years, with the contribution of three-dimensional synthetic environments, implemented by Virtual Reality (VR) technologies.

The virtual environment was designed in order to investigate:
- The nature of internal representations of students concerning space orientation, recognition and handling of two and three dimensional geometrical objects viewed from different viewpoints, following specific verbal instructions
- Language used by students to describe spatial relations in the virtual environment
- The eventual distance between spatial information acquired by exploring a geometric problem in the virtual environment and the one acquired by exploring a paper / pencil environment.

The set of all triads \((a,b,a+b) \in \mathbb{N}^3, (0 \notin \mathbb{N})\), \(a \leq b\) with the mappings \(L_t: (a,b,a+b) \rightarrow (a,a+b,2a+b)\), and \(R_t: (a,b,a+b) \rightarrow (b,a+b,a+2b)\) creates the structure. This was used as a tool in the research aimed at investigating the building of an infinite arithmetical structure.

**Research**

The set of triads that is equipped with left and right mappings serves as a good tool for research, diagnosing pupils’ abilities to build structure and is an educational field within recreational mathematics. The structure of triads as a research tool enables us to observe a whole process of creating an arithmetical structure because the graphical model of structure evidences many thinking structural processes of the pupils. The research has illustrated the following four facts:

1. Creating a global structure presumes necessarily previous insight into local structures (involving from two to five elements – the triads joined by the mappings).
2. The ability to create a concept of the structure of triads is profoundly individual. Pupils showing the same level of understanding of the structure of natural numbers get insights into the structure of triads at different rates.
3. A powerful tool is the ability to grasp the structure graphically and leads to the understanding of structure which does not depend whether a tree, representing the structure, is orientated up or down.
4. As the pupils solved the problems step by step they created other elements of the structure. During these activities the pupils had misconceptions. By realising this and by understanding the reasons for them, contributed to getting an insight into the structure. The following four cases of misconceptions were found:
   A. The notation of triads can be reduced, e.g. triads coded as dyads or monads.
   B. The triads on a line higher than line 1 can be written down automatically without thinking about mappings.
   C. The generated pattern from the left ‘branch’ can be applied to the right ‘branch’.
   D. The number of line can be used as an operator for generating an appropriate triad on the line (the triad on line 10 was made by doubling the numbers in the triad on line 5).

I will give specific examples of pupils’ solutions to illustrate the four cases of misconceptions mentioned above in my presentation.

Changing classroom environment and culture - Case study
Marie Kubinová, Jarmila Novotná, Charles University, Prague

The contribution continues the research presented in (Kubinová, Mareš & Novotná, 2000). It focuses on the analysis of concrete situations in two classes taught in different ways by different teachers in the past but taught by one teacher at present. The differences in students’ behaviour, teacher’s approaches and results achieved by students are diagnosed. It is shown that even if the teacher who wants to implement the change from instructive to constructive teaching, is sufficiently qualified, has long-term experiences with constructive teaching strategies and has no obvious external obstacles for implementing their plans, has to be open-minded and respect students and their prior experience.

When studying questions related to using constructivist approach to teaching (mathematics) we use variety of methods: longitudinal evaluation of teaching effectiveness by comparison of periodic testing of parallel classes, direct observation of the milieu of the classroom and analysis of teaching strategies, the teachers accounts of their own classroom experience, analysis of audio/video recordings of lessons and children’s written work. In the school year 2000-2001 we face a singular opportunity. One of the authors teaches mathematics in two parallel classes of the ninth grade (students are age 14). In one class she has been teaching for five years and using constructivist teaching methods (the SC type class in Kubinová, Mareš & Novotná, 2000). She has never taught the other class before. It is well known that previous teachers taught in an instrumental way.

Our research is in accordance with the ideas about powerful learning environments from (De Corte, 2000). “... the teacher becomes a ‘privileged’ member of the knowledge-building community, who creates an intellectually stimulating climate, models learning and problem-solving activities, asks provoking questions, provides support to learners through coaching and guidance, and fosters students’ agency over and responsibility for their own learning.” From our experiments it is clear that the teacher’s role is crucial, the teacher has to understand and respect the situation in each individual group of students, it is not possible to transmit the methods and forms of work which were successful with one group of students to another without any modifications, however it is possible to use experiences gained with one group of students to organise work in another group.

A FRAMEWORK FOR ANALYZING STUDENTS' MATHEMATICAL WRITING

Eri MATSUDA
Graduate School of Education, Tokyo Gakugei University, Japan

This study proposes a framework for analyzing students' mathematical writing to promote students' thinking in mathematics classroom.

The educational value of engaging students in mathematical writing has been explored in a variety of research. It helps students, for example, learn and externalize their thinking and feeling about mathematics. This study focuses on promotion of students' thinking through mathematical writing.

There has been much research focusing on writing activities, in particular, journal writing. It is necessary for students, however, to write mathematically in the process of classroom activity, as well as to look back their own thinking at the end of classroom activity. Writing activities should be incorporated into a whole classroom activity.

In this study, two dimensions of mathematical writing are identified. The first dimension is "aspect of mathematical thinking" (i.e. writing in the context of learning mathematics). The second dimension is "aspect of communication" (i.e. writing for and about someone's thought). Each dimension has some "modes" and "levels". The "modes" are used for describing what students write. The "levels" are based on the prescriptions of what teacher wants students to write.

Students' writing is expected to progress along with each of the two dimensions. With respect to the first dimension, students' writing progresses to sophisticated one. On the other hand, with the second dimension, students become more reflectively through mathematical writing. In other words, students' mathematical thinking can be promoted through mathematical writing.

Implications of the framework for teaching are also discussed. The framework can be used for developing worksheets and for planning instruction in the classroom. Classroom activity can be enriched by using mathematical writing.

Some examples of students' writing will be shown in the presentation.

CHARACTERISTICS OF COGNITIVE ACTIVITY OF STUDENTS WITH LEARNING DIFFICULTIES

Maryvonne MERRI
Ecole Nationale de Formation Agronomique, Toulouse (France),

Michael PICHAT
Research Team “Cognition and didactics”, University of Paris VIII

Marie-Paule VANNIER-BENMOSTAPHA
Institut Universitaire de Formation des Maîtres de Melun (France)

Observation of interactions between teachers and their students with learning difficulties emphasises the links between didactic and cognitive phenomena. More obviously than in any other environment, the status of interactions and knowledge seems to be two-faced. Students and teachers have to play both the didactic game and the apprenticeship game.

♦ One usual conception of teachers could be “when teaching to students with learning difficulties, one is not to let them inactive”. Thus, maintaining and showing off external activity under the pretence of an effective cognitive activity can become the major rule structuring the didactic game. Vannier-Benmostapha and Merri explain how teachers may support this phenomenon in scaffolding interactions. In order to understand how students may face this mechanism, Pichat focuses on the students’ pragmatic knowledge: a low level knowledge that allows them to maximise efficiency despite lack of real competency (Pichat and Ricco, in press). Therefore, transfer of responsibility concerning knowledge and skills may not develop in a proper way.

♦ However, we observe a few students taking advantage of such interactions. Two issues are presented. At a control level, they internalise the structure and the content of former conversational interactions; by this means, students develop self-control procedures which are isomorphic to the injunctions of the teacher. In this case, the teacher has a chance to be relevantly imitated. Moreover, a second benefit comes from experiencing functional limitations of their pragmatic knowledge; in such a case, pragmatic knowledge may be re-elaborated so as to be more efficient.

Getting teachers to be aware of these two phenomena could be useful for a better control of the effective cognitive benefit of their students.

Pichat et Ricco. What is the nature of mathematical conceptualisation in didactic institutions?, Cognitive systems, in press.

The South African authorities have realised the need for an education system which equip learners with the necessary knowledge, skills and disposition to cope successfully in the world when they leave school. As part of this strategy in mathematics, data handling was recently introduced in the curriculum of the intermediate phase (gr 4 - 6) and presently gr 5’s for the first time encounter data handling activities. Facilitating and assessing these activities according to the problem-centered approach gave rise to this experiment.

Peer-assessment is a powerful but lesser known assessment strategy in the new dispensation, and presented a challenge to the facilitator. The linking of classroom activities with real life situations in Outcomes-based Education and especially the assessment of learners' knowledge and skills in data handling has been the focus of this experiment.

Three classes of 30 learners each participated. The classes were divided into five groups of six each. Learners had to solve the problem of determining the most popular chocolate bar in the class and representing the information graphically, in an open socio-constructivistic learning environment. Activities include: collection of information, design of a data sheet to organise information, drawing of a graph, group presentation to explain the whole process, writing of recommendations to the school tuck shop owner based on the conclusions of the survey and assessment of the whole process. Materials: data sheets and graphs from newspapers and other sources, grids for peer-assessment, self-assessment and facilitator assessment of the groups.

Despite a lack of systematised procedural skills and a tendency to over decorate, learners enthusiastically joined in all the activities. Interesting information gathering and data organising techniques were used and different graphs drawn; group co-operation and presentation skills were also developed. The use of peer-assessment techniques proved a useful tool to the facilitator and the learners in the realising of the outcomes for the mathematics strand data handling.

The role of problems in the mathematics lessons of the TIMSS-Video-Study

Johanna Neubrand, University of Lueneburg

The TIMSS-Video-Study revealed great differences in the teaching of eighth-grade mathematics classes in the three countries involved, Japan, US, and Germany. Stigler & al. (1999) showed the existence of different cultural scripts in the teaching of mathematics. The reanalysis in this paper is based on the mathematical problems themselves and focuses therefore directly on the content related issues in the videotaped lessons.

Method: From the sample of the lessons in the TIMSS-Video-Study, 22 lessons in each country were selected. So, a sample of 1153 problems, some further divided into related subproblems, were analysed. The instrument used for this analysis is a classification system for mathematical problems, developed for this purpose.

Results and discussion: The most important results from this reanalysis will be presented graphically. The results capitalize the assertion „Teaching is a cultural activity“ (Stigler & al. 1999) from an additional point of view. „Cultural“ does already apply to the content itself. Mathematical problems play - as means to organize the construction of mathematical knowledge - different roles in the three nations' classrooms, not only in their number but also in the selection of the problem characteristics and their implementation in the lesson.

Mathematical teaching and learning by qualitative evaluation using ‘Open-Approach Method’ in school activities

Nobuhiko Nohda
Iwate University, JAPAN

Summary:
We will mention some findings concerning the use of both the ‘open-approach method’ and the ‘open-ended problem’ to make clear the meaning of ‘both activities by students and mathematics are open’. The aims of instruction using the ‘open-approach method’ are to foster both creative and mathematics thinking in problem solving by students simultaneously. From quantitative to qualitative evaluation of mathematical activities, which are the expression of both mathematical ideas and processes of the ways of thinking used to solve problems, are very useful. In order to develop this usefulness, we make the model for examining these activities which are convenient enough for us to deal with the students’ many kinds of processes of solving the problems.

SAME RULES, DIFFERENT CHALLENGES:
A SUITE OF GAMES FOR PRACTISING NUMBER EFFECTIVELY

Adrian J Pinel
University College Chichester

The card games to be presented through this poster were invented by the author in 1978. They can provide specifically differentiated individual and group based practice of mental recall and mental strategic thinking in number contexts. They progress from self-checked working out by one or two students of each set of 6 to 9 cards, through to speed practice in a game format by groups of 4 to 6 players, using packs of 24 to 72 cards. Discussions arising from playing the games can provide diagnostic and formative assessment, while enhancing the insights of students. Using the same rules, around 50 different sets have been designed to meet identified needs, so that students do not have to learn new rules to play gradually more advanced games.

The poster will:
➢ give full details of a variety of uses of an example game set;
➢ illustrate key features and how they differ from other superficially similar games;
➢ relate the use of these games to the ideas of productive practising;
➢ indicate responses of students in pre-school and elementary classes, and views of their teachers, over 2 years of use as a central part of their number curriculum;
➢ outline how these games relate to the English National Numeracy Strategy;
➢ relate the educational value of these games to the ideas of Vygotsky, Gattegno, Freudenthal, Wittmann and others.

INVESTIGATING AND LEARNING: A WEB BASED PROJECT

J. P. Ponte, H. Oliveira, H. Fonseca, J. M. Varandas, L. Brunheira
Centro de Investigação em Educação, Faculdade de Ciências da Universidade de Lisboa

Aims and context. This project aims to promote innovative perspectives for mathematics teaching and learning through the development of a Web site. It emphasizes the idea of investigation as a process of knowledge construction and provides a link for the community interested in this idea in different parts of the country. The project is developed from 2000 to 2002, as one initiative of Research Group DIF with the support of the Ministry of Education (DAPP). The target audience is all those directly interested in curriculum change in mathematics including teachers, prospective teachers, teacher educators, and pupils of different age groups.

Main assumptions:
(i) Investigations constitute an important form of construction of knowledge. Pupils and teachers may undertake mathematical investigations and, in addition, teachers may undertake professional investigations.
(ii) The Internet is a powerful medium, promoting cultural change. It enables the search for information. It also allows people to publicize their work. It is a medium that promotes interaction among people, enabling the development of new meanings and new identities.
(iii) Information and Communication Technologies (TIC) are a significant resource for teacher education. They also provide an important link between research and professional practice.

Activities carried out in 2000. These include, for example, the 1) set up of a search engine focused in mathematical investigations; 2) actualization of a data base of publications concerning mathematical investigations; 3) creation of a text bank (with documents to download); 4) update of short texts covering issues involved in carrying out mathematical investigations in the classroom; 5) exchange of teaching experiences; 6) update of a links page for other sites; 7) creation of a Web-based forum; 8) divulgation of the project and interchange; and 9) theoretical discussions.

Project interim evaluation. By the end of the first year of the project, we strengthened our perspective about the value of investigative activity as a fundamental strategy for knowledge construction. However, we note some difficulty in getting material, especially descriptions of classroom experiences, to include in the site. We also have some difficulty in promoting interactions with the target audience, as the participation in the forum is below our expectations. These are issues that we want to address in the future development of the project.

Initiatives for 2001. New material will be provided in the Web site, such as the analysis of new curriculum documents regarding the place given to investigative ideas. A closer connection to schools will be attempted, through sessions with features such as demonstrations of the site to teachers and students and research about the place of investigations in teachers' professional practice. We are also planning a survey regarding the how teachers use the Internet.

Graphical form. The poster will include images from several pages of the Web site as well as a global map of the site. A scheme of the project aims, activities, and evaluation will also be provided.
STUDIES ON THE QUALITY OF SCHOOL: ACQUISITION OF CONTENT SPECIFIC AND CROSS-CURRICULAR COMPETENCIES IN MATHEMATICS AND SCIENCE DEPENDING ON IN-SCHOOL AND OUT-OF-SCHOOL CONTEXTS

Manfred Prenzel, Susanne Koerber, Kristina Reiss*

Institute for Science Education (IPN) at the University of Kiel, Germany

*University of Oldenburg, Germany

Research on teaching and learning as well as the results of TIMSS have revealed that content specific and cross-curricular competencies students acquire in German mathematics and science instruction are rather insufficient. Among the most prevalent deficits are 1) a lack of flexible application of knowledge in new situations, 2) difficulties in solving complex problems, and 3) the decline of interest in mathematics and science during high school. It is obvious that these deficits not only concern subject specific achievement but also motivational variables and key qualifications relevant for the efficient acquisition of new knowledge in general (e.g. problem solving strategies, the competence for self-regulatory learning). As a response to these findings a priority program “Studies on the Quality of School...” was launched by the Deutsche Forschungsgemeinschaft (DFG) in 2000. The program aims at systematically identifying reasons for this unsatisfactory performance and at suggesting theoretically and empirically well grounded interventions to improve the quality of education in German schools with a particular focus on mathematics performance as well as on science, motivational variables and cross-curricular competencies.

One important but often neglected factor influencing the quality of instruction is the general pattern of the lessons, called scripts. It is eminent to find out, whether there exist consistent, presumably culture specific, patterns of instruction, which patterns dominate, and how they interact with and influence learning processes. Another focus concerns certain components of instruction, like the use of representations or instructional methods and media and their interplay. Apart from the actual learning context (the learning situation), also the wider context of learning has to be considered. Teaching and learning science and mathematics are embedded in a particular school context and are influenced by it. And finally, there is the broad context of the society schools are part of. Students' views of what mathematics and science learning is about and whether it is worth the effort rests also on the attitudes and beliefs of teachers, parents and the peers.

Currently, there are 23 projects working in this program. In most of them mathematics and science educators and psychologists co-operate closely. Cooperation between the individual projects is a further key feature of the program. The projects are problem oriented, i.e., educationally relevant basic research and applied research are combined. The poster presented will provide an overview of the philosophy of the program and the 23 projects funded during the first two year period.
Developing an understanding of probability depends on a wide range of activities but it is also dependent on an understanding of part-whole relationships, even before the stage of quantification is reached. This is particularly apparent in such probability tasks as sampling from collections of similar elements and using spinners with differently marked sectors. Since the work of Piaget & Inhelder (1951) much of the research in probability has centred around how children think about chance (Fischbein, 1975; Truran 1994, and many others). In most of the mathematics curricula probability stands apart from other areas of mathematics and how this is to change is a matter to be addressed. The focus of this presentation is on some aspects of a pilot study to explore ways in which early links can be made between foundational activities designed for developing an understanding of probability and for learning about fractions. This study was carried out with children in two age-groups, 7-8 years and 9-10 years, in three schools and consisted of several series of lessons for each age-group. What is presented in this poster outlines the experiences and activities used in one series of the lessons with the 7-8 year-old children.

DESIGN OF THE SYSTEM OF GENETIC MATHEMATICS TEACHING AT UNIVERSITIES

Ildar Safuanov, Pedagogical Institute of Naberezhnye Chelny

First, one should accomplish the analysis consisting of two stages: 1) genetic elaborating of a subject matter and 2) analyses of arrangement of a material and possibilities of using various ways of representation and effect on students. The genetic elaborating of a subject matter, in turn, consists of the analysis of the subject from four points of view: a) historical; b) logical; c) psychological; d) socio-cultural. In designing of the system of genetic teaching very important is to develop problem situations on the basis of historical and epistemological analysis of a theme.

The major aspect of logical organisation of an educational material consists in organising a material so that to reveal the necessity of the construction and development of concepts and ideas. It is necessary to arrange problem situations or tasks, for which the important concepts or ideas, which should be studied, would serve as the best solutions. It is necessary to analyse those problems of knowledge, for which the considered concepts and ideas serve as the necessary solutions. For this purpose, both historical analysis and epistemological considerations, and special search for appropriate problem situations and tasks can help.

When studying university algebra courses, the students usually are encountered with sequentially growing steps of abstraction - with a “ladder of abstractions”.

According to the theory of A. N. Leontyev, actions on learning concepts, as well as any actions, consist of operations, which are almost unconscious or completely unconscious. These operations are essentially “contracted” actions with the concepts of the previous level of abstraction. As M. A. Kholodnaya (1997) noted, “a contraction is immediate reorganisation of the complete set of all available … knowledge about the given concept and transformation of that set into a generalised cognitive structure”.

In our view, for reaching a contraction of an action with algebraic objects into (automatic) intellectual operation it is necessary, after sufficient training with this action, to include it in another action, connected with the construction of objects of the next step of abstraction.

After two stages of analysis, it is necessary to implement the project of the process of study of an educational material. We divide the process of study into four stages: 1) Construction of a problem situation. 2) Statement of new naturally arising questions). 3) Logical organisation of an educational material. 4) Development of applications and algorithms.

References:
The methodology developed during the research covers four stages:

1. **Structuring the information** to be learned, according to an epistemological model.

2. **Systematical training of the mental capacities** focusing in different manners on each of the following: understanding the concepts, computing procedures, and problem solving.

3. **Random training of the developed capacities.** This type of training plays an important role in consolidating the mental structures acquired by the child. The technique employed is the mental game starting from isolated information. The start could be: *isolated numbers, groups of numbers, computing exercises, problems, and symbolic schemata.* Examples could be given for different grades, but the most spectacular results could be seen in primary education. For example, in Grade 1, the teacher proposes the number 4 and asks for creating the sequence of natural numbers by fours till 20. Another riddle-game requires the composition of a number in which 4 is a compulsory component, or it is not at all a component. Moreover, the students are stimulated to create problems starting with the number 4. The problems could be connected to practical situations, but also to theoretical mental problems, for example: “Use 4 coins to compose a given amount of money”, “We know that we start with number 4 and we add its double. What is the number we get?”, etc.; it is important to practice both types and to pass from one to another. These procedures are then carried out starting from other numbers and practicing serial arrangements, comparisons, estimations, creating problems, problem-solving, composing and decomposing numbers. These are practiced orally, mentally, in written forms.

4. **Structured training,** which is targeted at the assimilation of invariants. This is done by constantly resorting to diagrams and models. The exercises become gradually complicated, following the initial model in various ways: with direct support from objects or concrete schemata, or without this support, by operating in an internal language, and later by operating with literal symbols for numbers. The mental structure created in this way is confronted with itself by “shifting” its elements, by applying different thinking operations, by passing from one level of abstraction to another, etc.

Instead of a “drill and practice” strategy, a “structure and practice” strategy is developed. This training leads to the creation of a dynamic mental structure, able to mobilize in various situations and to find creative solutions for complex problems.
The concepts of ratio and proportion are considered to be very difficult in elementary school and throughout high school. In fact, Piaget (1966) viewed proportional thinking as a key ability developed in the formal operational stage. Many adults, including student teachers and teachers and people in different occupations (nursing, fishermen, carpenters, etc.), do not understand these concepts well or used localized strategies to solve problems (Fisher, 1988; Keret, 1999 (PME); Klemer & Peled, 1998 (PME); Tourniaire & Pulos, 1985).

Although some ratio problems are very complex and demand abstract thinking, it is important to help children construct ratio concepts while they are young. At this age the children can develop intuitive understanding of the ratio concepts and they can have opportunities to model the problems with concrete objects or drawings. Hopefully, when these children grow up, they will have a sound conceptual base to build on.

This study documents solution strategies for ratio and proportion problems in young children (grades one to three). This data is part of a larger project of learning mathematics through problem solving in a constructivist way by a branch of Cognitively Guided Instruction (CGI) (Carpenter & Fennema, 1996). In this project there is an emphasis on children developing their own unique methods of solution. The children reflect on their solutions and ideas and communicate them to others. The teachers learn about the children’s thinking and build the instruction on it.

The children solved the ratio problems by using mainulatives and drawings and by seeing mathematical relationships. Almost all the children could solve the problems correctly, including sophisticated strategies (some needed direction from the teacher such as a request for drawings). Examples of problems: “For the price of 2 thick notebooks you can buy 5 thin ones. How many thin notebooks can you buy for the price of 20 thick ones?” “In a class there are 30 children. For every 3 boys there are 2 girls. How many boys and girls are in the class?” Other problems scale the amounts of ingredients in a recipe. Example: to make 500 grams of beans we used half a cup oil, a quarter teaspoon of pepper, 4 tomatoes etc. How much would we use to make 750 grams? An example of a third grader solution to the last problem: 250 grams goes twice into 500 grams and 3 times into 750 grams. So divide all the amounts by 2 and multiply by 3. So half a cup of oil corresponds to the 500 grams. 250 grams corresponds to ¼ cup. 750 grams corresponds to 3 times ¼ and this is ¾ cup oil.
Mathematics Curriculum Standards in China
— Present state and prospects for the future

Sun Xiaotian
Central University for Nationalities, Beijing, P. R. China

China has planed to make a change for education. The first action was happened in the field of mathematics education. The National Mathematics Curriculum Standard (NMCS 6—15) is the first new published “Standard” of the national educational development program in China. There are some new determinants in it. The main ideas were summarized in the fields of targets, curriculum structure, knowledge, learning and teaching, assessment and technology. These new determinants showed that mathematics curriculum should help children to build a practical basis for their continuing development in the future. As a bit soft approach than the former hard one, NMCS 6—15 can leave more rooms for processes, strategies, constructions, investigations and discourse to the students. NMCS 6—15 is a symbol and a fundamental step for achieving a changing and development of mathematics education in China. And there are also some new research characteristics for designing NMCS 6—15. It proved that NMCS 6—15 is a production that fully considered the nowadays-international developments and reflected the advantages of Chinese own. The revising is necessary. NMCS 6—15 should be more scientifically and practically. Whatever, NMCS 6—15 has illustrated a good idea. I hope our nation’s youth may both excel and hearts in mathematics under the guide of it.

An Analysis of the Experimental Mathematics Curriculum in Elementary School

Ning-Chun Tan, National Taipei Teachers’ College, Department of Mathematics Education

The experimental curriculum for elementary mathematics had been implemented in Taiwan during the period between 1992 and 1997. Researchers studied students’ learning processes and scholastic achievements to assess the effectiveness of the experimental mathematics curriculum. The main objectives of this study contain:

1. Investigate the differences in the effectiveness of mathematics learning between students following the experimental curriculum and those following the traditional curriculum in elementary school.
2. Conduct a follow-up study on the continuation of mathematics learning for those experimental students in middle school.
3. Compare the differences in achievement of mathematics learning between the experimental students and non-experimental students in middle school.

Five phases were carried out during this research. Phases I and II were conducted for students in their second semester of sixth grade. Three surveys were collected and analyzed, including Mathematical Learning and Experience Scale (MLES), Mathematics Attitude Scale (MAS), and Mathematical Problem-Solving Test (MPST). In phases III to V, the follow-up study was conducted for students in the first semester of the seventh grade and two mathematics classes were observed. During the period, open questionnaire about elementary and middle school mathematics learning experience was designed and math grades of the students were collected from three periodical test scores in math.

After one year follow-up study, findings were concluded as follows:
1. The experiment students had more positive attitude but less metacognition abilities than the control group students. However, habits of peer discussion, communication and cooperation learning were popular in experimental classes.
2. The students’ scores in the problem-solving test were much better in the experimental group than in the control group. The study also indicated that learning effectiveness was dramatically different among experimental classes.
3. Observations in middle school showed that focus of the process-based experimental curriculum is substituted by focus of outcome-based teaching in middle school. The researchers found that a change in teaching style in the math teaching community is difficult and that requires teachers to change their perceptions of mathematical learning.
4. Comparing math achievement in middle school between experimental and control groups, it was found that the achievement of city students is well above the average while the achievement of students in the suburbs is below average.

In view of the above-mentioned conclusions, some suggestions are provided:
1. Establishing professional development programs are essential and should be considered at the earliest possible time.
2. Teachers should increase their flexibility to meet the systemic change in math-teaching classes.
3. A concrete research and development system should be developed to serve as a resource center for math teachers to produce a set of information on structural math concepts.
SEARCHING FOR THE ILLUSION OF LINEARITY IN PROBABILISTIC MISCONCEPTIONS: A LITERATURE REVIEW

Wim Van Dooren*, Dirk De Bock**, Lieven Verschaffel* and Dirk Janssens*

*University of Leuven and **EHSAL, Brussels; Belgium

Recent studies by De Bock, Verschaffel and Janssens (1998) have shown strong empirical evidence for the strength of the tendency among secondary school students to apply the linear (or proportional) model on applied geometrical problems about the relationship between the length and the area/volume of similar geometrical shapes, for which this linear model is not suited. This overgeneralisation of the linear model (the so called 'illusion of linearity') has also been exemplarily described in several other mathematical domains, like elementary arithmetic, algebra and probability, however, without providing much empirical support.

This poster will report the results of a literature survey about the linearity illusion in students' probabilistic thinking. Taking Shaughnessy's (1992) review of the existing research on students' misconceptions about probability as the starting point, the poster represents an overview of those misconceptions that can be conceptually linked to the illusion of linearity.

With respect to each of the six identified probabilistic misconceptions for which such a conceptual link could be established, the poster will show (a) an example of a problem that is expected to elicit the incorrect answer resulting from an overgeneralisation of the linear model, and (b) a graph that shows the wrongly supposed linear relationship between the crucial variables in the word problem contrasted with the probabilistically correct nonlinear relationship. One example is given in the figure below.

![Graph Example]

If a fair die is rolled one time, there is a chance of 1/6 to throw a six. What is the chance of getting at least one six in five trials?

**Misconception:** 5/6 = 0.833

P(at least one six in n trials) = n x P(a six in one trial)

**Probabilistically correct:** 0.589

P(at least one six in n trials) = 1 – (5/6)^n

In our future research we will empirically investigate to what extent these probabilistic misconceptions can indeed be attributed to students' tendency to overgeneralise the linear model. This investigation will help us to further unravel some widely known probabilistic misconceptions, on the one hand, and to provide further insight into the range of the linearity illusion, on the other hand.

Our aim was to develop a unit for Grade 10 that deals with parabolas. We started by identifying, with the help of teachers, two main limitations of the traditional presentation of parabolas in the high school curriculum:

1. The difficulties students have in expressing the relationship between the parameter ‘a’ of the quadratic function \( y = ax^2 \) and the shape of its graph. Most of the students can determine when the parabola has a cup/hat shape. Students also say something about ‘stretching/shrinking’, or ‘opening/closing’ of parabolas, while the teachers are not sure which description is the right one. A common misconception is that ‘a’ is the ‘slope’ of the parabola (analogous to a line).

2. The gap between the two viewpoints on the parabola in the traditional curriculum: the algebraic view of the graph of a quadratic equation, and the analytic-geometry view of loci. This gap causes students to think that there are two different kinds of parabolas.

Our plan was to use the symbolic power and rich graphics of CAS to make connections between analyzing the shape of the parabola and viewing it as a locus of points. Naturally, we concentrated on the Focus point of the parabola. But, we did not find a constructivist approach that could direct students at this age (15-16). Consequently, we came with another idea - to develop the notion of “a special chord in a parabola” whose mid-point is the focal point. The chord, which passes through the Focus \( F(0, \frac{1}{4a}) \), has special properties. The length of this chord is \( \frac{4a}{m} \), which agrees visually with the fact that as ‘a’ increases, the parabola ‘shrinks’. When we calculate the distance between F and any point on the parabola \( P(m, am^2) \), using our ‘talented mathematical assistant’, we get the expression \( |P - F| = m^2 |a| + \frac{1}{4a} \). In addition, the slopes at the end-points of the chord are 1 or –1.

Our goal was then to develop a sequence of tasks that will help students to open a geometric window on the parabola. The poster will demonstrate critical stages in the formative development of the learning unit.

RESEARCH REPORTS
Highschool students' conceptions of graphic representations associated to the construction of a straight line of positive abscissas.

Claudia Acuña, México
cacuna@mail.cinvestav.mx

Abstract: The construction of a straight line of positive abscissas is a task that require to know how make a graph, you can use the point-by-point strategy, but if you don't have any equation is necessary to know where the graph is. We ask to three different samples of students (16 to 19 years old) where a straight line of positive abscissas have to build. We use a semiotic classification of variables visual and categorial for to find no relevant aspects in their answers, our analysis suggest that some of the students have an "one dimensional conception" about the Cartesian plane, they consider variations only in one coordinate and this conception seems coexist with the point-by-point graphics. They take the y-axis like an anchorage in their attention, it cut the x-axis leaving in one side negative numbers and the positive in the other side. And they use often one part of the graph y=x although they think a complete straight line.

Resumen: La construcción de una recta de abscisas positivas es una tarea que requiere de conocer cómo se hace una gráfica, pero si además no se tiene la ecuación entonces es necesario saber donde debe estar la gráfica. Propusomos a tres muestras distintas de estudiantes, de 16 a 19 años, la construcción de una recta de abscisas positivas. Utilizamos una clasificación semiótica de variables visuales y categoriales para detectar los aspectos relevantes de la tarea así como los que no lo eran en las respuestas, nuestro análisis sugiere que algunos de nuestros estudiantes tienen una "concepción unidimensional" sobre el plano Euclídeo, es decir, consideran solamente variación en una de las dos coordenadas y esta concepción parece coexistir con la graficación punto a punto. Toman al eje y como un elemento que ancla su atención y corta al eje x dejando de un lado a los números negativos y por otro a los positivos. Utilizan frecuentemente una parte de la gráfica de la recta y=x pensando en la recta completa.

Introduction

When studying Analytic Geometry, in which objects and conceptions may be expressed through different kinds of representations, Defining and Definiens must be clearly distinguished in accordance to current education, based on the construction of relevant concepts which cannot take place on the basis of only some of their representations.

For to build graphics is neccesary to pass from equation to the graphic and converse, this articulation is a one to one relation and always it is possible have one equation for each graphic although you don‘t know it.
The idea that there is a correspondence between the graph and the equation was used by Pierre de Fermat and Rene Descartes in the creation of Analytic Geometry, according to C.Boyer (1956) which -for teaching purposes- should be understood, as we mentioned before, in the sense that there is a one to one correspondance between each algebraic representations of straight lines and their graphic representations and converse.

In fact, the possibility of establishing the relationship between the graphication of the straight line and its equation can see since a semiotic point of view. In this case graph and equation are linking in a univocal way through visual elements (visual variables) in the one case and algebraics (categorical variables) in the other (Duval 1999).

In this paper we make a suggestion about the linking between categorical and visual variables in a construction task: the straight line of positive abscisas. We have been working with three different samples to see if the typical graphic answers appear on them. We describe the relevant aspects against no relevant aspects about the answers of the students too.

**Theoretical framework**

The Raymond Duval's point of view is that the conceptualization process involved in mathematical concepts or objects (noesis) through conversion of different semiotic representations (semiosis). Such point of view enables us to observe the conceptualization of mathematical objects or concepts in which all the meaningful variables between the graph and the equation are displayed, thus showing meaningfulness and allowing for the learning of the concept from a sign/significance perspective.

R. Duval (1999) develops a semiotic viewpoint based on graphic and algebraic representations that belong to different semiotic registers and articulation between them, they must be carried out through conversion.

As to the conversion between registers -which is necessary to make a conversion the graphic and the algebraic representations- one would have to establish the relationships between the visual and the categorical variables on the basis of general variables defined by Duval (1988), as follows, the general variables are: 1.Task implantation, figure sticking out from ground: a line or region 2.Task form: the line, whether it limits a region or not, whatever it is straight or curve. If it is curve, whether it is open or closed.

---

1 Categorical variables herein mentioned are those which make a difference from a semiotic point of view between one equation and another, between one graph and another, in case of visual variables.

2 Duval (1994) defines thus: "conversion is an operation which transforms a representation into a register change (p.222). It is also: the transformation of such representation into one of different register where all or only part of the former content is preserved". (1988, p. 21).
And three particular variables: 1. Direction of line's slope (goes up, goes down). 2. Angle and axes (symmetrical partition, major angle, minor angle). 3. Position on the y axis (cuts above the axis, below the axis or on origin).

We notice the following changes in its school treatment about straight line:

a) Graphism associated to the Euclidean straight line where position has no referents. Only the figure-form exists. Position is contemplated as a visual variable acquiring value when it is associated to other elements as a tangent or a bicectrice. The kind of process is called here an Euclidean straight line.

b) The straight line is treated almost like the Euclidean straight line. With almost complete freedom as to position, restricted only by the figure-ground, this is, by the coodinate axes. The equations are not the most important subject here. Relationship between figure-ground and figure-form is given on a figural manner. This kind of process is called here post-Euclidean straight line.

c) Straight lines' graphism is associated to linear equations. Equation use and its variables determine the straight line's position. The straight line's characteristics are manifested through points such as (0,b) and/or (-b/m, 0) or by the slope m of straight line y = mx + b. Visual variables are not considered, since the position is now expressed algebraically. We call this treatment algebraic straight line.

In the mathematics straight-line process, two principles can be noted: 1) The straight line is formed by an infinite number of points; 2) The straight line can be extended indefinitely to both sides.

These principles are strictly theoretical but they have a gestalt importance that is often missing. Every attempt to represent them figurally or algebraically is but an attempt to build an infinite set with a finite number of elements through a finite process as well, however is not possible miss these gestalt characters when they build this straight line.

For the current paper we must consider some works have demonstrated that when handling definitions, are influenced by certain kinds of examples called prototype, which are more popular than the others are. There is also a tendency to increase secondary or irrelevant characteristics in the definitions (Hershkowits, 1989; Vinner, 1991).

The problem

The main problem we have used for our observation is the following; the task is about geometric description on graphic register:

---

Footnote: From a point of view of the historical development of the mathematical knowledge the stages can be a) Euclidian line, b) Analytic line and c) Afin line, but here we want to consider the school treatment by programs.
6. Draw a line where all the abscissas of the points are positive, this is, where \( x \) is always \( x > 0 \).

In this task we only used one way in the double link of the conversion between algebraic and graphic registers and the algebraic register is support with the natural language.

In the sense of Duval (1988), we describe the general visual variables in our task:
1. Task implantation: a line; 2. Task form: Straight line. About particular variables we have: 1. Angle and axes: symmetrical position; 2. Lines slope: infinity; 3. Position on the \( y \)-axis: no cut. The draw conditions are: \( x = k, k > 0 \)

<table>
<thead>
<tr>
<th>Categorical variables</th>

</tr>
<tr>
<td>( k &gt; 0 )</td>
<td>The line put on the right side of ( y )-axis.</td>
</tr>
</tbody>
</table>

**Methodology**

In early papers, we have been doing research with highschool students between 15 and 19 years old, in relation to the graphication of points, straight lines and semiplanes, with special attention to their ordinate spatial character and observing the relationship between figure-form (graph) and figure-ground (axes) under a coordinate-based treatment, on the one hand, and to the relationships established by its graph, on the other. In the present paper we want to ask about how the student think the build a straight line no typical, where they have to show theirs conceptions about the straight line in the Cartesian plane. Our samples were:

<table>
<thead>
<tr>
<th>Sample</th>
<th>School</th>
<th>Age</th>
<th>Number</th>
<th>Questionnaire</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>CCH Sur</td>
<td>16</td>
<td>87</td>
<td>C2</td>
</tr>
<tr>
<td>B</td>
<td>CC Sur</td>
<td>17</td>
<td>77</td>
<td>C6</td>
</tr>
<tr>
<td>C</td>
<td>Sciences Department</td>
<td>19</td>
<td>42</td>
<td>C7</td>
</tr>
</tbody>
</table>
The sample C students are highschool graduates coming from different schools that answered the questionnaires on the first day of class at the Sciences Department, Math division, University of Mexico.

Students of the other samples were on 5o semester but the ones who are 17 years old were repeating the course, our intention with different samples was to see if the typical descriptions are present in different school information and age stages.

Localization of points on the plane may be considered a condition for graphicating point-to-point, although it is not enough for conversion between representations because the continuity gestalt condition is lacking. The following table shows performance when locating points on the plane.

<table>
<thead>
<tr>
<th>Sample</th>
<th>Point (4,7)</th>
<th>Point (-5,8)</th>
<th>Point (-4,-7)</th>
<th>Point (0,9)</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>95.4%</td>
<td>88.5%</td>
<td>94.2%</td>
<td></td>
</tr>
<tr>
<td>B</td>
<td>89.6%</td>
<td>85.6%</td>
<td>84.45%</td>
<td>74%</td>
</tr>
<tr>
<td>C</td>
<td>95.2%</td>
<td>97.6%</td>
<td>97.6%</td>
<td>95.2%</td>
</tr>
</tbody>
</table>

We have introduced in all of the questionnaires we have worked with a legend elucidating the difference between ordinate and abscissa to prevent confusion about axes from being the most relevant error. Table results indicate that once the difference is made, the task is reduced to applying the localization algorithm.

The problem dealt with in the present paper is proposed as a pencil and paper task on the Cartesian plane where we work with whole units around the origin. Students distinguish positivity on the plane as we have noted on their localization results, and they have built straight-line graphs point-to-point, supported by their equations as part of the highschool curriculum.

We consider their answers reflect their interpretation of the question in terms of their own conceptions since they have no background on questions like this; therefore, they are not influenced by their teacher's indications.

Below we have the answers to the problem:

The nest table show the relevant and no relevant aspects in the answers of the students we classify them like follow:

**Relevant aspects:**

\[ x = k \]
\[ k > 0 \]

0% in A, 6.5% in B and 40.5% in C

**No relevant aspects:**

In II the points are: \((x,y) = \{ y = x, x > 0 \}\) 62.1% A; 26%, B; 19% C
In III \((x,y) = \{ y = k, f(x)= y, x > 0 \}\) 1.1%A; 29% B; 16.7% C
In IV \((x,y) = \{ y = mx + b, 0 < m from infinity; x > 0 \}\) 24.1%A; 9.1% B;2.4% C
In V \((x,y) = \{ x = k, k > 0, y > 0 \}\) 3.4% A; 6.5% B; 7.1% C
In all wrong answers the students missed a hidden aspect, the continuity of the line, this aspect own to the treatments\(^4\), it is not a visual variable but it is necessary for focus the visual variable that we need for the conversion. The number of no relevant aspects that students consider in their answers are: one in IV \((y > 0)\), two in II and V, and three in III, besides the continuity condition (see the next before table).

**Analysis and Conclusions**

Previous results evidence that almost all of the students in sample A and B and almost 60% of sample C students make no difference between a straight and a cut straight line and, once the student incorporates this idea, he might think that, complementarily, the negative abscissas may be avoided if axis \(y\) is not exceeded as in answers II, III and V.

If we consider the item referring to the semi-straight line at \(45^\circ\), we may say that this prototype example is rather relevant in the teaching of Analytic Geometry. In fact, it cannot be missing in school texts or in class. This straight line has a figural characteristic in the sense that its special slope is synonymous of its angle.

We found that the wrong answers start when they no consider the gestalt continuity condition about the continuity and that the straight line can be extended indefinitely to both sides.

Among the answers given to our question, answer II has anchorage on the origin of the coordinate axes, this point is privileged because it makes the difference between positive and negative abscissas.

The cut straight line of answer III seems to be stopped by the \(x\) axis; the same happens with answer V. Anchorage is produced on the same axis in both cases.

How the requested answer is interpretad in the exercise might be rooted in the school legend that says: *positive to the right, negative to the left*, which is used when establishing positivity on the real straight line.

An anchorage would explain answer IV on the horizontal axis where the legend could be *positive above, negative below*.

In the present case, as far as figural treatment is concerned, we observe that students alienate figure-ground from figure-form in their graphic description. The straight line is treated like the post-Euclidean straight line with almost complete freedom as to position, restricted only by the figure-ground, this is, by the coordinate

\(^4\)Treatment of one representation is when it hava a converting inner the own semiotic register.
axes, though not in its coordinate character but as limits to positivity, the same way zero is the cutting limit between positive and negative numbers.

We may draw the following conclusions:

1. The figure-ground (the axes), in the case of no correct answers, is reduced to a general reference of the plane's positivity in one dimensional terms. Reduction is very important in the figural treatment produced by our students, because it is the reference, that the axes support, brings meaningfulness to the straight line's position, the reference's frame make the difference with a straight line in the Euclidean Space, they use the straight line like a post Euclidian straight line.

The straight line's position, for students that proposed some types of cut straight lines as solution, is linked to the legend positive above, negative below; on one side and other side positive to the right, negative to the left. When they use both conditions separate in fact they use it like a one dimensional element, defining like a single ordinate not like a couple.

2. Most of our students -mainly the youngest- use a cut straight line related to a prototype straight line where the general visual variable regarding the problem solution is not considered by them. Their conception were building with only one part of the definition, they miss that 1) The straight line is formed by an infinite number of points and 2) The straight line is extended indefinitely to both sides. The most important cause of mistakes in this task were the usefulness miss of this two conditions.

3. In the three samples they use the straight line and the cut straight line equally, according to convenience. This happen more in sample with youngest students but the oldest too made it. The straight line's figural properties as a geometrical object (using part of it or parting it) is used in solution without even noticing the difference.

In this paper we discuss two methodological issues that emerged through a teacher education research project at the University of the Witwatersrand (Wits). (i) If improved learner performance is an important indicator of professional development impact on the teacher, how can this be established? (ii) Given the complexity of teaching, and related qualitative methods in researching professional development, what kind of knowledge claims can be made? What might be their status? From our empirical experience, we argue that it is feasible to generalise about take-up from, and impact of, a professional development programme through 'fuzzy generalisations' (Bassey, 1999). We also raise concerns about one-off learner tests and inferences about professional development.

In 1996, the University of the Witwatersrand launched a Further Diplomas in Education (FDE) programme in Mathematics, Science and English Language teaching with the following goals: to broaden and deepen teachers’ subject knowledge, pedagogic subject knowledge and educational knowledge; to extend teachers’ reflective capabilities; to facilitate professional growth; and to enable access to further education. The team responsible for the development of the FDE set out to develop the programme through research. Undertaking the simultaneous development of, and research into, a programme was a considerable challenge, exacerbated at the time by a funding climate in South Africa in which teacher education was expected to demonstrate impact: education funders were demanding indicators of impact such as measurements of improved learner performance.

The push to learner performance as a significant component of research in contexts of educational change has recently gained further momentum. In their analysis of education research methodology, Taylor and Vinjevold (1999) observe that changing forms of educational activity do not necessarily lead to improved learning. From this they assert two implications for research methodology. First, “the final test of the effectiveness of teaching/learning strategies lies in the outcomes of learning” and this is best gauged from learner performance on “carefully designed tasks”. Second, observation needs to go beyond descriptions of form (p. 66). These are not new ideas. The issue is how is this testing and observation to be appropriately done, where appropriacy includes ethical research practice and possibilities for capturing the complexity of teaching and learning. In teacher education research, the underlying demand for accountability raises a key question. What kinds of data and analysis enable valid claims about learner performance and classroom practice and how do these lead to inferences about the effects of a teacher education programme? The double inference from learner performance to INSET effects is particularly problematic. We also need to ask whether INSET programme success can be inferred from qualitative descriptions of classroom practices on the basis of observation and/or videotext? What are the possibilities for generalised claims about substance (as opposed to form) of teaching and learning practices which, we would argue, require in-depth case studies? In short, what methodologies need to be employed to infer the worthwhileness of investment in in-service professional development programmes?

This paper begins with a brief discussion of the research methodology that evolved over the three years of the research project (See Adler and Reed, 2000, for more detail).
focus then foregrounds mathematics and turns to two broad methodological issues: (i) If learner performance is an important indicator of the impact of professional development, how can this be established? (ii) Given the largely qualitative methodologies employed in professional development research, what kind of knowledge claims can be made and what might be their status?

**Research methodology:**

The overall aims of the FDE research project were three-fold: (i) to investigate teachers’ take-up from the FDE programme in Mathematics, Science and English Language Teaching and to what extent and how this shaped the quality of their classroom practices; (ii) to contribute to knowledge about formal in-service professional development (INSET); and, (iii) to feed back into the FDE programme’s curriculum development through research.

The research team set out to describe and analyse continuities and changes in classroom practices within and across some participating FDE teachers over time, in relation to conditions in which teachers work and their pupils learn. Methodologically, while the research has ‘project evaluation’ elements to it, it is more appropriately described as a practice-based (Lampert and Ball, 1998), case study of cases (Bassey, 1999). The FDE programme is the overall case under study. It is a case of formal, in-service professional development designed to improve the practice of the practitioners in the programme, but also to contribute to policy and practice in the wider field of teacher professional development. The teachers we worked with constitute a collection of particular cases. The selection of 25 teachers across maths, science and English language, and their location in 10 urban/rural, primary/secondary schools is discussed elsewhere (Adler, Lelliott and Slonimsky, 1997). Our unit of study was the ‘contextualised teacher’, or the ‘teacher-in-school’. If take-up from the programme and the quality of classroom practices was to be understood, these needed to be contextualised and personalised, with a description of what happened over time with this teacher in these kinds of circumstances i.e. a set of case studies. However, given the goals of the FDE programme, the study also needed to enable the identification of patterns or trends across teachers and contexts, or a cross-case analysis. The overall research project therefore focussed on a relatively small number of teachers in the programme. There were 10 mathematics teachers in the study, a number small enough to enable us to look in depth at each teacher, and large enough for us to be able to identify patterns and trends across teachers.

There are also two dimensions to the practice base of the study. The study is embedded in the practices of the FDE as a mixed-mode delivery, professional development programme. It was carried out by a team of researchers, most of whom are practitioners in the programme. The research was also carried out in classrooms, on and with classroom practitioners. It was our intention from the outset to learn about ours and the teachers’ practices by investigating and theorising practice (Lampert and Ball, 1998) in local settings in all their complexity and diversity.

In relation to classroom practice, the key question that framed the overall study was: How are teaching and learning affected by resources (material; time; socio-cultural), by teachers’ subject knowledge, by teachers’ pedagogic knowledge and by teachers’ reflective capabilities? Data was gathered from: school inventories, classroom observation schedules, supplemented by field notes; learner classwork and homework tasks and projects; tests administered to learners; videotapes of some lessons; audiotaped interviews with teachers.
and school principals; questionnaires and narratives completed by the teachers. The research team worked in subject teams in the selected schools in the Northern Province and Gauteng for one week in each of the three years (1996-1998) of the project, with the data collected in 1996 serving as a base-line (see Adler, Lelliott and Slonimsky, 1998). The team attempted to develop portraits of each teacher, capturing as fully as possible, the texture of the teacher’s practice. Each portrait was similarly structured to facilitate cross-case analysis and the identification of patterns of ‘take-up’ within and across the three subject areas in the first instance, and then across the whole set of cases. Analysis of the data collected in 1997 and 1998 also began with the development of teacher portraits. By 1998 we had identified key issues that we believed were central to the FDE programme, teacher development and curriculum change in South Africa, and to in-service professional development more widely.

We proceeded to analyse the data over the three years according to the following key themes: the nature, availability and use of material and cultural resources as a function of programme take-up and the context of teachers’ work; the critical issue of the relationship between teachers’ knowledge-bases and development of high order knowledge and skills in their learners; the challenge of language-in-education policy and practice, particularly code-switching as a teaching and learning resource across contexts where English language infrastructure varies; teachers’ take-up of the forms and substance of learner centred practice; whether and how in-service professional development plays a role in teachers becoming reflective practitioners.

Discussion of each of these is summarised in Adler, Bapoo, Brodie, Davis, Dikgomo, Lelliott, Nyabanyaba, Reed, Setati, Slonimsky (1999). The research team faced considerable challenges as the research unfolded. Practical constraints continually raised concerns about the potential for mismatch between our epistemological and methodological assumptions, our research intentions and goals, and on the ground realities. Many of these have been discussed elsewhere (Adler et al, 1998; Adler and Reed, 2000). The focus here is on the challenges of an accountability context discussed in the introduction to this paper.

Learner “performance” as indicator of INSET success

What does learner performance on “carefully designed tasks” (Taylor and Vinjevold, 1999, p.66) tell us? About the learner? About the teacher? About the curriculum? About national standards? Learner performance on carefully designed tasks can tell us about any or all of these ... depending. It depends on the nature of the tasks set, when the assessment occurs, where the assessment occurs and how often. These assertions are not new. As Saljö and Wyndam’s (1993) study reveals, task “performance” is a function of the task and the learner in a particular setting at a particular time. There are thus significant issues in reading learner competence from single tests or tasks without significant attention to context, let alone moving from learner performance to the teacher’s competence.

Learner performance is typically accessed through some form of testing. While it was the original intention in the study to test learners, the complexities of doing this were completely underestimated. We kept coming back to how a particular test or set of tests would be an appropriate or adequate means of assessing learners (and which learners?) over three years, and moreover, in such a way that the impact of the FDE programme on the quality of a particular teacher’s practice could be inferred. For example, tests for the same learners at two different times in the year should show learning gains, but we could not see how to legitimately establish any kind of causality between learner gains and their teacher’s
participation in an in-service programme. More appropriate could be either comparative testing of programme teachers' classes with other similar classes in their schools, or with similar classes in different schools where teachers were not involved in the programme. But we did not believe we could control for intervening variables, nor that such an endeavour was conceivable. In addition, any of these tests meant the construction of new items in order to assess new forms of knowledge and skills valued in the programme. The reliability and validity of any new test could not be accomplished within the time frame of the project. As Cooper and Dunne (2000) have argued, there are significant validity issues in more complex forms of math assessment, particularly context-embedded items.

We considered the use of existing standardised tests e.g. tests that had been constructed by the Human Science Research Council (HSRC) prior to the first democratic elections in 1994. Aside from inappropriate cultural contexts to contextual mathematics items, there were few that assessed mathematical processes beyond set procedures. Our frustration and difficulties with test development does not mean that it is not important to design effective means for studying learner performance as an indicator of learning gains. As Jansen (1996) and Black and Atkin (1996) argue, there are limitations in evaluations of educational innovations when student learning information is lacking.

Despite difficulties, the FDE team did not abandon assessment of learner performance as an additional indicator of teacher learning. Each teacher observed had a set of his or her classwork books examined to ascertain the kind of written work that was being covered by learners - a coverage that could not be discerned from two or three lesson observations. Learner books are not direct indicators of learner performance. They nevertheless can reflect the kind of mathematics valued by the teachers through inscription and attempts at practice/ and mastery. These added to observations of mediated content during lessons. A detailed “Pupils’ Written Work Schedule” was constructed, refined in 1997 and 1998 and used to illuminate learner performance in the subject through all their written work accumulated between February and August each year. Classwork books, homework books, test books, exam papers, test papers and scripts of nine learners in a purposefully selected class (three good, three average and three poor) were examined and recorded in the schedule. In addition, some testing was conducted in Grades 7, 8 and/or 9 classes in each of the three subjects. In 1997 the tests used were constructed and conducted by members of the research team. These were exploratory, both in terms of how they were used, and what they revealed. In 1998, we accessed Grade 7 mathematics tests that had been developed as part of a project geared towards more appropriately normed tests than those available to us through the HSRC. We built on Grade 9 tests from 1997 and conducted learner tests in classrooms where teachers were teaching math at either Grade 7 or 9.

We learnt several lessons from this testing. Testing some learners revealed to us how this additional data provides for triangulation of data within case studies. The test performance of learners in different teachers’ classrooms by and large confirmed and thus strengthened the accounts of teaching and learning practices analysed and built into the teacher portraits. In instances where there was a mismatch between our independent test assessments and what we observed in learners’ written texts, including their in-school testing, we were able to explore these with the teacher and develop insights to enrich the overall portrait of teaching and learning. Testing learners as part of researching teacher development and INSET effects can be illuminating. This is “the good” side of such testing.
The bad side of the testing for us was that, in general, our independent test results confirmed the TIMSS messages with regard to levels of performance in mathematics and science across our schools. Our results were not at odds with test results obtained by most of the teachers themselves in their own testing. The bad is that this situation persists. Our broader data assisted us in seeing that pupil performance was not in any simplistic way, a reflection on the teachers’ knowledge-base. For example, one of the secondary level mathematics teachers, a teacher who demonstrated extraordinary take-up from the FDE programme, worked in an over-crowded, impoverished context. Her learners arrived in her Grades 8, 9 and 10 classes considerably under-prepared for the levels at which she was expected to teach and assess them. No wonder then, that on her own tests, let alone the independent tests we administered, performance was extremely poor. This learner performance tells us something about the state of the nation. However, to infer teacher quality and INSET programme quality from such “results” is extremely problematic.

The “normed” tests we used were themselves problematic. We found that some of the math items were ambiguous. This raised serious questions about reading off learner competence from their performance on tests that included such items. In addition, and as is the case with reform anywhere, for some of the learners, the form of the test items was unfamiliar. A simple prompt by a researcher on one occasion enabled a correct response by the learner. Crude analysis of test performance then will misrepresent learner knowledge. Testing is not simply a matter of “carefully designed tasks” but crucially a function of the testing context, including learners’ familiarity with the tasks. Test validity is a serious research endeavour. Our concern as a result of our experience is not that testing should not be done, but that research and development be undertaken to develop instruments appropriate to various processes of research. Wilson and Berne note similar in professional development research in the USA where the capacity of researchers to tie measures of teacher learning to measures of student learning is challenged by “the lack of robust and standardised measures of student learning” (1999, p. 197).

Testing is not the only indicator of learning gains. Our experience suggests that close analysis of learner written material is more illuminating than one off tests in the contexts of teacher education research. Close examination of learners’ classwork and test books, alongside the tests and examinations that teachers set and their marksheets were illuminating of depth and breadth of coverage over time by the teacher and the kinds of knowledge forms that were inscribed by learners hence indicating what is valued as knowledge within the school setting. We did not need independent tests, over and above such analysis, to reveal to us key challenges for teachers and hence the FDE programme. Learner written texts revealed learners’ limited exposure to knowledge, and how teachers, for a range of reasons, were not covering required areas of learning, nor enabling learners to engage with knowledge at anything beyond the most superficial levels of recall and repetition. We noted difficulties with selection, sequencing and grading of tasks across most of the teachers, and this was evidenced across learner written texts. This observation tells us not only about teaching practices, but also about assumptions in the FDE programme. Like the government of the day, the programme had not grasped the full extent of the breakdown of a culture of teaching and learning across schools in struggles fought against apartheid education in the 1970s and 1980s.
Teacher education research: the status of resulting knowledge claims  Bassey (1999) defines a case study as a “Study of singularity conducted in natural settings” (p.22). Earlier, we discussed how and why it was necessary to work in depth with a few teachers: qualitative multifaceted observation was required if we were to do any justice to the complexity of teaching as a social practice. How then do we, on the basis of diverse case studies, even with cross case analysis, make claims about teacher up-take from the FDE programme that extend beyond the specific research teachers, and hence to overall programme effects? Bassey (1995) distinguishes two kinds of empirical study in educational research: the search for generalisations (requiring investigation of large populations through carefully selected samples), and the study of singularities (case studies). The implication here is that case studies cannot lead to generalisations, and thus that they are limited in their use in educational policy and planning. Bassey argues that it is possible to develop what he describes as fuzzy generalisations from carefully conducted case studies. He uses the term “fuzzy generalisation” for a statement that makes no absolute claim to knowledge but hedges its claim with uncertainties. It arises when an empirical finding from a case study such as In this case it has been found that is turned into a qualified general statement such as In some cases it may be found that or If we do x rather than y then teachers may learn more. Bassey suggests that if educational researchers disseminate their findings in the form of “fuzzy generalisations” they are inviting teachers and education policy makers to enter into a discourse with these generalisations. Entry into such discourse is likely to be facilitated by access to an ‘audit trail’ - the evidence in support of the fuzzy generalisations which the case study has produced.

Bassey’s argument for “fuzzy generalisations”, and even weaker claims in the form of “fuzzy propositions” arises out of his extensive educational research experience, where he has seen numerous studies of quality not impacting on teachers and policy makers precisely because findings are deemed too specific. Our findings in the FDE research project, and the status of the related claims we believe we can and should make about the FDE programme as a whole, INSET practice in South Africa, and INSET practice more widely, resonate with Bassey’s notion of “fuzzy generalisations”. Indeed, “fuzzy generalisations” appear to be constitutive and reflective of other teacher education research.

In their review of “highly regarded” published research on “teacher acquisition of professional knowledge in” the USA, Wilson and Berne (1999, p. 194) identify a number of common themes, one of which is particularly pertinent here. They identify a concern with the labour intensity entailed in the qualitative nature of the research (hence expensive in human and related financial terms from our point of view), and the substantial commitment it demands in terms of examining teacher talk, and classroom practices. They point out that “[E]ach research project struggles with ways to document teacher knowledge” (1999, p. 195, emphasis added). Because of the complexity of classroom practice and the qualitative, case study nature of much of the research, documenting and hence evidencing teacher professional development is difficult. Claims made (“... programs ... were likely to ...”) are tentative, “fuzzy generalisations” in Bassey’s terms. To return to the FDE research, we will draw on our analysis of teachers’ take-up of language practices (Setati, Adler, Reed and Bapoo, forthcoming) to illustrate how we documented, evidenced, and then drew out recommendations at the level of the FDE programme, and fuzzy generalisations in relation to INSET policy in South Africa, and INSET research and development more widely.
We documented extent and frequency of teachers' and learners' code-switching practices over the three years of study. In the final year we also examined the production and reception of expressive and discourse-specific language. We used structured classroom observation schedules, unstructured videotape of lessons, structured observation of learners' written texts and teacher interviews. We found increased use of code-switching by teachers and learners in most classrooms, in particular increased drawing on learners' main language(s) as a resource. We learned from the teachers that their code-switching practices are intentional but dilemma-filled, particularly in the face of the dominance of English in the South African context. We also found widespread 'take-up' by most teachers of forms such as group work, and hence increased possibilities of learning from talk (i.e. of learners’ using language as a social thinking tool). However, our observations in 1998 raised the question as to whether most of the teachers were complementing this shift to learning from talk with strategies for learning to talk i.e. learning to talk and write formal mathematical discourse. We also found that while the above were general patterns across all the teachers, they concealed important attenuated differences across teachers in different contexts, levels and subjects. For example, because their primary goals differ, there was more code-switching by math teachers than English language teachers. There was less code-switching and more focus on using and modelling English in primary than secondary mathematics classes as primary teachers carry out their dual functions of teaching the subject, and developing learners' proficiency in English. This dual role and emphasis on English was complicated further in rural schools i.e. schools with limited English language infrastructure.

These ‘findings’ from our case study of cases, led us to the following recommendation for the FDE programme, and fuzzy generalisations for INSET policy and practice. The intent here is to inform ongoing curriculum review in the FDE programme, and to invite teachers and policy makers to “enter into a discourse” (Bassey, 1999, p.52) with these generalisations.

* At the level of the FDE programme, we need to pay more explicit attention to possible journeys from exploratory and informal talk in the main language towards formal mathematical talk and writing in English

*At the level of educational policy in South Africa, findings from our research suggest that some of the dominant ‘messages’ in current curriculum documents may need to be reviewed. For example, one of these messages in Curriculum 2005 is that group work is ‘good’ as it encourages exploratory talk and co-operative learning. The issue of how teachers and learners are to navigate the journey from informal spoken language (in the learners’ main and/or additional languages) to formal, written mathematics in English is not addressed.

* At the level of INSET: What we have shown from our study of FDE teachers in multilingual contexts is that firstly, take up is attenuated across contexts. This suggests the need for more serious engagement in teacher education with the possibilities of, and constraints on, what are typically presented as panaceas for ‘good practice’. The different English language infrastructures, levels and subjects in and with which teachers work appear to be significant for shaping INSET possibilities and constraints. We need further research and development programmes that dis-aggregate schools and classrooms along these three different axes (Setati, Adler, Reed and Bapoo, forthcoming, emphases added). In the presentation of this paper, I will present additional information on the overall research methodology employed in the FDE professional development project, as well as
some of the “audit” trial that lead to the fuzzy generalisations about changing language practices and their effects. Hopefully, through this reflection on issues emerging from a specific research project, this paper will contribute to the development of theory, practice and research, in their inter-relationship, in mathematics teacher education more broadly.

NOTES

1. The team that worked on the research over its three years, and to whom debt is owed for all research outcomes, including this paper, was: J Adler, A Bapoo, K Brodie, H Davis, P. Dikgomo, T Lelliott, T Nyabanyaba, Y Reed, M Setati, and L Slonimsky.
Ethical practice in mathematics education research: Getting the description right and making it count

Jill Adler and Stephen Lerman
University of the Witwatersrand
Johannesburg, South Africa
South Bank University
London, UK

Abstract Building on the work on ethics in educational research in recent publications, we present a framework for ethical practice in mathematics education research. In particular, we discuss what are the implications of claiming or denying a particular piece of research as acceptable within the community. We argue that researchers must be aware for whom they advocate, thus making it count. We present a map with which researchers should engage the ethics of their practice, and we suggest that they must consider whether they are getting the description right.

Howe and Moses (1999) have presented a detailed history of ethical practice in educational research, and Sowder (1998) has done much the same in a collection on mathematics education research. In the latter, Sowder also discussed issues of ethics in the dissemination of research findings. Together with these authors we wish to recognise: that educational research is always advocacy research inasmuch as it advances some moral-political (and so ideological) perspective; that educational researchers must be able to defend what their research is for (respect for truth); that the research must have points of contact with insiders’ perspectives (voice, respect for persons); and that it militates against race, gender, class and other biases (respect for democracy) (Bassey, 1999, p. 37).

Summarising these overviews, we propose that researchers should engage with the following questions:
- On whose behalf is the research advocating? Is it against racism, sexism, classism etc?
- What is the research for? Can the researcher defend the research? On what grounds?
- Does the research incorporate the insider's perspective?
- Is the research reflexive?
- Does the research take care of those being researched, especially avoiding their oppression?
- Does the research draw on refined notions of consent, autonomy, and privacy?

Our concern in this paper is to extend these ethical positions and to ask: On what grounds can one claim that a piece of research is or is not mathematics education research?

Sowder (1998) began her chapter with some scenarios. We will do the same here and through them we will present the main themes of our argument. The first is a fictitious
scenario but familiar to many of us in the issues it raises. The second scenario is a perspective on TIMSS. We conclude with presenting a map for researchers to elaborate an ethical framework for their research and applying that map to the two scenarios (for a more developed account see Adler & Lerman, in press).

**Scenario 1 (fictitious) - A research dilemma**

All over the world there is a tendency towards reform in mathematics teaching and learning which takes for granted the four following features:

- Rich mathematical tasks
- Relating mathematics to real life experiences and practices
- Learner-centred practice (valuing and working with learners’ mathematical meanings)
- Inquiry-based classrooms.

These reform initiatives are being researched and developed and, while emerging from practices in the developed world, they are nevertheless the object of desire in the developing world, despite substantive contextual differences. The underlying assumptions in the reform, and in much of its related research, is that these four features of mathematical classroom practice will lead to appropriate, meaningful and more successful mathematical learning.

Imagine a situation where the dominant forms of schooling are over-determined by selection rather than education. In poor countries there are enormous constraints on wide provision of public services (like health care) and public goods (like education). As Mwakapenda (2000) so vividly describes of Malawi, when only 10% of primary school leavers gain access to public secondary schooling, teaching and learning practices are inevitably driven by the forces of selection. Processes of democratisation and development – increasing equitable access to improved social and economic goods – in such a context are significantly different from those in the developed and dominant world. It goes without saying that mathematics education reforms will be shaped by such divergent conditions.

Imagine a mathematics education researcher from a developing context as described above, at the level of, say, PhD. As is often the case, this person gains entry into PhD study in an institution in the developed world, and is sponsored by the State Department of Education in his country. He enters a world where what counts as a problem in mathematics education is framed by the reform movement described above. He decides, after considerable exploration of the field, to study the implementation of inquiry-based mathematics teaching. He believes, as a result of his reading, discussion, and reflection on the educational situation at home, that inquiry-based approaches offer potential for improving mathematics teaching and learning in his country. He communicates with relevant parties at home, teachers are reported to be interested. He develops a programme and a set of materials that he believes are appropriate to his home context and he returns to set up the project, including at this stage, a series of workshops with a selection of Grade 7 mathematics teachers (the
Beyond the final year of primary school). During this time, he obtains their agreement and support for the project. Indeed, the teachers appear to enjoy the workshops where inquiry-based mathematics learning is modelled and issues discussed. The teachers share with him how they have been challenged mathematically and pedagogically. They express positive views of the potential for such practice in their own classrooms and a willingness to implement these ideas. He then spends a short period of time with one of the teachers in her class and together they try out activities in her classroom. On the basis of this piloting, he modifies and then leaves a set of materials for all the teachers to try out and develop and reflect on in their respective Grade 7 classes and returns to his academic institution.

Armed now with what has been agreed by his institution as sufficient ground-work and piloting, he proceeds with designing the next and critical phase of the research, the collection of data related to teachers’ implementation, and so interpretation, of inquiry-based mathematics learning. Three months later, as planned, he returns home, this time with a range of research tools (instruments) and a carefully formulated participant observation design process for data collection and analysis. To his dismay and frustration he finds, across all the teachers, that the materials have barely been touched – an occasional activity had been tried. Moreover, term dates have been unexpectedly changed. Instead of a process being underway where he could now work with teachers to interrogate their interpretations of inquiry-based mathematics teaching, the teachers are focussed on preparing their learners for the kinds of assessments they will face at the end of their primary schooling. Teaching is restricted to providing practice with algorithms for the operations on common and decimal fractions. What is more, the extended time he had thought would be available for participant observation has been curtailed by changed examination times. He now faces considerable practical, methodological and ethical challenges.

He could continue with a modified exploration of inquiry-based mathematics. He could, for example, organise additional time with learners and teachers from one or two schools, after school hours, where he himself teaches mathematics in an inquiry-based way. Through this research strategy he might be able to identify and describe the kinds of activities learners engaged with, how and with what effects. His overall description and explanation is, nevertheless, likely to proceed from a starting point of ‘failure’ in relation to mathematics education reform by the educational system in his country and include a description of how and why the teachers were unable to implement inquiry-based mathematical learning. The description would keep intact a decontextualised sense of the potential benefits of inquiry-based mathematics teaching, and lead to recommendations for how school mathematics needs to change in his country, and what is needed to support this change.

By contrast, he could abandon his orientation to inquiry-based mathematical learning and reorient the study so as to understand why and how testing has come to over-determine considerations of epistemology and pedagogy, and how and why the timetable changed, so ‘disrupting the data’ (Valero & Vithal, 1998). This would be a
difficult decision to take. Given time constraints for the study, he would need to proceed with a rolling plan for interviews, observations, where time for developing and piloting instruments was curtailed. If he travels this road he is likely to elicit data related to the selective function of mathematical performance, and to a range of socio-cultural and political conditions that shape the forms of school mathematics practice in Grade 7 in his country. His description and explanation of what happened through his research activity is more likely to focus on wider educational issues than strictly mathematical ones. He is also likely to be able to explain resistances in the system (as opposed to resistances in the individual teachers) to the intended ‘reforms’. In other words, to explore and understand what happened would require redesigning the study, and most critically, zooming out of inquiry-based mathematics and into the wider educational practices in which the teachers are positioned.

How should he proceed? Which route should he follow? Depending on where he shares his quandary, he is likely to experience quite diverse and unsettling responses, particularly if he presents a preference for the latter approach. In the wider educational arena he could be challenged as to his competence to take this more sociological and systemic approach to the research. He is likely to share this concern. At the same time, in the community of mathematics education research, he is likely to experience reactions like: “Well, this is no longer mathematics education research” (one of us was witness to precisely this negative reaction when a similar situation was raised for discussion at an international mathematics education research forum).

What we are raising here is that getting the description right and making it count across diverse interests are ethical issues that need to inform the practices of the mathematics education research community.

Let’s assume that because of this ethical standpoint, and within his financial and time constraints, the researcher proceeds along the more challenging path. He makes this choice despite not being an apprenticed sociologist and aware that it might well undermine goals for his own development and entry into the community of mathematics education research. He sets out to explore and explain teachers’ practices in their mathematics classrooms with tools from the interpretative turn, and so to chart a less clear methodological path. As intimated above, he finds his description of teaching practices are framed by an analysis of the educational system in his country, fiscal constraint, and its overall examination and selection processes. The knowledge produced becomes more about how the teachers interpret and explain their mathematical practice within such systemic enablements and constraints, rather than about teachers’ understandings of, and approaches to, inquiry-based mathematics. He goes on to include recommendations for a serious localisation of the notion of “inquiry-based” mathematics, and a speculation that a description of its forms and functions is likely to be substantively different from that which permeates dominant mathematics education discussion.
From our concerns with ethics in this chapter, this emergent description is 'right'. But our experience is that it does not easily count in the dominant field of mathematics education research. There is always the additional question: Is this research mathematics education research? From a research perspective this can be re-interpreted as: Can and will it add to the knowledge base in mathematics education?

Some, including ourselves, would answer in the affirmative. Despite limitations that are inevitable given time and financial constraints, this research could and should inform the knowledge base in mathematics education. The position here is that insights into the challenges of reforming the teaching and learning of mathematics in school lie precisely in an understanding of how mathematics takes shape in teaching and learning situations across school contexts. Such insights entail more than a grasp of the mathematics of the reforms intended, and their interpretation. Critically, getting the description 'right', and making it count for its participants, entails coming to grips not only with didactical transposition (Brousseau, 1989) but with recontextualisation processes inevitable in schooling. Curriculum change involves changes in how knowledge is classified and framed, and so too in relations of power and social control (Bernstein, 1996). Curriculum change will inevitably be contested terrain. It thus requires an in-depth understanding of school mathematics, and schooling itself, across diverse contexts.

This story and the questions it provokes are about the worth of the research reported, its quality, its boundaries and its methods, its financial constraints, and ultimately about ethics and values. We will return to this scenario in our concluding remarks.

Scenario 2 - TIMSS

This second description will be brief for reasons of space. In a globalising world, international comparative assessments make sense. They provide benchmarks for both internal and external comparisons. Such arguments have been made both by the key organisational hub for TIMSS (Plomp, 1998) as well as wider afield (Nebres, 1999). As it re-entered the world in 1994, participating in TIMSS in 1995 was an attractive option for South Africa. Here was a possibility for setting up a benchmark against which progress by the post-apartheid Government could be mapped and judged (Howie, 1998). The results of TIMSS are now well known, and need no rehearsal here. The question we pose is the broader ethical one that drives this paper. Did TIMSS get the description right? Keitel and Kilpatrick (1999) pointed to four problems: that the direction of the study has been over-determined by psychometric expertise; that financial support for the study influences the goals; that control over the framing and dissemination of results necessarily affects the results; and that there is an assumption that curricula across widely diverse contexts can be compared through learner performance presented as an average.

We wish to raise some questions, following their critique, and reflecting our concern with getting the description right and making it count:

- why were countries ranked as in a league table?
- whose interests are served by this?
- what kind of description is this?
- on whose behalf is TIMSS advocating?
- Given that the results served conservative agendas in so many countries, and that researchers are thought not to be responsible for how their work is used, where does responsibility begin and end in mathematics education research?

These criticisms of TIMSS are known. Why are we repeating them? Our point is that in the light of the above criticisms, TIMSS cannot get all of the description right, and in its omissions lie significant ethical issues, and thus for whom does this research count?

**Concluding remarks**

There has been a distinct Southern African focus in this paper. We are aware of the danger that some readers might marginalise the ethical issues we have raised because the history of the region, indeed the continent, is full of very dramatic inequalities, exploitation by the 'developed' world, and so on. We insist, though, that whilst inequalities might be more stark in Southern Africa than in many other places, inequalities and injustices are just as pervasive and ubiquitous in every part of the world and within every society, if sometimes less obvious. The cultural capital of success in school mathematics is common across the world: so too is the failure of so many students from working class and disadvantaged groups in mathematics. It is precisely the high levels of inequality that throw ethical issues into relief, issues that need to be confronted by all mathematics education researchers wherever they are.

We consider that educational research should be seen as located in a knowledge-producing community (Usher, 1996). What comes to the fore is the engagement with others and with history in an enterprise that should meet, as well as perhaps challenge, sets of socially constituted standards and values. Research communities, like all communities, are fragmented, with sub-groups, established and new paradigms, tensions, disputes, and boundary conflicts. These are indications of a normal healthy research community: the modernist image of a unified scientific group achieving universally accepted answers to universally agreed research questions is no longer expected. The complexity of the research enterprise is thus captured in the notion that it is a social practice.

Research can then be seen as a map:

<table>
<thead>
<tr>
<th>Goals of</th>
<th>A multiplicity of responsibilities to ownership by</th>
</tr>
</thead>
<tbody>
<tr>
<td>Subjects</td>
<td>Researcher</td>
</tr>
<tr>
<td>Academy</td>
<td>Public</td>
</tr>
</tbody>
</table>

2 - 22
Research must take account of this multiplicity. Thus, in our first scenario, our researcher's dilemmas concern:

Goals: to modify his study of inquiry-based mathematical learning, or to examine why testing overcame other issues. He needs to be aware of the goals: of his subjects, the teachers, to be supported in their struggles, not undermined, and not to have their trust broken; of the academy, to do what informs mathematics education research in ways that uphold if not develop the ethical standards of the community; and of the public, who want the best for their children, whatever that may mean, and who want their privacy respected.

Responsibilities: to his subjects, the teachers, to advocate for them, not to hold them up for criticism when they joined him in his plans in good faith, as his understanding of their situation changed; to himself, in gaining a PhD within the community to which he belongs and at the same time to be true to what matters to him in his research; to the academy, to advance knowledge of the teaching and learning of mathematics in its widest sense whilst challenging the community to recognise and value the research issue; to the public, to do research that takes care of teachers and students whilst informing for future policy.

Ownership: by the subjects, who see themselves to some degree as participants in the research, to improve the learning of their students, but pulled also by many other, perhaps stronger, constraints; by the researcher, who demands that his community also claim ownership through him; by the academy, that this matters to mathematics education research; by the public, that they should share in researching their schools.

In our second scenario of international comparisons, perhaps a question mark should be raised over the whole enterprise. If it does proceed to a FIMSS then the researchers' dilemmas concern:

Goals: of the subjects for the improvement of their life chances and therefore for the international publication of balanced, moderated results; of the researchers to endeavour to take account of all the factors that impinge on the results; to the academy to represent the subjects fairly so that the results are valid; and to the public not to misrepresent and do harm to their communities, including the educational community.

Responsibilities: to the subjects, to advocate for them; to the researchers themselves to produce democratically valid, generative results; to the academy to take responsibility for how their research might be used; to the public to represent appropriately the subjects of the research so as not to mislead and perhaps inadvertently encourage negative stereotypes.

Ownership: by the subjects, that they are included in the research at least by appropriate representation; by the researchers, again to worry about how their research will be used and by whom; by the academy to ensure that such research is for the researched as well as for the research community; and by the public so that the
large sums of money spent will be of value to them in improving the life chances of their children and their community.

The community is very successful in locating and engaging with issues and challenges where the mathematics is prominent. We are convinced that the community also needs to be more open to seeking questions and answers where the mathematics recedes behind a myriad of intersecting social and political issues. Let us be clear: social and political issues are not an irritation that gets in the way of research in mathematics education. We consider it our ethical responsibility to seek out these settings for research. Otherwise we collude in denying access to power and control over their lives for the majority of students.

References

Abstract. The paper describes a teaching experiment whose goal has been re-introduction of \( \varepsilon - N \) definition of the limit of a sequence into standard calc 1 instruction. It identifies the limit schema as the coordination of two processes, both involving epsilon. It is suggested that this coordination is the basic mental construction involved in the construction of the limit schema. The role of certain student misconceptions on the development of the understanding of the concept is also discussed.

Introduction. Why is it important to understand the fundamental concepts of mathematics from their basic definition? In particular, why is it important to develop a good understanding of the \( \varepsilon - N \) definition of the limit of a sequence among Calculus students, if, the majority of them are not math majors? It is so, in our opinion, because the understanding of the limit represents one of the more important achievements of modern mathematics, which helped to clarify its conceptual basis, and as such belongs to the area of general education. It is significant in acquainting students with the means of treating "infinity" with the help of only finite processes [7], and as such has a general educational and philosophical value.

Recent research [4], [5], [6], and not so recent [9] of students' understanding of the definite integral as the limit of Riemann Sums reveals serious absence of the knowledge of the relationship between the geometrical construction of Riemann Sums and the corresponding numerical sequence of partial sums, in the thinking of students of Calculus. It became clear that a mathematically correct understanding of the definite integral at the Calculus II level necessitates a precise understanding of the concept of sequences and their limits. The teaching experiment described in this article is first in the series devoted to the appropriate reorganization of the curriculum and instruction in that direction.

Whereas students' difficulties and treatment of this theme are quite well known (section below), yet at the same time there is a relative absence of reports about the successful incorporation of this knowledge into instruction, to advance its understanding among students of calculus. Our teaching experiment has been designed to bridge that gap.

Teaching experiment described in this was performed at Instituto Tecnologico de Monterey, Mexico, D.F. during the Fall 2000, with the specific goal of investigating the effectiveness of re-introducing \( \varepsilon - N \) definition of the limit of a sequence into standard Calculus 1 instruction. The discussion below will be presented in more of a conceptual manner rather than in a quantitative manner (although some broad assessment will be provided), due to the very short time which...
has elapsed since the experiment has been completed - yet some results are sufficiently important, and necessitate presentation in a preliminary fashion.

**Literature review.** Numerous researchers have found students to have seemingly inevitable cognitive and epistemological obstacles both with limits and the connected ideas of continuity, and differentiability [2], [7], [9], [10], [14]. In particular, Orton in [9], quotes some of the students he interviewed regarding the meaning of sequences in the context of Riemann sums, as saying that "the computation obtained in this way is approximate because the sequence never reaches the limit". This particular problem is related to the general issue of whether the sequence ever reaches the limit, and is discussed at length by [2], [7] and [10]. The authors of [7] discuss also another students' misconception, the neglect of the sequential order, which in our experiment turned out to be quite essential. The students often approach the limit in the context of $\epsilon - N$ definition, saying that the larger $N$, the smaller the distance $\epsilon$ between the term and the limit - a description, in some sense, reciprocal to that incorporated by the definition of the limit of a sequence.

The difficulties with all these concepts seem to be so profound that Cottrill et al [3] remark, "We have not...found any reports of success in helping students to overcome these difficulties".

In this bleak landscape of the instruction and understanding of limits, two brighter results are worth mentioning. In her work, "The effects of writing assignments on second semester calculus students' understanding of limit concept", [13], Walhberg mentions a measurable improvement of student understanding under the influence of writing assignments. Orton [8], on the other hand, mentions that when students were introduced to limits of sequences with the help of the Wallis technique [12] and apart from their interpretation in the context of the Riemann sums, they were quite adept in finding the limit as well. The Wallis technique of finding the limit of sequences was used for the first time in the Arithmetica Infinitorium [12] on the occasion of finding the area under a parabola. It consists in estimating the limit $L_e$ of the sequence given as a list of terms followed by the decomposition of each term $a_n$ into the sum of $L_e + "additional~term"$. The additional term, can, in many cases, be written generally as $\frac{c}{f(n)}$ where $f(n)$ is a linear function of $n$, so that this term can be shown to tend to 0 as $n \rightarrow \infty$, and that, consequently, the limit of the sequence is indeed $L_e$. In terms of the $\epsilon - N$ definition of the limit, the additional term is easily to be seen as the $a_n - L$, the difference between a term and the limit, whose absolute value can be made smaller, according to the definition, than arbitrary positive $\epsilon$. This suggests that there is a natural relationship between the Wallis technique and the $\epsilon - N$ definition, which could be exploited to students' advantage.
**Design of instruction.** The principles of instruction during the teaching experiment had three components, all suggested by either positive results indicated in the literature or by the critique of certain didactic practices:

1. The development of the intuition of the limit was based on the Wallis technique, which, as the time progressed, was joined by the standard technique of finding the limit from the general term by dividing it by the highest power of n and "sending" n in the new expression to infinity.

2. Using the positive and measurable results found by Walhberg [13] about the role of writing assignments in the promotion of understanding of limits, the process of written explanation and discussion of the results was introduced at the very beginning of the discussions of sequences. Every assignment and every limit related problem during the partial tests had both computational, and conceptual written components in order to encourage the dialectical relation between these two aspects of understanding.

3. **A substantial increase in the understanding of the limit concept and a coordination of all aspects involved therein, (more precisely, a substantial increase in the scope of the limit schema, explained in section below) was effected by the introduction of**

   a) the eps - N definition of convergence (sequences $a_n = \frac{f(n)}{g(n)}$, where $f(n)$, $g(n)$ are linear functions of n, constant sequences $a_n=c$ and the alternating versions of both: $(-1)^n c$, $(-1)^n \frac{f(n)}{g(n)}$), its negation as the basis for the discussion of non-convergence (alternating, not converging sequences i.e. $a_n = (-1)^n \cdot 5$ ) and by the precise definition of divergence, and of

   b) the Heine definition of the limit of a function which states that a function has a limit $L$ at $x= a$ if for every sequence $x_n$ which has a limit at $a$, the sequence $f_n = f(x_n)$ has a limit $L$. The strength of this definition (which is equivalent to $\varepsilon-\delta$ definition of Cauchy) consists in that it allows to unify the instruction of sequences, limits of functions, continuity and other concepts depending on the notion of the limit, around one central idea, that of the limit of a sequence. Its application (or of its negation) to the different types of discontinuities, to the limits at infinity (functions with horizontal asymptotes) and to infinite limits (functions with vertical asymptotes) allows for the simultaneous usage (thematization) of all three types of sequences discussed in a). Such a consequent use of the concept is a necessary condition, according to Piaget [17] as well as to other Piaget-based frameworks such as APOS [1], for the formation of an abstract object from a particular concept. Thus the main role of this definition was not so much to have students master its different applications, but rather to provide the ground where the definitions and usage
of convergent, non-convergent and divergent sequences in a natural mathematics context might provide a nourishing soil for the construction of the final object from the schema under investigation.

Theoretical framework. There are several definitions of a schema in the math education literature [1], [17]. For the purpose of this research the definition of the schema contained in the APOS theory [1], will be used:

a schema is a collection of processes, objects, and other schema which can be organized in a structured manner, that is used to deal with a certain category of mathematical problem situations. The structure of a schema gives it coherence in the sense that the individual has some means of understanding what kinds of situations a particular schema can be used to deal with.

The schema of the limit of a sequence described in the definition of that limit:

The sequence $a_n$ has a limit $L$, if for every $\varepsilon>0$, there exists $N$ such that for all $n > N$, $|a_n - L| < \varepsilon$

is the result of the composition of two processes, the process of choosing an $\varepsilon$ which is understood as a distance, hence, is part of a topological schema, and the process of establishing the relationship between $\varepsilon$ and $N$ through the inequality contained in the definition, where $\varepsilon$ is seen as an independent algebraic variable of the function which determines suitable terms $a_n$ (with $n>N$) of the sequence. The student has to start the first process by choosing some particular $\varepsilon$ understood as distance, then he or she has to change its meaning to that of an independent variable which can take on any positive real value, and then finally, to demonstrate the understanding of the values of $n$ so determined, he or she has to again go back to the concept of the distance; hence again changing the meaning of $\varepsilon$ from that of a variable to that of the measure of a distance. Such a coordination of mental processes has been described by Dubinsky [8] as one of the basic components of reflective abstraction.

We have taken the successful coordination of these two processes as the evidence that a foundation of the schema of the limit of a sequence had been constructed within the mental apparatus of the students. We have also taken the successful application of the schema to the non-standard problem situation as evidence of the coherence of the schema foundation required by the definition.

As a tool of assessment to determine whether students have the required understanding of the discussed coordination of two processes we have used the following credo that many veterans of mathematics teaching profession say to students: You don't know whether you understand a concept until you can explain it in words. Indeed, anyone who has ever been in the position of learning a new
mathematical concept and has been forced to explain it "in his/her own words" can recall the effort needed to follow, or even to formulate one's own thoughts and to give them the adequate verbal form of explanation while "thinking aloud" about a solution of a problem in question. This effort is precisely the effort of finding the meaning for the concept in question while the thought and the word are mutually accommodating to each other. This process of mutual accommodation between thought and word, under the name of a verbal thought, has been considered by Vygotsky [15] as the unit of meaning of a concept, which underlined his theory of concept formation. It makes sense therefore to take this relationship as the criterion for understanding of the \( \varepsilon-N \) definition of the limit of a sequence, especially since, explaining the meaning of procedures and discussing concepts in written words was one of the basic instructional strategies during the experiment.

Thus for the purpose of this research, only a student, who, while presented with the problem:

\[
\text{Find the limit of the sequence } a_n = \frac{3n+2}{2n-1} \text{ and prove using } \varepsilon-N \text{ definition, that the number you found is indeed the limit.}
\]

was able to show the necessary computational competence together with being able explain precisely why his or her calculations constituted the required proof, was classified as understanding the definition of the limit.

The sequence \( .9, .99, .999, \ldots \) sequence was taken as an instrument to assess the coherence of the schema. This type of a sequence had not been discussed in class during the course.

**Methodology.** The teaching experiment took place in a section of Calc 1 class with 32 students participating and taking the final exam. The sample of 10 students was chosen among them for the clinical interview which had lasted approximately an hour. The sample in this cycle of the experiment was representing better motivated students in the class. The criterion here was the judgment of the instructor; in the next cycle a well tested measure of motivation will be used.

The data for the study of the understanding of the \( \varepsilon-N \) definition of the limit of the sequence consists of transcribed clinical interviews at the end of the term, just before the final exam, and answers to two questions concerning the limit of sequences from the final exam. Whereas the full analysis of the data awaits the publication of the full report, here, the analysis of two questions from the clinical interviews will be presented and supported by a similar question from the final exam.

**Interview questions**

1. a) What does the statement "the limit of the sequence \( a_n = \frac{3n+1}{4n-3} \) is \( \frac{3}{4} \)" mean to you?
b) How one could prove that the number you found is indeed the limit of that sequence?

2. Find the limit of the sequence \( a_n = \{0.9, 0.99, 0.999, \ldots \} \). How would you prove it is, indeed, its limit?

Final Exam question

3. a) Find the limit of the sequence \( a_n = \frac{3n^2 + 2}{2n^2 - 1} \)

   b) Prove using \( \varepsilon \)-N definition of the sequence that the number you found is indeed the limit of that sequence (start your work by writing the definition of the limit of a sequence)

   c) Explain your work.

The questions 1 and 3 were supposed give information about students' understanding of the limit in the context of \( \varepsilon \)-N definition, while the question 2 was designed to provide the information about their ability to apply that definition in the unfamiliar context, and to check their mastery of the Wallis technique in conjunction with \( \varepsilon \)-N definition.

Data analysis. As mentioned above, the concept described by the \( \varepsilon \)-N definition is the result of the composition of two processes, the process of choosing epsilon and the process of establishing the relationship between \( \varepsilon \) and N. Clear articulation of the relationships between these two meanings of the epsilon, has been taken in this research as the indication that a certain conceptual whole has been mentally constructed by the students and that it can constitute the foundation of the construction of the schema of limits of sequences. Thus the student responses of the type (accompanied by the correct computations)

\[
\text{In order for the value of } \varepsilon \text{ to reduce itself, is necessary that } N \text{ is larger than } \frac{7}{4e} + \frac{1}{2}. \text{ This will give me the value closer to the limit than the value of } \varepsilon \text{ I desire.}
\]

or of the type:

\[
\text{Well, epsilon served as the base for ..., knowing the closeness which we want with epsilon, we can obtain that so great should be } N \text{ to obtain that particular closeness were considered as evidence of such a coordination.}
\]

On the other hand, the responses like:

- With that we can see that when \( \varepsilon \) is smaller, \( N \) is greater.
- With this we know that this great have to be the values of \( N \) to approach the limit.

were not considered such an evidence, even if they had elements of truth in them.

In the interviewed sample of students, 50% demonstrated such a construction while during the final exam about 25% demonstrated it.

These results seem to suggest that the coordination of the two processes constitutes a dividing line between students who had constructed the foundation of the schema and those who had not completed such a construction.

---

6 Translated from Spanish by authors of the presentation.
Consequently, the coordination of mental processes should receive a special attention during the instruction. Coordination of these two processes is most probably made still more difficult by the duality between the visual and algebraic approaches with which students are presented in the attempt to synthesize the concept of a converging sequence. The graphical representation of the limit and of the sequence seems to be clearly described by the statement that as $n$ is increasing to infinity, the distance between the term and the limit becomes smaller. This formulation, suggested by the graph of a sequence, and possibly, by the notation \( \lim_{n \to \infty} a_n \), is reciprocal to that suggested by the algebraic definition, where epsilon is an independently chosen measure of the distance and $N$ is its function. Thus students who are unable to transcend the "temporal"$[7]$ view upon the sequence and its limit could not make the connection with the formal definition at all. Below are samples of thinking of these students who, while computationally able, could not transcend the difficulty and hence did not construct the required schema:

- $N$ should be sufficiently large for $\epsilon$ to be sufficiently small. We want to demonstrate that the distance between $a_n$ and $L$ is small and is decreasing when $n$ is approaching infinity.

- $N$ should be sufficiently large for $\epsilon$ to be sufficiently small.

The presence of this type of confusion was already known the authors of $[7]$; however its significance for the construction of the limit schema was not as clear as it is now.

**Summary of the results**

As mentioned above, the teaching experiment described above is the first in a cycle of experiments whose goal is to successfully reintroduce the formal definition of the limit (taking into account the research conducted on this topic in the past several years) into the standard calculus instruction and the assessment of the results has to be viewed from that point of view. Whereas a 25% success rate in the class is not very high in terms of what could be achieved with respect to understanding the concept, yet we have obtained several invaluable insights, which will help to modify the instruction in the Spring Semester 2001. It is clear that a serious emphasis has to be made on the coordination of two processes participating in the definition. Moreover, it seems that among the discussed misconceptions of students, the one which needs to be dealt with most urgently is the temporal versus sequential conflict $[7]$ upon the relation between epsilon and $N$. Many students who have constructed the basic schema of the limit, were not clear about the meaning and significance of the sequential order. There are certain students' excerpts, which suggest that the emphasis on the development of input-output meaning of a function can be a help in this particular process of understanding.

The other commonly occurring misconception namely, the concern for the last term of the sequence, does not seem to impact students understanding of the
definition very drastically at the Calculus 1 level, and in our opinion the strategies designed to deal with it should be dealt with in Calculus 2 when that misconception starts to impact seriously the understanding of the definite integral [6].

Let us add that the Wallis technique contributed to high rate of success on question 2 of the interview. Every student who had coordinated the two processes was also successful on the application of the schema to $a_n=0.9, 0.99, 0.999$...

Bibliography

This paper explores one case study, typical of a large number of students, in the transition from school to university. This category of student has developed a view of mathematics as fundamentally procedural. This means that they are able to reason about specific objects, but cannot (and do not attempt to) acquire a meaningful conceptual understanding of university mathematics. We show that this procedural approach, adapted to the university level, leads to a loop in which the student's focus keeps him removed from the central ideas of university mathematics.

Background

Tom is good at doing mathematics, just not at university mathematics!

Tom was one of eighteen first year students taking part in a study of the effects of two different styles of teaching first term Analysis at a UK university (Alcock & Simpson, 2001). One was a standard lecture course to over 100 people, supported by assignments. The other involved students in small groups working through carefully structured questions which built up the analytic theory in the course (Burn, 1992). The study gathered data in numerous ways, though the data presented here comes from biweekly semi-structured interviews which the student attended in pairs. These covered their feelings about the course, general discussions about the mathematics they were encountering and a task-based section in which they were presented with a problem related to recent material. The data were examined using a grounded theory approach (Strauss & Corbin, 1990) and classes of common features emerged under categories such as the student’s informal facility with the material, their approach to reasoning about general objects and their view of their own role as a learner.

Patterns in the data across these categories led to the classification of “types” of learner, with the largest factor in a student’s mathematical development being their view of their own role as a learner and their resulting approach to the course. One clear category in this sense is those whose view we might call procedural (or instrumental in the sense of Skemp, 1976) – these students see mathematics as set of fixed procedures to be learned. This paper will examine the consequences of this procedural approach using Tom as an exemplar.
School and university mathematics

The procedural approach is associated with beliefs that are well documented in students at school level (Schoenfeld, 1992). While this may not be desirable, in school it is viable to believe that mathematics consists of procedures to be learned, that problems have only one “best” solution and that teachers are the expositors and arbiters of correctness (all of the eighteen students in the study attained an A in A-level mathematics and half of them exhibited some or all of these beliefs). In contrast university mathematicians see mathematics as being about concepts to be understood, problems with many forms of solution which demonstrate different insights, and correctness warranted by formal deductions (Tall, 1995, Moore, 1994).

Tom is typical of this procedural category. We will use his case (and illustrations from similar individuals) to demonstrate that those who bring these beliefs from school may attain some facility at the level of handling specific objects, but beyond this they tend to have a focus on detail, to be inflexible in their use of procedures and to have little meaning associated with them. We then consider how these characteristics lead such students to ignore and avoid changes in requirements at university level.

Tom’s background

In the first interview Tom credits his eventual success in A-level to the fact that:

“...we got to practise exam-style questions, and got used to it and just went through lots of examples really. I think that’s what you needed, lots of examples to practise.”

and says he thinks the best way to learn a new piece of mathematics is:

“Definitely step by step examples going through it. Like the teacher gives you step by step examples, so you can go away and look at them when you do questions and say ‘oh this is how you do it’. And get used to the method.”

This background was quite typical of this category of learner. Zoe, another procedural learner, expresses similar ideas:

“I just like the way we were taught at school...Where we, we have our notes, and then we practise so many times that it’s just sort of drummed into us. You just don’t forget it that way, it’s like, I don’t know...”

From this viewpoint there is an implicit reliance on the fact that teachers will provide procedures, and little onus the student to assess their suitability in novel situations. There is considerable security for the student in this approach; the responsibility definitely lies with an outside authority and a student who diligently learns what they are told can expect to do well (cf. Perry, 1970, Copes, 1982). However this ceases to be the case at university level, where these beliefs actively interfere with any learning on a more conceptual level, as we now see.
Effects of procedural beliefs

Focus on detail, not concepts

One result of procedural learning is that such students tend to focus on remembering the detail of what they have done rather than thinking about what this means in terms of the concepts studied. For example in week 3 Tom is asked what they have been working on in Analysis recently and says:

"Erm, we're learning about, different proofs with erm, modulus. All of those, like \( a - b \), all in bars equals - doesn't, is less than, \( a - b \) outside and things like that."

This appears to be a description of the triangle inequality, although it is hard to tell because he does not state the final result. Again Tom's response is typical of this category of learner. In this excerpt Wendy is describing a homework question that she found difficult:

Wendy: You had, you had to erm, find an increasing and a decreasing sequence that erm, converged to the same limit,

Xavier: Subsequence, wasn't it?

Wendy: Yes, subsequence and prove that the, sequence would converge to the limit. And it was like, we had to find one that, a decreasing sequence that converged to the same limit as an increasing sequence. And all this other stuff going round that, you had to use and...oh no!

Everyone tends to become less coherent when trying to describe something that they didn’t understand well. However Wendy is very focused on the instructions they “had to” follow; at no point does she state the result that this was supposed to lead to.

This lack of focus on conceptual relationships also shows up when Tom does attempt to use concept terms in sentences:

Tom: Erm, he’s just been giving us sequences, and we’re supposed to be proving them.

Laughter.
Interviewer: Proving what?
Tom: Just, proving that they’re true. The sequences tends to a limit, and...

His meaning is relatively clear at the second attempt, but his first does not make sense and he clearly is not fluent in describing the work in these terms.

Informal use of the ideas from the course

This is not to say that procedural learners don’t learn anything. Again Tom is typical, reasoning informally using the ideas from the course when asked to think about specific objects.

For example in week 5, considering the sequence given by \( a_n = \frac{1 + \cos n}{nx} \), he says:
"Well, because it’s cos \( n \), the greatest cos \( n \) can be is, 1, so the greatest that this can be, is, on the top is 2, so, whereas the bottom, is always going to get larger and larger."

And later:

"Then the bottom’s just going to, increase and increase and increase and even if, \( x \) is negative it’s going to, be increasing by so much, that the top is going to become irrelevant, and it’s just going to tend to zero."

He does not notice the problem with \( x=0 \), but does reach a correct conclusion about the eventual behaviour of the sequence for the remaining cases using strategies of considering the extreme values of the cosine function and making informal comparisons between variable quantities.

*Procedures as immodifiable wholes*

Difficulties arise for Tom when he tries to prove his assertions algebraically. Typically of the procedural learners in this study, he has procedures available, but if they are not applicable in very standard form he does not try to adapt them to fit the new situation. This is frustrating to listen to since he can identify problems with some precision. In this excerpt he is explaining why he doesn’t know how to write down an answer to the above question:

"Because we can’t really, bring that \( nx \) up to the top, on the other side, because we don’t know, whether \( x \) is positive or negative. And we can’t really use the squeeze rule, because, what happens - we don’t know what \( x \) is. It could be like 0.0001. And in that case, with it being on the bottom, it would increase the number."

His first approach is, in his own words, to “make \( n \) the subject”, showing some awareness of the routine for showing that the definition of convergence is satisfied (though whether he understands that this is what he is doing is open to question). Further thought would make either this or his other suggestion viable: he could treat positive and negative values of \( x \) as separate cases, or use the fact that if \( (a_n) \) tends to zero then so does \( (ca_n) \) (for any real \( c \)) in conjunction with the “squeeze rule”. What seems to happen is that when a particular algebraic manipulation routine does not give him a straightforward path to the desired result, Tom simply stops. We suggest that he does not think his role involves being creative in mathematics, so that once a procedure is invoked he simply follows this and will not attempt to adapt it.

*Lack of meaning associated with a procedure*

In the week 9 interview the students are asked to establish for which values of \( x \) the series

\[
\sum_{n=1}^{\infty} \frac{(-x)^n}{n}
\]

converges.
By this time Tom's earlier level of meaningful understanding has collapsed under his search for procedures. Whereas before we saw him instantiate a suitable procedures but lack the inclination to adapt them, here he attempts to use an inappropriate and incorrectly recalled "procedure" on the basis of surface similarities with the given question. He says:

"Oh right, I know, I remember, that the sum of $1/n$, tends to $\log n + \lambda n$. Or, it's the sum of, brackets minus 1 close brackets, to the power of $n$.
Divided by $n$, tends to, $\log n$, plus $\lambda n$. And I think it's the first one."

He appears to be explaining a confused memory of the process of finding the partial sums of the series $\sum_{n=1}^{\infty} \frac{1}{n}$, which form a sequence $\log n + \lambda n$, and so demonstrate that the series is unbounded. What he says would not be correct even if it were appropriate, since it would make no sense for anything to tend to the variable quantity $\log n + \lambda n$, but Tom apparently remains unaware of this. Also he says he "thinks" that the first expression is the one he wants, but although he is uncertain of this there is no attempt to do any reasoning to check; he seems to rely entirely on recall. He goes on:

"Okay this is just the formulas, not what they tend to. Formula 1 is the sum of $1$ over $n$, and formula 2 is the sum of brackets minus 1 close brackets $n$, over $n$.
To the power of $n$ or whatever. So, I think, formula 2, is very similar to the question, except for, $x$ has been given a number, 1, and we've just got to use, formula 1, to create formula 2, to see what it tends to."

The strategy of trying to manipulate a new situation so that it resembles a known one is good, and Tom's outline of a possible solution path is clearly explained. However, in addition to the apparent lack of meaningful understanding of what it is that he is suggesting, by this stage he has lost track of the question. The limit of the series is not required; only the values of $x$ for which it converges. Failing to monitor progress toward a solution may be simply a weakness in this particular area; perhaps he finds the material hard and cannot keep sufficient in his working memory to be able to make this judgement as well. However the evidence in this study suggests that these factors are all related for a learner of the procedural type and, we will see, form a loop.

A cognitive loop

Tom uses the phrase "we've got to" twice in the above excerpts, and we have seen that his use of procedures is inflexible and sometimes inappropriate. This suggests a continued belief that there exist externally-provided rules prescribing what should be done when, rather than natural approaches which he himself could generate based on the intrinsic meaning of the mathematics. We suggest that his lack of progress is due to being caught in a loop involving two complementary aspects – lack of meaningful checking and attending to procedural detail rather than concepts.
Tom does not feel the need to check whether his suggestions “make sense” in a meaningful way. He assumes that the algebraic procedures he is shown are generally useful; having faith that these will work with similar-looking examples, he does not attend to the concepts that the algebra expresses. This actually renders him more or less incapable of performing such checks; he has no meaning for the manipulations so he cannot assess whether the concepts involved in a new situation are really comparable. However Tom does not notice this, because that isn’t what he’s trying to do, and so on.

The challenge for the teaching at this level is that this does not cause him any great distress. He finds enough in the new mathematics to maintain his beliefs; university mathematics is not all proofs, quite a lot of it involves applying techniques to particular examples and at least at the beginning of the course Tom can cope with this. Combined with the fact that he is not looking for links between concepts, this means that he does not feel he is failing to understand.

A challenge for teaching

A student’s progress is limited by what it is that they are trying to do, and while procedural learners have individual strengths, on the whole they fare badly in this first course in Analysis. For example, Wendy can cope with the question about series, using generic examples to reason about different cases:

Wendy: Erm, if, if you take \( x \) is between nought and 1, say \( x \) equal to a half, erm, and put it into the series, you’d get, minus a half, plus a half squared over 2, minus a half cubed over 3, and so on...

Xavier: So that’s going to be smaller.

Wendy: Erm, the terms are decreasing in size, so... \( x \ n \), is bigger than, \( x \ n \) plus 1 (writing)

Xavier: And tending to zero.

Pause (writing).

Wendy: Converges?

This makes it appear that she is keeping up with the course, but in fact she shows serious weakness in forming more general arguments and a lack of understanding of important formal categories. For instance, it is very difficult to persuade her to consider sequences which are not monotonic (see Alcock & Simpson, 1999) and she ends the course believing that a convergent series have its sequence of partial sums eventually constant. Even Tom is not the weakest. Zoe, the other student mentioned earlier, has even less concern for meaning than Tom. Here she describes the approach she and Yvonne take to doing their assignments:

“What we usually do is when we have our notes, like sprawled out everywhere (laughs)... copy bits from here and here and like, put it all together. And hope it turns out right.”
Unsurprisingly, they find it difficult to get started even on the questions where Tom has some success, and it often appears that the interview is the first time they have given any meaningful thought to the work.

Of course there are students who have quite different goals. Jenny, for instance, expends a great deal of effort on her assignments and says that she “feels like a fraud” if she hands in something she does not fully understand. However the prevalence of procedural learners and their failure to attend to the aspects of mathematics their university lecturers see as central – the marriage of conceptual understanding and formal deduction (Yusof and Tall, 1995) – begs the question of the role teaching can play in helping students negotiate the transition from school to university.

The obvious direction in which we must now move is to address the question of breaking the loop generated by lack of meaningful checking and attendance to procedural detail. How do we help Tom to be as good at university mathematics as he is at his mathematics?!

What are we trying to achieve in teaching standard calculating procedures?

Julia Anghileri, Homerton College, University of Cambridge

Abstract

In societies that depend on calculators and computers for all important calculations, questions must be asked about the purpose of written calculation. Reforms in arithmetic teaching have led to a shift from the repetition and rehearsal of algorithmic approaches to a focus on developing pupils' own methods, but mastery of standard procedures remains a fundamental goal. This presents a dilemma for pupils who try to replicate a taught procedure which may not be their most effective solution strategy. This paper reports a study involving English and Dutch pupils (n=535) and highlights the way their efforts to implement taught procedures can inhibit more appropriate strategies using number sense.

Background

Classroom activities today involve pupils in observing patterns and explaining relationships so that they develop understanding of connections among different numbers and operations gaining a ‘feel’ for numbers often referred to as ‘number sense’ (Anghileri 2000). This term ‘number sense’ is widely used across the world in reform documents (NCTM 1989; AEC 1991) and refers to ‘flexibility’ and ‘inventiveness’ in strategies for calculating. It is a reaction against overemphasis on computational procedures and reflects ‘new numeracies’ (Noss 1998) that are more relevant to the skills and understanding needed in our social and working lives. At the same time, computational procedures remain an important element of the curriculum, for example, the National Numeracy Strategy for England states that ‘at least one standard written method of calculation should be taught in primary schools’ as these ‘offer reliable and efficient procedures which, once mastered, can be used in many different contexts’ (DfEE, 1998: 52).

English and Dutch teaching approaches

The ‘standard’ procedures to be taught will vary from one country to another and will reflect the teaching that has led up to the stage of written calculations. England and the Netherlands have different teaching priorities culminating in different standard methods. The role of place value is emphasised from an early age in England where ‘understanding about place value is required as a sound basis for efficient and correct mental and written calculation’ (SCAA 1997: 4). In the Netherlands, in contrast, holistic approaches to numbers include the development of counting skills as the basis for calculating (Beishuizen and Anghileri 1998). For the operation of division these contrasting approaches culminate in different
written procedures. Standard written methods for division in England are based on the traditional algorithm while the Dutch approach involves repeated subtraction with appropriately chosen multiples (chunks) for developing efficiency (Anghileri 2001). Progression from informal methods to standard written procedures is more clearly evident in the Dutch approach as will be shown in the results reported in this paper.

Purposes of written calculations

Ruthven (1998) identifies two distinct purposes for using pencil and paper for calculating: ‘to augment working memory by recording key items of information’ and ‘to cue sequences of actions through schematising such information within a standard spatial configuration’. The traditional algorithm is structured to ‘direct and organise’ (Anghileri 1998?), providing a highly efficient written method for solving problems but is not easy to reconcile with ‘the way people naturally think about numbers’ (Plunkett 1979). The formal procedure is also prone to errors in some cases due to its incompatibility with intuitive approaches (Anghileri and Beishuizen 1998; Anghileri 2000). The Dutch Realistic approach uses contextual problems as a starting point and a standard procedure is evolved from informal approaches based on repeated subtraction (Gravemeijer, 1994) with whole numbers retained at all stages.

Comparing the effectiveness of different approaches

Effectiveness of the different teaching approaches is compared in a study in the two countries. In cities with similar cultural characteristics, whole classes of year 5 pupils in ten English schools (n=276) and in parallel grade 4 classes in ten Dutch schools (n=259) were asked to write solutions to ten division problems. Pupils completed written tests in January involving five word problems and five symbolic (‘bare’) problems with similar numbers (Table 1).

The numbers were selected to encourage mental strategies and to invite the use of known number facts. The tests were repeated in June to establish changes in pupils’ strategies. In the second test, numbers in the context and non-context problems were interchanged to reduce the influence of memory.

**Results**

Solution strategies were classified into 8 categories. Low level strategies involved making tally marks or repeatedly adding or subtracting the divisor 1(S), partitioning the divisor or dividend (or both) 2(P), or use of small multiples of the divisor in low level chunking 3(L). Efficiency gains were evident with repeated subtraction of large chunks 4(H), or use of the traditional algorithm 5(AL). Where there was a solution but no working the strategy was classified as mental 6(ME). Some solutions involved the wrong operation 7(WR) or the strategy was unclear 8(UN).

Overall success was greater for the Dutch pupils who successfully completed 47% of the items in test 1 and 68% in test 2. English pupils successfully completed 38% in test 1 and 44% in test 2 (Table 2).

**Table 2: Percentage of questions successfully completed**

<th>English test2</th>
</tr>
</thead>
<tbody>
<tr>
<td>47%</td>
<td>68%</td>
<td>38%</td>
<td>44%</td>
</tr>
</tbody>
</table>

English pupils persisted longer in using low level strategies 1(S), 2(P) and 3(L) with 28% of attempts in test 1 and 22% in test 2. Dutch pupils used these strategies for 33% of items in test 1 but this reduced to 13% in test 2. With the large numbers involved pupils struggled to reach a successful solution using these strategies.

The most popular Dutch strategy in both tests involved repeated subtraction of large chunks, 4(H), which was often structured in a standard written format and was used for 41% of the items in test 1 and 69% in test 2. English pupils used the traditional algorithm, 5(AL), most extensively with 38% of items in the test 1, and 49% in test 2 attempted using this approach. The Dutch standard method, 4(H), led to a correct solution in 74% of attempts while only 47% of the English attempts to use the traditional algorithm 5(AL) were successful.

Mental methods were used equally by the Dutch and English pupils (11% of all items) with almost equal success (6% Dutch/5% English).

**Progression**

In the solutions of Dutch pupils there was evidence of progression from repeated subtraction of the divisor, to subtraction of small multiples/chunks which often involved long calculations, to efficient use of large multiples/chunks in a standardised written procedure (Beishuizen and...
Anghileri, 1998). At all stages, whole numbers were used and the written structure developed was the same for 1-digit and 2-digit divisors. Pupils written solutions showed extensive use of the structured written procedure at different levels of efficiency (Figure 1).

**Figure 1: Dutch written procedure for division**

```
432 : 15 =
    432
  - 150
   282
  - 150
   132
   - 120
    12
```

Progression was not evident in the English strategies where idiosyncratic written methods based on mental strategies did not appear to relate well to the traditional algorithm. Informal methods generally lacked any written structure and it was evident that difficulties arose for some pupils in following through their own working to give a correct solution (Figure 2).

**Figure 2: Unstructured recording of an English pupil**

432 children have to be transported by 15-seater buses. How many buses will be needed?

```
36 15 5 in 180 80
400
12 15 5 + 4 10
36 15 5 + 24 15 5 in 360
4 00 = 10 6 5 6 other
90 24 - 6 = 1 3 4
```

For a 2-digit divisor, attempts were made to partition the divisor or to operate on separate digits. A typical example was the problem 64 ÷ 16 which was solved by first dividing by 10 and then by 6, or as 6 ÷ 1 = 6 and 4 ÷ 6 = 1 r 2 (wrong use of the commutative rule) (Figure 3). Some pupils appeared to get stuck trying to divide 60 by 16. Use of the formal
procedure appeared to preclude any return to an informal approach and inappropriate results written in the answer space suggest that a written procedure had been followed which took no account of the approximate answer (Figure 3).

**Figure 3: Errors with the traditional algorithm**

![Figure 3](image)

**Single digit divisors**

In addition to having a procedure that related well to informal thinking about division, better results for the Dutch pupils may be explained by the fact that they meet division by a 2-digit divisor in grade 4 (Y 5) while most English pupils will meet only 1-digit divisors. Results were compared for those items involving only a single digit divisor. Scores in test 1 were close for the English and Dutch pupils with averages of 45.5% and 47.25%. Both were more successful in dividing the 2-digit numbers that in dividing the 4-digit numbers. In test 2 the English results improved to average 55% over the four problems while the Dutch result was 71% successful.

Improvements were similar for the items, 96÷6 and 98÷7, with Dutch/English increase in correct answers 8%/5% and 22%/21% respectively. For the 4-digit numbers, 1256÷6 and 1542÷5, the Dutch improvements were higher than those of the English children, with increases of 29% and 36% compared with 2% and 10%.

English pupils used the algorithm with low success rate for the 4-digit numbers. The Dutch pupils used repeated subtraction with large chunks and although the success rate is not as high for the 4-digit numbers, differences were less marked (Table 3).

**Table 3: Percentage use and effectiveness of the most popular strategies for test 2**

<table>
<thead>

<td>71 (52)</td>
</tr>
</tbody>
</table>

The figures in brackets give the percentage of correct attempts.
Errors by the English pupils included missing digits in the answer, but also many confused attempts often leading to impossible (and sometimes bizarre) answers (see Figure 3).

**Overall improvements**

When individuals' scores were compared for test 1 and test 2, changes in score varied from +9 (e.g. 1 correct in test 1 and 10 correct in test 2) to -6 (e.g. 8 correct in test 1 and 2 correct in test 2). Again, the scores of Dutch pupils showed better improvements with 69% improving their score while almost half of the English pupils (49%) showed no improvement or a deterioration (Figure 4).

**Figure 4: Changes in score from test 1 to test 2**
Conclusions
The Dutch approach to written division calculations, involving repeated subtraction using increasingly large chunks, builds progressively on a mental strategy and retains whole numbers at all stages. The success of the Dutch pupils reflects their mastery of an increasingly efficient approach that has the flexibility for individuals to use the knowledge of multiplication facts that they have. On the other hand, the traditional algorithm extensively used by the English children, introduces a schematic approach that focuses on separate digits with their true value implicit, rather than explicit. Not only is the traditional algorithm more difficult to understand and prone to errors, but also progression to division by a 2-digit divisor requires substantial adaptation that is not intuitively clear to pupils. There is no flexibility in the choice of multiplication facts that can be used and links with mental methods are not clear.

When a standard procedure for calculating is taught in school it appears to take precedence over informal methods and implementing the procedure can be at the expense of making sense of a calculation. A problem such as 64÷16 caused great difficulty to the English pupils because it does not respond readily to the traditional algorithm which was used in preference to informal approaches. Instead of recognising the number relationships involved, pupils used a procedure cued by the operation.

Developing efficient procedures that relate to pupils’ knowledge of numbers and to their intuitive understanding is crucial for developing the confidence that will encourage pupils to work on making sense of problems they meet. When presented with a meaningful problem the two approaches illustrated below show how the algorithm can lead back to the original calculation while a procedure that is better understood can encourage a solution that goes beyond the minimal requirements of a pure arithmetic calculation.

\[
\begin{array}{c}
72 \overline{)300} \\
- 144 \quad (2 \text{ days}) \\
\hline \\
- 144 \quad (2 \text{ days}) \\
- 12 \\
\hline \\
300
\end{array}
\]

A farm shop sells about 72 eggs each day. How many days will 300 eggs take to sell?

So it will take 4 days and a bit, so probably about 11:00 on the 5th day.

NEGATION IN MATHEMATICS: OBSTACLES EMERGING FROM AN EXPLORATORY STUDY

Samuele Antonini
Department of Mathematics - University of Pisa, Italy

ABSTRACT: In a previous research we have elaborated three schemes of behaviour to classify the difficulties of students in the interpretation and formulation of mathematical negation. This report provides a detailed analysis of one of these schemes, particularly its link with common practice, showing that some of the greatest obstacles in learning the meaning of mathematical negation are the difference between negation in mathematics and in natural language, and the tendency to classify into particular categories, that take into account the differences more than the analogies.

1. Introduction
In the works which involve the mathematical negation, the university students in the first year of the faculty of sciences often incur in errors. Such errors witness students' difficulties in understanding of mathematical negation and the presence of an obstacle to accept indirect proof.

There are currently few works in mathematics education directly concerned with negation. However, we would like to quote Thompson (1996), who report on the problems with proofs by contradiction due to the difficulties of negation. Thompson sees the correct formulation of negation as an important prerequisite for the use of indirect proof. Moreover, he draws up a list of some typical mistakes students make when negating a sentence. In Barnard (1995) there is a more detailed list of typical mistakes in recognising negations.

The theoretical framework which we refer to is Antonini (to appear). This framework, based on the notion of scheme of Piaget (1967) re-formulated by Vergnaud (1990), distinguishes three different schemes - scheme of the opposite, of the possibilities and of the properties - which guide the behaviour of the students in situations that involve the mathematical negation.

After a short description of the three schemes, we intend to widen the analysis of one of them (the scheme of the possibilities), by hypothesising about the existence of elements that, on the one hand, strengthen it and, on the other hand, can hinder the passage to the scheme more suitable to mathematics (scheme of the properties).

2. Method
The results we present in this report are related to a research study which, in this early stage, is essentially exploratory and based on a collection of data which can be furtherly refined. The goal of this first phase is to implement a framework of theoretical reference for a more detailed analysis. The author was support tutor in the first year of the calculus course, held at Pisa University in Italy. On this occasion, different types of students' behaviours were observed through questionnaires and discussions in the classroom. Furthermore, a number of interviews were conducted.
and then recorded with students of the fourth year of the degree course in physics at Pisa University.

3. Negation schemes
In this paragraph we shall try to classify the behaviour of students faced with situations concerning negation.
In this respect, we shall use Piaget's notion of scheme (Piaget, 1967), as re-formulated by Vergnaud (1990):

"On peut distinguer:
1) des classes de situations pour lesquelles le sujet dispose dans son répertoire, à un moment donné de son développement et sous certaines circonstances, des compétences nécessaires au traitement relativement immédiat de la situation;
2) des classes de situations pour lesquelles le sujet ne dispose pas de toutes les compétences nécessaires, ce qui l'oblige à un temps de réflexion et d'exploration, à des hésitations, à des tentatives avortées, et le conduit éventuellement à la réussite, éventuellement à l'échec.

[...]
Appelons 'schème' l'organisation invariante de la conduite pour une classe de situations donnée".

(Vergnaud, 1990)

A first classification of students' behaviour when facing with mathematics negation resulted in the definition of three mental schemes (Antonini, to appear), which can be briefly described as follows.

SCHEME A (of the opposite): The negation of "x is p(x)" is "x is q(x)" where q is "the opposite" of p. Examples of opposites are increasing-decreasing, even-odd, all-none, major-minor.
The subject is often aware that besides p and q there are other possibilities as well, but these are considered "exceptions", "extreme cases".

We observe that a concept and its opposite are strongly linked by analogies, symmetries, oppositions, and are often two aspects of the same concept (e.g. monotonicity: increasing-decreasing; order relation: major-minor).

The example which follows is designed to illustrate these features:

Interview to Vincenzo (4th year Physics student)
1.Int: [...] I say: f is an increasing function. What is its negation?
2.Vinc: f is decreasing (he answers immediately, without thinking).
(...)
3.Int: Well, you must prove by contradiction a theorem whose thesis affirms that f is an increasing function.
4.Vinc: by contradiction...
5.Int: Let us suppose by contradiction that ...
6.Vinc: That f(x) is decreasing.
7.Int: That f is decreasing; o.k. you start: let us suppose that f is decreasing.
8.Vinc: I must show ... (pause)
9.Int: Well, you start from decreasing f and then, what happens?
10.Vinc: I must show that I reach a contradiction ... of the hypotheses.
11. Int: Ok, at a certain point we reach a contradiction of the hypotheses.
12. Vinc: Yes.
13. Int: And so? Have you finished the proof?
14. Vinc: So... the fact is that it is not decreasing ... therefore it is increasing ... 
15. Int: Are you sure?

Vincenzo uses the idea of the opposite to construct the negation of “f is increasing”. In the last part of the protocol we notice how “f is decreasing” is for the subject the logical negation of “f is increasing”. As a matter of fact, in 14 Vincenzo says: f “is not decreasing ... and therefore it is increasing”.

SCHEME B (of the possibilities): If x is not p(x) then it can be p1(x), p2(x) or p3(x), etc. In other words, the statement “x does not possess the property p” means that there are various possibilities. Whilst there were only two possibilities for scheme A, for scheme B the negation dissolves in a multitude of different cases. What follows are some examples in which the students formulate the negations proposing various possibilities rather than using an opposite.

1) Written questionnaire (freshman Science students). One question was: “What is the negation of a proposition? (Try to give also an example)”. A reply: “For example: f(x)>0, negation: f(x)≤0.
In this case negation can include both < and =, that is all the possibilities in which the proposition does not occur. For example, if we were to deny that an f is increasing we should say instead that it is decreasing or constant or increasing and decreasing ...” (underlining is ours).

2) Test (freshman Science students) “We know that a certain function g is not strictly decreasing in the interval (-2,+3). Is there anything that you could define as being certainly true? (Give a justification for your answer).” A reply: “The fact that g is not strictly decreasing does not say anything about the function because it leaves the possibility of g being both increasing and constant and also that it is decreasing but not strictly or even increasing and decreasing at the same time. Therefore nothing absolutely true can be said about function g”. (underlining is ours).

SCHEME C (of the properties): If p is false we look for a property q common to all x for which p(x) is false. This scheme is commonly used in mathematical reasoning. On many occasions it leads to a really efficient behaviour from the operative point of view, for example if we want to deny that “f is increasing”, we could say that “there exist x, y such that x<y and f(x)≥f(y)”: this property is common to every non-increasing function, whether they are constant, increasing, discontinuous, etc. On the contrary this scheme is a very rarely used by students, who seem to prefer scheme B.
4. Dominance of scheme B

The proposed schemes represent a first attempt to classify the behaviours. We observe that, in keeping with Vergnaud (1990), the behaviour of a subject can be guided either by different schemes in various situations or by different schemes in the same situation.

The obtained results show that scheme B is very common. This scheme corresponds to some aspect of the everyday language. It is also easily extended to mathematical context, even though it leads to poor and wrong behaviours.

In this paragraph we intend to analyse more in detail the nature of scheme B. We think that this analysis allows to interpret and better understand the students' behaviours guided by this scheme.

We retain that two are the fundamental elements that strengthen scheme B and hinder the acquisition of scheme C:

1) the natural tendency to a certain type of classification;
2) the impossibility with the natural language, unlike that mathematical, to always express the negation in the affirmative form - for instance, in Italian, without the use of "non".

4.1. Classification

As far as classification process is concerned, previous studies have highlighted two different aspects which are fundamental. By referring to two different studies, we show two different aspects of the process of classification:

a) the necessity to differentiate (Mariotti-Fischbein, 1997);
b) the classification in cognitive categories (Lakoff, 1987).

a) In a study on definitions, Mariotti and Fischbein (1997) point out that the students tend to classify some solid figures on the basis of differences more than analogies:

"The figural differences between a parallelepiped and a hexagonal prism lead to a classification which aims to separate the two classes of objects, whilst, in the standard mathematical classification, the class of the parallelepipeds is included in the more general class of the prisms. In order to get such structural conceptualisation, differences between the particular objects should be overcome in favour of analogies between them." (Mariotti-Fischbein, 97) (underlining is ours).

The need to express the negation as a unique property therefore conflits with the natural tendency to classify different objects in different classes.

As a matter of fact, the objects which do not have a particular feature may represent even enormous differences.

Let us give an example: the set of non-continuous functions is made up of functions which are very different one from the other. There are functions discontinuous at a particular point but with right and left finite limits, functions unbounded at a point, functions discontinuous at every point, functions continuous only at one point, etc.

Mathematicians have classified the various types of discontinuity in three species. In each species there are functions which have some features in common.
The subject using scheme B, even though he realizes the possibility of many different cases, does not manage to assemble all the elements for which a proposition is false in a unique whole. He gathers them in cases or possibilities; each possibility contains elements with some common characteristics. Describing "non-p" with a list of possibilities therefore helps to overcome the difficulties encountered by treating with the differences. The more the objects are different, the more the necessity to find a common property (to generalise) conflits with the necessity to differentiate:

"The process of generalisation requested by a theoretical definition conflicts with the need of differentiating. Difficulties arise when theoretical constraints state the equivalence between ‘different’ things, requiring to cancel the variety once for all.” (Mariotti-Fischbein, 97).

b) There are different studies of the nature of human categorization and of the nature of the categories (see Lakoff, 1987):

"From the time of Aristotle to the later work of Wittgestein, categories were thought be well understood and unproblematic. They were assumed to be abstract containers, with things either inside or outside the category. Things were assumed to be in the same category if and only if they had certain properties in common. And the properties they had in common were taken as defining the category.” (Lakoff, 1987, p. 6)

Nevertheless, the formulation of Aristotle finds a series of great limits in the explanation of some experimental data. More suitable to explain the collected experimental data is the prototype theory of Eleanor Rosch (see Lakoff, 1987, chapter 2).

From the cognitive point of view, one category is not so much determined by the common characteristics of all of its elements but by the similarity with a particular element, said prototype; if an object is too different from the prototype it cannot belong to that category. All this is particularly valid for the so-called basic-level categories, defined in Lakoff (1987, p. 46). The categories at the basic-level are the ones better differentiated and it is at this level that a great part of our knowledge is organised.

"The complements of basic-level categories are not basic level. They do not have the kinds of properties that basic-level categories have. For example, consider non-chairs, that is, those things that are not chairs. What do they look like? Do you have a mental image of a general or an abstract nonchair? People seem not to. How do you interact with a nonchair? Is there some general motor action one performs with nonchairs? Apparently not. What is nonchair used for? Do nonchairs have general functions? Apparently not.

In the classical theory, the complement of a set that is defined by necessary and sufficient conditions is another set that is defined by necessary and sufficient conditions. But the complement of a basic-level category is not itself a basic-level category.” (Lakoff, 1987, p. 52)

In this theoretical framework we can explain the tendency of the subjects to behave by using scheme B in situations of negation: the objects that do not belong to a given category (ex. the non-increasing functions) do not set up a category, being composed
of too much different elements and often deprived of a prototype, but are an union of categories, each of which has a good prototype (ex. decreasing, constant and periodic functions).

4.2 Language
The second element that strengthen scheme B and hinders C is the lack of adequacy of the natural language to express a negation in affirmative form. In the natural language, to express the negation, often we can only affirm “non-p” (for example, sentences like “I did not travel by train" or "it does not rain" can be unlikely formulated in affirmative forms). Instead, in mathematics it is often possible to rephrase “non-p” in affirmative way, removing any trace of negation (for example, “f is a non increasing function” is the same as saying that “there exist x, y such that x<y and f(x)≥f(y)”). This is therefore a newness, that requires a specific educational approach.

5. Analysis of a protocol
The following protocol represents a very good example.

Interview to Carlo (freshman engineering student)
1.Int: What is negation?
2.Carlo: It is the opposite.
3.Int: What do you mean?
4.Carlo: If I say "switched on", the opposite is "switched off". But if I say "it is raining", there is no opposite, I can only say that "it isn’t raining".
5.Int: Do you know what a proof by contradiction is?
6.Carlo: It means proving that the opposite of a thesis cannot be true. I don’t know whether this is always possible, I think it is possible only in those cases in which I only have two possibilities, like "switched on" and "switched off".
7.Int: If I have a theorem whose hypothesis is that f is an increasing function. How would you begin a proof by contradiction?
8.Carlo: Let us suppose that it is decreasing ... (pause) ... no, because there are other cases which are not included ...
9.Int: And so?
10.Carlo:... (pause) Well, I should identify something in common ... I mean a property which is common to all the non increasing f, then prove that the f of the theorem cannot have that property, and therefore is increasing. But the proofs by contradiction turn out better when I have only two cases, like “switched on” and “switched off”.

1-4: Carlo distinguishes two types of negation: the first one is a typical opposite ("switched on" - "switched off"), the second an asymmetrical case. Only in the first case the language makes it possible to describe the negation in affirmative terms (not switched on = switched off); in the second case "I can only say that it isn’t raining."

5-6: Carlo retains that the proof by contradiction can be done only when there are two "possibilities", but it is important to underline that, while "switched on" and "switched off" are possibilities, "increasing" and "non increasing" are not considered as such, in accordance with that said above about the cognitive categories.
7-8: After having applied the opposite of increasing to build the negation, Carlo realizes that there are other "cases" (possibilities).

9-10: The subject builds by himself the idea to formulate the negation in terms of property. Nevertheless Carlo is not sure that this is really possible ("I should identify") and, actually, he does not try to do it. Our hypothesis is that the familiarity with the mathematical language could help to overcome this obstacle.

Finally, Carlo returns to the idea that the proof by contradiction "turns out better" in cases of opposites.

We can observe that the difference that Carlo underlines between the two types of negation is not considered from a logical point of view. In fact, given a proposition p, there are always only two cases: p and non-p (as "switched on" and "switched off"). The difference underlined by Carlo can be only explained with the fact that, while, in any case, we are in the presence of only two properties, we are not necessarily in the presence of only two possibilities (as "increasing" and "non increasing").

6. Conclusions

We have described three schemes that guide students' behaviour in situations which involve negation. These behaviours are sometimes guided by a single scheme, other times by the consecutive combination of various schemes.

These schemes are not correct or mistaken in themselves, since any of them can lead to results which can be both correct and incorrect; however they can be more or less adequate to the solution of the mathematical problem that we intend to deal with.

We can also observe that the difficulties that may lead to the use of schemes A or B are of a very different nature: while scheme A may lead to errors (see Vincenzo protocol), scheme B may lead to a block of mental processes (see Carlo protocol). From the didactic point of view, identifying the involved scheme can give important indications to differentiate the kinds of didactical approaches.

Moreover, scheme B is the most diffused scheme among the students, and for this, it requires an in-deepth study; in this article, we have suggested a first analysis of this scheme, and we have described two elements that strengthen it and hinder the passage to a scheme mathematically more refined.

Further investigation are required in order to fully highlight the complexity of the mental processes involved in mathematical negation.

The knowledge of elements like those we have described, of their origin and of their link with the common practice, is deemed very important as it provides the teacher with good indications for the construction of didactical approaches for the introduction to mathematical negation and to proof by contradiction. We retain extremely meaningful statement 6 of Carlo protocol, that individualises a narrow bond between the schemes of negation proposed and the problem of the learning of proof by contradiction.

The Students' Processes of Transforming the Use of Technology in Mathematics
Problem Solving Tools

Luis Moreno-Armella & Manuel Santos Trigo
Matematica Educativa, Cinvestav, Mexico.

The students' use of technology plays an important role in their learning of mathematics. Here we report the work shown by high school students who participated in problem solving activities that involves the use of dynamic software (Cabri-Geometry). A task proposed by the students themselves is used as a means to illustrate three different approaches that appeared during the students' work. Each approach shows diverse mathematical processes and resources that helped them explore and solve the task.

Recent curriculum proposals identify the use of technology as a powerful tool in the learning of mathematics (NCTM, 2000). There are different ways in which technology can be used by students, in particular, the idea that with the help of some software or calculators they can achieve easy representations, explore different cases, and find loci or trajectories of points (segments or figures) seems to be attractive in designing students' learning activities. What type of mathematical resources do students need in order to show an efficient or significant use of technology during their learning experiences? When does the use of technology become a powerful tool for students? These are questions that provide information to explain what students achieve in classroom that promote the use of technology. In this paper, we document features of students learning that show a process of students' adaptation in the use of technology. At this latest stage, students not only search for different approaches to represent and solve problems, but also they explicit redesign or formulate their own questions or problems.

Conceptual Framework

In a changing and demanding society the study of mathematics becomes an important need for all students; however, as Romberg and Kaput mentioned:

the changes make it imperative that any answer to the question "What mathematics is worth teaching"? Be periodically considered". ... regardless
of the specific content, the aims of mathematics teaching can be described in terms, as teaching students to use mathematics to build and communicate ideas, to use it as a powerful analytic and problem-solving tool, and to be fascinated by the patterns it embodies and exposes (pp.15-16).

The use of technology can play an important role in helping students represent, identify, and explore behaviors of diverse mathematical relationships. An important goal during the process of learning mathematics is that students develop an appreciation and disposition to practice genuine mathematical inquiry during their school learning experiences. The idea that students should pose questions, search for diverse types of representations, and present different arguments during their interaction with mathematical tasks has become an important component in current curriculum proposals (NCTM, 2000). Here, the role of students goes further than viewing mathematics as a fixed, static body of knowledge; it includes that they need to conceptualize the study of mathematics as an activity in which they have to participate in order to identify, explore, and communicate ideas attached to mathematical situations.

...Students themselves become reflective about the activities they engage in while learning or solving problems. They develop relationships that may give meaning to a new idea, and they critically examine their existing knowledge by looking for new and more productive relationships. They come to view learning as problem solving in which the goal is to extend their knowledge (Carpenter & Lehrer, 1999, p. 23).

It is also recognized that instructors should provide a class environment that promotes students' experiences in reflecting, conjecturing, and persisting. In this context, the design and implementation of tasks, which favor the use of these experiences, continue to be a great challenge in problem solving instruction (Santos, 1998). We document that the use of technology eventually becomes a powerful tool for students to make sense of information, to propose conjectures, and to examine different
approaches to the problems. Students were encouraged to work as a community in which they valued not only personal contributions, but also the participation as a group. Students’ engagement in processes of inquiring and explaining became the key ingredient while working with the tasks.

**Methods and Procedures**

Sixteen grade 12 students participated in a four weeks seminar that included two sessions per week (2.5 hours each session). The general idea of the seminar was to employ dynamic software to solve mathematical tasks initially provided by the instructor. Later, the same students were encouraged to propose their own tasks or problems. During the first two sessions the instructor gave a general introduction to the use of the software and illustrated the use of some commands to the whole class. In general, a student worked individually first, later in small groups of four members, and at the end of each session there was a general discussion with the whole group. Students could also exchange files and receive feedback from other participants. For the analysis of the students’ work, we have chosen a task that was proposed by a small group. This task was solved during the last two sessions of the seminar. Throughout the analysis, we attached some comments or observations to describe particular students’ behavior that appeared during this implementation; however, there is no attempt to show a detailed analysis of transcripts of their work. Instead, we identify a set of observations that illustrate mathematical relationships that emerged from students’ interaction with the task. In some cases, the teacher’s participation played an important role in orienting the students’ discussion which eventually led them to propose and examine those relationships.

**Origin of the task.** An important activity that appeared during the sessions was to ask students to formulate their own questions or problems. So, during the students’ interaction with tasks or situations, they were free to explore connections or change original statements to examine and document the behavior of other relationships. A
member of a small group mentioned that in order to formulate questions, it was important to identify basic properties attached to different figures. For example, what do we know about rectangles? They have four sides (two pairs of parallel sides, perpendicular sides, four right angles, two diagonals, one center (diagonal intersection), and attributes such as areas perimeters and include pair of congruent right triangles (Pythagorean Theorem). Indeed, students agreed that in order to represent a task via the software, it was important to think of all figures in terms of properties and then select proper commands to achieve particular representation.

Can we construct a rectangle if we know only its perimeter and one of its diagonal? This was one question proposed by one student to the whole class. Three different students' approaches emerged from the students' work in this task. Although in all of them the use of technology appeared to be relevant, we focused on identifying two approaches in which the software functioned as powerful tool not only in achieving the solution but also in exploring other geometric properties of present figures.

**Solution Process shown by three small groups**

How can I represent the perimeter geometrically? What information does the perimeter provide about the sides of the rectangle? How the perimeter information is related to the diagonal? These were some of the initial questions discussed within a small group that eventually led students to represent basic information and use the software dynamic to connect such information. The important stages are described next:

(i) Students represented the semi-perimeter as segment AB and chose point Q on it. That is, $a + b$ is segment AB where $a$ & $b$ are sides of a rectangle. With this information they constructed the corresponding rectangle EHGF (figure 1). Here $a = AQ = EH$ and $b = QB = HG$.

(ii) Students realized that by moving point Q along segment AB, a family of
rectangles with a fixed perimeter was generated. Indeed, they decided to find the locus of point G when point Q is moved along AB (figure 2).

![Figure 1](image1.png)

![Figure 2](image2.png)

(iii) They found that the locus was the segment ST and explained that when point Q becomes point B, then ET will become segment AB. Similarly, when point Q coincides with Point A, and then segment ES becomes AB. That is, they noticed that the rectangle they wanted to find was one of those that can be inscribed in the right triangle EST. Indeed, they realized that the rectangle could be drawn in two different positions except when the rectangle became a square (figure 3).

![Figure 3](image3.png)

Another approach shown by two small groups was to focus on the algebraic
representation of the situation. That is, they decided to use $x$ and $y$ for sides of the possible rectangle and wrote the following equations:

$$y = -x + \frac{P}{2}$$
$$x^2 + y^2 = D^2$$

Here, a student suggested to graph both equations, he mentioned that since $P$ and $D$ were given numbers, then the first equation represented a line and the second a circle. They showed the following procedures and representation:

Here, it is important to mention that students spent significant time analyzing the cases in which it was not possible to construct the rectangle. Eventually the graph became a referent to explain the existence of such rectangle (the circle might intersect the line in one point, the case of square, two point, the above figure, and no intersection points). The other small group which followed this approached gave an algebraic explanation regarding the solution of the system of equation.

Yet another students' approach was to construct a family of triangles with perimeter
equal to the sum of two sides of the rectangle plus the length of the diagonal. Here, they chose the given diagonal as a fixed side of the triangle and the other two sides of the triangle as the semi-perimeter of the rectangle. The software became a powerful tool to find the family of triangles with fixed perimeter (figure 5).

Segment AB represents the given diagonal and segment PR is the semi-perimeter. Students drew two circles, one with center on A and radius PQ and other with center on B and radius QR. These two circles get intercepted in C. The locus of point C when Q is moved along PR is an ellipse (foci A & B and constant PR). Here, students focused on finding the triangle with angle ACB a right angle. To find it, they drew a circle with center, middle point of the diagonal AB, and radius half of the diagonal. The intersection of the ellipse and the circle will determine the vertex of the right triangle. Here, they also noted that there were cases in which angle ACB never became a right angle. In this case, it is observed that there is no intersection between the circle and the ellipse.

When these solutions were discussed within the whole class, it was evident that students realized that the use of the software provided a means to explore the task from diverse angles and perspectives. In particular, they were surprised that a variety of mathematical resources and ideas were present in each approach. At the end of the session, a student asked: Can we construct a rectangle if we have its diagonal and its area (instead of its perimeter? Here, students again were ready to explore this question through the software.

Remarks

The work shown by students during their interaction with the task illustrated different mathematical qualities that allowed them explore strengths and limitations of their approaches to the task. For example, the dynamic approach in which students focused on finding the locus of the fourth vertex provided enough information for them to
identify all rectangles with fixed perimeter. Here, they introduced the diagonal information to find the rectangle. The students' algebraic approach relied on a static representation in which they basically represented a particular case and discussed other possibilities of behavior of the two graphs in terms of the graphs intersection. The third approach in which students decided to construct a family of triangles with a fixed perimeter combines both a partial representation of the rectangle, that is a right triangle and the power of technology to find all of them with a fixed base (the diagonal). When students moved points, found diverse loci, assigned measurements, and formulated and supported conjectures, it was clear that the software became a powerful mathematical tool for the students.

THE USE OF REAL WORLD KNOWLEDGE IN SOLVING MATHEMATICAL PROBLEMS

Dalia Asman
Gordon College of Education, Israel

Zvia Markovits
Oranim College of Education, Israel

The focus of this paper is the issue of reality in relation to mathematical non-routine problems. Findings pointed to three gaps: the gap between the world of in-school mathematics and the out-of school world; the gap among “realities”, different realities between teachers and students but also different realities among the teachers and among the students; the gap between teachers’ theoretical knowledge of the kind of problems they should teach and between what they actually teach in class.

Introduction

Mathematics has been a large part of the school curriculum. Students study mathematics from kindergarten through elementary and secondary school. Mathematics is also an integral part of our everyday life and much of the mathematics knowledge is acquired outside of school. Thus, it seems reasonable for students to use everyday life considerations when solving mathematical problems in school and use mathematics learned in school when dealing with everyday life situations. Moreover, it seems reasonable that the two mathematical worlds - the in-school world and the out-of school world, will complement one another. However, Resnick (1987) describes the gap between learning mathematics in school and the out-of school world, saying that children frequently do not bring to school knowledge that was not studied formally, while knowledge acquired in school is not used adequately outside school. She concludes that the gap between “school intelligence” and “practical intelligence” should be minimized. Schoenfeld (1992) lists students’ beliefs about the nature of mathematics. Students believe that mathematics learned in school has little or nothing to do with the real world. Nunes, Schliemann and Caharrer (1993) explored the use of “school mathematics” and “street mathematics”. They found that unschooled street-vendors, fishermen and carpenters performed their street mathematics calculations competently. On the other hand, students did not know how to use mathematics studied in school and sometimes arrived at absurd solutions. Young street vendors who had some schooling performed their street mathematics calculations much better than when trying to solve the same problems using their school mathematics. These young street vendors solved problems they encountered in their jobs more easily than when the same problems were given to them in school. The detachment of school mathematics from the reality outside of school is documented in several research studies in which it was found that school children had difficulty in applying real world knowledge in problem solving (for example: Saljö, 1991; Greer, 1994). This difficulty is not unique to students. Verschaffel et al. (1997) found that pre-service teachers also had the same difficulties.
One of the reasons for this gap may be embedded in the mathematics itself. Resnick (1987) suggests that at school children learn rules and symbols but tend to lose the relationship to what these symbols represent. The detachment of the symbols from what they symbolize may cause difficulties in applying real world knowledge in mathematics lessons and vice versa. Another reason for this gap may derive from the repertoire of problems that appear in the textbooks and are studied in school. It is well known that teachers rely "heavily" on textbook problems. Researchers criticize the “stereotyped” problems studied at schools (for example, Nesher, 1980; Reusser, 1988; Gravenmeijer, 1997). Russell (1996) criticizes textbooks’ problems for not being “real life applications”. She gives an example of a problem found in a textbook in which the student is asked to find the average length of the world’s seven longest rivers. Russell claims that the problem is “silly”. “Why would we want to know the average length of these seven rivers?” Children should be given the opportunity to solve practical and realistic problems, otherwise they become bored, often causing them to dislike problem solving. On the other hand, when Nesher and Hershkovitz (1997) gave students non-routine problems taken from their lives, children did use real world considerations when solving those problems. (The problems dealt with dividing pizzas among children in a summer camp).

Our research adds one more piece to the puzzling relationship between school mathematics and everyday life. It is part of a larger research which investigated knowledge, beliefs and attitudes of elementary school teachers with different professional backgrounds toward non routine problems, as well as attitudes and beliefs of sixth graders to these problems (Asman, 2000). In four out of the 11 problems used in the research real world considerations had to be taken into account. In this paper we report some of the findings regarding these four problems.

Methodology
30 elementary school teachers were interviewed. Each interview lasted for about one hour and a half. After some personal information concerning the teacher’s background, each teacher was asked several questions regarding her beliefs and perceptions about problems in general. For example: why do we teach problem solving? Or, what is a "good" problem? Then each teacher was presented with 11 non-routine problems one at a time and asked to solve the problem. If the teacher was not able to solve it, or solved it incorrectly, she was given some hints by the interviewer who helped her to arrive at a reasonable solution. At this stage the teacher was asked about her beliefs regarding the non-routine problem she just solved: Would she give the problem to her class? In an examination? Has she encountered such problems in textbooks? In workshops for teacher development? After going through all 11 problems the teacher was asked for some feedback on the interview. Each interview was recorded and then transcribed.

In order to find out how do different professional backgrounds affect teacher knowledge and beliefs, we chose the 30 teachers as follows:
- Ten pre-service teachers specializing in mathematics, at the end of their third year...
of college. (PST)

- Ten in-service teachers, teaching in the higher grades of elementary school. (T)

- Ten in-service teachers teaching in the higher grades of elementary school, who
  had participated in long-term mathematics intervention programs. (TT)

265 sixth grade students participated in this research. They studied the 11 non-routine problems in class. Their teachers (T and TT teachers) who participated in this research study taught them. The students answered a short questionnaire regarding their beliefs and attitudes toward the problems.

In addition we observed two sixth grade classes studying these problems.

The Problems

The following are the four problems which in their solutions one needs to take into account everyday life considerations:

1. A bus can hold 40 students at the most. How many buses will be needed to transport 175 students? (Transportation Problem)

2. When looking at a 35° angle through a magnifying glass that magnifies four times, what size angle will you see? (Angle Problem)

3. Four families live in Dan’s building, altogether they have 10 children. What is the average number of children in each family? (Average Problem)

4. John’s parents bought furniture for their dining room. The table cost $1.1 and each chair $0.4. What is the total amount they should pay if they bought one table and four chairs? (Furniture Problem)

Results

The Transportation Problem

This problem is well known in research literature and was first used (with different data) by Carpenter et al. (1983). The exercise 175:40 is only the first step in solving this problem. The second step is adjusting the result to real life.

All 30 teachers solved the problem using everyday life considerations. For example, a (T) teacher said that five buses are needed. However, she would try to seat more students in each bus since she works in a neighborhood where the parents can not afford to pay for five buses. Another teacher (PST) commented that although each bus can hold 40 students there is no need for them to crowd the children and sit 40 in four buses and 15 in the fifth and they can divide the number of students more comfortably among the buses. Another teacher (T) said they could order four buses and one minibus in order to decrease the expenses. It seems that teachers used their experiences in ordering buses for field trips, which is something teachers frequently do. As for the students, many solved the problem just by performing the mathematical exercise, without using everyday life considerations, saying that 4.375 is the number of buses to be ordered. Some realized that 4.375 was an unrealistic number of buses, thus they wrote “4.375 – illogical”, not knowing how to adjust the
answer to everyday life or not knowing that the answer could be different from the result of the exercise they had just performed. This situation seems not to be a part of students' reality. One TT teacher commented that her students would probably know how to solve such a problem, since before going on a field trip they used to calculate the expenses per student. Thus, she said, for them this problem would be a "real" problem and a significant one.

The Angle Problem
Two numbers are involved in this problem (35 and 4), but in order to solve it one is not supposed to do any calculations with these two numbers. The use of real life considerations should be the clue to this problem. One needs to understand that when looking through a magnifying glass, the shape of the object being viewed does not change, thus the angle should remain the same. But even if the solver did not use everyday life considerations and obtained 140° as the answer her/his common sense should start working since they started with an acute angle, which turned into an obtuse angle. One should wonder what would happen to a right angle? Would it turn an angle of 360° when viewed through a magnifying glass? And what about a 150°? What would it look like?

23 teachers (4 T, 9 TT and 10 PST (all 10 PST were exposed to this problem in one of their courses)) said that the angle would remain the same. Some of them explicitly indicated that they relied on considerations from everyday life, as in the following explanation given by a pre-service student:

"I used my real world knowledge, I wear eyeglasses. When I put on my eyeglasses do I see a different angle? But I am not sure that children would see it the same way as I do."

7 teachers (6T and 1 TT) gave 140° as their answer. During the interviews all of them were led to the correct solution. One of the teachers (T teacher) explained:

"It is a difficult problem, a magnifying glass is something that I have never worked with nor have the students."

Both teachers expressed their concerns about the way students will deal with this problem, since this is probably not from students' real life.

Many students did not look for reality when solving this problem. It seems that the numbers and the "key words" that appear in the problem confused them. Many of them explained that they were distracted by the words "magnifies four times". They were surprised how simple this problem actually was.

One student who did take into account that the problem reflects out of school reality, explained her solution:

"The angle would not change in degrees, when we look at a bug through a magnifying glass, does it change its shape?"

The Average Problem
Relying on everyday life considerations (without knowing the meaning of the term average) might be an obstacle in correctly solving this problem. This was the case
with 13 teachers (3 T, 2 TT and 8 PST). They used their “real world knowledge” but since “We deal with children and not with tomatoes” and since “there is no half a child” 2 ½ cannot be a reasonable answer. Some teachers rounded off the number either to 2 or to 3 so it would make sense. These teachers did not know that the average is a statistical datum and is not representative of reality. They were surprised to find out that the correct solution is that each family has an average of 2½ children. They complained that in their textbooks, when dealing with an average concerning people, the average is always a whole number, therefore they had never encountered such a problem. A (TT) teacher who solved the problem correctly said that since the material in textbooks is not authentic she brings her class authentic materials from the newspapers, like information about surveys. From this resource her students can learn about mathematics in real life.

In the classes we observed most students tended to round off the quotient. However there were students who left 2 ½ as the answer not paying attention at all to the possibility that it might be problematic. Only one student said that he saw in the newspapers that when dealing with averages regarding human beings it is o.k. to write fractions. This might take us back to the 13 teachers. We may wonder how could it be that they did not pay attention to the numbers in the newspapers, on the radio or television. Or is it that they did pay attention, but "their reality" in which we can not have 2 ½ children as an answer to a problem was the deciding factor in their reasoning?

The Furniture Problem
In this problem the prices are extremely unrealistic. The first purpose for including this problem in the research was to find out if teachers and students would notice the absurd prices. The second purpose was to find out more about teachers' beliefs regarding the question: Should the data that appears in math problems, stand the tests of reality? Only 5 teachers (4 TT and 1 PST) noted that the prices were unrealistic. The fact that most teachers solved the problem, expressed their beliefs toward it but were not bothered at all by the extremely unrealistic prices, illustrates the gap between in-school mathematics and out-of-school mathematics. When the interviewer raised the issue of the extremely unrealistic data, 25 teachers agreed that word problems should reflect reality and therefore if they had noticed that the data were unrealistic in the first place they would have changed the numbers. Five teachers (2 T, ITT and 2 PST) thought that it does not matter if data reflect reality:

“I do not care about the numbers in the problem. It is important for me that they would be simple. I care about the strategy of solving, not the numbers since students calculate with calculators” (TT)

“I would not change the prices since the problem is for an exercise, not a test of reasoning”. (PST)
Teachers who thought that prices should be changed to real ones expressed their opinions saying:

"I would change prices since we must bring reality into class". (TT)

"We should adapt prices to reality since children constantly ask why should I study this or that? They are motivated to study only if they are convinced that what they learn will help them in everyday life or in the future. As a child I did not want to study stuff that I was not sure that it would be applicable in my everyday life. If the mathematical problem reflects a real problem from everyday life, the child will be interested". (PST)

"A child should be prepared for real life. He should understand the value of things. If he vandalizes a desk in class, he should know its value, and this is surely not $1.1." (T)

The last sentence is an authentic example from the real life experiences of a teacher who is teaching in a low socio-economical neighborhood. She explained why a child in her class should know the real price of furniture.

As for the students, most of them did not notice anything peculiar in this problem. In one of the classes we observed a student made a remark about the “funny” prices. This opened a discussion in class, whether prices should be real. Most students thought that the numbers in the problems are not important since teachers give problems in order to find out if the student knows how to solve and calculate. Only a few students thought that it would be better if the data would match reality.

One (TT) teacher reported that when she gave this problem to her students, a student (weak in mathematics) laughed and said that the prices are senseless. In the discussion held in class, as to whether the prices should be real, he was quite assertive saying that prices should be changed to real ones. The teacher was surprised since this student never showed any interest in mathematics lessons. The teacher explained that this student is helping his father in his shop after school and prices are part of his reality.

Discussion

It seems that the findings in this research may point to three gaps regarding the issue of reality and problems in mathematics. The first gap has to do with "theory and practice", between what teachers believe in theory and what they do in class. When asked about their beliefs of problem solving in general and “good problems” in particular, almost all teachers said that problems should be from students’ lives, indicate authenticity, and promote reasoning. However, when asked to give examples of problems that they teach in class, most examples did not reflect these characteristics. Moreover, only very few paid attention to the unrealistic prices in the Furniture Problem. It might be that others did pay attention, but did not say anything since the numbers in the problem do not have to be realistic for them.
The second gap is the gap between in-school mathematics and the out-of-school world. This gap was prominent for example when teachers and students did not use their out-of-school knowledge when solving problems in school. Furthermore, unrealistic data did not bother them as long as the problem was solvable.

The third gap that emerged is the gap between different “realities”. We could see that teachers' reality was different from students' reality, but we could also see different realities among teachers and different realities among students. It seems that when problems are from the solvers’ reality it might reinforce their willingness to be involved and might increase their chances to solve the problem correctly. A (T) teacher aptly described this gap mentioning the student's world, her world and her husband's world:

“......"good problems" are surely not those in textbooks, which are irrelevant to a child's life or culture. There are some problems that do not belong to the student's cultural world. This is a disguise, it is not his world, therefore he does not understand it, and it frustrates him. ...sometimes I do not know myself what they mean, and I have to ask my husband for an explanation. If it is not even from my world, how could the child possibly understand it? For example, problems which involve filling a swimming pool with two pipes. Neither my students nor I have witnessed such a situation. The solution should be logical too, not with difficult fractions, and not with four or more digits after the decimal point. Such numbers may be relevant for my husband who is an engineer and works with small particles, but surely not for our students”.

There are probably many sources and many reasons for these gaps. The gap between what teachers say and what teachers do (a well-known gap among teachers in general) may be partly explained by the materials they use in class. During the interviews teachers complained about the textbooks, saying that textbooks are their main source for problems but criticized the textbook problems for being “stereotyped”, not authentic, and boring. However, the TT teachers who participated in long-term mathematics intervention programs, reported that they also have other sources for word problems and that they do not rely on the textbooks only. The textbooks might also be the reason for the gap between in school mathematics and everyday life out of school. Another reason for this gap might be students' learning to play according to different rules. They have the "in school rules" to solve mathematical problems in class and "out of school rules" to deal with out of school situations which involve mathematics. They probably are familiar with considerations from everyday life but they do not think that they are supposed to use them in school (Bishop and de Abreu, 1991).

The existence of the gap of different “realities” is very clear. But does it mean that the teacher has to generate problems to fit the reality of all students in class? Is it possible? Is it the right thing to do? Must all problems be realistic? Wouldn’t academic mathematics be lost?
It seems that more research is needed in order to answer these questions and to more deeply explore the puzzling relationship between mathematics and everyday life.

References
This paper reports an investigation into the effects of instruction in probability concepts on the decision making strategies of twenty-four 11-12 year olds. The instruction, based on small-group practical activities, had an overall positive influence on performance in specific probability tasks. It was also found that the particular experiences within the small groups of students had a strong influence on decision-making strategies in the final 'test' tasks. Groups that experienced sets of random outcomes in their activities that were not representative of the structure of the sample space tended to use inappropriate reasoning in later tasks.

Research into probabilistic reasoning has identified various strategies used by people in situations including sequences of randomly generated outcomes, and in particular involving the expectation (or prediction) of the most likely 'next' outcome. One such strategy that has received considerable attention is representativeness (for example: Fischbein & Schnarch, 1997; Shaughnessy, 1981), which is the expectation that a random set of outcomes should be representative of the composition of the sample space. Amir, Linchevski & Shefet (1999), working with 11 and 12 year olds explained that;

The ‘representativeness’ heuristic includes two distinct and independent dimensions: the tendency to expect a sample space to reflect the numerical proportion of the parent population; the tendency to expect the sample not to be too orderly, to look ‘random’. (p. 2-32)

Closely related to representativeness is the type of thinking known as negative recency (Fischbein & Schnarch, 1997) where there exists the expectation that as the frequency of a particular outcome increases the probability of that outcome occurring again decreases. For example, when repeatedly flipping a coin, a run of heads would lead to the expectation of the next flip being a tail.

Another, little studied, influence on decision-making is the confirmation or refutation of the ‘prediction’ by the actual next outcome. Truran (1996), working with a known sample space, analysed the changes in prediction of primary and secondary students in regards to the next outcome. One finding was that when the more-likely outcome was predicted, it didn’t really matter whether the next outcome confirmed or refuted that prediction. However, if a less-likely outcome was predicted, the subject was highly likely to change the prediction, particularly if the following outcome refuted the less-likely prediction. Similarly, Ayres & Way (1998, 1999), working with unknown sample spaces, found evidence that upper primary-aged students would change their prediction patterns according to how successful they were in their predictions. Although students would choose the most frequently occurring outcome under specific conditions, they would change strategy if their predictions were not
rewarded. Consequently, Ayres & Way (1999, 2000) argued that children may be influenced in their probability judgments by confirmation or refutation of their predictions rather than by their knowledge of the overall situation.

In the context of mathematics education, the apparent instability of students' understanding of basic probability concepts such as randomness and sample space, makes the influence of instruction an important area for investigation. Watson & Moritz (1998) reported that after five years inclusion of probability and statistics in an Australian state's curriculum (primary and lower secondary), no improvement in students' performance in chance measurement tasks was found. However, Jones, Thornton, Langrall & Mogill (1996, 1999) found clear indications of improvement due to instruction in chance concepts in Grade 3 children. The Jones et al. (1999) study suggested several key aspects of instruction; overcoming misconceptions about sample space and its relationship to likelihood, the application of part-part and part-whole reasoning, and the development of language to describe probabilities. Further research into significant experiences that may help or hinder the development of understanding of probability concepts is required. For example, little is known about the impact of commonly used classroom-teaching techniques, such as group practical work and whole class discussions, on the development of probability ideas.

The study reported here is the latest in a series of investigations into probabilistic reasoning and utilises the established 'controlled randomness' video (see Ayres and Way, 1999) as an assessment instrument. The aim of this particular study was to carry out an initial investigation of the effect of instruction, based around small-group practical activities, on the basic decision-making strategies of upper-primary students.

**INSTRUCTION PERIOD**

Participants. Twenty-four grade-six students (11-12 year-olds) from an independent Sydney (Australia) primary school for girls participated in this study. No student had been formally taught probability theory in any mathematics classes. The students were drawn from the top mathematics class of the grade and a state-wide numeracy test indicated that each participant ranked above the State average on this test. The students were randomly assigned to six groups

Procedure and materials. The instruction period consisted of two 1-hour sessions over consecutive days. Because of space restrictions, this paper will focus on the first session which consisted mainly of a small group practical activity. Initially (approximately ten minutes), a whole-class discussion with one of the researchers (Investigator 1) was completed on the basic ideas associated with likelihood and chance. Although the class had received no previous school-based instruction on likelihood, it was clear from the discussion that many students had a reasonable understanding of likely and unlikely events in the real world. Furthermore, some students demonstrated knowledge of theoretical probabilities associated with obtaining a head in coin-flipping ("1 in 2", "fifty-fifty") or a six in dice-rolling ("1 in 6").
Each group received a paper bag containing ten coloured tiles. Two groups received a bag containing 5 Green, 3 Yellow and 2 Blue tiles; two groups received a bag with 6G, 3Y and 1B tiles; and the remaining two groups received a bag with 7G, 2Y and 1B tiles. Ratios varied to investigate the impact that these differences might have on the overall results. Prior to the start of this phase, a demonstration of a game was given by the researcher to the whole class using a bag with colours in the ratio 1: 3: 6. A total of four games were completed. The only information given to the students was that the bags contained green, yellow and blue tiles. Students were required to predict the colour of a tile before it was withdrawn from the bag. Students took turns within groups to select a tile, which was returned to the bag before the next selection. Students were told that it was a game and the winner would be the one with the most correct predictions overall. Students were required to record each prediction and the actual colour that occurred in a booklet. A game consisted of five predictions. After each game, students were required to tally their correct predictions and discover the winner(s) for that game in their group. Furthermore, after each game, students were asked to discuss the game within their groups and to ascertain why the winner won, and to record this reason/discussion in their booklets.

On finishing the last game, students were asked to count the number of correct predictions they made over the four games and to discover who the overall winner was in their group. They were then asked to reflect on winning strategies and how they could have improved their own predictions. After all tasks were completed, students were allowed to examine the contents of the bag. This session was closed with a whole class discussion around the main idea that there were more greens in the bags, therefore the best prediction strategy was to choose green.

The second session (which will be reported in more detail at a later date), focused on two central themes related to the structure of the sample space and its relationship to likelihood. Firstly, selecting the most frequently occurring colour in the outcomes was a good strategy. Secondly, this strategy does not always work as less likely events can occur. A practical activity based on the strategy of choosing the most frequently occurring colour over a number of trials was completed.

Results. The mean number of greens (there were more greens in each bag than any other colour) predicted by each group is reported in Table 1. There was a significant difference between the groups on this statistic, measured by a 1-way ANOVA; F(5,18) = 5.43, p < 0.01. In terms of the number of correct predictions made (see Table 1), a 1-way ANOVA also revealed a significant difference between groups; F(5,18) = 3.67, p < 0.05. Whereas these results are not necessarily surprising considering the differing bag contents; it is clear that Groups 2 and 3 observed a reduced frequency for green to what might be expected from the theoretical probabilities: 35% compared with 50% for Group 2, and 40% compared with 60% for Group 3. The small number of occurrences of green influenced both groups' selection of green and ultimately their prediction successes, as there was a correlation of 0.89 (Pearson product-moment coefficient, p< 0.001) between prediction success and choice of green. Students who regularly chose green were more successful in their predictions.
from individuals indicated that students from Groups 1, 4, 5 and 6 believed that green was the dominant colour in the sample space and students would enhance their prediction rates if they chose more green. In contrast, Group 2 concluded that luck was involved and success depended upon being able to “spot the patterns”. Group 3 generally believed that there were more yellows in the bag and success depended upon “knowledge of previous games.”

Whereas, many students (particularly in groups 1, 4, 5 and 6) were able to give reasons consistent with an understanding of likelihood, the winner of Group 2 (9 out of 20) gave a very unexpected answer during an interview.

I worked out a theory. The teacher (researcher) is English and he pulled out a yellow tile. My dad’s English and I also pulled out a yellow tile. Alison’s dad is Australian and Australia is on the opposite side of the world to England, therefore she would pull out a blue tile and she did. Maria’s dad is Greek, therefore she should pull out a green tile and she did.

In Group 2, students were taking turns selecting from the bag. The winner changed her choice according to who was making a selection. By coincidence, she was the most successful of her group, and this misconception became her “successful” strategy. Overall, quantitative and qualitative data revealed that most students demonstrated a good understanding of likelihood in this domain. However, it became evident that selection strategies and the reasons given by individuals tended to converge within the groups.
TEST PERIOD

Participants. The 24 participants were the same students who completed the instruction period. However, two students (one each from Groups 1 and 3) were absent.

Procedure and materials. To test the effectiveness of the instructional phase, the students were given prediction tasks based around a video recording. The video, previously constructed by Ayres and Way (1998, 1999) with pre-ordained outcomes, featured a presenter making thirty selections of coloured balls from a box with replacement. Students were required to predict the next colour after observing the five previous selections. In all, six predictions were required. In the video, 19 whites (63%), 7 blues (23%) and 4 yellows (13%) were drawn from the box. However, the emerging colour sequence was manipulated so that the less likely outcomes (blue and yellow) appeared consistently (four out of five) at the prediction locations, whereas the most likely colour (white) appeared only once. As a consequence of this design, students found that predicting a number of whites was not a successful strategy and switched from using "the most likely strategy" to strategies based on misconceptions such as colour patterns and negative recency (see Ayres and Way 1999, 2000 for more detail). In this present study, it was anticipated that this particular task would prove a considerable test of student beliefs in employing the "most likely" strategy consistently without reverting to common misconceptions.

Previous research by Ayres and Way (1999, 2000) also found that knowing or not-knowing the sample space made no overall difference to the prediction strategies employed on this video task. This aspect was also investigated in this study by randomly assigning students to two groups. One group (sample space known) was informed that the box contained 10 balls (6 white, 3 blue and 1 yellow), which was approximately equivalent to the experimental probability of the sequences. In contrast, the second group (sample space unknown) were only given information about the colours of the balls (some white, blue and yellow balls in the box). Both groups observed the same video recording. After each prediction, students were required to give reasons for each decision. All students were told that the prediction tasks were a game and they should try to predict as many correct colours as possible.

Results. A record of each student prediction was made. Previous studies by Ayres and Way (1999, 2000) found that students often changed their strategy over the last three predictions compared with the first three predictions. Consequently, the number of whites chosen in the first and last three predictions were also reported (see Table 2). A 1-way ANOVA (known v unknown ratios) with repeated measures (first 3 and second 3 predictions) were completed on this data. For the main effect, knowing the sample space made no difference; F(1, 20) = 1.88, p > 0.05. However, students chose significantly more white balls during first 3 predictions than during the second 3; F(1, 20) 7.12, p < 0.05. Consistent with previous research with Ayres and Way (1999, 2000), this particular outcome sequence caused many students to switch from using the "most likely" strategy to strategies based on common misconceptions. Qualitative
data (due to space restrictions, this data will be reported more extensively at a later date) also confirmed an increased use of misconceptions over the last three predictions, such as "its yellows turn" and "the colours are forming a pattern". However, nearly half the students (45%) continued with a strategy of choosing the most frequently occurring colour for the last 3 predictions.

To explore the influence of the initial group instructional activities further, prediction means were calculated for each of the instruction groups (see Table 3). Although there were no significant between-group effects (group numbers were very small) on 1-way ANOVAs for these measures, group means did vary considerably. On the crucial measure of the second set of predictions, Groups 4, 5 and 6 chose almost twice as many whites as Groups 1, 2 and 3.

It was noticeable that there appeared to be a match between the group data for this measure and some of the statistics shown in Table 1. Correlation calculations revealed that the number of whites predicted on this trial was significantly correlated to both the actual number of greens (dominant colour) that occurred during the group activities ($r = 0.45, p < 0.05$) and the number of correct predictions made during these activities ($r = 0.55, p < 0.01$). Both fairly strong positive values suggest that the differing experiences within groups had an effect which transferred into the video trial.
CONCLUSIONS

The main aim of this study was to test the effectiveness of an instructional period, featuring small group practical activities, on primary aged students' development of probabilistic reasoning. Whereas, students generally showed a good understanding of likelihood, when faced with an unrepresentative set of outcomes (the video trial) many students reverted to strategies based on misconceptions. In a similar fashion to the previous studies of Ayres and Way (1999, 2000), students chose less white balls (the most commonly occurring colour) over the final three predictions compared to the first three, indicating that their use of the "most likely" strategy was reduced. However, it is worth noting that the prediction rates of white in this study were higher than previously found. For example, in the Ayres and Way (2000) study with grade 8 students, overall mean values for this video outcome sequence was 2.0, 1.4 and 3.4, for the first 3, second 3 and total predictions respectively. In the Ayres and Way (1999) study with grade 6 students, the mean values were 1.5, 1.2 and 2.7. Both sets of data were lower than those found in this study (2.5, 1.8 and 4.2). These comparisons suggest that the instructional period in this study, as short as it was, may have helped students developed a better understanding of chance.

Of considerable interest in this study was the group effects which appeared. During the small group activity, students were exposed to different sample spaces, which produced varying sets of outcomes. Some groups were more successful in predicting than other groups, with success rates apparently dependent upon the observed outcomes. Groups which observed a set of outcomes representative of the sample space tended to demonstrate a better understanding of likelihood than groups who observed less likely outcomes. Furthermore, these differences during instruction appeared to influence decision making during the final video trial.

The implications of this study are as follows. Firstly, instruction in this domain seems to have, at least in the short term, a positive effect. Secondly, the types of outcomes observed in these random-based activities, seem to have an influence on future decision making strategies. Consequently, we believe that any instruction of this nature must ensure exposure to different types of outcomes to provide students with the opportunity to develop a clearer understanding of the relationship between sample, randomness and likelihood. Furthermore, because the groups had different experiences, teachers need to be aware of the possibility of collective misconceptions forming within groups.

Finally, it must be acknowledged that this was a small study based on a particular sample of students. It is our aim to investigate these findings further, using a broader sample of students and modified versions of the instructional period.

SYMBOLIZING DATA INTO A ‘BUMP’

Arthur Bakker, Freudenthal Institute,
Utrecht University, Utrecht, the Netherlands
email A.Bakker@fi.uu.nl

Abstract

In this paper we analyze how concepts and symbolizations co-develop in the case of statistical data analysis. The focus is on the development of distribution, which ranges from a very concrete, intuitive understanding to a formal, mathematical concept. Examples from teaching experiments with 11 to 12-year-old students illustrate how their concept of distribution develops in relation to what the graphs they use and make mean for them. In particular we discuss an episode in which a student symbolizes data into a so-called ‘bump’ and we give examples of how other students reason with this ‘bump’ in connection to distribution.

Introduction on Symbolizing

Symbolizing as a field of research has been receiving more and more interest within the community of mathematics educators (Cobb et al. 2000). Our point of departure is that the students’ way of symbolizing and what these symbolizations come to signify develop in a dialectical way. The learning-teaching process is organized in such a way that the conceptual development benefits from the development and use of symbols, and vice versa. In teaching experiments on statistical data analysis we aimed for the gradual emergence of the multifaceted concept of distribution rather than a collection of loosely related concepts and graphs. In this paper we analyze how symbolizations and their meaning co-evolve in the case of distribution and graphs of data sets (cf. Meira 1995).

The Concept of Distribution

Basically, the notion of distribution refers to how data are distributed in a space of possible values. Mathematically seen, distribution could be defined as a frequency or density function. In this paper we use the term ‘distribution’ for the whole range from a very concrete, intuitive level to the statistical concept. The concept of distribution is tightly connected to many other statistical concepts such as frequency, skewedness, spread, and even mean and median. It is also highly interwoven with certain visual images that ‘show’ distributions, the most famous one being the bell-shaped curve of the normal distribution.
In statistical data analysis we are not very interested in individual cases; instead we focus on group characteristics such as center and spread, or skewedness of data. Even if we want to use the mean or median we have to take the whole distribution into account (Zawojewski & Shaughnessy 2000). For example, if there are many outliers or if the distribution is very skewed, we probably will not use the mean. From the numerical data it is hard to see how they are distributed, so we need to look at the shape of the data.

There are two other reasons we focus on distribution. First, students tend to see data as individual cases instead of values of a variable (Hancock et al. 1992). That is why they find it difficult to see group characteristics. Focusing on the shape of the data is one way of dealing with this problem. Second, we wanted students to reason proportionally instead of absolutely with parts of the graph. By proportional reasoning we mean reasoning with proportions as opposed to absolute numbers. If students, in comparing parts of two samples with different size, reason with absolute numbers then we call it absolute reasoning, whereas if they reason with proportions we call it proportional reasoning (Cobb (1999) calls this multiplicative reasoning). If students focus on the shape of distributions they are supported in reasoning more globally with groups and are maybe led away from absolute numbers. A helpful tool for this purpose is the box plot since it shows proportions, for instance where the middle 50% of the data is, without showing individual data points.

For statisticians distribution has a clear experiential meaning. For 11-year-old students, however, distribution initially is not on the horizon. Still, young learners can deal, for example, with questions concerning the way data are distributed. They can solve problems that involve looking at how the data are spread out or bunched up. To foster this kind of reasoning demands that the tasks in statistical data analysis must have certain features. First, they have to conduct the students' reasoning to characteristics of the distribution, even if the students do not talk in terms of distributions. Second, these characteristics must be expressible both in terms of the context and with statistical concepts. Anticipating the next section we mention that just one problem concerning the life span of batteries initialized discussions around center, spread, outliers, majority in terms of the context. A sample of a good battery brand has a high mean and a sample of a reliable brand has small spread and few outliers (figure 1). Of course none of these notions were very precise yet, but still they formed a basis for the development of more formal concepts.

In solving such problems the students used so-called statistical minitools. These software tools have been designed for the teaching experiments of Cobb, Gravemeijer, and others (Cobb 1999; McClain et al. 2000). The minitools do not contain any ready-made conventional statistical graphs. Instead the students can structure the data in various ways they might use when they just have pencil and paper. Still, some grouping options are precursors to conventional graphs such as using equal interval width underpins the histogram and using four equal groups underpins the box plot (figure 2).
Value Bars Come to Signify Data

The first step of symbolizing was inscribing data as case value bars, which offers a visual way of dealing with the data (figure 1). The horizontal bars are motivated by a sense of linearity that many variables have. The first data set analyzed by the students concerned the life span in hours of two battery brands. The task was to decide which brand was best and to report an analysis to the Consumer Reports.

![Figure 1. Value bar graphs in minitool 1. 1a: Life spans of two brands of batteries in hours. The upper ten and lower ten are of different brands. 1b: Visually finding the mean with the value bar.](image)

Already in this type of graph it is visible, for statisticians, that the distribution of the first brand is skewed and has outliers; the second brand has smaller spread and has a symmetrical distribution. Here distribution is symbolized on a very concrete level. The students did not talk of distributions but they discussed the outliers of the first brand and the high maximum of the second brand. Some argued that the first brand was better since 'it has more higher values' and others opposed that the second brand 'has less bad outliers'. The second brand was considered more reliable or predictable (compare this with the notion of consistency on which Cobb (1999) and Sfard (2000) report). Students were very well able to invent data sets that could be of a very good but unreliable brand or a bad brand with the same spread as one they had encountered before.

After a few lessons the students developed a visual way of estimating means by mentally cutting off 'what was too much on the right side' and 'giving it to the left side', as they expressed it (see figure 1b). Such an activity was made possible by the inscription of the case value bars. We conjecture that students would not have done this with numerical data or with dots in a dot plot. This supports our claim that every symbolization influences the way students see the data or the context problem. On the other hand, a suitable problem may give rise to developing a new symbolization that helps in answering a question. This exemplifies the dialectical co-development of meaning of the context and of the symbolization (cf. Meira 1995).
Dots Come to Signify Value Bars

As the preceding section shows, the students developed a statistical language that was situated in the context of battery life spans and other problems. In thinking about such problems the students focused on the end points of the bars. These end points of the bars in minitool 1 were to collapse down onto a horizontal axis in minitool 2. The dot plot appears here as an image of a variable; the dots get a place in a space of possible values. This dot plot is also one step closer to the conventional graphs in which a unimodal distribution appears as a hill-shaped curve. As mentioned above some grouping options were close to conventional graphs such as histogram and box plot (figure 2), both being helpful tools in describing distribution.

In analyzing data with this second minitool, students further developed their statistical language. Since we wanted students to view data sets as a whole with certain characteristics we hoped that they would start looking at the shape of the data in minitool 2. Unfortunately they did not talk of hills as students in other experiments did (Cobb 1999); they only talked of majorities and still reasoned absolutely in some cases.

Symbolizing Data into a ‘Bump’

We tried another route that turned out to be more promising. The basic ideas of symbolizing and guided reinvention (e.g. Gravemeijer 1994) suggest that students also should create their own graphs. For the eleventh lesson we therefore asked them to represent their weight and height data in a graph that would be clear for a particular purpose: a balloon rider had to decide how many seventh-grade students could join a balloon ride and she did not just want to know the mean.

The students came up with many different graphs resembling minitool 1 and minitool 2, but also a scatter plot of weight and height, and one graph we will discuss in more detail. For the designed learning process we focused on graphs that could help students in seeing a data set as a whole, or in other words, could help them in constructing distribution as an object-like entity which they could reason with. This was why
Michiel's graph (figure 3a) was discussed extensively. He explained his graph as follows.

Michiel: Look, you have roughly, averagely speaking, how many students had that weight and there I have put a dot. And then I have left [y-axis] the number of students. There is one student who weighs about 35 [kg], and there is one who weighs 36, and two who weigh 38 roughly. And then I have put, yeah/
Teacher: Have just put dots.
He then explained in more detail what the dots stood for. The dot above 48, for example, signified that four students had weights around 48 kg. After discussing other graphs the teacher asked the following question.

![Figure 3a and 3b](image-url)

**Figure 3a and 3b. Michiel and Elleke’s graphs of weight data. Elleke’s includes height represented by the darker and higher bars. Her graph is called a value bar graph.**

Teacher: What can you easily see in this graph [of Michiel]?
Laila: Well, that the average, that most students in the class, um, well, are between 39 and, well, 48.
Teacher: Yes, here you can see at once which weight most students in this class roughly have, what here is about the biggest group. Just because you see this bump here. We lost the bump in Elleke’s graph.

It is the teacher who uses the term ‘bump’ for the first time. Later in the discussion one student explained where the bump in Elleke’s graph was.

Nadia: The difference between ... they stand from small to tall, so the bump, that is where the things, where the bars are the closest to one another.
Teacher: What do you mean, where the bars are closest?
Nadia: The difference, the ends [of the bars], do not differ so much with the next one.
Another student commented on this.
Eva: If you look well, then you see that almost in the middle, there it is straight almost and uh, yeah that/ [teacher points at the horizontal part in Elleke's graph].

Teacher: And that is what you [Nadia] also said, uh, they are close together and here they are bunched up, as far as height or weight is concerned.

Eva: And that is also that bump.

From these excerpts and further analysis of the episode (Bakker 2001) it became clear that these students did not just rely on visual aspects of the bump. They were able to relate the different graphs to one another by thinking about what the bars and dots signified. From the analysis of this lesson the question remained whether the bump just signified the majority for the students or that it signified a characteristic of the whole distribution.

Reasoning with the ‘Bump’

From consequent lessons we inferred that the bump not just signified the majority. We give a few examples of how students reasoned with the bump. What is interesting in this respect is that many students used the term ‘bump’ even for the straight part of value bar graphs for where most data were. It became clear that they related this visual characteristic of the symbol also to statistical concepts such as outliers and sample size.

Laila: But then you see the bump here, let’s say.

Ilona: This is the bump [pointing at the straight vertical part of the lower ten bars, like in figure 1b].

Res.: Where is that bump? Is it where you put that red line [the value bar]?

Laila: Yes, we used that value bar for it (...) to indicate it, indicate the bump. If you look at green [the upper ten], then you see that it lies further, the bump. So we think that green is better, because the bump is further.

Here the bump seems to have become a reasoning tool.

One question in a class discussion was what a graph of eighth-graders’ weight would look like. Some of the answers follow.

Luuk: I think about the same, but another size, other numbers.

Guyonne: The bump would be more to the right.

Teacher: What would it mean for the box plots?

Michiel: Also moves to the right. That bump in the middle is in fact just the box plot, that moves more to the right.

Turning to a different question, the researcher (the author) asked the class how the graph would change if not just their own class but all seventh-graders in the province were measured. He was curious if the bump only signified the majority or that it was also linked to outliers and sample size. Earlier in the class discussion Elleke had mentioned that with more students one has more chance for outliers.

Elleke: Then there would come a little more to the left and a little more to the right. Then the bump would become a little wider, I think.
Res.: Is there anybody who does not agree?
Michiel: Yes, if there are more children, then the average, so the most, that also becomes more. So the bump stays just the same.
Albertine: I think that the number of children becomes more and that the bump stays the same.
Nadia: I think that if there are less children, you have more chance for outliers. Maybe some are very thin and some very heavy or so. But I think that it stays roughly the same.

A few students were able to see in figure 1a which distribution was 'normal'—defined in an informal sense—and which was skewed. They were exceptions though.

Albertine: Oh, that is normal (...).
Nadia: That hill.
Albertine: And skewed if like here the hill is here [the upper ten bars].

Conclusions

In the process of symbolizing data were first inscribed as value bars in the first minitool. The end points of the bars collapsed down onto an axis and formed a dot plot. It was shown that every symbolization has its advantages. The bars helped the students in seeing data as values of a variable and made it reasonable to the students to find means in a visual way and the dots made it easier to structure the data in other helpful ways. Finally, one of the students' graphs led to interesting discussions about bumps. At this stage, the learners were able to reason in a more global way without focusing on individual data points and they also argued in a more multiplicative way.

As we demonstrated, focusing on the concept of distribution, being a multifaceted notion, has the advantage of being strongly related to almost all other statistical concepts. In this way we could help students to gradually build up their understanding of these concepts in close relation to one another. We also showed how students came to construct an intuitive understanding of distribution in close relation to how they come to signify meaning to a series of graphs. As the examples illustrate the students related statistical concepts to characteristics of the graphs. It is clear that the students' way of symbolizing and what these symbolizations come to signify develop in a dialectical way, but also that the development of a concept, in this case distribution, cannot be separated from the development of the symbols.

In this paper we consider the theory of ‘cognitive units’ introduced in ‘Cognitive Units, Connections and Mathematical Proof’ (Barnard and Tall, 1997) and compare it with other theories of cognitive construction. We find that it includes a theory of ‘cognitive compression’ to reduce the cognitive strain involved in thinking about more complex concepts that is related to the ‘varifocal theory’ of Skemp. It generalises the notion of process-object and schema-object encapsulation to give a broader theory of rich cognitive units, with connecting links that minimise cognitive strain and maximise thinking power.

Cognitive units, connections and compression

The notion of ‘cognitive unit’ that we consider here is ‘a piece of cognitive structure that can be held in the focus of attention all at one time’ (Barnard and Tall, 1997). We are particularly interested in cognitive units with rich internal links that allow them to be thought of as a single entity. For instance, the equations

\[ P = QR, \quad \frac{P}{Q} = R, \quad \frac{P}{R} = Q \]

may initially be conceived as three separate items, together with links between them carried out by performing the same operation to both sides. Later this perception may become compressed into a single relationship between the quantities involved, seen as different ways of saying the same thing (Barnard, 1999).

Such pieces of cognitive structure do not exist in a vacuum. Intimately connected with them are other ideas in the mind that may readily be called to the focus of attention in turn. Our theory is that rich, compact cognitive units allow the thinker to manipulate these ideas in efficient, insightful ways, whereas students with diffuse structures will not find it so easy to make connections between concepts that are themselves diffuse and vague. There is already considerable evidence to support this thesis (Barnard & Tall, 1997; Chin & Tall, 2000; Crowley & Tall, 1999; McGowen, 1998). Not only do such units operate as a form of shorthand, linking many aspects of a complex structure, they also carry along with them connections that are able to guide their manipulation. Such activities may set up new links which may in turn become increasingly strong so that new cognitive units may be formed, building a network of nested mental structures that may span several layers of thought. This offers a manageable level of complexity in which the thought processes can concentrate on a small number of cognitive units at a time, yet link them or unpack them in supportive ways when necessary.
These ideas are closely related to Skemp’s (1979) “varifocal theory” of cognitive concepts, where a concept may be conceived either as a global whole, or viewed under closer scrutiny to reveal various levels of detail. He referred to this conceptual detail as the interiority of the concept. Powerful cognitive units have a rich interiority appropriate for the task in hand.

The building of cognitive links in such a way that one item in the focus of attention can refer at will to a variety of closely connected pieces of knowledge will be termed compression. In some cases a physical compression is known to occur in brain activity:

As a task to be learned is practiced, its performance becomes more and more automatic; as this occurs, it fades from consciousness, the number of brain regions involved in the task becomes smaller.

(Edelman & Tononi, 2000, p.51)

More generally, however, a process of long-term potentiation occurs in which connections between neurons become more easily activated and therefore resonate together as a single structure (Carter, 1998, p. 159). As mathematicians we see an analogy in which the brain has not only ‘substructures’ that work as a unit, but also ‘quotient-structures’ caused by the identification of separate units. A possible example is the cortical system for vision which has twenty or so separate regions each of which perform a specific task (eg recognising colours, changes in shade, edges, orientation of edges, movement of edges, identifying objects, and so on). We suggest the manner in which these disjoint areas are connected together to give a unified visual perception may be considered as such a quotient structure. As mathematics educators involved in thinking we have no physical evidence for this, so we pass the metaphor on to neurophysiologists to evaluate its usefulness. Meanwhile it is our role to collect evidence that intimates how mathematical structures may be held as manipulable cognitive units with an interiority that is able to both guide manipulation of the unit and also be subsequently expanded without loss of detail.

**Process-object duality**

Process-object duality is at the heart of several theories of mathematical development, for instance the encapsulation of process into object (Dubinsky, 1991) or the reification of process into object (Sfard, 1991). Unlike Skemp’s theory which sees the schematic structure consisting of object-like concepts which are linked by properties and processes, these encapsulation theories describe how sequences of activities can become routinized into thinkable processes which are then in turn conceived as mental objects. This is described by Asiala et al (1997) as follows:

According to APOS theory, an action is a transformation of mathematical objects that is performed by an individual according to some explicit algorithm and hence is seen by the subject as externally driven. When the individual reflects on the action and constructs an internal operation that performs the same transformation then we say that the action has been interiorized to a process. When it becomes necessary to perform actions on a process, the subject must encapsulate it to become a total entity, or an object. In many mathematical operations, it is necessary to de-encapsulate an object and work with the process from which it came. A schema is a coherent collection of processes, objects and previously constructed schemas, that is invoked to deal with a mathematical problem situation.

(Asiala et al, 1997, p. 400.)
Sfard (1991) proposed a corresponding sequence, affirming that operational mathematics (use of processes) almost invariably precedes structural mathematics (use of objects). Dubinsky and his colleagues followed the process-object sequence for several years before the strict sequence was loosened:

... although something like a procession can be discerned, it often appears more like a dialectic in which not only is there a partial development at one level, passage to the next level, returning to the previous and going back and forth, but also the development of each level influences both developments at higher and lower levels. (Czarnocha et al, 1999, p. 98.)

Gray & Tall (1994) took a different view of the relationship between process and object. They saw the role of the symbol as being pivotal in the thinking process in a very special way. A symbol such as “3+4” could act as a pivot between a process (of addition) and the concept (of sum). This immense power—which is characteristic of symbolism in arithmetic, algebra and calculus—allows the thinker to switch between using the symbol as a concept to think about or as a process to calculate or manipulate to solve a problem. They formulated the notion of procept as a combination of process and concept evoked by a single symbol. This theory saw the notion of procept becoming richer (in interiority, to use Skemp’s terminology) as different symbols and processes represented the same object, for instance, 6 as 5 + 1 or 2 + 4. From this range of associations it is possible to compute, say 8 + 6, because 6 is 2 + 4 and 8 + 2 gives 10, and 10 and 4 gives 14. The notion of ‘procept’ was extended to include all the triples of process-object-symbol that have the same object in a given cognitive context. For instance, 6 is a procept which embraces 3 + 3, 5 + 1, 2 + 4, and so on. Later in the development of the individual, it might also come to embrace 12/2, √36, 3 · 5 + 2 · 5. In our terminology, a procept is therefore a special case of a cognitive unit that grows with interiority as the cognitive structure of the individual gets more sophisticated. This compression of mental schemas or schemes into a cognitive unit features in a range of theories of cognitive development.

Schema-concept duality

Mathematical thinking involves two different kinds of mental activity which are both referred to as schemas or schemes. One is a sequential action scheme that occurs in time and is stabilized by long-term potentiation, strengthening and coordinating cognitive links such as the “see-grasp-suck” scheme in the young child. Another refers more specifically to the physical structure of the brain, which offers a multi-connected schema in which many possible links are available at any given time. The process-object theories seem to focus more on the first of these, theorizing that sequential schemes are encapsulated or reified as mental objects. The second type of schema offers a more subtle way of building up mental concepts that can operate flexibly as cognitive units.

Crowley and Tall (1999) consider how the “linear equation schema”, for formulating and solving linear equations may represent the same idea in different forms:

- the equation \( y = 3x + 5 \),
- the equation \( 3x - y = -5 \),
- the equation \( y - 8 = 3(x - 1) \),
- the graph of \( y = 3x + 5 \) as a line,
- the line through (0,5) with slope 3,
- the line through the points (1,8), (0,5).
For some college algebra students these may all be compressed into a single cognitive unit, with the various representations just alternate ways of expressing the same thing. But it is also clear that there are students who see the structure as consisting of distinct ideas with procedures (that they may not be able to carry out) required to get from one thing to another. A student with such a diffuse view of linear equations may therefore have a partial schema for relating the various representations but not a global schema that easily sees them all as essentially the same cognitive unit.

Dubinsky and his colleagues extended their APOS theory so that, in addition to a process-object construction, there was also a schema-object construction:

As with encapsulated process, an object is created when a schema is thematized to become another kind of object which can also be de-thematized to obtain the original contents of the schema.

(Asiala et al, 1997, p.400)

In this way, highly connected mental structures are built up at different levels of detail, connected in various ways.

The distinction between procedural thinking that allows limited success in familiar contexts and conceptual thinking that is more adaptive in new problems has long been a subject of study. Hiebert and Carpenter (1992) proposed two alternative metaphors for cognitive structures—as vertical hierarchies or webs:

When networks are structured like hierarchies, some representations subsume other representations, representations fit as details underneath or within more general representations. Generalisations are examples of overarching or umbrella representations, whereas special cases are examples of details.

In the second metaphor a network may be structured like a spider’s web. The junctures, or nodes, can be thought of as the pieces or represented information, and the threads between them as the connections or relationships. (Hiebert & Carpenter, 1992, p. 67.)

Skemp’s formulation would allow the nodes in a web to be seen as varifocal hierarchies, thus allowing the two structures to be used together. Likewise a concept could be considered as a web of connected ideas, allowing both hierarchical and web-like structures to coexist in a single structure.

However, the notion of webs and nets are still simplified metaphors for a far more sophisticated mental system. Greater subtlety is essential to be able to reflect on the way we think in mathematics. Consider for example, the statement: \( \sin 60° = \frac{\sqrt{3}}{2} \). This may be conceived by an individual as a cognitive unit and linked to a picture such as that in figure 1.

This in turn is related to many other ideas such as “the angles in an equilateral triangle are all equal”, “the angles in a triangle add up to 180°”, “an angle in an equilateral triangle is 60°”, “the line joining the vertex to the midpoint of the base (of an isosceles triangle) meets it at right angles”, “if the side is two units, half a side is 1 unit”, “Pythagoras’ Theorem”, “\( a^2 + b^2 = c^2 \)”, “\( b^2 = c^2 - a^2 \)”, “the square of \( \sqrt{3} \) is 3”, “\( 1^2 + (\sqrt{3})^2 = 2^2 \)”, “the sine of an angle is opposite over hypotenuse”, “the opposite is \( \sqrt{3} \), the hypotenuse is 2”, etc. In this way we see a single cognitive unit linking

\[ Figure 1: \text{Relationships within an equilateral triangle} \]
theorems about triangles, definitions of the trigonometric functions, algebraic representation of a sum of squares, numerical facts about a specific triangle, and so on. It is possible to formulate these partly in terms of hierarchies, for instance, Pythagoras’ Theorem has “$1^2 + (\sqrt{3})^2 = 2^2$” as a special case, the definition of sine also includes this special case in terms of $\sqrt{3}/2$ as “opposite over hypotenuse”. The many links involved also relate to other ideas; the definitions of trigonometric formulae relate to notions of similar triangles having sides in the same ratio; the trigonometric functions have relationships between them such as $\sin^2 + \cos^2 = 1$. Processes of the brain allow these ideas to become intimately connected in such a way that they are easily linked and manipulated.

Professional mathematicians build up highly subtle cognitive units packed with meaning. By focusing on commonly occurring properties which prove useful in making deductions, they build up a range of different theories based on generative concepts translated into chosen systems of axioms. For example...

... the concept of a group captures the essence of the notion of symmetry and is connected in a precise way to the concept of an equivalence relation, which itself is a precise abstract formulation of the notion of ‘sameness’ with respect to a given property. Not only are the properties defining a group sufficiently general to be satisfied by a large variety of relatively concrete mathematical objects, but they are also sufficiently special to have lots of powerful consequences at the abstract level. Thus a group is a precisely defined concept which sits at a major junction in the mathematical network of relations. Indeed, one of the most beautiful features of mathematics is the way it allows such precision at even the deepest levels of abstraction. (Barnard, 1996)

Performing cognitive compression

A common method of compression is to use words and symbols as tokens for complex ideas. In particular, words can be used in a way that allows a hierarchical structure to be conceived. For instance, a square is a special case of a rectangle, which is itself a parallelogram, which is a quadrilateral. In the early stages a square and a rectangle may be seen as quite different entities, both having four right angles, but a square has all sides equal, whereas a rectangle has only opposite sides equal. The cognitive unit “rectangle” develops greater sophistication and interiority, growing from meaning just a perceived figure, to a whole collection of rectangular figures (including squares) in any orientation. The realization that squares are special cases of the class of rectangles is an example of cognitive compression where one class of objects is subsumed (for certain purposes) within another.

Language supports the communication and refinement of ideas, both between individuals and within the mind of the individual. It allows verbalized properties of perceptions to be used as a foundation for the development of cognitive units that are sophisticated mental idealizations. These include the notion of a point having position, but no size, or a line having arbitrary length and no thickness. These go on to play their role in proving relationships in elementary Euclidean geometry and perhaps later in more abstract forms of geometry.

A cognitive unit may, or may not, be associated with a natural visual label. For example, in contemplating a mental image of angles written around a circle, in degrees and in radians, there is no need to convert, say, $\frac{\pi}{4}$ radians to 45 degrees (by multiplying...
by the factor \( \frac{90}{180} \). The symbols \( 90^\circ \) and \( 45^\circ \) are simply different labels for the same angle. On the other hand, the steps of algebraic manipulation involved in seeing that 'a linear combination of a linear combination of quantities \( x \) and \( y \) is a linear combination of \( x \) and \( y' \) is an idea that may be compressed into a cognitive unit without there being a clearly defined label associated with the manipulation process.

Compression can also occur in other ways. For instance, when a collection of ideas or symbols is 'too big' to fit into the focus of attention, it can sometimes be 'chunked' to group into a single unit using some kind of alternative knowledge structure. The four digit number 1914 may be seen not just as a number, but as the year at the beginning of the first world war. This kind of associative link may be used to chunk numbers together into sub-units that can now be held in the limited short-term memory. Most individuals would find the 12-digit number 138234098743, impossible to remember on a single hearing. However, the twelve-digit number 246819141918 can be 'chunked' and remembered as the sequence ‘2, 4, 6, 8’ followed by the dates 1914–1918 of the First World War.

Although it is possible to formulate a range of possible compression strategies, individuals do not use them all to the same extent. This leads to different individuals processing mathematical ideas in ways which may have very different outcomes that may lead to success in some and failure for others. Gray and Tall (1994) noted that children who use the longest counting process—count-all (count one set, count the second, put them together and count them all)—could also remember certain “known facts” such as 1+1 is 2 or 2+2 is 4. But none of these ever put together “known facts” to obtain “derived facts”, such as “4+3 is 7” because “4+4 is 8”, or “12+2 is 14” because “2+2 is 4”. Instead, they always computed arithmetic problems (whose answers were not immediately known facts) by counting. We hypothesize that the sums performed by these children are seen as counting processes and not as meaningful cognitive units with any interiority. The “known facts” for them were isolated and not in a sufficiently rich compressed form which could be mentally manipulated as cognitive units. On the other hand, children who were able to derive new number facts from known related ones were able to perform arithmetic in a far more flexible way which used numbers as compressed cognitive units with powerful interiority.

Another bifurcation occurs in elementary algebra. Here an expression such as ‘\( 2 + 3x \)’ stands for a potential arithmetic operation such as “add 2 to the product of three times whatever \( x \) is”. This can cause discomfort for students who feel that a problem “must have an answer” as it does in arithmetic. They are therefore faced with manipulating expressions as mental objects that have only a potential, rather than an actual, internal process of evaluation. This can lead simply to procedural compression in which students learn to carry out a solution process by rote (“collect together like terms”, “get the numbers on one side and the variable on the other”, “simplify to get the solution”, etc). Others are able to conceive the algebraic expressions as entities that can be manipulated. They may go on to conceive of the equation itself as a cognitive unit expressing a given relationship, with a “solution process” as a cognitive unit that can be unpacked to give an efficient route to the solution.

Krutetskii (1976) studied this curtailment of mathematical reasoning, in which capable students would compress their solutions in a succinct and insightful manner.
... mathematical abilities are abilities to use mathematical material to form generalized, curtailed, flexible and reversible associations and systems of them. These abilities are expressed in varying degrees in capable, average and incapable pupils. In some conditions these associations are performed “on the spot” by capable pupils, with a minimal number of exercises. In incapable pupils, however, they are formed with extreme difficulty. For average pupils, a necessary condition for the gradual formation of these associations is a system of specially organized exercises and training.

(Krutetskii, 1976, p. 352.)

Great success in calculation may be developed with a huge range of connected ideas, some meaningful, some rote-learnt, as Nobel Prizewinner, Richard Feynman reports:

I memorized a few logs and began to notice things. For instance, if somebody says, “What is 28 squared?”, you notice that the square root of 2 is 1.4 and 28 is 20 times 1.4, so the square of 28 must be around 400 times 2, or 800. If somebody comes along and wants to divide 1 by 1.73, you can tell them immediately that it’s .577 because you notice that 1.73 is nearly the square root of 3, so 1/1.73 must be one-third of the square root of 3. And if it’s 1/1.75, that’s equal to the inverse of 7/4 and you’ve memorized the repeating decimals for sevenths: .571428...

(R. Feynman, 1985, p. 194.)

Mathematical proof

Mathematical proof involves cognitive units and connections of a more general type than those encountered in elementary mathematics. (Barnard & Tall, 1997). In addition to sequential procedures of calculation or symbol manipulation found in arithmetic and algebra, mathematical proof often requires the synthesis of several distinct cognitive links to derive a new synthetic connection. For instance, in the standard proof that \( \sqrt{2} \) is irrational, having written \( \sqrt{2} = a/b \) as a fraction in its lowest terms, the step from “\( a/b \)” to “\( a^2 = 2b^2 \)” is an elementary sequence of algebraic operations, but the step from “\( a^2 \) is even” to “\( a \) is even” requires a subtle synthesis of other cognitive units, such as “\( a^2 \) is either even or odd” and “if \( a \) were odd, then \( a^2 \) would be odd.” These synthetic links constitute an essential difference between the elementary procedures of arithmetic or algebra and the more sophisticated linkages involved in mathematical proof.

Students often say that they can follow proofs when the lecturer goes through them in class, but they are unable to construct proofs for themselves when required to do so for homework. One explanation of this phenomenon (Barnard, 2000) has to do with the shifting of focus through the different layers of detail in the cognitive units to be manipulated: statements, statements within statements, expressions within statements, symbols within expressions, etc. In a lecture, the lecturer may implicitly specify the level of items that are to be the primary objects of thought at any stage. For example, in a proof by induction on \( n \) of a statement \( P(n) \), the distinction needs to be made as to when \( P(n) \) is to be thought of as a compressed item within the statement, “\( P(n) \) implies \( P(n + 1) \)”, or when it is to be unpacked for a finer grained manipulation.

It is this focus shift of compression and expansion that often lies at the heart of the difficulty when students try to construct proofs for themselves. It is a bit like knowing when and how to change gear while driving. When students ask the seemingly bizarre question, “How do you do proofs?”, they may simply be reacting to a predicament similar to that of trying to drive without awareness of the existence of gears.

(Barnard, 2000.)
The wider challenge in mathematics education is how we can help students to construct appropriately linked cognitive units that are flexible and precise to help them build mathematics as a coherent and meaningful structure. These cognitive units arise naturally in human thinking and take on a wide range of roles – general strategies, specific information, routinized sequences of steps, linked together to produce mathematical thinking. Without cognitive units of appropriate manipulable size, thinking becomes diffuse and imprecise and is far less likely to be successful. Even with the development of manipulable cognitive units in individuals that give current success, there will still be challenges requiring intelligent reconstruction to cope with novel situations.

INVESTIGATING MATHEMATICAL INTERACTION IN A MULTILINGUAL PRIMARY SCHOOL: FINDING A WAY OF WORKING

Richard Barwell

University of Bristol

How is it possible to investigate student interaction in a multilingual mathematics classroom? As researcher, I have little access to students’ language, culture or experience, making it difficult to make claims about their meanings or interpretations as they work together on mathematics tasks. This paper discusses the development of a methodology based on the discursive psychology of Edwards (1997), which makes possible an investigation of the participation of English Additional Language (EAL) learners in mathematical interaction. The aim is to find a way of working which avoids making assumptions about what students mean by what they say. Analysis proceeds from looking at what participants attend to, to examine how they think together.

Introduction.

Although there has been considerable interest in the role of language in mathematics education, there is much less work which considers the teaching and learning of students who are still in the process of acquiring the classroom language. This paper concerns students in a UK primary mathematics classroom for whom English is an Additional Language (EAL) [1]. How do EAL students participate in the complex environment of the mathematics classroom? And how can this be investigated?

The literature contains much that relates to these questions, though little which addresses them directly. Several quantitative studies have used written instruments as a basis for comparisons between different language groups (e.g. Dawe, 1983) or to compare language proficiency with mathematical attainment (e.g. Cocking and Mestre, 1988; Clarkson, 1992). These outcome-based studies give little insight into learning processes. There has been a modest amount of work which examines interaction in multilingual mathematics or science classrooms (e.g. Warren and Roseberry, 1995; Moschkovich, 1996; Gibbons, 1998; Setati, 1999) although this work does not generally problematise the difficulties of making interpretations as an analyst in such culturally complex environments. More generally, there is a wider body of work which examines mathematics classroom interaction from different perspectives, examining such notions as mathematical communication (e.g. Steinbring, 2000), argumentation and the role of narrative (e.g. Krummheuer, 2000). As this work is typically based in monolingual classrooms, issues of cultural heterogeneity tend to be overlooked.

Complexity.

One of the aims of the research reported in this paper is to develop a methodology which does take account of students’ cultural, linguistic and social histories in analysing data. On a substantive level, I am seeking to explore the nature of EAL
students' participation in mathematical interaction as they engage with tasks from their mathematics lessons. I am seeking evidence of what EAL learners can do in mathematical interaction, rather than conceiving of their language status as a barrier to be overcome. In this paper, however, the focus is primarily methodological.

In considering students' classroom talk, I start from the position that I cannot have direct access to students' personal, subjective meanings, since these meanings are related to students' "individual histories" (Bruner, 1996: 14), their unique social and cultural experiences. The individual experience of each student is a crucial part of how they make sense of the world around them, including the world of the mathematics classroom, since this experience entails the participation in and enculturation into patterns of language and behaviour, which in turn allow the interpretation and production of situated meaning (Bruner, 1990: 19). Given that EAL students in the UK come from a wide range of cultural, linguistic and social backgrounds and have often experienced life in several parts of the world, sometimes in difficult or traumatic circumstances, it is clear that it is unrealistic to assume that a researcher is in a position to understand students' interpretations.

The discursive psychology of Derek Edwards (1997) (also Edwards and Potter, 1992), which draws on conversation analysis and ethnomethodology, offers both a theorisation of language in use and a methodological approach to analysis with the potential to address the problem set out above. Language is conceptualised as primarily "a medium of social action rather than a code for representing thoughts and ideas" (Edwards, 1997: 84, original emphasis). Social action is foregrounded as the primary function of language, which is seen as having evolved through social interaction, and therefore as being structured both by and for social interaction. From the plurality of possible forms and modes of expression at any given moment of interaction, only one utterance can emerge. The path taken through this plurality of expression is determined by the social action and interaction of the participants. So for example, an utterance designed to persuade will take a different form from an utterance designed to attack, even if the 'content' is the same. The patterns of language through which these different actions take their form derive from each individual's experience of social interaction, their cultural and linguistic history. Thus, rather than attempting to analyse what students mean, discursive psychology seeks to examine how meaning is constructed and situated in discourse. Analysis of classroom discourse asks "not what do children think but how do children think" (Edwards, 1993: 216, original emphasis).

Discursive psychology also offers an approach to discourse analysis which emerges from the theorisation of interaction presented above. The process of analysis is based on the principle that language-in-use makes explicit that which participants are concerned with, and as a result, makes their interpretations available for analysts (Sacks, Schegloff and Jefferson, 1974: 728-729). Developing these ideas, Edwards and Potter (1992) outline five distinctive aspects of the discourse analysis of discursive psychology:
1. Analysis is of naturally occurring talk and prepared texts.
2. Analysis is concerned with the content of talk and its social organisation. This includes seeing talk as sequential and analysing utterances within the sequential context in which they occur.
3. Analysis is concerned with action, construction and variability. Different ways of talking are used in different circumstances and for different rhetorical purposes.
4. The rhetorical organisation of talk and thought is designed to counter potential alternative versions which may arise. The form of an utterance is determined by the action it is designed to perform, including the prefiguring of potential future courses of interaction.
5. It is the consideration of 'cognitive' issues such as intention or meaning in terms of how they are dealt with in discourse that leads to this approach being characterised as 'psychological'. The focus is on looking at how participants construct and rhetorically deploy psychological concepts in interaction. This is not to deny that people have intentions or meanings, but to argue (Edwards 1999: 272) that we can only examine how such notions are interactionally employed in different ways to suit different occasions and thereby accomplish different social actions.

In this paper I offer an example of this approach to analysis of interaction. First however, it is necessary to provide some context.

**Research context.**

I have been visiting the Year 5 (aged 9-10) mathematics lessons in a multilcultural urban UK primary school of approximately 150 students from a variety of cultural and linguistic backgrounds. In Year 5 (1999-2000) there were six students recognised as EAL. Initially I had hoped to record EAL students as they worked in order to obtain records of naturalistic interaction. I particularly wanted recordings of student-student interaction, rather than of the more heavily cued exchanges between students and the teacher. As classroom-based recording proved impractical the approach was modified: small groups of students were withdrawn from the classroom and recorded while they worked on a task together. Although not identical to classroom situations, the teacher frequently asks students to work together in this way. Furthermore, the task and the combinations of students selected were based on classroom observations. Thus although the interaction was not completely natural, neither is it particularly artificial.

The research design at this pilot stage was based around a topic about calculators. A task, that of writing addition word problems about money, was selected from the teacher’s plan for the week. Six pairs or threes of students were recorded both before and after the calculator topic as they worked on the task. The primary data consist of fully transcribed audio recordings of the interaction. The analysis offered in this paper is of the first pair of students recorded before the lesson sequence. ‘Cynthia’ comes from a Cantonese speaking background and arrived in the UK about 18 months ago from Hong Kong, since when she has learnt virtually all her English. Her
English in Year 5 was assessed by the school as ‘stage 2’ on a 4 stage scale, where ‘stage 1’ indicates almost no proficiency in English. ‘Helena’ is an English speaking African-Caribbean student.

**Interaction: extract 1.**

Cynthia and Helena are working together on their first word problem. As with many of the recordings in the pilot study, Cynthia and Helena start by choosing a name for a character in the problem and then proceed with much negotiation to construct their problem. The result (see [2]) consists of twenty words and reveals little of their deliberations, as recorded in more than 70 lines of transcript. As noted above, it is possible to examine ‘participants’ concerns’ (Sacks et al, 1974; Edwards, 1997) in interaction, as these concerns are made available for other participants, and therefore are also available for analysts. In this paper, I will show how an examination of **what** the two students attend to as they work together leads to insights into **how** they think together. Lack of space makes it impossible to reproduce a full analysis, including the fully transcribed sequence. I shall therefore use sections of the transcript to illustrate the approach (see [3] for transcription conventions; line numbers are indicated in the text in parentheses).

In the transcript discussed in this paper, Cynthia and Helena display two broad areas of attention. One concern is with the genre (or typical form; see Gerofsky, 1996) of word problems; the way they are constructed and the nature of the language they contain. They also attend to the mathematics of the problem which in this case is closely bound up with the requirements of the task. These foci are evident in the short extract below, which comes from near the beginning of the sequence:

**Extract 1a.**

56 H  Daniel um  writes
57 C  Daniel um
58 H  went to the shop
59 C  n-no can/ umm/ um write that/ Daniel work/ n-no/ Daniel/ w=um/
60 Daniel/ well if he work/ (...) he have/ he have/ hundred pound/ and how
61 many/ in/ the month/ (for example) like easy one

As the students begin their discussion, they first attend to the general form, or genre (Gerofsky, 1996) of word problems, selecting a character (56-57) and a scenario for the problem (58-61). Cynthia offers a partial version of a problem (59-61). She then offers an evaluation of her problem, switching attention to the ‘easiness’ of her problem “like easy one” (61), so focusing on the mathematics and the task they have been set as she interprets it. It could be argued at this point that Cynthia’s problem is deficient; she has not included enough information. Does this mean she does not ‘understand’ what a word problem should include? Or is it that she has a suitable problem ‘in her head’ but is unable to articulate it? These are not questions that can be answered from the perspective of discursive psychology. Instead, we should continue to follow the sequence of the transcript, examining what it is that the
participants themselves attend to. In this way it is possible to examine how thinking is jointly accomplished by Cynthia and Helena.

Extract 1b.

62 H but you've got to use it in addin'/ addin'/ addition/
63 C oh yeah
64 H so you say Daniel/ yeah it's kind of like a addition thing isn't it/
65 because/ Daniel went to work/ he had hundred pound/ a month?
66 C um/ a week
67 H oh that's (okay then) a hundred pounds a week/ how many/ how
68 many um/ how ma=how much money do he have in a month
69 C yep
70 H (okay then)

Helena's initial response to Cynthia's offer (62) attends to the mathematical nature of what she has heard Cynthia suggest (which is not necessarily the same as what Cynthia thinks she has suggested), which is related to the task as she understands it. She states what is ostensibly part of the instructions "you've got to use it in addin'", so evaluating Cynthia's suggestion as potentially not 'addin' and therefore not compliant with the task. By using the form of words "you've got to" she carefully manages her implied criticism as being based on an external criterion and therefore as being less personal. Although apparently citing a 'rule', Helena's evaluation is situated and constructed in the context of the ongoing interaction, designed as a part of the students' social (inter)action.

Helena continues to focus on both genre and mathematics, but goes on to develop her interpretation of Cynthia's problem by reconstructing it as a potential addition problem (64-65). In doing so she identifies something that requires clarification: "a month?" (65); Cynthia has not stated how often Daniel gets his hundred pounds. Here Helena attends to the mathematics of the problem, as well as to the generic form of word problems, the two intersecting in her question, "a month?". In responding to Helena, Cynthia supplies an extra piece of information "a week" (66), thus taking account of the recent attention to the problem genre and the scenario-under-construction, as well as the mathematics of the emerging problem and the task in hand. Cynthia's response is not seen as an act of recall, providing a missing piece of information that was omitted in her original version but which was somehow 'in her head' all along. Instead, it is viewed as a situated response specifically designed for the moment of interaction in which it was used. This shows a highly sophisticated awareness of what is going on in the discussion with Helena.

This extract concludes with Helena reformulating the question that completes Cynthia's original problem, taking account of the preceding exchange (67-68). It is not possible to say here if this is what Cynthia originally intended, but that is to miss the point. The interaction shows Helena and Cynthia thinking together [4] as they generate their problem. It is not possible to separate the contributions of the two students. Although words and ideas can be superficially attributed to either Cynthia
or Helena, this is merely the result of the constraints of organised talk. They must take turns and speak one-at-a-time if they are to work (and think) together. Each contribution, however, must be seen as contingent on what has gone before, guided by the students’ joint orientation to completing the task. Thus when Cynthia decides on “a week” (66), it is simplistic to claim that this is all Cynthia’s idea, since it comes as a response to the previous discussion between both students, as well as an awareness of the potential future course of interaction.

**Interaction: extract 2.**

The above analysis shows how an initial focus on ‘participants’ concerns’ (Sacks et al, 1974; Edwards, 1997) makes it possible to examine how thinking together is accomplished. Analysis of the rest of the transcript reveals similar insights. Extract 2 is taken from the last few lines of the transcript of the students’ work on their first problem, which has evolved a little from the version apparently agreed on in extract 1. Prior to this extract, Cynthia and Helena have agreed on and Helena has written down: “Daniel has a job he gets pay £415 in a month”. They are now negotiating the question which will conclude the problem.

**Extract 2.**

100 C  how many in a week/ no oh yeah/ how many in a week
101 H  (...) okay then/ how many/ how many/ how much money does he get/ in
102 C  a year/
103 C  in a week
104 H  a week?
105 C  no that’s (...)
106 H  no cause/ you said in a month/
107 C  yeah/ no/ I said/ [ no/ I said/ Daniel has a job he gets paid four &
108 H  [ how many
109 C  & hundred and fifteen pound in a month/ how many in a week
110 H  how much he gets
111 C  yeah/ how-how much he get/ on one week
112 H  that’s dividing innit
113 C  oh yes that’s divide/
114 H  that’s sort of like dividing cause there’s four/ four weeks in a month so
115 C  that’s four divided by (three) I mean four hundred and fifteen
116 C  I’ll just do/ how many in a year// [ (inaud.)

Cynthia suggests “how many in a week” (100). Helena responds with a reformulation, emphasising the key point of difference, “a year” (102), and thus revealing the two students’ current concern. The detail seems important, since the choice between ‘week’ and ‘year’ affects the kind of problem they produce – either partitive or additive. Cynthia continues to attend to this choice, saying “in a week” (103). There is a sense at this point of both students being focused on this one detail, and so on the mathematics of the problem. The discussion moves forward through Helena and Cynthia trading “contrasting versions” (Edwards and Potter, 1992: 3) of what Cynthia ‘said’ (106-109), with the focus remaining with the choice between
‘week’ and ‘year’. In Helena’s version of what Cynthia ‘said’, she draws attention to a detail from the agreed on problem-so-far (now written down). By setting her version up as something Cynthia ‘said’, Helena explicitly links the choice between ‘week’ and ‘year’ with what has gone before. She is now attending to the mathematical structure of the emerging problem by looking at the relationship between ‘month’ and ‘year’.

Cynthia responds by also constructing a version of what she ‘said’ - another reformulation of the problem. In fact elements of her restatement were originally said by Helena (“gets paid” (107)), but again, the point is not to check Cynthia’s claim about what she said with what she actually said, but rather it is to look at what is accomplished by her claim, which has been constructed to suit the particular circumstances in which it was made. In this latest version, Cynthia makes a clear choice for ‘week’ in the context of Daniel’s “four hundred and fifteen pound in a month” (107, 109). Helena is then able to identify Cynthia’s version as “dividing” (112) and therefore, as in extract 1, implicitly not compliant with the task. It is noticeable that Cynthia now accepts this point quite easily and along with Helena’s earlier suggestion of “how many in a year” (116). It is not possible to say, however, that this is due to her mathematical understanding of the argument, or because of the persuasive nature of Helena’s rhetoric, i.e. because Helena is convincing, or because she just wishes to get the problem finished, or for any other reason.

Conclusions.

Analysis of what the students attend to as their discussion unfolds reveals two foci. Firstly, they attend to the form of the problem, both in terms of the generic ‘contents’ - such as a character and a situation - and in terms of the kind of language used (see 67-68), a feature more apparent in later sections of the transcript. Secondly, there is a focus on the mathematical nature of the problem as it emerges, a focus which is closely related to the task the students were set. These patterns, which are evident throughout the transcript, are an important feature of the interaction, as they enable Cynthia to think together with Helena. It is important to note that Cynthia does participate successfully in this discussion, a remarkable performance considering she has been learning English for less than 18 months. One way in which Cynthia and Helena are able to accomplish this thinking together is to use language to establish joint foci of attention. Cynthia is able to do this even at her relatively early stage of English language development.

Methodologically, the above illustration of the nature of analysis demonstrates the efficacy of the discursive psychology approach to discourse analysis. The broad interest in what the participants do rather than what they mean, makes it possible to examine interaction without needing to make assumptions about meanings or intentions. Thus in the first short extract discussed above, there was no speculation regarding Cynthia’s initial attempt to formulate a problem (59-61), which would clearly be difficult to make sense of. Instead the focus was on how her problem was constructed within the flow of interaction and how it was used in subsequent
discussion. The arguments and exemplification of analysis set out in this paper therefore demonstrate the possibility of analysing interaction in multilingual, multicultural settings without needing access to the languages or cultures of the participants.

NOTES.
1. English additional language (EAL) refers to any learner in an English medium environment for whom English is not the first language and for whom English is not developed to native speaker level. Native English speakers are described simply as monolingual.
2. The final written problem, typed but unedited except for the name, was: “Daniel has a job he gets pay £415 in a month. How much money does he get in a year?”
3. Bold indicates emphasis. / is a pause < 2 secs. // is a pause > 2 secs. (...) indicates untranscribable. ? is for question intonation. ( ) for where transcription is uncertain. [ for concurrent speech. & for utterances which continue on a later line. ^^ encloses whispered speech.
4. Although the expression ‘think together’ has been used by Mercer (2000), my analysis does not draw directly on Mercer’s work.

REFERENCES.
Educational Studies in Mathematics 14(4) 325-353.
This paper describes a mathematics teaching approach which uses PowerPoint to replicate traditional non-computer teaching by manipulating virtual copies of real materials (Baturo, 2000). It reports on three case studies of primary teachers who admitted to having computer technophobia as they attempted to integrate learning technology in their classrooms even though they had undergone an extensive school-based computer skilling program. The results show that the generic software approach is a powerful way to encourage teachers to use computers in mathematics teaching, manipulating virtual mathematics materials facilitates learning, and teacher mathematics pedagogy knowledge is the determining factor in enhancing learning through computers. It is much easier to provide computer expertise than mathematics pedagogy knowledge.

Technological change is expected to transform teaching and learning. For example, the Department of Education Queensland (1995) has argued that computer technology will change the nature of student learning, the roles of both teachers and students, and “support and enhance the achievement of educational goals across the P-12 curriculum” (p.3). However, many teachers who have not grown up with computer technology have developed high levels of stress (technophobia) when faced with a teaching future that appears to be inexorably leading to the integration of learning technologies (e.g., Morton, 1996). As Eraut (1994) conceded, “using an idea in one context does not enable it to be used in another context without considerable further learning taking place” (p. 33).

According to Reilly (1997), successful teaching with computers tended to focus on knowledge-construction activities that actively engaged students in solving problems both as individuals and as members of a team. These types of activities tended to change, quite significantly, students’ conceptions about the nature and discourse of the subject-matter being studied (Clements, 1994) with accompanying qualitative changes to students’ mental models of the phenomena being studied (Woodruff & Meyer, 1997). As McRobbie, Nason, Jamieson-Proctor, Norton and Cooper (2000) argued, understanding of mathematics in computer related activities is dependent on the following: (1) degree of difficulty – computer activities have to be carefully chosen so that the mathematics being taught is within the students’ zone of proximal development (Vygotsky, 1978) or the students will be unable to make the leap to the new knowledge; (2) links to non-computer activity – activities should integrate on and off computer activities (Kaput & Rochelle, 1997); (3) scaffolding – the mathematics behind an activity needs to be fully understood by teachers so that they can provide the necessary scaffolding to assist students’ construction of knowledge from the computer activities (Bagley & Hunter, 1992); and (4) reflection - opportunities should be provided after computer activities for students to discuss and reflect on what they have done and learnt (Davis & Rimm, 1998).
In Australia, current pedagogy believes that mathematics understanding is best constructed by each child through a combination of: (1) work with materials (concrete then pictorial); and (2) discussion and reflection with peers and teacher (e.g., Booker et al., 1999). Most activity with real or concrete materials in number and space involves sliding, joining, separating, grouping, ungrouping, partitioning, turning and flipping actions. All of these actions are available on computer through mouse movements and images of the materials ("virtual materials") using the commonly available generic "office" software (e.g., MicroSoft Office, ClarisWorks) (Baturo, 2000). Real materials are multisensory (i.e., they can be seen, smelt, moved, picked up, touched, weighed) whereas virtual materials are bisensory (seen and moved) so virtual materials are more abstract than real materials. Therefore, real materials may develop a more detailed memory structure (schema) than virtual materials. However, on the other hand, mathematising is about refinement and abstraction so that the multisensory nature of real materials may actually hinder the abstraction process as the child may not know which are the salient features to focus on.

Some actions are neither as overt as they are with concrete representations nor as covert as they are with pictorial representations. For example, with respect to numeration processes, grouping virtual base-10 materials will require the child to activate a “selection” tool, hold down the left mouse key as s/he “draws” a box around the objects to be grouped, go to the Draw menu on the Drawing toolbar, and then select “Group” from the menu. Thus, there is indirect physical manipulation through the mouse but the regrouping process will require much more dexterity than the direct physical manipulation. Furthermore, the grouping process has to be known but held in memory as the child performs the sequence of operations that will make the transformation from ones to tens. Similarly, but slightly less difficult, actions are required for the ungrouping process, namely, select the object to be ungrouped by clicking n it, going to the Draw menu, and selecting “Ungroup” from the menu. Figure 1 shows that, from this analysis, virtual materials should provide a conceptual bridge from concrete to pictorial representations.

![Figure 1. The role of virtual representations in developing whole-number concepts and processes.](image)

Some actions are indirect. For example, for spatial processes (see Figure 2), the sliding actions requires the child to select the shape by placing the mouse on the shape and clicking, then to s/he simply slide the shape to a new position. For flipping actions, the child selects the shape by clicking, activates the Draw menu, selects Rotate or Flip, and then selects Flip Horizontal or Flip Vertical. For rotating actions,
the child selects the shape, activates the Draw menu, selects Rotate or Flip and then selects any of the Rotate options (Free Rotate, Rotate Left, Rotate Right).

Tessellations and tangrams (which require sliding, flipping, rotating actions) are spatial activities that are enjoyed by all age groups. However, assembling a class set of real materials is time-consuming. Virtual materials require only one template which can be downloaded for individual student’s use. The students themselves can then quickly copy the shapes required and, with respect to tessellations, have access to a variety of colours to enhance the final product.

![Sliding the shape from one position to another](image1)
![Flipping the shape from one position to another](image2)
![Rotating the shape from one position to another](image3)

*Figure 2. Spatial actions (sliding, flipping, turning) undertaken on virtual shapes.*

The project

The study used a combination of action research (Kemmis & McTaggart, 1988) and teaching experiment (Romberg, 1992) approaches in which the mentors worked with three volunteer teachers (Monica, Andrea, and Janice) in the development, implementation, and evaluation of a sequence of mathematics lessons taught with computers. Data gathered was predominantly qualitative.

**Subjects.** Monica – a Year 5 teacher with 20 years teaching experience; Andrea – a Year 4 teacher with 5 years experience; Janice – a Year 2 teacher with 12 years experience. The three teachers had been trained to use computers to support their teaching (e.g., preparing worksheets, publishing a newsletter for parents) but not as part of their teaching. All three teachers said they were severely technophobic before this training. At the start of the project, they rated their confidence in computer skills at about 4 on a 5-point scale but their confidence in teaching with computers between 0 and 1.

**Monica** wanted to use computers in mathematics, have the children and herself develop computer skills and have children use computer skills to learn mathematics; **Andrea** wanted to further her knowledge and use/application of technology in the classroom; and become more confident when teaching use of technology in the classroom; while **Janice** wanted to access information/ideas on how to transfer my “new” computer skills into learning situations for my class, isolate and define particular computer skills that can be taught and assessed in whole class to small group activities, and “have a go” and continue to learn about mathematics and computing.

**Mentors.** The three mentors consisted of the research team and **Greg.** Greg was a Year 4 teacher with expertise in the use of computers in the classroom who acted as liaison between the research team and the 3 teachers, providing “just in time” technical support when needed. The school’s administration gave Greg half-time release from teaching duties for the duration of the project (6 weeks).
Procedure. There were four main stages built into the project, namely, skilling, planning, implementing, and evaluating. For the skilling stage, two inservice sessions (each 1-day) were undertaken with the three teachers to introduce the MS Office program, PowerPoint. The teachers’ originally associated PowerPoint with high-quality presentations and high levels of computer expertise so were skeptical about their ability to acquire the skills that would be needed. For the planning stage, the teachers prepared a mathematics unit of four sequential lessons. The project team (mentors and teachers) then met for half a day to refine the plan, to discuss classroom management techniques with respect to computers, and to begin the construction of the computer activity in PowerPoint. Activity construction was to be done predominantly by the teacher but mentoring by the researchers was available when needed. For the implementing stage, the teachers conducted the computer activities in their own classroom or in the school’s Year 7 mini laboratory of 8 computers. Each lesson was video-taped and all mentors were available for help if needed during implementation. For the evaluation stage, the research team met with the teachers and Greg to evaluate the activities in terms of effectiveness in promoting learning, and in terms of personal professional development. The three teachers were then asked to complete a questionnaire whilst Greg was asked to write a report on his role in the project in terms of the type and amount of “just in time” support, and the quality of the mentoring component. The results of the meeting and questionnaire are reported in this paper.

Cases

Monica. For her Year 5 class, Monica planned a sequence of lessons using tangram activities to introduce flips, slides, and turns (transformations). To this end, she developed a series of PowerPoint tasks in which tangram pieces were combined to form shapes and prepared a program that integrated on and off computer activities. The students were introduced to the virtual materials in the first week as a whole class with the use of a data projector. The students then worked on paper tangram activities and, when these were completed, went on to virtual activities (replicates of the paper activities). They were rotated through the computer activities, 6 students at a time. The classroom had three computers that were kept in a small room at the back of the class.

The students enjoyed the challenge of the paper tangram activities and were motivated to continue by the promise of computer time. With respect to the computer tangram activities, the students were highly motivated by the colourful pieces and the clear, succinct directions were easy to follow. They worked collaboratively on the computers and were soon personalising the pieces by using their own colours and exploring “what would happen if …”. During the computer session, where three pairs of students were working collaboratively on the three computers, the following conversation was overheard: These are easier than the paper ones to see where they go (John). I reckon the paper ones are easier ‘cos you can pick them up (Allison). Both points of view were supported by other students nearby.

Monica herself was also motivated and encouraged by her ability to develop the virtual materials that the students used. She successfully introduced the necessary understandings of PowerPoint and the school’s network structure to enable the students to retrieve,
manipulate (flip, slide and turn) and save the tangram activities. However, some students experienced difficulty solving the tangram puzzles and the tangram activities were not explicitly connected to transformations.

The tangram activities were not sequenced; they did not move from simple to complex, increasing the number of tangram pieces and providing increasingly less detailed templates. They did not differentiate between puzzles that involve flips (more difficult) and those that did not (less difficult). The on and off computer activities were also at different levels of difficulty. The paper tangram activities had solutions provided on their templates, the computer activities did not. Finally, there was no explicit teaching of the role of flips, slides and turns in the formation of the puzzles. The result of this was that a section of the class needed support to solve any problems and the achievement of the students was less than expected.

Andrea. For her Year 4 class, Andrea developed a unit of work on polygons. She had taught the mathematical properties of polygons earlier and the computer activities were viewed as a means of assessing the extent to which the students understood the concepts. The first activity provided a range of 1-D, 2-D, and 3-D shapes (see Figure 3) and the students were required to sort them into Polygons/Not Polygons. Later activities involved students constructing their own polygons. The students worked in pairs; half the class at a time, on 8 computers in a small laboratory while the teacher with whom Andrea shared a double teaching space supervised the other half of the class.

![Figure 3. A polygon assessment activity designed by Andrea (Lesson 1).](image)

Andrea tried to direct the activities so that all students listened to her and then did part of the activity. She was very structured (scaffolded) in the way she implemented the lessons because, unlike Monica, she was teaching the mathematics concepts and requisite technology skills simultaneously. These skills consisted of knowing how to retrieve and save files, and how to use “click and drag”, text boxes, and the Draw, AutoShape and colour features of PowerPoint. She also was at pains to ensure both students in each partnership had time on the computer and that there was a period at the end of each activity where students reflected on what they had learnt. They were required to type these
reflections into text boxes, an activity that revealed that the students had acquired the appropriate knowledge and language.

Although Andrea’s initial lessons did not allow time for students to explore the enhancing features of PowerPoint (e.g., colouring lines and shapes; playing with different fonts), students nevertheless did so. One student showed his group how to change the colours of the lines and the enclosed space and before long all students were exploring the Format feature. This activity highlighted the motivational power of the computer, the collaborative nature of student learning when engaged on a task, and the need to let students explore first and learn later.

Andrea realised that this aspect of her lessons needed attention in her review. She stated that there was not a lot she would change except have smaller groups and more investigation in the mini-laboratory situation (“I used a similar teaching style as in the classroom - very structured and controlled - perhaps give children more experimentation time at the end of lessons”).

Janice. In her Year 2 class, Janice developed materials to introduce and reinforce two-digit numeration. She used the data projector to introduce simple “click and drag” PowerPoint skills and then rotated the children through activities on three computers where they moved virtual base-10 blocks to form two-digit numbers or numbers and words to label pictures of base-10 blocks. She also taught the children to open folders and save the results of the manipulations. Although there were some difficulties with the computer hardware, the students were so highly motivated that they kept coming back to the activities during their free time (lunch and before school).

Janice had been fearful that her Year 2 students would not be able to save, retrieve and “click and drag”. This proved unfounded; the children quickly acquired computer skills. Where Janice needed support from the researchers was in developing activities that appropriately sequenced numeration development and which ensured all connections between materials, language and symbols were made.

Reviewing the study

In the review of the study, three findings became evident. First, for technophobic teachers, the replication of traditional mathematics activities via PowerPoint provided a bridge from the acquisition of computer skills to the implementation of classroom activities.

Reflecting on her achievements, Monica stated, “Well, I’m now a PowerPoint junkie”. She said she was confident in using her computer skill with the class and that she hoped that her children realised the value of computers in mathematics. She proudly said, “They liked my PowerPoint creations!” Andrea also indicated that she had become a lot more confident overall and had tackled projects and basic teaching activities that she would not have previously. She stated, “I feel more able to tackle using technology to integrate other subject areas”. Janice simply cried, “MORE!!!” She described how she used the multimedia projector and prepared tasks involving specific computer skills (“click and drag, copy and paste”) in PowerPoint. As she said, I developed an understanding of
“where I’ve come from” to “where I want to go”. At the end of the study, Monica was very positive, “I am confident to use PowerPoint in my preparation and implementations of my program”; Andrea described how she was very stressed at first but gained confidence as the lessons went better than expected; while Janice described how she was initially concerned, learnt to have confidence in her own planning, and was “most impressed with the eagerness of the children to access computers and work folders in their own time and to complete mathematics and computer tasks”.

Second, where there were no mathematics-education difficulties associated with sequencing or activity type, the virtual materials provided a powerful medium for mathematics learning. Both the weaknesses and strengths of the cases reinforced the importance of ensuring activities: (1) were within students’ zone of proximal development (Vygotsky, 1978) – the jump to complete set tangram puzzles was too difficult for some students in Monica’s class; (2) integrated on and off computer tasks (Kaput & Rochelle, 1997) – the links between real and virtual base 10 blocks and between the paper and virtual tangrams were a source of understanding for students in Monica’s and Janice’s students; (3) were appropriately scaffolded and reflected upon (Bagley & Hunter, 1992; Davis & Rimm, 1998) – this strength of Andrea’s activities appeared to be the reason for her success in the concept of polygon.

Third, teachers’ mathematics pedagogic knowledge remained a major determining factor in enhancing learning when computers are integrated into the mathematics classroom. The study showed that learning is maximised when instruction takes account of: (1) sequencing and connections – this was a particular problem for Monica and the tangram activities; (2) interpretation and construction – Janice needed support to ensure her virtual base-10 blocks activities exhibited both these; (3) sharing and recording findings – this was needed by Monica to go beyond the puzzles to flips, slides and turns; and (4) creative extension – Andrea found she had to add this to her activity sequences. In the study, the teachers believed they lacked expertise in using computers to teach mathematics but not in teaching mathematics itself. Therefore, they were more receptive to advice regarding technology than mathematics instruction. This was particularly evident in the response of Monica when asked what she would do differently if they were to attempt the same project again. She stated that she would learn the features of PowerPoint well beforehand and practise it more (“I would spend more time with giving skill lessons to children, then I’d move slowly through the activities over a longer time”).

Becker (1994) claimed that difficulty in accessing suitable software (time spent searching, getting it funded through the school) has contributed to many teachers’ reluctance to incorporate computer learning in their mathematics programs. However, Sarama, Clements and Jacobs-Henry (1998) argued that teachers’ beliefs about computer learning were of more concern. Their research showed that if teachers believe that mathematics cannot be taught effectively with computers, then they will resist attempts to incorporate them in their classrooms. Thus, there is a need to provide mathematics computer activities that teachers feel are easy to develop, do not require specialist software, and will promote positive learning outcomes. The manipulation of virtual materials described in this paper
meets this need. There were difficulties particularly with respect to sequencing of mathematics content but no problems with confidence in using the computers.

References

Eighteen Year 12 students and 2 cohorts of final-year BEd students (74 students) were shown a “fair” (equiprobable outcomes) spinner with three noncontiguous colours and asked whether each of the three colours had the same chance of “being spun”. Half of the Year 12 students either gave unequivocal incorrect responses derived from inappropriate considerations of sector size or number of sectors per colour, or vacillated between correct and incorrect responses and were unable to make a decision (equivocal). These findings were echoed with the university students although their incorrect responses tended to be more unequivocal than equivocal. Validation through trialing (with the university students) did not help as the results did not show exactly $\frac{1}{3}$ for each colour and, in fact, were interpreted as supporting an incorrect response.

Hawkins and Kapadia (1984) identified four types of probability, namely: (1) theoretical – derived from making assumptions of equal likelihood; (2) frequentist – calculated from observed frequencies; (3) intuitive – generated from personal belief and perceptions; and (4) formal – calculated precisely from the mathematical laws of probability. Of interest to this study are the latter two which relate to intuitive and analytic cognitions (Fischbein & Schnarch, 1997). They defined the intuition cognition as “self evident, directly acceptable, holistic, coercive and extrapolative” (p. 96) which was distinguished from the analytic cognition by “the feeling of obviousness, of intrinsic certainty” (p. 96).

Probability ranges from 0 (impossible event) to 1 (certain event) so possible events are represented numerically by fractions (part of a whole). It is well-documented (Behr, Harel, Post, & Lesh, 1992; Nik Pa, 1989; Payne, Towsley, & Huinker, 1990) that continuous area models are more conducive to facilitating construction of the part/whole notion than discrete set models. Therefore, when developing the part/whole notion of probability, it seems reasonable to begin with spinners (continuous area model in which all possible outcomes are visible) than with coins, dice, marbles, tickets, or playing cards (discrete set models where all possible outcomes often need to be held in memory).

The literature is replete with misconceptions in students’ probabilistic thinking (e.g., Fischbein, 1975; Fischbein & Schnarch, 1997; Hawkins & Kapadia, 1984; Jones, Langrall, Thornton, & Mogill, 1999; Kahneman & Tversky, 1972; Piaget & Inhelder, 1975). Fischbein and Schnarch’s (1997) study set out to determine whether 7 main known misconceptions (e.g., representativeness, negative and positive recency effects, compound and simple events) diminished, increased or remained stable across the years (Grades 5, 7, 9 & 11). They found that the only stable (and frequent) misconception across the ages was related to compound and simple events. However, the example given
refers to the comparison of events in two similar sample spaces. Jones et al. (1999) referred to this type of comparison of events as Level 3 whilst the probability of an event in one sample space was classified as Level 2. They found that even after persistent instruction, misconceptions at Level 2 remained stable for some Year 3 students.

Apart from the subjective and experiential beliefs that students invoke when analysing probability tasks, one of the major problems related to the teaching/learning of probabilistic notions is the difficulty of validating responses because of the large number of trials required. This can be extremely time-consuming and the results are not always persuasive for students who have a deterministic view of mathematics. (See Discussion for elaboration of this point.)

This study explores a very elementary probabilistic notion, namely, the probability of an event in a single sample space (Level 2 – Jones et al., 1999) using a spinner (continuous part/whole area model) with Year 12 students who were individually interviewed on the task to determine the extent of their conceptions (including misconceptions). The study was replicated, to some extent, with university students but was extended to include validation of their conceptions.

**Study 1 – Year 12 students**

*Background.* Sixteen Year 12 students comprising 8 students from an algebra-based university entrance mathematics (designated as UM) and 8 students from a “social” mathematics course that involved no algebra (designated as SM) were involved in this study. Within each of the mathematics categories, there were 4 males and 4 females with 2 high- and 2 low-achievers in each gender group.

This paper reports on one (see Figure 1) of several elementary probability tasks that were undertaken with the students in semistructured individual interviews conducted out of school in the student’s home. The tasks incorporated both continuous area models (spinners) and discrete set (marbles) models.

---

**Figure 1. Spinner used to determine the robustness of student’s probability notions.**

(“Fair” is used to denote equiprobable outcomes.)

*Is this a fair spinner? How can you tell? [Contingent: Does each colour have the same chance of being spun?]*

*If you were playing a game with this spinner, is there a colour that would give you a greater chance of winning? Why?*

---

The spinner used in this study was designed to be provocative, that is, to provoke conflict between intuitive and analytic cognitions. To help students invoke the part-whole fraction notion of probability, a simple area model (familiar to Queensland students) was used but was made more difficult because students were required to *reunitise* (Behr et al., 1992; Baturo & Cooper, 1997, 1998, 2000) either: (1) the red and green sectors as two parts, each of which was equal to the yellow part, thus realising the spinner was actually partitioned into sixths; or (2) reunitise the two yellow sectors as one sector, thus realising the spinner was actually partitioned into thirds. Therefore, although the spinner had only
three colours to consider, the noncontiguous nature of the colours increased the difficulty level of the task (Jones, 1974). Furthermore, to provoke conflict between intuitive and analytic reasoning, the first question was designed to promote analytic reasoning (a consideration of “fairness” – equal chances) whilst the second question was designed to promote the intuitive reasoning that is often invoked by games and winning.

Thus, the task had three main purposes: (1) To determine the robustness of the students’ analytic reasoning in determining the probability of an event; (2) To ascertain whether the students displayed any conflict between visual perception/intuitive cognition (the amounts of colour do not look equal) and analytic cognition (knowing that if the two yellow parts were adjacent, they would cover the same amount of area as each of the other two colours); and (3) To determine whether the student’s dominant form of processing was intuitive or analytic.

Each interview was videotaped then transcribed into protocols for analysis in terms of intuitive or analytic cognitions.

**Results.** The students either responded with a firm conviction regarding the correctness of their response or they vacillated with their answers. To indicate the conviction or the vacillation, the responses for this task were categorised as unequivocal (immediately stated and incontrovertible) or equivocal (ambivalent, indeterminate) with correct and incorrect subgroups within each category. (See Table 1 for the results.)

Only half of the students gave the correct response (including those 2 in the equivocal correct category). Of the two students in the equivocal correct category, Matthew’s (UM/H) initial response was negative, but his change to a positive response was almost instantaneous, perhaps indicating that, to him, intuitive reasoning is still a powerful factor in processing information but not so powerful that it dominates his analytic cognitive processing. The other student, John (SM/H), took about 10 seconds before responding but his explanation was rather interesting.
... because there's an even amount of each colour; like these two [red and green] have the same odds, right, but ... these two [2 yellow] have got to vary between each of their coordinates [indicating the width of each yellow section with the fingers of each hand]; add these [the 2 yellow] both add up and I think they would equal the green and the red.

Of these 8 students who gave correct responses, there was an equal number of the higher-level UM and lower-level SM students, an equal number of high and low-performing students, as well as an equal number of females and males. Therefore, this study did not find that course, achievement, or gender impacted on the ability to process the probabilistic notion of equally likely outcomes analytically.

The incorrect responses were based on strategies related either to number of like colour sectors or to sector area. For example, of the five students in the unequivocal incorrect category, Karoline (UM/L), Marney and Joe (both SM/L) maintained that yellow had more chance of being spun than either red or green because there were two yellow portions and only one red and one green portion. Nicholas (SM/H) and Malcolm (UM/L), however, had no doubts that red or green would have a greater chance of being spun than yellow because each of them had a larger area for the needle to land on than yellow.

The remaining students, those in the equivocal incorrect category (Eddy, Jane, and Kerri), fluctuated between intuitive and analytic processing. Ultimately, though, the intuitive cognition was more dominant than the analytic cognition. Their protocols reveal the conflict invoked by the task.

Eddy: No, maybe because these two colours [yellow] are right opposite so these two [yellow] would have more chances. But if these two [yellow] joined together are the same as these two colours [red and green] then it would be a fair spinner but these two [red and green] would have more chances.

Jane: I think if you put those two [yellow] together, they'd probably be the same as the others but I think that the red and the green are probably more dominant. Like your object [indicating the needle on the spinner] is more likely to land on the red or the green.

At this stage, Jane's (SM/H) understanding of fair and unfair as they applied to spinners was investigated. She was first shown a spinner which was half blue and half orange and asked if this was a fair spinner to use in a game. Jane said that it was because you had the same chance of landing on either colour. She was then shown another spinner which had all equal parts (4 blue, 3 red, 1 green) and all colours were contiguous. Jane said that this was a fair spinner, too. When asked if she were playing a game and could only win if she spun green, she said: Oh, no, it wouldn't be fair then. Oh, do you mean to look at the colours? No, not fair [referring to the original spinner in Figure 1] because there's two of them [yellow].

Kerri's responses were indeterminate on all the tasks and were therefore difficult to probe as the following protocol reveals.

Kerri: Um ... that is not a 50% fair spinner. It's probably 2 thirds.
What colour would you prefer to have in a game?

Kerri: Prefer or most likely?

I: Well, if you say that's not a fair spinner, then one colour must have more or less chance of occurring.

Kerri: Well, it'd be the two yellows because they're smaller and there'd be either the red or the green.

I: Are you saying that red or green would have more chance than yellow or –?

Kerri: Definitely (interrupting). Yes.

Study 2 – BEd students

Background. The task in Study 1 was tendered for discussion in a tutorial/workshop with 2 cohorts of final-year BEd students (39 and 35 students). As for the Year 12 students, responses were either correct, unequivocally incorrect or equivocally incorrect. (The conflict provoked vociferous and robust arguments as each group of students tried to convince the others that their thinking was appropriate.) With respect to the incorrect responses, the university students had the same misconceptions as the Year 12 students. No new misconceptions were proffered.

Validation results. The spinner (with colours) was shown on an overhead transparency and then a transparency copy of the spinner partitioned into sixths but without colour was placed on top (see Figure 2). The students were then asked what the probability was of getting red, green or yellow. For these students, the fact that they could see that each colour had 2 sixths (or 1 third) of the area did not offset their initial intuitive cognitions regarding the fact that one of the colours was split and therefore red or green had a better chance (because of sector size) or yellow had a better chance because there were two parts, albeit smaller parts.

Figure 2. Attempt 1 to "prove" that all outcomes are equiprobable on the given spinner.

The students were then shown the spinners in Figure 3 and asked if any of them were "fair". All agreed that Spinners A and B were fair (A because the colours were contiguous; B because the noncontiguous allocation of the colours was "even") but continued to maintain (or be indecisive) that Spinner C was not.

Figure 3. Attempt 2 to "prove" that all outcomes on the original spinner are equiprobable.
Each class decided that, if this occurred in their teaching career, they would ask their students to undertake an experiment with Spinner C. The BEd students were allocated to 10 groups and each group was provided with a model of the spinner. Each student in the group was asked to spin the needle 10 times and to record his or her result for each spin. Table 2 shows the outcomes of this trial as well as those undertaken by a second cohort.

Table 2
Results of An Experiment Undertaken by Two Cohorts of BEd Students to Validate Predicted Outcomes for Spinner C

<table>
<thead>
<tr>
<th>Results</th>
<th>Red</th>
<th>Yellow</th>
<th>Green</th>
</tr>
</thead>
<tbody>
<tr>
<td>1st cohort (n = 390)</td>
<td>136</td>
<td>117</td>
<td>137</td>
</tr>
<tr>
<td>2nd cohort (n = 350)</td>
<td>116</td>
<td>119</td>
<td>115</td>
</tr>
</tbody>
</table>

Note. In this table, n refers to the number of trials in the experiment.

With respect to the first cohort, the students who had thought that the spinner was not fair because red or green would be more likely to be spun than yellow felt vindicated by this result. They believed that the results supported their prediction that the spinner was not fair. With respect to the second cohort, the students who thought that the spinner was not fair because yellow, with its two parts, had more chance than either red or green also felt that the results vindicated their reasoning. The first cohort was unimpressed by the suggestion that there should have been more trials whilst the second cohort was unconvinced that the results were very close to a third of all trials (indicating a deterministic view of mathematics).

Discussion and conclusions

Cognition. As both studies showed, misconceptions with respect to the spinner in Figure 1, which had only three possible outcomes to consider, were evident in a large percentage of students. Half of the Year 12 students and many of the BEd students gave either an incorrect response or vacillated between correct and incorrect responses when shown the spinner. The incorrect responses revealed that students had two main misconceptions which were an artefact of the task, namely: (1) the larger sectors (red and green) had more chance because they were "dominant" (Jane); and (2) the two smaller yellow sectors had more chance because they gave 2 chances whereas the red and green sectors gave 1 chance only. The students who gave unequivocal incorrect responses appeared to be operating from intuitive cognitions based on comparing either the size of the parts or the number of like colours. That is, they were estimating chances using a part-part ratio schema rather than measuring probability with a part-whole fraction schema (Fischbein, 1975).

This result supported Fischbein and Schnarch's (1997) study in which they found that the probability of an event produced stable and frequent misconceptions across age levels. It also extended their findings by showing that these misconceptions continue into adulthood. Furthermore, the task used in this paper was more simple than the one used by
Fischbein and Schnarch because only one sample space had to be considered, indicating that the problem is deep-seated.

**Validation.** Validation of reasoning was not successful as the results of the 2nd study showed. Neither encouraging reunitising by overlaying a transparent replica of the spinner showing sixths (see Figure 2) nor a consideration of structurally isomorphic spinners (see Figure 3) was sufficient to persuade students to focus on the fraction schema embodied in the task (i.e., analytic reasoning). The university students all stated unequivocally that Spinner A and Spinner B (see Figure 3) had equally likely outcomes (red green, yellow) but maintained that Spinner C (task spinner) did not. Spinner A had all contiguous parts whilst Spinner B had all noncontiguous parts. However, Spinner C had some contiguous and some noncontiguous parts thereby producing the conflict between equality (2 red, 2 green, 2 yellow), inequality through sector size (red and green both larger than either yellow) and inequality through number of sectors (1 red, 1 green, 2 yellow). These inequalities appear to be linked to the part-part notion of ratio rather than to the part-whole notion of fraction.

Validation through experiment was equally unsuccessful for two reasons: (1) the insufficient number of trials produced skewed results (see Table 2), thus inadvertently supporting a misconception; and (2) the students’ deterministic view of mathematics was so entrenched that they were dissatisfied with any result that did not exactly show 1 third of the trials for each colour (as for the 2nd cohort of university students).

**Teaching and learning.** The major implication for teaching and learning is that probability schemata must be connected explicitly to fraction schemata through language, exemplars, and symbols. In this study, the students who vacillated between correct and incorrect responses clearly were unsure as to whether to trust their perceptual/intuitive processing (comparison/ratio) or their cognitive processing (fraction). Eddy, the top-performing mathematics student in his school was obviously perplexed by his inability to decide. He had a well-developed fraction schema but it seems as though he did not realise the validity of this cognition, possibly because his probability learning experiences did not focus on the connection between probability and fractions. As Study 2 showed, this situation is exacerbated by problems with validation. Neither logical argument nor experimentation may convince students of the errors in their answers.

Probability, possibly more than any other mathematical domain, is plagued by a plethora of informal and formal language to denote possible events. A diagram such as that in Figure 4 was found to be useful for the BEd students in this study because it provided an organisational framework for plotting the language “mathematically”.

Teachers need to be aware of the strengths and weaknesses of common probability exemplars and should be guided in their use by sound pedagogical principles rather than by their real-world appeal. For example, the sequence of probability exemplars should follow the sequence of exemplars used to develop the part/whole notion of fractions, that is, continuous area models such as spinners before discrete set models such as marbles. However, spinners can be partitioned in different ways and the outcomes (colours, shapes or numbers) can be arranged either contiguously or noncontiguously. If contiguous parts only are used, students may inadvertently come to rely on the intuitive and inappropriate comparison/ratio schema. Therefore, provocative tasks such as the one in this paper should be incorporated to provoke conflict between intuitive and analytic cognitions to provide insights into the appropriateness of student’s thinking.

In the early stages of learning, the common fraction recording facilitates connection to the fraction schemata required for processing probability tasks. Unlike decimals or percents, common fraction symbols indicate the total number of outcomes (denominator) and the number of outcomes under consideration (numerator).

MOVING SYMBOLS AROUND OR DEVELOPING UNDERSTANDING: THE CASE OF ALGEBRAIC EXPRESSIONS

L. Bazzini, Dipartimento di Matematica dell'Università di Torino
P. Boero, Dipartimento di Matematica dell'Università di Genova
R. Garuti, IRRSAE Emilia-Romagna, Bologna

Abstract
This paper deals with the complex relationship between the meanings and symbols of algebraic expressions. The study reported here uses a theoretical model to interpret some basic dynamics of algebraic thinking in the analysis of students' protocols. The strong difference noticed in protocols by students who have been given very different instructional approaches, suggests further investigation on the sources, mainly in view of educational implications.

Introduction
The complex relationship between the meaning of algebraic expressions and their symbolic representation is a major issue in research. Many authors have pointed out the incapability of relating symbolic expressions to their meaning (see, for example, Linchevsky and Sfard, 1991, Mac Gregor and Stacey, 1996). In the inadequacy of such a relationship are the roots of many misunderstandings, wrong performances and blind manipulations with algebraic symbolism. A consequence of this is that many secondary school students do not master the sense of those symbols which they have learned to handle formally. On the other hand, some students, even if clever "algebraic calculators", seem to be unable to see and use algebra as a means suitable for understanding generalisations, to grasp structural connections, and to argue in mathematics (Boero, 1994).

Our study is originated by noticing strong differences in protocols provided by students: on the one hand "moving symbols around", on the other "good mastery and understanding". This "surface element" has been recognised in need of further investigation, by means of a theoretical model apt to interpret some basic dynamics of algebraic thinking. This application has revealed to be very useful to guess hypotheses about the origin of such great differences in the students' behaviour: as a result we assume that such differences are strongly related to differences in the teaching styles. This report aims at describing the work we have been carrying out, in view of further development as far as school practice is concerned.

The theoretical framework
The relationship between thought and language is a key point in didactic research. Algebraic thinking is generally recognized to be inseparable from the formalized
language with which it expresses itself. However, it is “reductionist” to believe that algebraic thinking exists only at this level. In such a case everything would be reduced to a manipulative mechanism, which often does not work in students' hands.

Vygotsky's theory, with reference to verbal language, suggests a functional interaction between thought and language. They are considered as intertwined and mutually dependent aspects of the same process.

In the specific case of algebraic language, a vygostkyan point of view is taken by Radford (1999). According to Radford, instead of seeing signs as the reflecting mirror of internal cognitive processes, we consider them as tools or prostheses of the mind to accomplish actions as required by the contextual demands in which individuals find themselves located.

Furthermore, signs bear a kind of “embodied intelligence”, in that they were historically built for some purpose and, as such, carry patterns of previous reasoning. Signs, tools and other cultural artefacts, do not speak for themselves, but acquire life in the life of individuals through acts of communication and interaction where they become endowed with meaning.

So, becoming endowed with meaning is at the very core of our investigation.

In the following, we will adopt the theoretical model by Arzarello, Bazzini and Chiappini (1993, 1994, 1995), aiming at interpreting the very nature of algebraic thinking.

This model has taken its inspiration from the epistemological triangle by Frege, which specifies the distinction between sense and denotation of a given expression.

In particular, an algebraic expression (E) incorporates in its writing the mathematical object involved (the denotation) and the way in which such an object is expressed (the sense). For example the expression $y = x^2-2x-3$ denotes a set of couples which satisfies the given relation. This expression activates, for example, the sense (S) of finding y by starting from x, squaring x, subtracting 2x and finally subtracting 3. A different sense (S') could be that of thinking of x and y as coordinates in a Cartesian plane (hence the graphic of a parabola)

Furthermore, if we transform $y = x^2-2x-3$ into $y = (x-1)^2-4$, this new expression (E') activates a new sense (S''), which points out the coordinates of the vertex of the parabola.

Thus, algebraic transformations are closely related to the activation of senses: doing algebra means interpreting expressions and relating them with senses, coherently with the given denotation.

The theoretical model outlined here provides us the means to approach our investigation of the students' protocols, when they face algebraic formulas.
Aims and methodology of the study

In this report we are mainly interested in the differences that students show when required to face algebraic expressions and to relate them to meaning.

Additionally, we are also concerned about the level of awareness students have when dealing with algebraic language and its relationship to instruction.

For this purpose, we addressed our attention to students coming from different instructional treatments and we tried to relate their typical behaviours to the didactic interventions they had received previously.

Our assumption is that different instructional approaches highly influence the mastering of algebraic expressions, especially as far as the triangle sign-sense-denotation is concerned.

In the following, we report the description of four paradigmatic protocols: the first two show a limited and incorrect reading of algebraic expressions, while the others witness to understanding.

Legend: I for interviewer, S for student.

**Student A** (Mario, 16 y.o., medium scores, High School, humanistically oriented course, Liceo classico, traditional teaching).

*I* - $-8x - 3x^2 + 11 = 0$, what is this?

*S* - It is a second grade equation; it could be the equation of a parabola.

*I* - Which kind of equations do parabolas have?

*S* - $ax + bx^2 + c$.

*I* - What?

*S* - Equals 0.

**Comment**: there are conflicting ideas about the word equation. The writing $-8x - 3x^2 + 11 = 0$ is not connected to its denotation. The equation of a parabola is evoked, due to similarity in writing. When requested to make it explicit, the student is not able to link the denotation (i.e. the couples of numbers) of the parabola to its algebraic representation.

**Student B** (Stefania, 16 y.o., high scores, High School, scientifically oriented course, Liceo Scientifico, traditional teaching).

*I* writes

$y = x^3 + 6x$

$y = x^3 + 3x^2$
and says; “Compare these two functions, try to say when a function is "greater than the other" (questo è un modo per dire: quando i punti del grafico di una funzione stanno sopra i punti del grafico dell'altra).

S.: I would make a system (and she puts { )

\{ y = x(x^2+6) \\
y = x^2(x+3)

I: Solving a system means finding the common solution of the two equations, I have asked you just to compare, that is saying when, for example, \( x^3+6x > x^3+3x^2 \).

S: and y, where does it go?, Ah, it is the solution.

I: It doesn't matter

S: So, why is there a y and then it disappears?

I: If you consider the system, you have y = y, thus also \( x^3+6x = x^3+3x^2 \), do you agree?

S: Yes

I: So, go on.

S: I should solve the inequality \( x^3+6x > x^3+3x^2 \), so

\[-3x^2+6 > 0 \quad \text{and} \quad -3x(x-2) > 0 \]
\[ -3x > 0 \quad \rightarrow \quad x < 0 \]
\[ x-2 > 0 \quad \rightarrow \quad x > 2 \]

and this is what she wrote

\[
\begin{array}{ccc}
0 & 2 \\
+ & - & - \\
- & - & + \\
- & + & - \\
\end{array}
\]

\[ 0 < x < 2 \]

I: What does that mean?

S: Perhaps, if I substitute a value which is between 0 and 2, the equality is true. But I don't know if it is true, or whatever. That is, maybe the inequality is true.
Comment: Stefania feels lost in front of symbols. This task is not a standard task for her, however, she has all the knowledge needed to solve the problem.

As for student A, this student evokes senses starting from a very superficial reading of the formula. The writing of the functions evokes the sense of solving a system, which is totally out of place here. Also, in following the procedure, no connection between signs, senses and denotations seems to exist.

Student C (Davide, 14 y.o., medium scores, Junior Secondary School, teaching strongly oriented to understanding and verbalizing)

I: Take the function \( y = x^2+3 \): what does it remind you of? Do you first think of numbers which change or how the graphic might be?

S: \( y = x^2+3 \) I first think of the graphic, which is a raised parabola with the x axis of 3 cm. This helps me to understand how it works. In fact, with positive numbers, \( x^2 \) increases \( y \) of 0, 1, 4, 16... and with the negatives it increases on the opposite side. Then +3 does not allow the values to reach zero \( 0^2+3=3... \)

At the beginning, I think of the formula without doing any calculation, because I know how it works in each part...

I: Namely?

S: \( y = x^2+3 \) is like taking two equal numbers, multiplying them and adding 3 to the value: 3 increases the value. Within the negatives, the two numbers which have been multiplied become a positive in any case, because we know that + \( x++=+ \) and -\( x-=+ \).

This is the reasoning when facing a formula, after having seen the formula I see the graphic which represents the formula itself.

Finally Davide concludes:

The function is a unique thing. It is important to consider it as a whole, however it is important to understand each part, in order to grasp it globally.

Comment: Davide clearly shows a holistic view of the function \( y = x^2+3 \). The numbers which change and the related graphic are closely related and Davide is able to pass from one sense to another easily. This student also shows a global approach to the notion of function in general (the function is a unique thing...).

Student D (Federico, 14 y.o., high scores, Junior Secondary School. Same class and same teacher as Davide)

Federico has the same task as Stefania (student B): He is required to compare these two formulas from an algebraic and graphical point of view, then to guess how the graphic is and finally he has to draw a sketch.

\[ y = x^3 + 6x \]
\[ y = x^3 + 3x^2 \]
Here is Federico’s solution

**Algebraic comparison**

- the first part is the same in both formulas
- they are two curves, because the increment from one value to another is greater every time
- if x is positive, then y is positive too, because there are no “minus signs” in either formula
- if x is negative, then in the first formula (the right side) is negative too, because $x^3 = x \cdot x \cdot x$ and $((-x) \cdot (-x) \cdot (-x))$ and also $6(-x) = \text{neg}$. In the second formula y is positive from -3 to 0, because $(-3)^3 + 3 (-3)^2 = -27 + 3 \cdot 9 = -27 + 27 = 0$. From -3 down, i.e. -4, -5, etc, y becomes negative because the first piece becomes greater and greater, after 3, than the second one.
- the first formula is greater than the second one from 0 to 2 and smaller from 0 down and from 2 up.
- If $x=0$, then $y=0$ in both formulas, because $0^3 + 6 \cdot 0 = 0 \quad 0^3 + 3 \cdot 0^2 = 0$

**Graph comparison**

- they are two curves, because the increment from one value to another is greater every time
- and he does the following calculation

\[
\begin{align*}
y &= 2^3 + 6 \cdot 2 = 20 \\
y &= 3^3 + 3 \cdot 2^2 = 20
\end{align*}
\]

\[
\begin{align*}
y &= 3^3 + 6 \cdot 3 = 27 + 18 = 45 \\
y &= 3^3 + 3 \cdot 3^2 = 27 + 27 = 54
\end{align*}
\]

- they pass through the origin, because there are not + with fixed numbers which are not multiplied by x
- the first curve passes through the first and third quadrant, because when x is positive, then y is positive too; when x is negative, y is negative too. The second curve passes through the first, second and third quadrant, because if x is positive, then y is positive. If x is negative from 0 to -3, then y is positive because the first term is negative and the second positive, but the second term is greater because it is multiplied by a number greater than x, then it goes to the negatives, because the first term becomes greater than the second, in terms of numbers, not of signs.

628
Predicting the curves

- they are two curves, because the increment from one value to another is greater every time
- they pass through the origin
- the first curve passes through the first and third quadrant
- the second passes through the first, second and third quadrant.

Finally, he draws the graphs correctly

Comment:

This student has a great mastery of algebraic symbols and he relates them to the graphical representation. Different senses are activated and they work together.

As in the case of Davide, Federico is able to manage the triangle sign-sense-denotation. This allows him to approach and solve the problem easily, notwithstanding the lack of advanced mathematical techniques (this task was given at the end of junior secondary school).

Provisional results and implications for teaching

The protocols show quite different behaviours: students A and B seem to move symbols around, while students C and D are much more concerned with understanding. The theoretical model allows us to read such behaviours in terms of the sign-sense-denotation relationship. Starting from an algebraic formula, different senses can be activated: some of them are coherent with denotation, some others not.

Students A and B evoke senses starting from a very superficial reading of the formula. Mario evokes the equation of a parabola incorrectly, due to similarity in writing. Similarly, Stefania evokes the sense of solving a system, when facing the writing of two functions. For both students, no connection between signs, senses and denotations seems to exist.

Things go differently for students C and D, who approach and solve the task from a very global point of view.

Davide approaches the function \( y = x^2 + 3 \) by considering the changing numbers and the graphical representation. He is also able to pass from one sense to another easily. A similar behaviour is noticeable in Federico's protocol: both students master algebraic symbols and are able to relate them to the graphical representation of the functions. In short, the triangle sign-sense-denotation is handled fruitfully.

Let us remind that the NCTM Principles and Standards 2000 suggest "...Being able to operate with algebraic symbols is also important because the ability to rewrite algebraic expressions enables students to re-express functions in ways that reveal different types of information about them" (p.301).
As already pointed out, the analysis of the protocols has suggested a closer investigation on the origin of such great differences.

Our main assumption now is that previous instruction plays a major role. In fact students A and B come from a traditional approach: they are able to solve standard tasks (for example that of solving equations) but feel lost when required to handle symbols and meaning. On the other side, students C and D (who are two years younger) have been provided with innovative teaching, strongly oriented towards understanding and verbalising. From early algebra, these students have been asked to compare different expressions and different senses, with special attention to link geometrical investigation to the representation by numbers and letters. Furthermore, the use of metaphors have been highly encouraged: teaching and learning algebra has been framed in an embodied cognition perspective (Bazzini, Boero and Garuti, 2001). Further investigation on long term research (Malara, 1999) is needed to confirm our assumption: specific teaching experiments have to be designed to suit this purpose.

Finally, focusing on implications for teaching, we remind that, according to the NCTM Principles and Standards 2000, algebra is much more than moving symbols around. Doing algebra is not just formal manipulation, but rather a competence which deeply involves understanding. In this perspective, new emphasis should be given to research studies on the mutual relationship between algebraic expressions and their meaning and, consequently, on related educational choices.

PROFESSIONAL DEVELOPMENT THROUGH CLASSROOM COACHING

Joanne Rossi Becker
San José State University, USA

Abstract

This paper presents preliminary results from an ongoing study of classroom coaching in elementary mathematics classes. Seven teachers who have been involved in a professional development program for several years are released from the classroom to work as coaches. I have been observing the coaches in their coaching work, and also observing the teachers whom they are coaching. The purpose of the research is to ascertain whether coaching is effective in improving instruction in mathematics. In this paper I identify three styles of coaching I have observed, and discuss their promise for promoting classroom change.

Purposes

The main purpose of this ongoing project is to investigate the efficacy of classroom coaching in improving instruction in elementary mathematics classrooms. The coaches involved in this study have been participants in a state-funded professional development program for a number of years. That program includes three major aspects:

• an intensive 3-week summer institute focusing on mathematics content, pedagogical content knowledge, and leadership skills;
• summer lab schools for children organized and run by participants, who themselves, with staff support, provide professional development for team teachers who teach the classes;
• comprehensive follow-up activities including workshops with leading national and international mathematics educators.

Part of the leadership development strand has included training in classroom coaching, using a peer coaching model. With private foundation funding, the coaches in this study have been released from classroom duties to be full-time coaches in mathematics in their districts. This ongoing study has been designed to ascertain the impact these coaches are having in the classrooms in which they work, and indirectly, the impact of the professional development in which they have participated. In particular, the study was designed to document how coaches worked, how they interpreted their roles, and how they affected the teachers with whom they worked.

* This research has been partially supported by a grant from The Robert Noyce Foundation. Views expressed are those of the author alone, and do not represent those of the Foundation.
Background

In the last edition of the Handbook of Research on Teaching, the chapter on mathematics education (Romberg & Carpenter, 1986) hardly mentions research on in-service teacher education. As Grouws pointed out (1988), and as is still the case, there is little information available about the overall design features of in-service education programs which maximize changes in teacher beliefs and ultimately classroom practices. Grouws called for studies that focus on the impact of various features of in-service education on classroom practice. More recently, the Handbook of Research on Teacher Education (Sikula, 1996) does not even include coaching in the index of the volume. The meager research that has been reported in mathematics about classroom coaching as a means of professional development predicts considerable promise for this technique. For example, Becker and Pence (1999a,b) identified classroom coaching as the most important component of a professional development program for secondary teachers. In these studies, the coaching was done by the authors, who also designed and implemented the whole professional development program. Coaching that was intended as a non-evaluative mechanism for identifying the impact of the professional development itself became the most important aspect of the in-service for participant teachers. Those studies concluded that coaching might itself be a worthy, though time-consuming and expensive, planned component of professional development.

There are a number of models of coaching extant within the educational community. For example, Evered and Selman (1989) define coaching as conveying a person from where he or she is to where he or she wants to be. The metaphor of an old stagecoach communicates this perspective. In this model the teacher is considered a thoughtful decision-maker who, through support and collaboration, can further develop her/his ability to reflect on and improve instruction. A second model is content-focused coaching (Institute for Learning, 1999), which focuses on the content of the lesson in relationship to issues at the core of the teaching-learning process. From my reading and viewing of videotapes in which content-focused coaching is used, it appears to be a bit more directive, in that the coach may use the pre-conference to "teach" content to a teacher who seems to lack content knowledge related to the lesson, may interrupt the lesson and even take it over, and may provide her/his own solutions during pre- or post-conferences. However, both models have the following characteristics in the ideal situation: a pre-conference to discuss the lesson and its goals and the teacher's focus for the observation; an observation of the lesson in which the coach records as much data as possible; and a post-conference to debrief. Coaching might also include demonstration lessons, co-teaching, or joint lesson planning. In this study I applied aspects of both models during observations of coaching sessions as seemed appropriate. That is, I focused on
interactional moves of the coach, such as listening skills, strategic questions, and use of feedback, as well as content specific moves, such as clarifying the goals of the lesson, anticipating and diagnosing difficulties, or reflecting on students' attainment of lesson goals.

**Methodology**

This was a qualitative study using participant observation techniques (Glaser & Strauss, 1967). Observation sessions varied depending upon what the individual coach had planned and how s/he worked with teachers. For example, one coach, Lewis, is working with two fourth grade teachers at the same school. They plan lessons together in a meeting a day or two before the lesson. Then the coach views half of the lesson with one teacher and half with the other, and holds a joint post-conference with both teachers during lunch. Because of scheduling and prohibitive distances involved, in this case I meet with the coach before the lessons to determine what was discussed in the pre-conference. Then we jointly observe the classes, interacting with the children as they work on activities. I observe the post-conference, providing my input when asked or when it adds to discussion of, for example, student work. In this case I am more on the observer end of the participant-observer continuum.

In another case, I spend the whole morning at a school with the coach, Nellie, and the two fifth grade teachers with whom she is working. We have a brief pre-conference with each separately, one before school, the other during a break, identifying areas of focus for the observation. We observe the whole mathematics lesson of each teacher, with the coach making notes that she hands to them during the post-conference. The post-conference usually takes place with both teachers during lunch. There are other variations but space limitations preclude discussing these.

All notes from observations and interviews with teachers and coaches are typed and expanded, with patterns and questions to investigate further identified as work progressed (Glaser & Strauss, 1967). The aim is to identify patterns of coaching work and its impact on teachers, and subsequently, to ascertain how participation in the professional development program has affected the coaches and their work. Data include field notes, interview transcripts, and artifacts from the classrooms such as assessments.

**Data Sources**

The study is ongoing during the 2000-2001 academic year. Seven coaches are being observed, each with at least one teacher, for a total of 13 teachers and 7 coaches. Due to space limitations this paper will discuss the case of three coaches, here called Lewis, Nellie, and April to preserve anonymity.
Lewis is a former middle school teacher who has been with the professional development project for three years. This is his third year as a coach. Lewis is a European American male who has been teaching over 20 years. He works in a small district of eight K-8 schools in northern California. This district uses Mathland as its curriculum at the elementary level, and Connected Mathematics for middle school. College Prep Math is also used for two eighth grade algebra classes. Lewis is working with two fourth grade teachers, Sally and Susan, both young and relatively new teachers.

Nellie is a former intermediate school teacher who has been with the professional development project for two years and is in her second year as coach. Nellie is a European American female with over 30 years of teaching experience. She is working with two female fifth grade teachers, one in her first year of teaching. Nellie works in a small K-8 district in an urban area with a very diverse student population. Many students are emerging English learners, especially in the primary grades.

April is a former primary teacher who works in a small-city unified (K-12) district. April is a European American female with 15 years of experience. She has been in the project for five years and a coach for three. April is working with two first and two second grade teachers and I am also observing two other teachers with whom she has worked in the past (third and fourth grades). Here I will be focusing on her work with the primary teachers.

Results

At this point in the study three different modes of coaching have been identified based upon how the coaches interact with the teachers with whom they are working and on how they seem to define their role. I am calling these: coach as collaborator, coach as model, and coach as director.

Coach as collaborator. Lewis is an example of what I am calling a “coach as collaborator.” He endeavors to be one of the group of three who are working on this lesson together. Thus the post-conferences tend to be about the structure of the lesson rather than specific as to how each teacher implemented the planned lesson. In fact, by viewing half of each lesson for Sally and Susan, Lewis cannot really ascertain how the second teacher developed the core of the lesson [he does switch order each visit]. Lewis does not keep written notes from the lessons, and does not give the teachers written feedback. However, he works closely with children, frequently asking questions, and seems to have a good sense of what they are understanding. For example, in one lesson the teachers were developing multiplication facts greater than 10; they wanted children to work them out without use of the standard algorithm. In Sally’s class, as students shared their methods orally, it was clear that this was difficult for those who knew the algorithm. One girl even verbalized the whole standard algorithm by visualizing...
it in her head (the problem was 12x6). Both Sally and Susan noted in the post-conference that students seemed wedded to an algorithm. Lewis had noticed in his questioning of children in both classes that many did have other strategies for figuring out 12x6. Lewis suggested to the teachers that they ask children to find more than one way to do the problem to get them beyond an algorithm. Sally and Susan liked this suggestion, and in later observations, both were observed asking for more than one way in other contexts.

Although much of his work is collaborative, it is clear that Lewis has a slightly different role from that of the teachers. He provides performance assessment practice items for teachers’ use, scores them for the teachers, and does the class presentations of the problems and the rubric scoring to help children get familiar with that type of testing. Although Lewis does not provide feedback specific to how a teacher organized the lesson, he does concentrate on what students seemed to understand. By being active in the classroom, watching and questioning students, he gleans considerable information about student understanding to share with teachers. From Lewis’ perspective, perhaps the most important part of his role is encouraging and facilitating the team planning and reflection that are occurring. Without his presence as coach, this level of collaboration would not be taking place. The planning time forces each teacher to think through the lesson, its goals, and how they plan to implement them beforehand. Because they are working as a team in this way, they have a mutual responsibility for the lesson and its pros and cons. The teaming that Lewis has encouraged has extended to consistent planning throughout the week, even when he is not visiting. Thus Lewis’ model encourages the elimination of the isolation many teachers in the USA feel by working alone in their own classrooms.

On the other hand, lack of specific feedback to each teacher precludes Lewis from the possibility of influencing the teachers’ teaching strategies. A lesson may be the same but may be implemented in quite different ways. Thus Sally has a need for full control at all times in her classroom, so that she shows students exactly how she wants them to do problems. This discourages multiple methods of solution, such as sought for 12x6. Susan’s more open style generates more ways of solving problems. Peer visits or feedback on pedagogy might provide both with more ideas on instructional strategies that would lead to further mutual professional growth.

Coach as director. Nellie is an example of what I term “coach as director.” Nellie’s model of working with Harriot and Debra is much more directive. Although in the pre-conference she asks them what they would like her observation to focus on, Nellie feels free to interject her opinion on something that occurred in the lesson even if that was not the specific focus of the observation. For example, in one observation of Harriot, the teacher had the children start on a two-day lesson in which they had to measure 100m outside the room. After some
measurement of the room and estimation of 100m, she asked how they would actually measure 100m. By very persistent questioning and major hints, she finally got someone to say what she had intended: to make a longer measuring instrument than the meter stick using register tape. Nellie felt that Harriot should have given students more opportunity to develop their own method rather than leading them to “her” way. She told Harriot that after the observation, and wrote it in her notes to her. While Lewis might have raised a question and collaboratively worked with the teachers to come up with alternative strategies, Nellie was very explicit as to what Harriot should have done.

Although Harriot and Debra teach at the same school, there has been no attempt at team planning and in fact on each visit they have been teaching totally different units of content. Nellie seems to view her role not so much as “fixing” teachers but very directly providing guidance and alternative strategies that she believes will work. As Nellie is much older than either Harriot or Debra, the relationship seems to be a motherly one, in which direct guidance is accepted rather than resented. Thus Nellie seems to have quite good rapport with both teachers. However, I have yet to see either teacher subsume Nellie’s suggestions into her own repertoire of teaching strategies. Perhaps Nellie’s style is not supporting instructional change in the way she might like because she is not promoting thoughtful decision-making and self-reflection with these two teachers.

Coach as model. April exemplifies “coach as model.” April has developed a unique way of working with teachers new to her. First she presents several model lessons, leaving the teachers materials and ideas on how to continue that work until her next visit. Then she moves into modeling a peer coaching model, in which she is the teacher and the classroom teachers act as coach for her. Then she plans to facilitate, by covering their mathematics classes, their serving as peer coaches for each other.

For example, I observed two second grade lessons that April did several weeks apart. In the first lesson, April was investigating growing patterns. She first modeled finding the first five steps in a geometric pattern on the overhead projector, engaging the children in finding the pattern and describing how it was growing. Next children were given pre-made patterns to copy with cubes, then extend to the fourth and fifth steps. Patterns ranged in difficulty and were exchanged as children completed them. April did this lesson in both classes for each teacher, then left the materials behind asking them to give children more practice in finding growing patterns and extending them. At the next lesson, a two-day one, children had to complete five steps of a pattern with cubes, then color in the first five steps on inch grid paper, then make a poster of their pattern and a description of how it grew. This lesson ramped up the concept as children had to also fill in a table showing how many cubes were used at each step; this was also modeled with the whole group. Interestingly, April adjusted her
instruction of the second lesson in the second class as one aspect, looking for patterns in a 100s chart, confused the children. This difficulty and her adjustment provided interesting topics for discussion after the lesson.

Thus April is acting as a model on several dimensions. She presents exemplary lessons and is always prepared with materials, manipulatives, and everything needed for the lesson. Her lessons always begin with a whole-group activity in which she models what she would like the children to do. She clearly does long-range planning as teachers can infer from the work she leaves them to do. She wants them to do peer visits, so she first models that to help them understand and feel comfortable with it. Perhaps it is April’s background in primary school that makes her affinity for modeling so ingrained.

Summary

This study identified three different ways of coaching. These could be considered to range on a continuum from less to more directive. April is perhaps the least directive as she tries to stimulate professional growth in teachers through modeling. Lewis is still quite non-directive, but he does raise questions regarding instruction that he tries to work through with the teachers through collaborative dialogue. Nellie is the most directive of this group, explicitly giving her opinions and suggestions even if not requested. Since I have yet to see the teachers with whom April is working teach on their own (this is a slow development April has planned), I cannot judge directly how her approach will impact their teaching. But teachers seem somewhat awed by what their children can do mathematically and seem eager to emulate April’s approach to classroom discussion. Lewis seems to have had a positive affect on the teachers with whom he works by encouraging their own decision-making and by encouraging the collaboration which they have transferred to all lessons. Nellie’s approach seems to have the least potential for stimulating teacher growth; no substantial changes in teachers’ instruction is evident at this point in the study.

Of course these are three individuals who have a personal style that must match their own personality. I would not want to generalize that everyone should work in one style. However, these three cases are thought-provoking and stimulate questions that will be investigated with the rest of the sample of coaches:

Is there a style of coaching that is most efficacious in promoting growth in teachers?

Is there a range of skills and dispositions that are needed by a coach?

What is effective coaching?
How does a coach develop a practice of effective coaching?

ADAPTING PIRIE AND KIEREN'S MODEL OF MATHEMATICAL UNDERSTANDING TO TEACHER PREPARATION

Sarah B. Berenson, Laurie O. Cavey, Matthew R. Clark, and Katrina Staley
North Carolina State University

Abstract
This theoretical paper examines a conceptual framework for studying prospective teachers' understanding of what and how to teach high school mathematics. The framework draws from Pirie and Kieren's model of mathematical understanding and incorporates ideas from Schoenfeld, Ma, and Lave. Several conjectures are made for future study in relation to folding back and primitive knowledge.

1.0 Focus. The focus of this theoretical paper is to examine the model for mathematical understanding proposed by Pirie and Kieren (1994) with respect to the preparation of high school mathematics teachers. We adapted the model for teacher preparation to accommodate for prospective teachers' understanding of school mathematics and their understanding of strategies to teach school mathematics.

2.0 Conceptual Frameworks. Among three distinct types of research frameworks, Eisenhart (1991) proposed that conceptual frameworks bring more flexibility to the research process than those based on theory or practice. She argued that the adoption of frameworks built exclusively from a single theory excluded the reporting of a broad range of results whereas conceptual frameworks provided a more comprehensive approach to the intended inquiry. The conceptual framework described in this paper scaffolds several broad ideas related to teaching and learning. They include what prospective teachers plan to teach [school mathematics], and how they plan to teach [teaching strategies]. The framework is intended to capture the dynamic process of learning over time and task.

Schoenfeld (1999) expressed the need to bridge the two dominant theoretical frameworks in education - cognitive and social. He proposed that theories or models of content competencies and acting-in-context have potential to span the divide between the two current research traditions. Further, Schoenfeld proposed that researchers consider how to maximize their contributions to fundamental understanding and, at the same time, contribute to practice. Studies of teachers in context, conducted by Schoenfeld’s Berkeley team, are cited as examples of research directed toward the development of a theory of thought and action. This study draws from this proposition with respect to studying prospective teachers’ understanding of teaching high school mathematics in the context of teaching tasks. Related to Schoenfeld’s work is the Ma (1999) investigation of elementary teachers’ content knowledge [thought] and strategies [action]. Ma chose to examine what Chinese and American elementary teachers’ knew about topics in school mathematics and the strategies they selected to teach those topics. This approach gave more depth to her investigation of teachers’ understanding of teaching mathematics.
The model of mathematical understanding proposed by Pirie and Kieren (1994) is a keystone of this conceptual framework. Modifications were made to accommodate for the cognitive and social dimensions of what the prospective teachers understand about school mathematics and teaching strategies. From the model of mathematical understanding we drew heavily upon the first five activities in the model: 1) primitive knowledge, 2) making an image, 3) having an image, 4) property noticing, and 5) formalizing. The meanings of these activities, as defined by Pirie and Kieren, were maintained for this framework. Their model was used to examine processes related to mathematical understanding, but we are proposing to adapt that model to study prospective teachers' understanding of what and how to teach. We expanded the Pirie-Kieren model to accommodate for the tasks of teacher preparation. Tasks such as lesson planning, teaching, and assessment all require an understanding of what and how to teach. A prospective teacher may have formalized the school mathematics related to rate of change, but is making an image of what teaching strategies to use to teach rate of change. The conceptual framework considers the understanding of school mathematics to be a function of mathematical understanding in which prospective teachers access their primitive knowledge of mathematics to make connections with what is taught in high school. Depending on the amount of mathematical study, the prospective teachers' primitive mathematical knowledge can be extensive. The primitive knowledge of teaching strategies, on the other hand, may be quite limited for the prospective teachers. This dichotomy will be discussed later in this paper. The process of folding back, taken from the Pirie-Kieren model, is a critical feature in changing the prospective teachers' understanding of teaching.

3.0 Related Literature. In this section we will briefly review two areas of the literature that Schoenfeld (1999) suggested as having potential to bridge the cognitive versus social divide. We consider those who have used frameworks built around content competencies and those who have approached their inquiry from an acting in context perspective.

3.1 Content competencies. Skemp (1976) argued that for mathematics teachers to make a reasoned choice between instrumental and relational approaches to instruction (how to teach) they require a relational understanding of the mathematics (what to teach) itself. His ideas laid the groundwork for many mathematics education research efforts related to content competencies. Ball's (1990) research illustrated the importance of relational or conceptual understanding when prospective elementary teachers attempted to develop application problems of division of fractions. In a study of Chinese and US elementary teachers, Ma (1999) noted that "a teacher's subject matter knowledge may not automatically produce promising teaching methods or new teaching conceptions" (p. 38). She suggested that new ideas about teaching (how to teach) cannot be realized without strong support from subject matter knowledge (what to teach). We assumed that prospective teachers' knowledge of what and how to teach is enriched with both instrumental and relational understanding of mathematics.
3.2 Acting in context. Lave (1991) claimed that the decontextualized practices of schooling contradicted her theories of learning in context but suggested that a view of peripheral participation may prove valuable in analyzing learning in school settings. She defined peripheral participation as actions within a community of practice over time and discussed changes in the apprentices’ thoughts and actions. A number of researchers in mathematics education have situated their studies within the classroom to analyze students’ or teachers’ thoughts and actions within specific contexts over time. Maher and Martino (1996) reported on a five-year study of the thoughts and actions of one student’s developing understanding of mathematical proof. An international study of prospective teachers’ understanding of area within the context of a lesson planning activity reported a variety of thoughts that apprentices as peripheral participants bring to the community of practice (Berenson, et al. 1997). In a much larger study, Eisenhart et al. (1993) examined the many contexts of the educational communities affecting practice to better understand the field experiences of one prospective teacher. Decontextualized practice, the key term in Lave’s description, is of great importance to the conceptual framework proposed here. We contend that to maximize prospective teachers’ experiences as apprentices in the community of teaching high school mathematics, their preparation must engage them in the tasks of teaching. This does not imply that all tasks occur in the classroom with students; teachers can engage in a variety of tasks outside the classroom, such as developing lesson plans and creating assessments. These tasks are repeated in one form or another and occur over time as the prospective teachers participate peripherally within the community of mathematics teaching.

4.0 Activities of Understanding. In this section, descriptions of the first five Pirie-Kieren levels of understanding are given with some data from previous research. Together they are intended to clarify the application of these levels to our conceptual framework. In the previous study, prospective teachers were asked to plan a lesson to introduce the concept of rate of change to an Algebra 1 class and to relate the concept to ratio and proportion. The lesson plan was viewed as acting in context while content competencies were needed to complete the task. Individual interviews were conducted before and after the planning task. Subjects were 19-21 year old undergraduates with Grade Point Averages between 3.2 – 3.75 [out of 4] who had completed 6-8 university mathematics courses.

4.1 Primitive knowledge. Primitive knowledge was defined by Pirie and Kieren as all that is known mathematically before coming to the new learning task. There were several aspects of primitive knowledge accessed during the interviews including college mathematics, college physics, college chemistry, school mathematics [what], and teaching strategies [how]. We defined school mathematics of this task to refer to the specific mathematics (rate of change) and the related mathematics, such as, slope, fraction, ratio, proportion, and rate.

4.2 Making an image. At Pirie and Kieren’s second level, image making, one uses primitive knowledge in new ways. In their model, one’s image-making activity is an important step toward the understanding of a mathematical concept.
Amy’s Lesson: An Example of Image Making
What to teach: Interpreting changing rates
How to teach: Collecting and representing distance/time data

The following excerpt is an example of Amy’s image-making process in terms of what to teach [school mathematics]. She began tentatively to explain the relationship between the circumference of a circle to pi as an example of a ratio. The interviewer’s prompt caused Amy to revise her formalized definition of a circle’s circumference, folding back to make an image of the relationship between the circumference and the radius.

A: ... what I was thinking about is the way that pi is related to ... kind of makes a ratio out of the circumference and the radius, maybe.
I: What happens if you solve algebraically for pi?
A: [Considering the formula c=2πr, she divides both sides of the equation by 2r to solve for pi] Yeah, the circumference over 2r. I think that is what I was thinking about.

One teaching strategy developed by Amy involved students in collecting distance/time data using toy cars and stopwatches. Making an image of how to teach, she tried to explain her ideas to the interviewer. In the process, she remade her image of how to teach, deciding that a table of data was better than recording the data directly onto the graph.

A: ... they want to go another 50 and maybe do it slower or faster. And then plot the next point, how long it took them, for the second time, and then do it a third time for another 50 centimeters. ... And you know, now that I think about it, it might be even easier to have a little chart of first time, second time, third time and the distance for each time already given.

4.3 Having an image. According to Pirie and Kieren, image having occurs when a person uses a mental construct to assist his/her understanding without having to repeat related activities. One has an image when he or she can mentally manipulate ideas to consider different aspects of the learning tasks.

Chris’s Lesson: An Examples of Image Having
What to teach: Comparing distance/time ratios and calculating rates of speed
How to teach: Collecting and calculating distance/time data

Throughout the pre-planning interview Chris had an incorrect image of ratio as fraction.

C: I remember from the early years doing shading in squares and parts of the circle. And how much of the squares this covered. That’s the majority of what I remember.

Then she drew a representation to explain her meaning of ratio. She drew a 3x3 square, shaded 4 out of the 9 squares, and explained that the ratio of shaded parts
was 4/9. The lesson planning process helped Chris to fold back, changing her image of ratio as fraction as is shown below.

Chris had an image of how to teach rate of change that involved her students going outside to collect walking and running data using meter sticks and stopwatches. She was able to mentally manipulate her image of data collection to describe how those data would be used for teaching back in the classroom.

C: And then when you come back inside, [we will] talk about what we did and put up an example on the board of how we can use these numbers to find a rate of how fast we were traveling. ... if Jane ran 12 meters in 3 seconds what is her rate in meters per second? So that is like two ratios.

4.4 Noticing properties. Pirie and Kieren explained that property noticing occurs when one manipulates or combines aspects of an image to identify related properties or contexts. This level of understanding is closely related to the images that the prospective teachers made and had about their lesson plans.

Sam’s Lesson: An Example of Property Noticing
What to teach: Solving missing value problems
How to teach: Students working problems and teacher demonstration

Sam planned for her students to use hands-on materials while working in small groups to solve a missing value problem. Explaining her solution, she noted that one way to solve the problem was to use the simplest whole number ratio and that another option was to find the unit rate. This demonstrated her noticing properties about the ways proportions can be solved and ratios can be simplified.

S: I would give them the trophy problem that was in the book and then each group would have blocks... and fake dollars... If they struggled with this, I would ... help all of them see the ratio of 3 blocks to 2 dollars and then go through my solution of the tall trophy... Our rate of cost here is $2 per 3 blocks. We could also break this down into ... I can show them how we could call it $2 for 3 blocks or 67 cents per block.

Sam had noticed properties of teaching with concrete materials and their usefulness in teaching mathematical ideas to high school students. She based these properties from her lab experience in a high school classroom.

S: [The lab teacher] didn’t use hands-on manipulatives, and I could see a lot of students struggle with that. I would use hands-on manipulatives.

4.5 Formalizing. The activity of formalizing occurs when a person identifies common features of the image he or she has made. Examples include finding patterns, applying an algorithm, or creating a formula.

George's Lesson: An Example of Formalizing
What to teach: Unit conversions of rates
How to teach: Calculations, data collection, graphing
George formalized his meaning of rate of change to be the slope of a line, a derivative, and speed, but when describing what he would teach, he focused narrowly on only one aspect of rate of change, unit conversions.

G: I looked at [the lesson from] more of a physics standpoint than a trig-math standpoint. I figured the most important thing about proportions and rate of change is the units because if you have the units wrong the answer is wrong. I would start with some basic unit measurement and conversion type deals.

George planned to ask students to collect time/distance data using toy cars, stopwatches, and tape measures and then work through a series of unit conversions. The interviewer's comment below encouraged George to fold back to make a new image of how to teach.

I: Would you have them do any graphs along the way to look at representations like the one you drew earlier?

G: I think that after we did all the units and stuff, we'd graph the speed of the car. I think I would do one on the board or overhead and say OK, so this is time and draw a straight line like I did before. Depending on whether or not they had slope yet, I would introduce that to the class.

4.6 Folding Back. As defined by Pirie and Kieran, folding back is a revision process that occurs when a new issue is raised with respect to one’s current understanding. It is a recursive process in which a person folds back to an inner level of understanding in such a way as to inform and change that inner level. For example, Amy folded back to her primitive knowledge to remake her image of how to teach rate of change to include a table-making activity for her students. She also folded back from her formalized knowledge of school mathematics to remake her image of the relationship between circumference and radius. We consider folding back to be critical to the development of prospective teachers’ understanding of what and how to teach high school mathematics. In George’s example, the interviewers were unable to precipitate his folding back from the formalized level of unit conversions to remake his image of what to teach about rate of change.

5.0 Conjectures and Implications. In this paper we were prepared to discuss and apply Pirie and Kieren’s first five levels of understanding activity. As our research expands to involve tasks of teaching in the classroom, results may inform the last three levels of prospective teachers’ understanding: observing, structuring, and inventising. From another perspective, perhaps only expert teachers attain these outer levels and that they do not pertain to apprentices. We have made several conjectures for future discussion among ourselves and other researchers. The first conjecture involves the critical nature of the process of folding back to extend and expand prospective teachers’ understanding of what and how to teach. The second and third conjectures consider the retrieval and storage functions of primitive knowledge of school mathematics and teaching strategies.

Conjecture 1. Folding back is critical to the development of prospective teachers’ understanding of what and how to teach and can be prompted by conversations.
with others. This function of understanding appears to be critical to the preparation of teachers and one that we will explore more fully in future research. The interviewing processes of the lesson plan task opened a dialogue between the mathematics educators and the prospective teachers in such a way as to encourage the apprentices to rethink their knowledge of school mathematics and approaches to teaching. An important feature of the dialogues was that they were focused on the lesson planning task, thereby situating the conversations in context. The implications of this conjecture to teacher preparation is that extended dialogues between educators and apprentices can increase understanding if situated within apprentice tasks involving what and how to teach.

**Conjecture 2:** Deep stacks of primitive mathematical knowledge may hinder the process of folding back to revise images of what to teach in school mathematics. The difficulty may stem from one’s memory search functions or the ability to unpack one’s knowledge base of college mathematics to find the connections to school mathematics. We noted that the prospective teachers in our study were readily able to access what they had learned in college mathematics, college physics, and college chemistry, but were unable to recall what they learned in Algebra 1. Several described rate of change to be the derivative but were unable to see the relationship to Algebra 1 topics. Some were surprised to learn that the slope of a linear equation was a ratio. Perhaps the depth and/or the lack of connections of their accumulated mathematical knowledge made it difficult for them to unpack their stacks of university learning to retrieve their understanding of school mathematics. A number of studies, primarily at the elementary level, have noted the lack of mathematical understanding of prospective and practicing teachers. Ma (1999) redefined mathematical understanding as profound understanding of fundamental mathematics [PUFM]. This definition may have important implications for the practices and programs of high school teacher preparation.

**Conjecture 3.** Shallow stacks of teaching strategies are to be expected among prospective teachers. The lack of primitive knowledge allows the prospective teachers to search through their strategy stacks quickly. Additionally, they appear to be more receptive to interviewer’s probes so as to revise their images of how to teach and add to or pack these stacks with new ideas. The interviewers’ prompts promoted folding back by the prospective teachers to their primitive knowledge of teaching strategies. We concluded that their stacks of primitive knowledge were thin because of the two basic strategies used by the prospective teachers. They either planned to give information directly or to have students collect data, reserving the generalizations from the data as the teachers’ roles. This lack of strategy knowledge on the part of the prospective teachers, provided opportunities for folding back to pack their understanding of how to teach. For example, one interviewer asked if the prospective teacher would consider using a graph to represent the data. Another asked what would happen if the prospective teacher placed the student activity at the beginning of the lesson rather than the end. In all instances, the prospective teachers incorporated these strategies into their lessons. A goal of teacher preparation is to pack more understanding of how to teach into the
prospective teachers' primitive knowledge. We suggest that instruction in teaching strategies be associated with the tasks of teaching and the content of high school mathematics to increase prospective teachers' understanding of how to teach.

We plan to ask Susan Pirie and Tom Kieren to provide us with critical comments on our proposed conceptual framework. We will apply the revised framework to analyze data from another study on prospective teachers. Finally, we plan to revise our own practice: what to teach prospective high school mathematics teacher about teaching and how to teach them about teaching.

INTEREST IN MATH BETWEEN SUBJECT AND SITUATION
Angelika Bikner-Ahsbahs
Universität Flensburg, Germany

Interest is an important factor in learning and achievement. In my research, I reconstruct phenomena of interest change in everyday mathematics classroom education, and I identify conditions influencing the development of interest in mathematical objects. This leads to an approach to an empirically-grounded theory on interest based learning in math classes.

1. Introduction

An interested pupil pays attention in class, works in a concentrated and an engaged way, learns more, is involved in the activities, enjoys his/her involvement, wants to go on with the activity (Hidi/Berndorf 1998), and sometimes does not notice how time goes by. In this state of affairs close to that of flow (Csikszentmihalyi 1987) capacity and challenge fit perfectly (Bikner-Ahsbahs 1999 p. 52 ff). Research has shown interest to be a strong predictor of quality of experience in mathematics classes, i.e. potency, intrinsic motivation, self-esteem, importance and the perception of skill (Csikszentmihalyi/Schiefele 1993, Schiefele/Csikszentmihalyi 1995). However, interest also is a predictor of mathematical achievement. Thus it is an important factor in learning and development (Bauer 1988, Krapp 1996, Deci 1992, 1998). But how does interest arise? Undoubtedly, interest is a phenomenon of social negotiations (Renninger 2000, Krapp 1996, Deci 1992, 1998). However, there is little research analysing social processes (Deci 1992, Krapp 1996, Schiefele 1998, Wild/Krapp 1996).

In 1988, Bauer was the first to introduce interest research in German math didactics. Taking up Bauer’s reflections, Bikner-Ahsbahs has worked out an empirically grounded concept of fostering mathematical interest in everyday lessons (1999). The study was based on questionnaires about a project encouraging interested pupils in extra curricular mathematics. Referring to the empirical research on interest, the results were applied to everyday lessons. However, the social processes of the development from interest in daily classroom situations haven’t yet been investigated. Because of this lack of investigation in social processes I’ve designed a study to develop theoretical components through the reconstruction of phenomena concerning interest development, in order to explain the emergence of interest in everyday lessons, its development, encouragement and hindrance.

2. Theoretical Framework

Krapp et al (Krapp 1992) have proposed interest to be a construct describing a person-object-relation which can be seen in activities with three characteristic aspects: expansion of competence (cognitive aspect), association with predominantly positive feelings (emotional aspect) and assigning advanced value to the interest matter (valuable aspect) (1992, 1996). An interested person identifies himself/herself with the
matter of interest. The self-determination theory describes this process of identification (Deci 1992, 1998). Deci regards motivation as a continuum between extrinsic and intrinsic motivation whereas interest is taken as an object-specific type of intrinsic motivation. An extrinsically motivated activity may be increasingly self-determined leading to individual interest by taking the steps of introjection, identification, and integration (Krapp 1992, Deci 1992). Using the basic needs for competence, autonomy and relatedness, Deci is able to explain the emergence of priorities (Deci 1992, Krapp 1996). Several studies show that competence- and autonomy-supportive teaching enhance intrinsic motivation and interest (Deci 1992), and that the experience of competence and autonomy is related to the development of interest (Wild/Krapp 1996, Prenzel/Drechsel 1996). Investigations focus on two different kinds of interest: individual interest on the intrinsic side and situational interest on the extrinsic but self-determined side of motivation (Hidi/Berndorff 1998, Mitchell 1993).

2.1. Individual interest

Individual interest develops slowly but in a relatively stable and situationally independent way. (Hidi/Andersen 1992). The observation of developing processes of individual interest can only be achieved in a long-term project. Renninger (1992, 2000) compares extended interest to non-interest and attraction. Her concept of interest is associated with increased levels of knowledge and value bringing together positive and negative emotions. The connection to Krapp’s concept of interest can easily be explained in the context of mathematics education: My experiences in fostering mathematically interested pupils have shown that pupils with high individual interest like to find mathematical proofs on their own, although these processes are associated with frustration. However, pupils with low individual interest are likely to avoid such frustrations. They derive more pleasure from finding proofs in a group with the support of a teacher. As individual interest in math increases, value gets more important than the experience of positive emotions.

2.2. Situational interest

Situational interest is influenced by the environment and is therefore fickle (Hidi/Andersen 1992). Little is known about how situational interest develops and how situational interest might lead to individual interest (Hidi/Berndorf 1998).

Mitchell’s research (1993) indicates a multifaceted structure of situational interest in school mathematics with five subfacets. First of all, situational interest consists of a catch-facet and a hold-facet. Interest is caught by a situation of cognitive, sensory, or social stimulation. Mitchell shows that pupils at the age of 14 to 16 get interested in mathematical activities by using computers and puzzles and by participating in group work. For smaller children I would expect a sensory stimulating facet to catch interest, too, and my investigations indicate, that not all forms of group work are interest-catching. Even Mitchell asks the question under what conditions group work is perceived as interesting by students (Mitchell 1993, p. 433).
Environments which catch interest need not necessarily hold interest. Situational interest can be held if students perceive lessons as meaningful (meaningfulness) and if they feel involved in the activities (involvement). Thus, suitable environments and social contexts influence situational interest (Mitchell 1993). But what does suitable mean? In my study, I look for situational conditions of environmental and social interactions in natural settings which influence situational interest. The pursuit of conditions for long-term individual development then leads to conclusions about a possible development of individual interest.

2.3. Interest and learning in mathematics classroom education

Social processes of interest development cannot be observed directly. They are inferred from indicators by means of an "interaction analysis". Therefore I use the theoretical approach of the "interpretative Unterrichtsforschung" of the German math didactics (Krummheuer/Naujok 1999). Concerning this theoretical approach, the individual and social learning processes are based on the construction of meaning (Krummheuer/Voigt 1991). In everyday math classes, mathematical meanings are produced through negotiation. As they are results of interactions they are taken-as-shared. The participants of an interaction do not clarify symbols and meanings in an extensive way. They accept ambiguity as far as the interaction process can go on (Krummheuer 1992, Voigt 1995); progressive questions indicate the interest of a pupil. In the social-constructivist approach of his interactional learning theory Krummheuer conceives learning both as a creative, individual, innerpsychic process and at the same time as a socializing social process directed at convergence (Krummheuer 1992, p. 167). In this process the mathematical subject matter, the individual learning process, and the social interactions are mutually dependant. So it seems reasonable to assume that the development of interest is triggered by social interactions (cf. Deci 1998).

Learning in lessons is regarded here from a social-constructivist view as a process based on the individual constructions of meaning which are at the same time results from collective interactions. Therefore, students are active knowledge designers and also participants in a collective learning process. The teacher arranges the learning environment as an initiator of the learning process, which he/she accompanies and observes more or less. Otherwise he/she is a participant of the interactions. Mutual dependence of all the aspects suggest that the development of interest is influenced by the individuals, the learning environment, and the interactive situation.

During an interaction, individuals structure situations consciously or unconsciously according to the acquired cognitive relation schemes and regard the situation from a certain viewpoint. This definition of the situation changes in the course of the interaction processes. Standardized and routinized definitions of the situation are called frames (Krummheuer 1992, p. 24).

In everyday lessons, a common goal links the teacher and the students, namely studying of math. Therefore students are usually willing to get involved. It can occur
that this willingness changes to lower activity when an activity will be refused or the attention focusses on something else. On the other hand it can happen that the activity becomes more intensive or despite disturbances the activity remains intensive. In both cases we observe an interest-change phenomenon. However, some of these phenomena cannot be observed in teaching situations because they take place inside a person. For that I use an instrument reflecting those inner processes.

Reconstructing these phenomena, I look for conditions fostering or hindering the unfolding of situational interest.

3. Methodological framework

According to the theoretical framework, I use a triangular design to structure my investigations. An individual and an interactional perspective are considered as additional methodological components. Concerning the object matter of interest, the process of analyses will include a subject-related view as a third perspective.

In order to gain empirically based theoretical components, the process of discovery proceeds "subsumtively" or "abductively" (Kelle 1997 p. 143 ff, Beck/Jungwirth 1999). In the case of "subsumption" a phenomenon is assigned to a known category (e. g. meaningfulness and involvement). In the case of "Abduktion" (the German term) a phenomenon which is inexplicable by known theories, is picked up. Theoretical knowledge then serves as a basis for the construction of new explanation patterns describing the observed phenomenon.

In accordance to the difference of individual and situational interest, the core data consist of individual and situational data: For nearly half a year, the fraction lessons of a group of students at the age of 11 to 13 were observed and videotaped. Relevant situational data are taken from the video recordings. Transcripts of selected episodes are taken as documents for an interaction analysis. The individual data stem from a one-to-one correspondence of students, who want to become math teachers, with the pupils of this study.

Having identified interest-change phenomena, I reconstruct these phenomena as case studies with the methods of an interaction analysis. This approach involves the interpretative paradigm, i.e. methodological limitation in the research process using the following steps (Krummheuer/Naujok 1999 p. 66 ff, Beck/Maier 1994): transcription and interpretation of the selected episodes, common sense description, extensive interpretation, developing and proving of the interpretation hypotheses, combining the hypotheses of situational and individual data and working out a theoretical structure based on the comparison of similar and different cases.

4. Some data and first results

Up to now, only some interest-change phenomena are reconstructed. Nevertheless, first hypotheses have emerged which indicate that:

- the stimulation of interest is lowered by opposing definitions of the situation and is intensified by corresponding matters of interest.
• the construction of meaningfulness does not come about automatically but must be stimulated.
• exercises with formats that activate algorithmic-mechanical frames (Krummheuer 1992) prevent students from getting deeply involved with constructions of mathematical meaning. The construction of meaningfulness remains superficial.
• particular competition situations generally prevent the students from holding situational interest.

The data I selected confirm the last statement.

4.1. Competition situation

Competition is a rather usual form of learning mathematics in classes. These situations are meant to be especially motivating. But do they foster interest in mathematical objects? (cf. Deci 1992).

Competition must be fair for all participants. Therefore, rules have to be fixed beforehand. Usually the candidates know about the types of competition tasks they have to expect. Often a referee makes sure that the rules are followed during the contest. The primary goal in a competition situation is to win and not to get involved or to increase the knowledge of the task matter except when involvement is part of the task itself.

Rules for a learning situation are rather flexible and they can change during a learning process. Normally the teacher determines the kind of learning tasks the students have to work on.

The following translated transcript shows a competition situation with short-question-routines demonstrating typical conflicts the teacher and the students have.

The students are divided into two teams standing on either side of the teacher's desk. The teacher allocates the task to the first two candidates. The one who solves it first may sit down, the other one has to go to the end of the line. Tobi and Anti are the next candidates.

1  T (rubs his hands) the ggT (German term for largest common denominator) (.) the ggT of 19 and 41 (...) (looks at Anti, looks up, puts the forefinger at his mouth) a bit more quiet
2  Tobi one
3  T (looks at Tobi) right why is it one' Tobi.
4  Anti oha (turns round and goes out of the line)
5  Tobi um because 19 is only divisible through itself and one
6  T exactly and 41 too. (Tobi goes out of the line.) what ,what do we CALL these numbers 19 and 41' (bends down to the left as if he wants to pick up something, comes up again and points at the candidates Kia and Eric with both forefingers at the same time.)
7  (Kia, at the left from the T, an some students from the other team are raising their hands, Kia und Eric are the candidates, Lea und Ina are standing behind Eric. Kia raises her hand but Eric does not. The T looks at Kia first, then at Eric and then at
Kia again.

Kia prime numbers

T right (does a circling movement with his right hand above Kia's head and looks at her, but Kia does not go out of the line.)

Kia (doubtfully) oh should I sit down?

T yeah that was it.

/Eric sch (turns)

Lea oh well oh well he didn't know that

/Ss he didn't know that

/Eric I didn't know that

Lea he didn't know that

T (...) that was a question (...)scht

(Eric turns round and goes to the end of the line.)

/Ss that's mean

/Lea that's mean Mr K

(The protest of the pupils gets louder.)

T no, a question (...) (The pupils all shout out at once.)

The teacher defines the situation as a learning situation using the opportunity to repeat the knowledge about prime numbers (3-6). Tobi is the first to give the right answer, so the next question for him cannot simply be another competition task (3-5). From the view of the students, too, the learning process is defining the situation (3-6). As usual in the contest, the teacher looks at the next candidates alternately and points at them. But by raising their hands the students do not regard the next question as a competitive one (6; 7). There are three reasons for that: The task still belongs to the previous learning context, the teacher's movement (6) gives the task a casual status and the question does not ask for a number as it usually does in this competition, but for a term.

As Kia is allowed to sit down, the students of the other team probably feel at a disadvantage (13-24) and protest vehemently: Obviously the pupils are more concerned with winning the contest than with learning. The teacher however seems to know about the problem with the situation (17, 22), but he gets the upper hand.

From the students' viewpoint, learning and competition situations are incompatible. Changing the situation must be clearly pointed out to avoid confusion. The teacher regards the whole situation as a learning one; competition just serves as motivation. So the teacher thinks he can change rules during a game but that is not compatible with the role of a referee.

Further transcripts show: If these conflict situations appear frequently, the possibly motivating effect of a competition can decrease, as it is already the case here with students not in the queue any more. Thus the possibly motivating effect of competition:
• can only be kept, if the teacher separates explicitly and clearly the learning from
  the competition situation.
• concerns only the participants of the contest and
• is primarily concerned with winning the competition.

Competition games must be fair. That means that rules must be precisely fixed. Thereby, it is impossible for students to become immersed in the task, to think deeply about it, to analyse mathematical peculiarities, …, unless that is part of the task itself.

• Competitions with short question-answers-routines foster at best the interest in
  competitions or the routine in dealing with mathematical exercises but do not hold
  the situational interest in mathematical objects, for competition games do not al-
  low the development of meaningfulness and involvement.

Learning situations at school require that there are individual differences among the students. It is even desirable that teachers encourage their students according to their individual differences in various ways. Further transcripts show that special encouragement in a competition situation immediately gives the impression of a lack of fairness, for students demand sticking to the rules. Competitions expecting short-term answers do not permit any personal freedom for students. Therefore, interest in mathematical objects usually cannot be developed in these situations.

4.2. Conclusions

The central criterion to win in the competition situations I’ve investigated so far is the promptness to solve mathematical exercises. It is still uncertain if every kind of competition in math lessons hinders the development of mathematical interest. If, above all, the quality of resolution is the criterion to win a contest, these competition situations may initiate deep, intensive, and meaningful explorations of mathematical issues, so that students might be more likely to develop interest in mathematical objects. The contest character may not always be in the centre of a competition situation in math classes. More research has to show conditions, under which competition situations are likely to foster mathematical interest.

THE ‘PARTICULAR’, ‘GENERIC’ AND ‘GENERAL’ IN YOUNG CHILDREN’S MENTAL CALCULATIONS

Chris Bills and Eddie Gray
Mathematics Education Research Centre, University of Warwick
COVENTRY CV4 7AL, UK.
email: chris.bills@warwick.ac.uk and e.m.gray@warwick.ac.uk

When asked to perform a mental calculation and then to say what was in their head when doing it, young pupils sometimes describe what they did with the particular numbers given. In some descriptions, however, pupils use the numbers as generic examples to explain the procedure that is used. In other descriptions they may simply state a general rule. Responses given in six interviews over a two year period by UK pupils aged 7 to 9 years have been analysed in terms of these categories of generality. Results suggest that the use of non-particular expressions of generality is a characteristic of pupils who are successful in mental calculation. There was evidence also that the use of these modes of expression did not necessarily bring success in difficult questions where flexibility was needed.

INTRODUCTION

Studies of the influence of classroom activities on young children’s mental representations have been described in Bills & Gray (1999, 2000). In a two-year longitudinal study pupils have been asked to perform a total of 45 mental calculations in the six interviews. Their subsequent descriptions of what was ‘in their head’ when they performed a calculation fall broadly into three categories. After calculating 48 add 23, for instance, some descriptions have been categorised as ‘particular’ because the pupil simply said what they had done with those numbers, e.g. “I just added 20 then I just added 8”. Other descriptions are ‘generic’ because they use the numbers as a vehicle to describe a procedure, e.g. “if it’s 40 with 20 is 60, 48 add 20 comes 68 and then you add 3 on”. The ‘general’ category of response makes little mention of the numbers, e.g. “I just added the tens and added the units and then added them both together”. When questions answered correctly were compared with incorrect answers it was found that ‘particular’ expressions most frequently accompanied wrong answers. Correct answers were more often accompanied by ‘generic’ or ‘general’ expressions. Moreover, high-achieving pupils were more likely to use non-‘particular’ expressions than low-achieving pupils.

Responses to questions about non-numeric procedures and non-mathematical concepts were also categorised into three similarly designated categories. The data shows that pupils of all achievement levels, in mental calculation, can use ‘general’ expressions in non-calculation contexts. This suggests that the use of non-‘particular’ expressions in descriptions of mental calculations is not simply a sign of a pupil’s linguistic sophistication. The analysis of responses to difficult questions suggests, however, that flexibility in mode of response is required. The implication for the teacher is that the style in which a pupil describes a calculation procedure may be a useful indicator of understanding.

ASPECTS OF GENERALITY

Procedural and Proceptual Thinking

The distinction has been made between ‘instrumental’ and ‘relational’ understanding (Skemp 1976) where relational understanding requires knowing both what to do and why, whilst instrumental understanding involves simply knowing how to do something. Gray and Tall (1993, 1994) argue that those who fail at mathematics have failed to progress satisfactorily from the procedures of counting to the processes of arithmetic and similarly fail to generalise from other learned procedures in other areas of mathematics. They distinguish between flexible, ‘proceptual’ thinkers, for whom a symbol is a mathematical object that can be manipulated in the mind, and instrumental, ‘procedural’ thinkers for whom the symbol simply signifies a procedure to be carried out.

Pupils may thus use a procedure without understanding. This view was endorsed by Harries (1997) in a study with low attaining children. He described one pupil’s use of the written algorithm for two-digit addition where she failed to carry (her answer for 49 + 22 was 611). Her consideration of the correctness of the answer was based on her perceived accuracy of the process not on the basis of the objects she was working with.

Particular, Generic and General

Mason and Pimm (1984) in their paper “Generic Examples: Seeing the General in the Particular” use the term ‘generic example’ when a particular number is used to stand in for others and doesn’t rely on any specific property of that number. More generally, a generic example has been described by Balacheff (1988,p 219) as “an object that is not there in its own right, but as a characteristic representative of the class”. The use of the word ‘generic’ to imply a representation of something more general is common, Johnson (1987) for instance, gave a definition of ‘schema’ as a cluster of knowledge representing a particular ‘generic’ procedure, object, percept, event, sequence of events, or social situation. He suggests that this cluster provides a ‘skeleton structure’ for a concept that can be instantiated with the detailed properties of the particular instance being represented.

The notion that a particular instance is recognised as typical of a class and is used to represent that class is also the key to Rosch’s theory of categorisation. In her view (Rosch, 1977) categories are not coded in the mind as lists of individual members of the category nor as lists of category inclusion criteria but as ‘prototypes’ of the most characteristic members of the categories. This theory suggests that learners construct concepts by comparing new experiences with prototypical or generic examples which represent their current knowledge. Thus our representation of the general is in terms of the particular. For the purposes of this paper ‘generic’ will be used as a label for both generic examples used in procedures and proto-typical exemplifications of concepts. The terms ‘particular’ ‘generic’ and ‘general’ will be used as categories both of modes of expression and of the mental representations that they might reveal.
Pavio (1971, p18) insisted that it is “simply asserting a truism” to say that modes of representation evolve within the individual from the more concrete to the more abstract. Luria (1982) for instance found that young children, asked for a definition such as “What is a dog?”, gave proto-typical associations (“a dog barks”) but older children responded with a more abstract verbal-logical category definitions (“is an animal”). In this paper ‘particular’ is used to signify a ‘concrete’ representation both in pupils responses to procedure questions, were descriptions involve what was done with particular numbers, and to concept questions where a particular object is given. ‘General’ is the most abstract representation for procedures, where a rule is expressed without reference to numbers, and for concepts, where a definition is given. Between these two levels of abstraction ‘generic’ uses a particular instance as an exemplar of the general. As previously noted, however, (Bills and Gray, 2000) literature on mental representation generally supports a view of variability within and between individuals rather than the existence of developmental levels.

METHOD

Lesson observations and pupil interviews were first conducted with two classes from Year 3 (pupils aged 7 and 8 years) in a school for children aged 5 to 11 years in a large middle-income village near Birmingham U.K., from September 1998 to July 1999. The same pupils were observed and interviewed in the following year. The 80 children in the year group had been placed in one of three groups for Mathematics based on their previous attainments. Lessons with the high attainment and the middle attainment groups were observed and a sample of 14 pupils from the first and 12 from the second was interviewed in December, March and July in each year. The samples were chosen to represent the spread of achievement levels in each group.

Examples have been given in the introduction for each of the categories of response for calculation questions. In the numerical procedure questions, such as “Tell me how to multiply by ten”, pupils described what to do with a particular number (e.g. “ten times ten you add ten ten times”) or chose a generic example (e.g. “like if it was 8, just add a nought on to it, so it’ll equal 80”) or gave a general rule (“just add a zero”). The non-numeric procedure questions evoked similar types of response. For instance “Tell me how to tell the time”:

- ‘particular’ if the big one was at the top and the small one was at the bottom it would be 6 o’clock
- ‘generic’ I’d look at the big hand first so if it was like at 8 past I’d round it to the nearest 5, which would be 10 so I’d say like 10 past 6
- ‘general’ The big hand points to the minutes, the little hand points to the hours.

Pupils were also asked first “What is the first thing that comes into your head when I say ...?” for mathematical concepts (centimetre, three, millions, fraction, polygon) and then to say more about each. Similarly for non-mathematical concepts (shadow, ball, adjective, Christmas, animal). The responses fell into three categories: pupils mentioned a particular object, gave a proto-typical property (also termed ‘generic’) or a general property that amounted to a definition. For example “three” and “ball” elicited the following:
Over the six interviews 78 questions were used. They were classified into 10 calculation types and 6 non-calculation type. Each was presented verbally and followed by “What was in your head when you were thinking of that?”

**RESULTS**

**Context differences**

In the calculation questions there was a marked difference in the distribution of the categories of generality between questions answered correctly and those answered incorrectly (chi-square test significant, $p<0.005$). Those who gave a ‘generic’ or ‘general’ response were more likely to be correct and those who expressed themselves in ‘particular’ terms were more likely to be wrong:

<table>
<thead>
<tr>
<th>Number of responses (percentages of row totals in bold)</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
</tr>
<tr>
<td>Right</td>
</tr>
<tr>
<td>Wrong</td>
</tr>
<tr>
<td>Totals</td>
</tr>
</tbody>
</table>

Descriptions of the procedure in some way other than what was done with the particular numbers are thus associated with accuracy.

Categories of generality were also compared across all aspects of the interviews and there are distinct differences between distributions in the different contexts:
Pupils demonstrate in non-mathematical contexts that they can give responses at all levels of generality but in calculation questions, mathematics-procedure and mathematics-image questions they are more likely to express themselves in ‘particular’ or ‘generic’ terms. This is emphasised when mathematics questions are grouped:

<table>
<thead>
<tr>
<th>Subheading</th>
<th>Particular</th>
<th>Generic</th>
<th>General</th>
<th>Totals</th>
</tr>
</thead>
<tbody>
<tr>
<td>Maths Calculation</td>
<td>331</td>
<td>434</td>

<td>281</td>
</tr>
<tr>
<td>Totals</td>
<td>521</td>
<td>741</td>
<td>307</td>
<td>1569</td>
</tr>
</tbody>
</table>

Pupils differ in their use of particular and generic expressions when grouped by their levels of achievement in the three written mathematics tests (SAT) conducted at the end of each year. The higher achieving pupils use more non-‘particular’ expressions of generality than the lower scoring pupils in calculation questions (p<0.005):  

<table>
<thead>
<tr>
<th>Subheading</th>
<th>Particular</th>
<th>Generic</th>
<th>General</th>
<th>Totals</th>
</tr>
</thead>
<tbody>
<tr>
<td>Higher SAT scores</td>
<td>136</td>
<td>253</td>
<td>100</td>
<td>489</td>
</tr>
<tr>
<td>Lower SAT scores</td>
<td>195</td>
<td>181</td>
<td>37</td>
<td>413</td>
</tr>
<tr>
<td>Totals</td>
<td>331</td>
<td>434</td>
<td>137</td>
<td>902</td>
</tr>
</tbody>
</table>

The differences in pupils is more pronounced when grouped by their performances in the interview calculation questions. The three groups: High- (scores greater than 1 sd above mean), Middle- (scores within 1 sd of mean) and Low- (scores less than 1 sd below mean) accuracy pupils, express themselves quite differently (p<0.005):

<table>
<thead>
<tr>
<th>Subheading</th>
<th>Particular</th>
<th>Generic</th>
<th>General</th>
<th>Totals</th>
</tr>
</thead>
<tbody>
<tr>
<td>High-accuracy</td>
<td>59</td>
<td>89</td>
<td>36</td>
<td>184</td>
</tr>
<tr>
<td>Middle-accuracy</td>
<td>191</td>
<td>305</td>
<td>87</td>
<td>583</td>
</tr>
<tr>
<td>Low-accuracy</td>
<td>81</td>
<td>40</td>
<td>14</td>
<td>135</td>
</tr>
<tr>
<td>Totals</td>
<td>331</td>
<td>434</td>
<td>137</td>
<td>902</td>
</tr>
</tbody>
</table>

Once again there is no statistically significant difference between the groups in non-mathematics contexts though here high-accuracy pupils use a higher proportion of ‘particular’ expressions than the other pupils:
Difficult and easy questions

The facility level of questions varied from 0% to 100%. Eleven questions were answered correctly by ten or fewer pupils. When these ‘difficult’ questions are compared with the others the change in styles of response are similar for groups of children with different levels of success. ‘High-success’ pupils were correct in more than 4 of these. ‘Low-success’ pupils did not answer any correctly. Each group is less likely to use non-‘particular’ expressions in difficult questions and the swing toward ‘particular’ is most marked in the response of the most successful:

<table>
<thead>
<tr>
<th></th>
<th>Particular</th>
<th>Generic</th>
<th>General</th>
<th>Totals</th>
</tr>
</thead>
<tbody>
<tr>
<td>High-success easy</td>
<td>47</td>
<td>28</td>
<td>32</td>
<td>170</td>
</tr>
<tr>
<td>High-success difficult</td>
<td>25</td>
<td>42</td>
<td>9</td>
<td>60</td>
</tr>
<tr>
<td>Mid-success easy</td>
<td>109</td>
<td>51</td>
<td>59</td>
<td>351</td>
</tr>
<tr>
<td>Mid-success difficult</td>
<td>48</td>
<td>41</td>
<td>10</td>
<td>116</td>
</tr>
<tr>
<td>Low-success easy</td>
<td>78</td>
<td>48</td>
<td>24</td>
<td>163</td>
</tr>
<tr>
<td>Low-success difficult</td>
<td>24</td>
<td>36</td>
<td>3</td>
<td>42</td>
</tr>
<tr>
<td>Overall easy</td>
<td>234</td>
<td>34</td>
<td>115</td>
<td>684</td>
</tr>
<tr>
<td>Overall difficult</td>
<td>97</td>
<td>45</td>
<td>22</td>
<td>218</td>
</tr>
</tbody>
</table>

The most successful pupils use a more even spread of ‘particular’ and ‘generic’ in difficult questions and their proportion of ‘general’ expressions is not as reduced as the other pupils. The sense that pupils carry on describing procedures even in questions they get wrong by failing to use the procedure correctly, is re-enforced when two similar questions are compared:

<table>
<thead>
<tr>
<th>Year</th>
<th>Term</th>
<th>Correct</th>
<th>No response</th>
<th>Particular</th>
<th>Generic</th>
<th>General</th>
</tr>
</thead>
<tbody>
<tr>
<td>3</td>
<td>1</td>
<td>597+10</td>
<td>17</td>
<td>6</td>
<td>13</td>
<td>5</td>
</tr>
<tr>
<td>4</td>
<td>1</td>
<td>1097+10</td>
<td>8</td>
<td>6</td>
<td>14</td>
<td>3</td>
</tr>
</tbody>
</table>

Many pupils described the procedure in similar terms in each instance but failed to deal with the thousand appropriately, 2007 being a common wrong answer.

Differences over time

There appears to be no evidence of progression from concrete to abstract when individuals’ categories of generality are analysed. Some pupils were consistent in their mode of explanation but most showed variability over the six interviews. A few did move from ‘particular’ to ‘general’ in comparable questions with an accompanying improvement in accuracy. There was little change in the distribution of categories for groups of children over the two years. When the total number of responses in each category in Y3 is compared with totals for Y4 the main difference between the groups is in the number of questions that they could respond to:
Against this background of global lack of change it is instructive to consider performance in one question, “48 add 23”, used in the first five interviews:

<table>
<thead>
<tr>
<th>Year</th>
<th>Term</th>
<th>Correct</th>
<th>No response</th>
<th>Particular</th>
<th>Generic</th>
<th>General</th>
<th>Totals</th>
</tr>
</thead>
<tbody>
<tr>
<td>Y3</td>
<td>3</td>
<td>13</td>
<td>6</td>
<td>3</td>
<td>14</td>
<td>3</td>
<td>23</td>
</tr>
<tr>
<td></td>
<td>4</td>
<td>17</td>
<td>3</td>
<td>7</td>
<td>7</td>
<td>9</td>
<td>23</td>
</tr>
<tr>
<td>Y4</td>
<td>1</td>
<td>13</td>
<td>6</td>
<td>3</td>
<td>14</td>
<td>3</td>
<td>23</td>
</tr>
<tr>
<td></td>
<td>2</td>
<td>16</td>
<td>5</td>
<td>4</td>
<td>14</td>
<td>3</td>
<td>23</td>
</tr>
<tr>
<td></td>
<td>3</td>
<td>14</td>
<td>3</td>
<td>3</td>
<td>15</td>
<td>5</td>
<td>23</td>
</tr>
<tr>
<td></td>
<td>4</td>
<td>23</td>
<td>2</td>
<td>8</td>
<td>11</td>
<td>5</td>
<td>23</td>
</tr>
</tbody>
</table>

The proportion of non-‘particular’ is higher than the average for correct answers as might be expected for a relatively easy question but the breakdown for the number of responses in separate interviews in each term in each year is more revealing:

<table>
<thead>
<tr>
<th>Year</th>
<th>Term</th>
<th>Correct</th>
<th>No response</th>
<th>Particular</th>
<th>Generic</th>
<th>General</th>
<th>Totals</th>
</tr>
</thead>

<td>8</td>
<td>11</td>
<td>5</td>
<td>23</td>
</tr>
</tbody>
</table>

This shows a high level of ‘recipe-following’ in Y3 when the ‘generic’ responses reflect the use of frequently practised written algorithms. In Y4 pupils were encouraged to use more of their own mental strategies and this meant initially both more ‘particular’ and more ‘general’ responses. In the final interview the pupils were most accurate yet used a high proportion of ‘particular’ expressions

**DISCUSSION**

The initial picture presented by the data suggests that expressions at a ‘generic’ or ‘general’ level are strongly associated with accuracy. Accurate answers are most often explained in one of these modes and accurate pupils use more of these expressions than the least accurate. They are good at ‘instantiating’ their ‘skeleton’ mental representations of procedures. This does not imply, however, that achievement in mental arithmetic is due simply to an ability to express oneself in this way. The analysis of non-mathematical items shows that all pupils are capable of non-‘particular’ expressions of generality and, if anything, the most accurate reserve this mode for calculation questions more than in non-mathematical contexts.

When the responses to difficult questions are considered the pupils use fewer non-‘particular’ expressions than in easy questions. This is predictable because these
questions are associated with low accuracy. Those pupils who are most successful in the difficult questions, however, show a greater flexibility by switching more to `particular' modes of expressions. The others continued to use similar proportions of `generic' expressions to those they had used with easy questions. This same picture of advantage in flexibility of expression emerged when the responses to one question which occurred in five interviews were examined. Initially pupils spoke predominantly in procedural terms, typically "you add the ...", but when the standard procedure was practised less often in the classroom they showed greater variation in expressions of generality and there was a higher level of success.

At one level this paper seems to provide one more measure which discriminates the successful from the unsuccessful. The least successful are less likely to describe their calculations in 'generic' and 'general' terms than the more successful. The data also demonstrates, however, that pupils can describe procedures without being aware of the correctness of their answers. They use a similar proportion of 'generic' expressions in easy questions, that they get right, to the proportion in harder questions, that they get wrong, using the same procedures. There is evidence here of 'instrumental' understanding. Teachers may have an indication that pupils know a procedure by their use of expressions of generality but need to be aware that this does not imply that the pupils understand what they are doing.

Shifts in the Meanings of Literal Symbols
Liz Bills
Mathematics Education Research Centre
University of Warwick, UK
e-mail: Liz.Bills@warwick.ac.uk

The difference in roles played by literal symbols has been used as an organising principle for various aspects of the learning of algebra. In this paper I draw attention to the shifts in the meanings attached to literal symbols which may take place during certain problem solving procedures. I argue that students' appreciation of these shifts can contribute to their meaningful use of these procedures.

Introduction

Much of the literature on children's understanding of algebra uses as an organising principle the notion of different uses of literal symbols.

Küchemann's (1981) early classification of children's use of letters consisted of six types of response to test items: letter evaluated, letter not used, letter used as an object, letter used as a specific unknown, letter used as a generalised number and letter used as a variable. The last three of these six were thought of as demonstrating some kind of algebraic competence.

Usiskin (1988) describes four meanings of variable linked to different purposes of algebra. These are generalisations, if algebra is seen as generalised arithmetic; unknowns if algebra is seen as a procedure for solving certain kinds of problems; parameters or arguments if algebra is seen as the study of relationships between or among quantities; finally, arbitrary objects which are members of an abstract system.

In contrast Sfard and Linchevski (1994) trace the historical development of algebra through the following stages: algebra as generalized arithmetic (operational and then structural phases), algebra of a fixed value (of an unknown), functional algebra (of a variable), and finally abstract algebra (algebra of formal operations and abstract structures).

Ursini and Trigueros (1997) consider the algebraic skills necessary for undertaking undergraduate studies under three headings: variable as unknown, variable as general number and variables in a functional relationship. They assert that “College students should be able to cope with all of them, moreover in order to handle the variable as a mathematical object they should be able to integrate its different uses in one concept and shift between them depending on the requirement of the task” (p 256). However in this paper and in Trigueros and Ursini (1999) they focus on tasks which demonstrate understandings of one of these roles rather than of shifts between roles.

Each of these studies has a slightly different purpose for the notion of different uses of literal symbols. Küchemann uses it to classify children's responses; Usiskin links it to different understandings of the purpose of algebra; Sfard and Linchevski use it to identify stages in the historical and epistemological development of algebra and Ursini and Trigueros use it to identify and classify algebraic skills. This paper will consider, not the categorisation of algebraic activity by different uses of variables, but the kind of thinking required to move flexibly between different uses.

The study which gave rise to this paper was undertaken with sixteen and seventeen year old pupils. A key feature of the mathematics curriculum which they were studying
was the introduction of problems which involved differing roles of literal symbols within the same problem, for example:

- using "standard" forms such as \( y = mx + c \), \( ax^2 + bx + c = 0 \), where the roles of the \( x \) and \( y \) variables are familiar, but \( a, b, c \) and \( m \) are replacements for what have, up till now, been numbers
- considering functions such as \( k(k - 1)x^2 + 2(k + 3)x + 2 \) in which the roles of the two variables could be seen as equivalent but are more likely to be seen as very different because of the familiarity of one (\( x \)) and the relative unfamiliarity of the other
- using the notion of a variable point, (\( x, y \)) or (\( a, b \)) rather than a single variable, or of a variable line or curve.

Problems of this kind are often described simply as those involving parameters but this description seems to miss some important distinctions between roles of literal symbols which will arise in the later discussion. Moreover, as my second example above illustrates, the role of a literal symbol within an equation or problem situation need not be inherent to that situation but may be determined by the perspective and actions of the individual. It would be mathematically correct to describe the expression \( k(k - 1)x^2 + 2(k + 3)x + 2 \) as a quadratic in \( k \), but much more likely that it would be seen as a quadratic expression in \( x \) with \( k \) as a parameter.

Amongst recent studies of students' work on problems involving 'parameters', Furinghetti and Paolo (1994) undertook a larger scale study which involved setting questionnaires to 199 sixteen and seventeen year olds. Amongst the points which arise from the researchers' analysis of the replies are the following:

- letters in apparently symmetrical roles, e.g. \( kx > 0 \), cause difficulties for students
- some letters elicit a stereotyped expectation of role

Their main conclusion, however, is that the majority of the students they surveyed had difficulty in expressing the difference between unknown, variable and parameter.

My study led me to the conclusion that very many of the problems that my students were tackling involved a subtle shift in the role played by the literal symbols; moreover it was this shift which in each case provided the power that made the solutions to these problems 'standard methods'. I will argue that it is these shifts of meaning that allow students to perform these standard methods flexibly and not by rote.

My use of the word 'shift' follows, but is not the same as that made by Mason and Davies (1988). The kind of 'shift' I am pointing to is a 'shift of attention' which occurs within the mind of the individual. By connecting them to certain classes of problems I am claiming that such shifts are associated with success with these problems and flexibility in the application of the methods of solution.

Shifts

'Variable' to 'unknown-to-be-found'

By considering the range of types of problem that the students were working on I identified four kinds of shift. The first shift is in the role of \( x \) or \( y \) from 'variable' to 'unknown-to-be-found'. By 'variable' I mean a quantity whose importance is entirely in its relationship with another quantity, rather than in its value or values. The term 'unknown-to-be-found' means a literal symbol which has a particular value which is to be discovered. For example, in a solution to the question 'Find the co-ordinates of the
point where the line \( x + 2y - 4 = 0 \) meets the line \( y = 2x - 2a + b'x \) and \( y \) are first seen as variables whose importance is in their relationship to each other. Each can take any real value. However as soon as the learner begins to solve these as a pair of simultaneous equations, \( x \) and \( y \) take on the roles of unknowns, whose numerical values are to be found. Other examples of problems involving this shift are questions which require the co-ordinates of points of intersection with the axes or of turning points. Although it is a significant issue in earlier years at school, I found no evidence that simple problems involving this shift were still causing difficulties for students at age sixteen.

However, when this shift occurred within a more complex problem one group of students produced a very interesting response. Below is a reproduction of the work of one group on the problem "Find the point on the curve \( y = e^x \) at which the tangent goes through the origin"

\[
\begin{align*}
\text{gradient of tangent} &= e^{x_1} \\
\text{equation of tangent} &\Rightarrow y = e^{x_1}x \\
\therefore e^{x_1} &= e^x \\
\therefore x &= 1 \Rightarrow y = e.
\end{align*}
\]

On a first reading I was struck by the fact of the various meanings of \( x \) in their workings. They drew a sketch of the curve and in their diagram they recognised the particular nature of the point of tangency by labelling it \((x_1, y_1)\) and the gradient of the tangent \( e^{x_1} \). However, in their working to find the \( x \) coordinate of the point of tangency, they dropped the subscripts and wrote \( y = e^{x}x \) as 'equation of tangent'. According to one analysis, the first 'x' in this equation refers to a particular value of \( x \) which occurs at the point where the tangent touches the curve. The second 'x' is a variable in a relationship between \( x \) and \( y \) which can be represented by a straight line.

At this stage, in their notation they have lost the distinction between \( x \) as a variable in an expression of a relationship represented by a straight line and \( x \) as an unknown coordinate of the point of tangency (as expressed by \( x_1 \)). Both these meanings of \( x \) exist within the same equation.

In the next equation, \( e^{x_1} = e^x \), they equated the \( y \)-coordinate of a point on the tangent with the \( y \)-coordinate of a point on the curve in order to find the value of \( x \) at the point of contact. Now each \( x \) in the equation refers to the unknown value previously called \( x_1 \) and \( x \) is unambiguously an unknown-to-be-found. The students did not see the need to use two different letters to make the earlier distinction. However the elision between the two meanings of \( x \) did not prevent them from going on to find the particular value of \( x \) required.
This ambiguous use of \( x \) occurs because of a shift from variable in the equation of a curve (in the equation \( \frac{dy}{dx} = e^x \), \( x \) stands for the first coordinate of any point on the curve \( y = e^x \)) to unknown particular value of \( x \) (in the statement 'gradient of tangent = \( e^x \)' \( x \) stands for the first coordinate of the point where the tangent touches the curve).

**'Placeholder-in-a-form to 'Unknown-to-be-found'**

The second shift I have identified involves the role of placeholder-within-a-form. By this I mean literal symbols which carry a special meaning by virtue of being frequently encountered in a specific context e.g. \( m \) and \( c \) in \( y = mx + c \). The special status established by these literal symbols is discussed in Bills (1997). The shift in question takes place from the role of placeholder-in-a-form to that of unknown-to-be-found. For example in answering the question 'What is the equation of a straight line with gradient 3 which passes through the point (2, 8)?' a student might substitute \( x = 2 \) and \( y = 8 \) into the form \( y = 3x + c \) to find a value for \( c \). As a result of this substitution, \( c \) changes from being a placeholder for 'the y intercept' within a standard form, to being an unknown-to-be-found. This shift was also identified by Bloedy-Vinner (1994) as follows:

'Moreover, the meaning of a letter as a parameter or as an unknown or variable, might change throughout the process of solving a problem ..... Solving this problem ('Find an equation for the line through (2, 5) with slope 3”) starts with writing an equation \( y = ax + b \), where common knowledge determines that \( x \) and \( y \) are variables whereas \( a \) and \( b \) are parameters. The process continues by substituting the constant 3 for \( a \), and solving an equation with unknown \( b \), where constants are substituted for \( x \) and \( y \). The process terminates by substituting the constants found for \( a \) and \( b \), and by letting \( x \) and \( y \) be variables in \( y = 3x + 1 \)' (p89-90)

Again, students at this level find it relatively straightforward to learn and use procedures which involve this shift. However a slightly different picture emerges when the problem offered to students is non-standard in some way. For example, in the extract below there is insufficient information given to find the equation of the line.

Paul and Trevor had asked me to give them a revision session on aspects of coordinate geometry because both had missed some of the lessons on this topic. I began by speaking to them about the general form for the equation of a straight line, \( y = mx + c \), and how they would use it to find the equations of particular lines. I asked them to explain what they could tell about the equation of a straight line if they knew the line went through the point (1, 2), and, after their answer, I continued by asking them what they could say about the equation of a line which passes through (0, 4).

**Trevor:** \( c \) has to equal 4.

**Paul:** \( c \) equals 4, because 4 equals 0 + c

**Trevor:** So the gradient is 0.

**Liz:** It tells us that \( c \) is 4, which is, you could have done that by a slightly different sort of reasoning because, \( c \), you said to me was the point on the y-axis where it cuts.

**Trevor:** Yeah.

**Liz:** And this point (0, 4) is on the y-axis. It goes through (0, 4) then \( c \) is 4. What does it tell us about \( m \)?

**Paul:** That it’s 0 because ....

**Trevor:** I don’t know if it would be 0, cause you are just saying that \( x \) is 0. It still could be at an angle

**Paul:** We know, we know that \( y = 4 \), in this particular case and we know that 4 is \( c \), so we know that \( mx \) has got to equal 0.
Trevor and Paul's attention throughout this extract and most of the rest of the conversation was on substituting values for \( x \) and \( y \) into an equation for a straight line in order to find the values of the placeholders, \( m \) and \( c \), now treated as unknowns. They began by treating the point \((0, 4)\) in the same way. My agenda was different. I wanted them to see that \((0, 4)\) can be treated differently because it is on the \( y \)-axis, but my intervention failed to shift their attention away from the substitution they had made. In response to my question about the value of \( m \) they returned to their equation \( y = 0 + 4 \) and Paul deduced that \( m \) must be equal to zero. One interpretation of his line of argument is that, knowing that he was seeking information about \( m \), he chose to treat \( x \) as indeterminate, a varying quantity which must be given freedom to vary, rather than treating it as a known value, \( 0 \). The situation was compounded by the fact that there was insufficient information to calculate a value for \( m \). The students expected to be able to find the value of \( m \) and taking \( x \) as indeterminate rather than given enabled them to do so. However their focus on the role of \( m \) as unknown eventually allowed them to see a solution.

This incident is also an example of what Furinghetti and Paolo (1994) speak of as students' difficulties with letters in apparently symmetrical roles i.e. \( mx = 0 \). The confusion might be understood as one between the two different roles of the letters in an equation which gives no clues as to which letter is playing the role of unknown and which the role of given.

'Unknown-to-be-taken-as-given' to 'Unknown-to-be-found'

The third shift can occur when an analytic solution method is used. I use the term analytic in the sense of Klein (1968). He describes "analysis of the first kind" as a method of solving problems algebraically which assumes the unknown as known and then transforms the equation to identify the unknown. For example, in solving analytically the problem 'Find the point of contact of the tangent to the curve \( y = x^2 + 1 \) which passes through the origin', the first step is to name the unknown by choosing a letter to stand for the \( x \) coordinate of the point of contact. The chosen letter, \( a \) say, is then treated as given and used to form equations which express relationships between \( a \) and other quantities. Finally those equations are solved for \( a \). The shift that takes place then is from unknown-to-be-taken-as-given to unknown-to-be-found.

A number of students worked on a similar task at my request. The adapted task was "Find the equation of the tangent to the curve \( y = x^2 + 1 \) which passes through the origin".

When Paul was given this question to work on he recognised that it could not be solved by the synthetic approaches he had used so far:

Paul: Because you've, you've got no place to start after you've done that. You know that it passes through the origin, it could do that, it could do that (he indicates lines passing through the origin with different gradients) whatever, be a tangent to the curve and pass through it.
don't know, you can only do it one. Well you know it passes through the origin but you've got no, no idea where it touches and you need to know where it touches to be able to get the gradient and you need to have the gradient to know where it touches. So you've got a loop which you can't, you can't solve that easily.

From my standpoint I can understand Paul's description as saying that this question requires an analytic rather than synthetic approach. An 'analytic' approach works from the unknown, treating it as known in order to discover its value. A synthetic approach starts from the known and works towards the unknown. Paul wanted to work from the known to the unknown but found that he could not do so.

I tried to encourage him to use an analytic approach. However he understood my suggestion as advising him to guess a particular value rather than to express ignorance by the use of a letter. He eventually solved the problem by a guess and check procedure, beginning by guessing a value for the gradient. Next he found the x coordinate of the point on the curve where the gradient was equal to his chosen value. Then he checked that this point on the curve also lay on the line through the origin with chosen gradient.

Paul went through this guess and check procedure twice, first starting with a gradient of 1, which he found did not fit all the conditions, and secondly with a gradient of 2, which did. His first step in each case was to find the x coordinate of the point on the curve which had the given gradient. In other words, having decided on a trial value for m he used it to find a value of x which fitted certain conditions. A little later in the conversation I encouraged him to develop this approach into an analytic one, where the unknown gradient is named as m and the testing procedure is adapted to set up equations from which the value of m can be calculated.

Liz: .. think back to what you did to start with. You said 'suppose the gradient's 1,'
Paul: oh, yes.
Liz: Now go back to that stage and think 'suppose the gradient's m.'
Paul: If you put .... y = mx + c (inaudible). You know it's zero, you know it's y = mx
Liz: yes
Paul: equals, ...... ah m = 2x doesn't it, because the gradient's - m is going to equal 2x, so it's y = 2x^2

His earlier reasoning was along the following lines (although I have no evidence that his mental image was in terms of equations and implications)

\[
\text{gradient} = 2 \quad \Rightarrow \quad 2x = 2 \quad \text{at point of contact} \quad x = 1
\]

With m as gradient however he proceeded in this way

\[
\text{gradient} = m \quad \Rightarrow \quad 2x = m \\
\quad m = 2x \\
\quad \text{tangent is } y = mx \quad \Rightarrow \quad y = 2x^2
\]

If Paul had followed his guess and check procedure, his first stage would have been to say that the point on the curve at which the gradient is m is given by 2x = m, so that \(x = \frac{m}{2}\) at this point.

However, rather than finding x in terms of m, that is treating m as the known and x as the unknown, he took an expression for m in terms of x as his next stage. Even though it would have led him along a route parallel to that which he had already travelled when using his 'guess and check' approach, he was not able to treat m as known. This
approach led him into difficulties because the x he was working with here was the x coordinate of the point of contact rather than the x coordinate of any point on the tangent. Seeing that he had derived $y = 2x^2$ as the equation of the tangent alerted him to the need to rethink.

'Unknown-to-be-taken-as-given' to 'Variable'

The fourth shift takes place when a quantity which was originally conceived of as constant, though unspecified, is allowed to vary, that is it is a shift from unknown-to-be-taken-as-given to variable. This shift frequently occurs in solutions to locus problems, for example 'A point P, co-ordinates $(a, b)$ is equidistant from the x-axis and the point $(3, 2)$. Find a relationship connecting $a$ and $b$. In the solution to this problem, $a$ and $b$ are first taken to be fixed but unspecified, so that expressions for the distances from $(a, b)$ to the x-axis and $(3, 2)$ can be formulated in terms of these unknown-to-be-taken-as-givens. Once these expressions have been equated the equation formed can be seen as a relationship between variables and $a$ and $b$ can be allowed to vary in order to map out a parabola. In this question this last stage, which represents the locus aspect of the problem, is not emphasised, because the question asks merely for a relationship between $a$ and $b$. An emphasis on the locus aspect of the problem is usually accompanied by a change in notation which allows the final relationship to be expressed in terms of $x$ and $y$. This notational change allows the shift to seeing the letters as variables to take place more easily because the conventional roles of $x$ and $y$ are as variables.

My students were set a test and one of the questions was as follows:

"A circle has centre $(2, 4)$ and passes through the point $(-1, 5)$. The point $(p, q)$ lies on the tangent which touches the circle at $(-1, 5)$. Find an equation linking $p$ and $q$. Hence write down the equation of the tangent."

Of the students who made any substantial attempt at the question, all but one worked from the outset with $x$ and $y$ rather than $p$ and $q$. Some obtained an equation in terms of $x$ and $y$ and then substituted $p$ and $q$ into it. Some did not include $p$ and $q$ in their answer at all.

The method used by the students was to find the gradient of the radius and hence of the tangent and then to obtain the equation of a straight line with this gradient and passing through $(-1, 5)$. The focus was always on the tangent as a line and not on the point $(p, q)$ on the tangent. A method which focused on the point $(p, q)$ might have been based on expressing this fact: that the line joining $(p, q)$ and $(-1, 5)$ and the line joining $(2, 4)$ and $(-1, 5)$ are perpendicular and therefore that the product of their gradients is 1.

The students' choice of method and of letters indicates that they were following a standard procedure for finding the equation of a tangent to a circle, rather than responding meaningfully to the problem which had been set. Their understanding of the standard procedure does not include an awareness that at the outset $(x, y)$ represents a point on the tangent, and hence they ignore the cue in the question to use $(p, q)$ as that point. An interview with one of the students suggested that his choice of $(x, y)$ was unconscious.
Conclusion
I have shown how considering shifts in the meaning of variables can give a new perspective on standard problems and routine procedures in this area of algebra, and illustrated how students' appreciation of these shifts can be related to their meaningful performance of these routines. In my first example students showed by their use of notation that the shift they were making was unconscious. This unconsciousness put them at risk of making an error. In my second example Paul and Trevor were able to solve a non-routine problem because they were confident in the role of m as unknown-to-be-found, even though it had been introduced as a placeholder. In the third, Paul was, at least initially, unable to pursue the analytic approach because he wanted to shift too soon from m as unknown-to-be-taken-as-given to unknown-to-be-found. Finally, students faced with a locus question use an established routine rather than approaching the question as set because their understanding of the routine does not include an appreciation of the shift in meaning of the letters.

If, as the papers I have cited earlier suggest, understanding of the different meanings of variables is a problem for students, it may be that drawing their attention to the shifts in meanings involved in some standard problems and their routine solutions would be an effective way of helping students to improve such understanding.

Do Teachers Implement Their Intended Values in Mathematics Classrooms?

Alan J. Bishop, Gail E. FitzSimons, & Wee Tiong Seah; Monash University

Philip C. Clarkson, Australian Catholic University

There is little knowledge about what values teachers are teaching in mathematics classes, about how aware teachers are of their own value positions, about how these affect their teaching, and about how their teaching thereby develops certain values in their students. This paper from the VAMP project presents parts of the case studies of two Australian mathematics teachers which concern the relationship between their intended and their implemented values. As well as discussing data about these teachers' values, two possible approaches to the analysis of the interview and observational data are also presented.

At PME 24 FitzSimons, Seah, Bishop, and Clarkson (2000) outlined the Australian Research Council funded three-year project which included the goals of: (a) investigating and documenting mathematics teachers' understanding of their own intended and implemented values, and (b) investigating the extent to which mathematics teachers can gain control over their own values teaching.

Values in mathematics education are the deep affective qualities which education aims to foster through the school subject of mathematics (Bishop, FitzSimons, Seah, & Clarkson, 1999; Bishop, 1996) and are a crucial component of the mathematics classroom affective environment. While accepting that values, beliefs, and attitudes are dialectically related (see Krathwohl, Bloom, & Masia, 1964; McLeod, 1992; Raths, Harmin, & Simon, 1987), our concern is with the values of mathematics, mathematics education, and education in general (see Bishop, 1996), rather than more global values such as social, ecological, moral and so forth - although these are by no means incompatible, and indeed may influence teachers' personal value systems.

As Bishop, FitzSimons, Seah, and Clarkson (1999) note, there is little knowledge about what values teachers are teaching in mathematics classes, about how aware teachers are of their own value positions, about how these affect their teaching, and about how their teaching thereby develops certain values in their students. Values are rarely considered in any discussions about mathematics teaching, and a casual question to teachers about the values they are teaching in mathematics lessons often produces an answer to the effect that they don't believe they are teaching any values at all. It is a widespread misunderstanding that mathematics is the most value-free of all school subjects, not just among teachers but also among parents, university mathematicians and employers. Mathematics is just as much human and cultural knowledge as is any other field of knowledge; teachers inevitably teach values, and adults certainly express feelings, beliefs and values about mathematics which clearly relate to the mathematics teaching they experienced at school (FitzSimons, 1994; Karsenty & Vinner, 2000). More fundamentally we believe that the quality of mathematics teaching would be improved if there were more understanding about values and their influences.
It has long been recognised that teachers are continually making decisions in the classroom (Bishop, 1976) and that they are often in the position of having to judge between two or more competing values (Bishop, 1972). It is also recognised that there are differences between the values that are officially planned and those espoused by teachers (e.g., Lim & Ernest, 1997), as well as between teachers’ espoused beliefs and their actual classroom practices (Lerman, 1998; Sosniak, Ethington, & Varelas, 1991) – due in part to differential positionings as interview subjects and as teachers.

This paper, then, concentrates on parts of the case studies of two Australian mathematics teachers which concern the relationship between their intended and implemented values. One teacher is an early-learning years teacher in a suburban Catholic primary school and the other teaches at the lower secondary level in a rural government school.

Methodology and Justifications

This project relied on working with, rather than on, teachers. Initially we talked about values with groups of teachers, using video clips and written classroom incidents as prompts, in professional development settings. From among the teachers who attended these sessions, and from others who completed a circulated questionnaire, we established a small group of teachers willing to work with us in their classrooms.

The basic approach adopted with each teacher was a cycle of preliminary interview, classroom observation, and post-observation debriefing interview. This cycle was repeated on two or three days. The classroom observations were video-taped, and the interviews audio-taped. This process not only asked teachers to reflect on their teaching practices and to say what values they were intending to teach; it also asked for authentication of the teacher’s analysis by seeking to observe those values being implemented in the classroom situation, devised by the teacher.

Using this strategy we studied whether the teachers could articulate their own intended values, and whether they then implemented these in their classrooms. Before each observation lesson, the teacher presented the observer with a brief lesson plan including the flow of content and the teaching strategies, and also nominated the values they were intending to teach in the lesson. During the observation lessons we looked specifically for those values being implemented, but also we looked for other values being portrayed by the teacher.

We are transcribing and analysing the audio-tapes, but the video-tapes were used to stimulate discussion with the teacher. In some post-observation interviews the video-tapes became the key memory prompting device for the teacher, who then was able to elaborate on values-related episodes for the researcher. The researcher had also noted points at which both explicit and implicit values teaching seemed to be occurring, and the use of the video-tape helped both teacher and researcher to recall the detail of these episodes. The aim of the post observation interview was for the teacher and
researcher to come to a shared agreement on some particular examples of when and how values teaching occurred in a particular lesson.

In the following two case studies, we present two possible approaches to the analysis of the interview and observational data. (This project is still ongoing and more data will be available at the conference.) The first takes an holistic approach to intended and implemented values, and the second focuses more on the particular values nominated by the teacher and/or observed by the researcher.

**Case Study 1 (Kay): Grade1/2 (6-8 year-old students)**

This middle-class, suburban Catholic primary school, of about 400 students in total had, independently of our project, adopted a general “Value of the Week” programme; on one particular week the value was “purposefulness.” The female teacher, Kay, with 16 years experience, interpreted this value as: “If you have a dream you work to it.” One observed class began with two girls modelling purposefulness by attempting to build and rebuild a house of cards, while Kay led a class discussion about what they might have been thinking and feeling — a good example of what we are calling explicit values teaching.

The activity Kay called “Ticket maths” arose as a means of overcoming the lack of coverage for the topic of number skills, and to keep students gainfully employed, interested, engaged for about 20 minutes – while she worked more closely with a smaller group. It was an open-ended activity, with short questions, such as: “write all you know about the number 0” written on small slips of paper. The students could choose any ticket they liked, and as many as they liked. The teacher had tried to keep the questions within the ability range of all groups - wanting the children to experience success as well as to extend the grade 2 students. The intention was to involve literacy skills in the correct writing of numbers as well as accuracy of calculations.
In the interview prior to the lesson, Kay had indicated that her intended values were: (a) to give freedom of choice within structured activities, (b) for students to internalise rewards, and (c) for students to challenge themselves (purposefulness). These may be considered as mathematics education values, and have the potential to generate creativity and independence. The intended mathematical values were to develop number skills and a variety of means of expression for these, both written and oral. These values were to be made explicit to the children through whole-class discussion and/or the nature of the activity itself. Extracts from the transcript of the pre-lesson interview reveal these ideas.

Researcher: Why do the children like ticket maths?

Kay: Maybe it’s a bit of a win-win situation … It is also good to make use of existing resources … [Last time] I didn’t say ‘don’t get counters’ and I didn’t say ‘do get counters’. It was interesting [to see] the children who worked without counters. … [About values] ‘I’m wanting you to give your best.’ … I’ll be really pushing purposefulness tomorrow. It’s a really good value for working. … I hate rewarding what’s normal behaviour in children.

Researcher: So you want them to internalise the rewards?

Kay: Oh, yeah. …I hate behaviour being manipulated by a bit of silver paper [a silver star reward]. I want behaviour to be manipulated by your own sense of place and space. ‘I’m wanting you to challenge yourself. I’m wanting you to give your best.’

The lesson observation indicated that values (a) and (c) were implemented explicitly, but that value (b) was only implemented implicitly. In addition there were other values implemented which were not nominated by Kay. For example, group norms had been established so that the children began as a whole group sitting on the floor, in order to focus on the lesson content in its fullest sense of mathematical activities and ways of working mathematically, and in accordance with this week’s Value (i.e. purposefulness). In addition, other norms had been well established, such as the idea that the small focus-group was not to be interrupted if possible, and that there would be a breakup of activities within the allocated timeslot for mathematics.

The researcher’s interpretation of the values implemented but not nominated by Kay include the need for motivation of the students, and the need to avoid causing the students shame or humiliation. For example, during the activity “Ticket maths” she left the small group and circulated among the other students, checking their work, praising them verbally, and even drawing ‘smiley faces’ on their pages. This behaviour appears to contradict her earlier espoused value of students seeking intrinsic rewards, but it is not uncommon for teachers to have to make decisions between competing values. It also happened that one student, whom Kay recognised as attempting to please her, had made an error (writing 9 x 9 instead of 9 + 9). Following her non-judgemental suggestion that he lay out the problem again with counters, he discovered his mistake.
In addition, Kay was aware of the need to justify her actions to parents and other teachers. Over a career lifetime teachers develop and formulate certain values in order to articulate them when called upon to do so, but mostly they remain tacit. In the terms of this project, we consider them as ‘not nominated’.

One possible way of demonstrating the relationship between Kay’s intended and implemented values is presented in Table 1 (above).

a This refers to Josh’s valuing of scientific practice, such as in starting a lesson with a definition, encouraging student collection of data/information to conduct the appropriate analysis, and the way in which his activity worksheet layout resembles a student laboratory work report.

Josh teaches mathematics to a Grade 7 class in a middle-class, rural secondary school, which has a student population of about 900. He was a chemist in the local dairy centre before entering the teaching profession 14 years ago. This industry experience has obviously influenced his outlook towards the purpose of education in general, and towards the inculcation of values through (mathematics) teaching in particular. In his questionnaire response to a student hypothetical question of the purpose of studying mathematics in school, Josh wrote that the school subject “will help you prepare for dealing with a range of situations throughout life – especially solving problems”. In his response to another hypothetical situation of several students protesting against working in a group, his view was that while one may work better individually, “this will not always be possible, especially later in life when you
are working. Everyone needs to be able to learn to get on with other people in a cooperative fashion”.

Thus Josh is a teacher who perceives both the subject of school mathematics and the ways through which this subject is taught as means of preparing students for meaningful daily living. Josh’s espousal of this value of ‘relevance’ also drove the group investigative activity entitled ‘Handspan and foot pace calibration’ in one of his ‘measurement’ lessons. In this activity, students calibrated their individual handspans and foot paces, used these to measure (in groups of two or three students) several real-life objects, compared their measurements with those obtained with a tape measure, and answered several questions given at the end of the worksheet.

Josh introduced the activity to the class in the following way:

“Now, what we are going to do today — going to the next exercise stage, is to find out how many centimetres this hand (showing and referring to his hand), your handspan (pointing at students, referring them to their own hands) is that you can use that to measure — things when you — might not have a ruler handy ... so when you need a quick estimate of something that’s — long and you want to, a bit more accurate than to just say that, oh, (pointing to a student desk) the table is somewhere between two or three metres, or one and two metres, is that right. You want to — you get it more accurately. And — particularly handy for ... people who work on farms, and that means you might be out, and you got to get back to the — to the shed or workshop to get some something, and you are going to — interrupt in the end quite a bit of your work or something. So, that’s the first thing we have to do. We are also going to measure your pace, so I’m going to see how many centimetres (demonstrates striding across the front of the classroom) — you can comfortably step. Say, you can use your pace or your step to also also estimate distances.”

The value of relevance Josh espoused is both mathematical and mathematics educational in nature. Mathematical knowledge is portrayed as relevant and useful knowledge; at the same time the pedagogy of this knowledge employed by Josh (e.g. the ‘Handspan and foot pace calibration’ activity) demonstrates that the internalisation of this value is useful for students’ own present and future experiences and challenges. This value, in turn, influences Josh’s portrayal of other values in his lessons, such as cooperative work, exemplified in his questionnaire response given earlier in this section, and in the following statement made in one of the post-lesson interviews:

I want you to — to learn how to, how to work with different people. I always — go — go on to say, look, you know — the school here, seventy teachers, you know. Seventy teachers! And we got to work together. I can’t just, just [say] ‘Oh, I’m not going to teach — such and such people and teach someone else I happen to like’.
Here is another value which is not only nominated by Josh, but is also explicitly implemented and espoused in his lessons. Some other values, however, might have been intended but were not implemented, at least not observable by the researcher. Yet others were implemented (or portrayed) but not intended, or at least not nominated by the teacher. For example, there were several occasions on which Josh explicitly emphasised that students listen to him, or to one another. When a student asked him to read out a question again, he replied that “you got to listen here.... We do this [mental mathematics exercise through verbal dictation of questions] so that people practise listening!” Yet this is a value which Josh was unaware of implementing. Table 2 (above) lists some of Josh’s values that were observed in his lessons.

Issues and Further Questions

This project has one more year to run, so this report is of work in progress. As indicated above, we are exploring various means of analysis in this new mathematics education research territory. The tables shown above can only ever present a partial picture, and we recognise the need to avoid simplistic dichotomies. For example the use of the word ‘implemented’ implies that a certain value is already intended to be taught by the teacher. But as we have noted with Josh, teachers may well be portraying certain values in their teaching that were not intended, and of which they were unaware. These could well include values with negative connotations. Are teachers aware of this possibility? And are there any strategies to help them overcome this problem?

We can also raise questions about the validity of the researchers’ interpretations; each of us is working from multiple positionings and making subjective decisions about salient features of the data. The interviews and discussions with the teachers do help to clarify ideas, but one danger remaining is the likelihood of world-views being already shared between researchers and teachers. Is this a problem?

We believe it is not a problem because we are less concerned with discovering what values teachers are teaching, and more concerned with aim (b) above - discovering how much control teachers can gain over their values teaching. So the next phase of the project involves teachers nominating values that they are not currently implementing, or implementing explicitly, and then monitoring their attempts to do so.

We hope that by clarifying the relationship between the teachers’ intended values and their portrayal of values in the classroom we will be able to offer teachers and teacher educators appropriate strategies for developing this neglected but crucial area of values education in mathematics.

References

The purpose of this study was to use Valsiner’s (1987) constructs of the zone of free movement (ZFM) and zone of promoted action (ZPA) to understand the zone of proximal development (ZPD) of a pre-service secondary mathematics teacher during her student teaching semester. Using classroom discourse, we characterized the zones established by the teacher and identified an additional 'phantom' zone of promoted action (PZ) whereby the teacher appeared to promote certain events but in reality did not permit them to occur. We found the PZ to be a precursor to the reconfiguration of the ZFM established by the teacher and thus, potentially, a developmental necessity for the teacher. The existence of a PZ seemed to be an external manifestation of the ZPD and thus a predictor of one’s readiness for professional development. We also found the teacher’s capacity to construct a communal ZPD (Wells, 1999) in the classroom significant in her ability to reorganize the PZ into a true ZPA.

Theoretical Perspective and Purpose

In a Vygotskian perspective on learning, the zone of proximal development (ZPD) is postulated as the space characterizing one’s potential capacity for development with the assistance of a more knowing other (Vygotsky, 1962). Moreover, the ZPD is predicated upon how that more knowing other organizes, or “scaffolds”, the task at hand. As such, it is important to understand one’s ZPD in order to design appropriate instruction. However, in spite of the significance of the ZPD in characterizing one’s growth (Oerter, 1992), it is largely inaccessible as a diagnostic for instruction. As such, we need a more accessible route into the ZPD so that we can more effectively scaffold an individual’s development.

The purpose of this study was to explore Valsiner’s (1987) zone theory as a way to understand the novice teacher’s ZPD. Within the context of child development, Valsiner (1987) extended the notion of a ZPD to include two additional zones of interaction: the zone of free movement (ZFM) and the zone of promoted action (ZPA). The ZFM is an “inhibitory psychological mechanism” (p. 99) set up by the adult to constrain the freedom of the child’s choices of thinking and acting. The ZFM limits access to different areas of the environment, determines availability of objects in the environment, and constrains ways of acting with objects in the accessible area. It ultimately canalizes the direction of development for the child, providing a framework for cognitive activity and emotions. In essence, the ZFM addresses the question of what is allowed by the adult (or teacher). On
the other hand, the ZPA describes a “set of activities, objects, or areas in the environment” (Valsiner, 1987, pp. 99-100) with which the adult attempts to persuade the child to act in certain ways. It is defined by what is being promoted by the adult without obligating the child to comply. The ZPA is contained within the ZFM, since theoretically the adult cannot promote what he or she does not allow. The ZFM and ZPA are seen as equivalent when the child’s only choice becomes what the adult requires.

The ZPD is connected to the ZFM and ZPA in that learning is optimized only when the child’s ZPD lies completely within the options the adult makes possible. However, a portion of the ZPD always lies outside the ZFM because only part of a person’s potential can be realized in a given environment at a given time (Oerter, 1992). Since the ZFM and ZPA are socioculturally determined, the child can only develop those aspects of the ZPD that are advertised by the adult (ZPA) and not prohibited (ZFM) by the culture in which he or she is acting. This anomaly exists because in every social interaction where development is promoted, a “canalization occurs that excludes other options of the ZPD” (Oerter, 1992, p. 193). In other words, when a particular experience is promoted (and hence allowed), some other event is necessarily excluded. We include here our rendering of Oerter’s (1992) depiction of the relationship between these three zones (See Figure 1).

Figure 1. Relationship between the ZFM, ZPA, and ZPD.
The classroom provides a further illustration of how these zones interact. For example, if a teacher chooses to promote only individual seatwork comprised of repetitive mathematical exercises, then he or she is necessarily excluding the possibility of an open, inquiry-based classroom from the ZFM/ZPA complex. As a result, the student’s full potential of development within the ZPD cannot be realized because he is not exposed to collective mathematical inquiry. In this case, the learning environment (ZFM) necessary for establishing a ZPD in which students realize their potential for mathematical thinking based on activities of public conjecturing and argumentation fails to be established. The implication is that the individual’s ZPD would not be fully contained within the ZFM, thereby creating a canalization in his or her development.

If we consider that the ZPD is ontogenetic (i.e., within the learner) and the ZFM/ZPA complex is microgenetic (i.e., between the learner and the environment), (see Lightfoot, 1988), then it seems reasonable to explore an individual’s ZPD by identifying the ZFM and ZPA in which development occurs. We have previously used this approach to describe the complex interactions occurring in the professional development of science teacher interns (e.g., Carter, Westbrook, & Wheatley, 1998). The data from those studies led us to conclude that professional development was most likely to occur in situations where the cooperating teacher structures a large ZFM, thus increasing the likelihood of overlap between the intern’s ZPD and ZFM. Applying the zone concepts in that context provided a glimpse into the conflicts that arise when the beliefs and practices of a novice teacher are not congruent with those of a more experienced teacher acting as the more knowing other.

Elsewhere, we have used Valsiner’s (1987) zone theory to examine patterns of discourse established by pre-service mathematics teachers (Blanton & Westbrook, 1998). Our inquiry showed that these teachers funneled students’ thinking through leading questions that restricted the ZFM and established a ZPA organized around the teacher’s conceptions. Such patterns of discourse appeared to promote verbalizations in the classroom that provided the illusion of sense making, yet instead established cognitive boundaries in the classroom. In the study reported here, we again use an analysis of discourse in a novice teacher’s classroom to extend this previous inquiry into the practical and developmental applications of Valsiner’s zone theory. Our premise here was that the way the novice practitioner organized the ZFM/ZPA complex in the classroom would additionally inform us about his or her development within the ZPD. That is, by identifying what a teacher allowed (ZFM) or promoted (ZPA) in an instructional context, we could better understand that teacher’s trajectory of development and thereby more effectively scaffold his or her development. In this sense, we claim that the ZFM and ZPA provide a more accessible route into the teacher’s ZPD.

Methodology
At the time of this study, the student teacher participant, Mary Ann (pseudonym), was in her final academic year of teacher preparation and was student teaching in an urban school. She was assigned to a 7th-grade classroom in which she taught general mathematics and pre-algebra. She had a supportive cooperating teacher whose intent seemed more collaborative than authoritative. We observed Mary Ann approximately once per week during the one-semester student teaching practicum. Each visit was documented by field notes and audio and video recordings and consisted of two classroom observations and a 45-minute interview.

We used (verbal) classroom discourse to identify the ZFM/ZPA complex that Mary Ann established in her classroom. In particular, the analysis focused on identifying what Mary Ann allowed or promoted during the course of instruction and how this might have shifted throughout the practicum. Our focus on discourse draws on a genre of research in teacher education in which classroom discourse analyses have been successfully used to understand teachers' developing practices and to identify the social and cognitive aspects of the learning environment (see, e.g., Blanton, Berenson, & Norwood, in press; Peressini & Knuth, 1998; Wood, 1995). The tapes, transcripts, and the researchers' notes served as the primary data sources for this study. The research team independently and collectively analyzed the transcripts, viewed the videotapes, and developed assertions from classroom discourse about the zones established by Mary Ann.

Analyses and Interpretation

In the process of identifying the ZFM and ZPA established in the classroom, we found that part of the ZPA could be illusionary. That is, Mary Ann at times established what we describe as a 'phantom' zone of promoted action (PZ), or, a zone in which she seemed to promote actions that in actuality were not permitted. We characterize this zone as a phantom zone because it reflects an apparent contradiction in how the ZPA and ZFM interrelate. That is, in theory the ZPA should be contained within the ZFM; one can only promote what is at least allowed. However, the PZ represents precisely that which appears to be promoted (hence allowed) but in fact is not. In this sense, we maintain that part of the ZPA can be illusionary and thus exist outside the ZFM/ZPA complex.

For example, we found discourse patterns in Mary Ann's early practice that appeared to promote the illusion of sense making, yet established cognitive boundaries in the classroom. We include the following protocol as representative of the discourse characterizing Mary Ann's early classroom practice during her first month of student teaching (see also Blanton, Berenson, & Norwood, in press). In it, Mary Ann led a whole-class discussion with her students about the following problem:

Alex had $5 left in his wallet after he spent $12 on snacks and souvenirs at the Jubilee. How much money did he take to the Jubilee?
Teacher: How much money did he spend?

Jim: Twelve dollars.

Teacher: Twelve dollars. OK, if he spent $12, would he be minus or plus?

Students: Minus.

Teacher: Minus. He's going to be minus. So how much money he took to the Jubilee is an unknown. It's something that we don't know.... So, how do we represent unknowns?

Students: Variable.

Teacher: A variable. OK, what variable do [you] want to use?

Mark: M.

Teacher: OK, so m is the amount of money he has, and how much did he spend?

Carol: Twelve.

Teacher: Twelve dollars. And how much did he have left over?

Students: Five.

Teacher: (Mary Ann writes the equation ‘m - 12 = 5’ on the OP to be solved.) OK, what was the very first step [in solving this equation]? What was the very first step that I gave you yesterday Chad?

Chad: Isolate the variable.

Teacher: Isolate the variable. OK, how did we isolate the variable?

We infer from this episode that, while Mary Ann promoted the illusion of sense making, her forms of questioning necessarily restricted students' ZFM. That is, by asking short-answer, leading questions (e.g., 1, 3, 7, 13) Mary Ann seemed to be restricting students from essential problem-solving activities such as purposeful conjecture and argumentation. In essence, she promoted students' (verbal) participation, yet her questions placed cognitive limits on their thinking. In this sense, we would argue that Mary Ann established a PZ in that students were invited to participate in class discussions, but only in a manner that funneled their responses toward Mary Ann's approach for solving the problem. Thus, while it was clear to us that Mary Ann valued having students participate in her class, we maintain that she promoted a type of interaction with students in her early practice that necessarily canalized the development of their mathematical thinking in a direction which treated mathematics as a procedural body of knowledge.

Numbers refer to lines in the protocol.
In Figure 2, we identify the ZFM, ZPA and PZ established by Mary Ann in her classroom during her early practice. We note that the nature of the relationship between the ZPD and the ZFM/ZPA complex suggests that those areas contained within the PZ established by Mary Ann represent areas not developed within the student's ZPD.

Figure 2. The ZFM, ZPA, and PZ established in Mary Ann's early classroom practice.

The PZ became significant in our understanding of the ZFM/ZPA complex and thus Mary Ann's ZPD. In particular, we found the PZ to be a precursor to the reconfiguration of the ZFM established by Mary Ann and as such, we posit that it constituted a developmental necessity for her. For example, Mary Ann ultimately expanded her ZFM by promoting (and permitting) students' activities of conjecture and argumentation. Thus, what had been a PZ for Mary Ann transitioned into a set of events (e.g., argumentation and conjecture) that ultimately she promoted and allowed. Thus, we argue that the PZ potentially signals a necessary, although not sufficient, condition for development. As such, we suggest that the existence of a PZ may be an external manifestation of the ZPD and thus a predictor of one's readiness for professional development.

We find further support for this claim in Vygotsky's theory on concept formation. In particular, we suggest that the construct of the PZ parallels Vygotsky's (1962/1934)
notion of pseudo-concept, which he used in describing the development of higher mental functioning in children. Vygotsky argued that the pseudo-concept is an essential bridge in children's thinking to the final stage of concept formation. While the pseudo-concept a child possesses is phenotypically equivalent to that of an adult, it is psychologically different. As a result, the child is able to "operate with [the concept], to practice conceptual thinking, before he is clearly aware of the nature of these operations" (p. 69). Applying this to our study, we concluded that the PZ signals that desirable teaching practices might be within the teacher's ZPD although the teacher might not yet have a fully articulated understanding of those practices. As such, the PZ is therefore a zone of possibility, or a ZPD where with mediation there is potential for growth. Thus, identifying the existence of a PZ in a teacher's practice helps us to understand his or her potential for growth. As such, we maintain that when a teacher is operating within a PZ, she is in a place of transition, or a pseudo-conceptual stage, and has the potential for professional development.

Finally, we conjecture that Mary Ann was able to reorganize her ZFM because she allowed herself to make sense of students' ideas, and as she did so, she became engaged by students as a learner. Through this process of co-participation with students, she seemed to shift towards more student-centered inquiry. We thus argue that a teacher can potentially effect the transition of the PZ into a true ZPA if she is able to construct a communal ZPD (Wells, 1999) as Mary Ann did. Wells' notion of a communal ZPD entails a community of inquiry whereby "jointly undertaken activity creates a context in which all participants – teachers ... as well as students – can assist each other in their zones of proximal development" (p. 312). He further argues that "for learning to occur in the ZPD, it is not so much a more capable other that is required as a willingness on the part of all participants to learn from and with each other" (p. 324). From this perspective, we found that Mary Ann's participation in a classroom communal ZPD facilitated her reorganization of the ZFM in a way that diminished the PZ.

METAPHORS IN TEACHING AND LEARNING MATHEMATICS: A CASE STUDY CONCERNING INEQUALITIES

Paolo BOERO, Dipartimento di Matematica Università di Genova
Luciana BAZZINI, Dipartimento di Matematica Università di Pavia
Rossella GARUTI, IRRSAE Emilia-Romagna NRD Università di Genova

ABSTRACT: In this paper an embodied cognition perspective is considered in order to frame teaching and learning problems concerning inequalities. The nature and functions of some "grounding metaphors" are discussed, as well as the possibility of enhancing their use by students.

1. Introduction

Since the beginning of the eighties metaphors have been reconsidered as crucial components of thinking (see Lakoff and Johnson, 1980). The relevance of body-related metaphors in mathematical thinking has been clearly stated by Lakoff and Nunez (1997) and Nunez et al (1999) with some examples concerning, in particular, natural numbers and continuity.

Nunez (2000) describes conceptual metaphors as follows: "It is important to keep in mind that conceptual metaphors are not mere figures of speech, and that they are not just pedagogical tools used to illustrate some educational material. Conceptual metaphors are in fact fundamental cognitive mechanisms (technically, they are inference-preserving cross-domain mappings) which project the inferential structure of a source domain onto a target domain, allowing the use of effortless species-specific body-based inference to structure abstract inference". Considering conceptual metaphors, Lakoff and Nunez (2000) (see also Nunez, 2000) make a distinction between grounding metaphors (i.e. conceptual metaphors which "ground our understanding of mathematical ideas in terms of everyday experience") and other kinds of conceptual metaphors (Redefinitional metaphors, Linking metaphors).

This paper has three aims:

- to show how different kinds of grounding metaphors can intervene (as crucial tools of thinking) in novices' approach to inequalities;
- to discuss possible refinements of the idea of a grounding metaphor deriving from the analysis of students' behaviour and related to the cultural variety of possible everyday life source domains;
- to investigate how grounding metaphors can become a legitimate tool of thinking for students.
In order to fulfil these aims, we will consider a teaching experiment performed in two VIII-grade classes (13-14 years old students) with the main purpose of detecting the young students' potential in dealing with inequalities approached in a functional way (i.e. by considering them as comparisons of functions). We will consider also four Ph. D. students' behaviour in similar tasks.

2. Grounding Metaphors and Communication Metaphors

In mathematics as well as in other domains, many metaphors are frequently used with pure communication purposes: we will call them communication metaphors. For instance, in a sentence like "The proof of this theorem was like an obstacle race: once some progress was made, immediately another difficulty appeared" the obstacle race metaphor fulfils a pure communication purpose which has no mathematical content. Communication metaphors can also be employed in order to substitute for technical expressions which are not shared by the interlocutor: this happens frequently in a popularisation situation.

Can metaphors fulfil other functions, in particular thinking tool functions? The examples produced in recent papers by Lakoff and Nunez (1997; 2000), Nunez, Edwards and Matos (1999) and Nunez (2000) show how some metaphors (conceptual metaphors) can function as thinking tools, in particular as ways of thinking about peculiar mathematical objects; these authors go further in hypothesizing that conceptual metaphors (in particular, grounding metaphors - i.e. those referring to everyday body actions and relations) are not exceptions, but usual ways of thinking in mathematics.

The distinction between communication metaphors and grounding metaphors, and the very existence of grounding metaphors in a given mathematics domain, are relevant for educational purposes: indeed communication metaphors could not solve deep learning problems and so they would demand weak engagement by teachers. On the contrary, teachers should legitimate and enhance the use of grounding metaphors as tools of thinking. Special attention should be paid to the existence and functions of grounding metaphors in those mathematics domains where difficulties of learning are greater: indeed ignoring specific grounding metaphors could be one of the reasons for students' difficulties (see the analysis of the difficulties inherent in the learning of continuity, in Nunez, Edwards and Matos, 1999).

In this paper we deal with grounding metaphors in the domain of inequalities; as we will see in the next section, for different reasons (including students' difficulties) this subject is poorly covered in current teaching. The challenge coming from an embodied cognition perspective (Lakoff and Nunez, 1997; Nunez, 2000) is to ascertain at what extent grounding metaphors can support the teaching and learning of this subject and overcome some of the students' difficulties.

Another problem concerns the necessity of establishing whether novices' grounding metaphors do substitute more advanced thinking tools; in this case their
importance should be only temporary in the students' career. For this reason in our experimental study we considered both novices (VIII-graders) and university students (in particular, four Ph.D. students in mathematics) engaged in structurally similar tasks (even if the level of difficulty was different: see Annexes).

3. Rationale of the Experimental Study

In spite of their importance in pure and applied mathematics, inequalities constitute a neglected and ill-treated subject in secondary school curricula. In most countries, inequalities are taught as a subordinate subject (in relationship with equations), dealt with in purely algorithmic manner which avoids, in particular, the difficulties inherent in the concept of function (see Assude, 2000; Sackur and Maurel, 2000). As a consequence, students are unable to manage inequalities which do not fit the learned schemas. For instance, according to different independent studies (cfr. Boero, 2000; Malara, 2000) at the entrance of the university mathematics courses in Italy most students fail to solve easy non standard inequalities like $x^2 - \frac{1}{x} > 0$.

Concerning the mathematical relevance of the current teaching of inequalities in school, we may observe that it does not take into account the importance of inequalities in pure and applied mathematics (for instance in the case of the concept of limit or to deal with asymptotic stability) and the fact that in many cases equations are solved with approximation methods which are based on inequalities (thus reversing the usual approach to inequalities in school - as a subject subordinate to equations).

This brief presentation brings to the following conclusion: the prevailing manner of teaching inequalities in school neither is efficient (as concerns the results, in terms of the capacity to deal with a large set of rather simple but non standard inequalities) nor fits relevant aspects of the professional (mathematicians') practice about inequalities. In order to try to find the reasons of this situation and elaborate tools for overcoming it, we can observe that the functional aspect plays a crucial role in mathematicians' work, both for equations and inequalities. This fact is often neglected in traditional teaching. From a functional point of view, inequalities fully involve difficult concepts like variable and function in situations which need a complex treatment. As suggested at the beginning of this section, we can recognize that the traditional teaching of inequalities avoids the "function" concept and reduces the difficulties inherent in the variable concept and the complexity of the solution process by treating inequalities as a special case of equations.

Keeping in mind this analysis, when planning the teaching experiment with two VIII-grade classes our basic cultural choice consisted in treating equations and inequalities from a functional point of view, i.e. approaching them as special cases of comparison of functions.
Here some details about the classes, educational choices and classroom activities are reported:

- 36 VIII-grade students (divided into two classes) were involved; as usual in Italy, they had started to work with the same mathematics and science teacher in grade VI;

- the didactic contract established in grades VI, VII and at the beginning of grade VIII was coherent with the methodological choice of a cooperative, participated, guided enrichment of tools and skills in the planned activity. A rather common routine of classroom work consisted in individual production of written solutions for a given task (if necessary, supported by the teacher with 1-1 interventions), followed by classroom comparison and discussion of students' products, guided by the teacher and, possibly, by the adoption of other students' solutions in similar tasks. Another aspect of the didactic contract included the exhaustive written wording of doubts, discoveries, heuristics, etc.;

- the approach to the concept of function was built up through activities involving tables, graphs and formulas and mainly concerning geometric entities (lengths, perimeters, areas, etc.). After some initial activities on functions as machines (operational view) and then as x to y correspondences (correspondence view: see Slavit, 1997 for a survey about these different views), point-by-point drawing of graphs was discouraged, while making hypotheses about their shape (starting from their formula) was greatly encouraged;

- the role of the teacher was to help students through 1-1 interactions and manage students' classroom discussions. In particular, students were encouraged to communicate their ideas with words, gestures, graphs drawn at the blackboard, etc..

Collected materials from the two classes consisted in individual protocols, audio-recordings of classroom discussions and detailed teachers' notes. The same materials were collected in the case of the four Ph. D. students in Mathematics involved in this study for comparison purposes (see end of Section 2).

4. Grounding Metaphors and Inequalities

In the Annexe 1 some excerpts of a student's solution are reported; they are representative of a large set of protocols deriving from the written solutions of the 36 VIII-grade students considered in this study. Also a solution from a Ph. D. is reported (Annexe 2), to show impressive similarities between the novices' strategies in dealing with open problems concerning inequalities and the efforts of an expert young mathematician in dealing with a similar, more difficult task (in fact, a task not covered by learned procedures).

Different metaphors surface in students' protocols. For space restrictions we will consider only one crucial step of the solution: the search for *pivot points*
around which the direction of the inequality changes. In many protocols we find one (or more) of the following metaphors:

- dynamical reference to increasing and decreasing values, and the necessity of a meeting point supported by consecutive dynamical gestures of one hand (firstly indicating increase, then decrease, or vice-versa); words are coherent with this body dynamic representation: students speak about going up and going down of the two functions (formulas, graphs, etc.), and thus they must "meet in one point" (meeting metaphor): "one graph goes up steeper and steeper from below and must meet the other which increases and then goes down" (see Annexe 2).

- reference to the imagined (or drawn) shapes of the two graphs, and the necessity of a meeting point supported by static crossing of the two arms; again words are coherent with this static body representation: the two graphs "must have one point in common" (intersection metaphor);

- balance metaphor: in this case the idea of a possible equilibrium between the values of the two functions drives the student's attention towards values of x which are near to satisfy the equation. A reference to physical trials performed in order to reach the equilibrium point is evident. We may note that the balance metaphor was used by students to guide the search for the equilibrium point in different ways: in particular with numerical trials on the two sides in order to approach the equilibrium point; or through a regular movement from left to right (see Annexe 1 for an example).

5. Discussion

In our opinion, the reported excerpts and the examples of the metaphors surfacing in VIII-grade students' attempts to find the 'pivot points' (as well as in the Ph. D. students protocols: see Annexes) raise three relevant questions:

Can we speak of grounding metaphors?

The communication function does not seem to be the most important function in the students' protocols: metaphors "project the inferential structure of a source domain onto a target domain", according to Nunez's description of conceptual metaphors (see Section 1), and the relationships established in the different source domains (for instance: balance equilibrium) serve as crucial references to infer conclusions in the target domain (functions and inequalities). In particular, the necessity of a point belonging to both graphs derives from the necessity that can be experienced in the source domain (see later for a detailed analysis).

Can we consider the grounding metaphors used by students as spontaneous, or may we identify their origin in classroom activities?

The knowledge of students' background brings to the hypothesis that words and gestures (strongly encouraged by the teacher during the previous classroom activities on functions: see Section 3) allowed different kinds of grounding
metaphors concerning functions and variables to become legitimate and spread in the classroom. We would like to make some comments about legitimacy and spreading. Legitimacy means that students were allowed to overtly reason through those kinds of grounding metaphors. This is not frequent in mathematics teaching (even in lower grades): abstract reasonings are privileged. Spreading means that overt, legitimate gestures and words were freely adopted by the schoolmates, according to their personal needs; by this way different grounding metaphors became accessible as thinking tools for dealing with variables and functions. For instance, the balance metaphor was produced by the author of the first protocol (Annexe 1) in a previous situation; the teacher promoted a discussion about it; then it spread in the classroom (9 students used it in the task reported in Annexe 1).

If this perspective is appropriate to describe what happened in the two classrooms, the teacher's role seems to be crucial in order to provide students with the opportunity of accessing powerful grounding metaphors. We can imagine that potentially every student can use them; but this potential does not translate into an effective, appropriate use if this use is not legitimate and supported by appropriate signs (particularly words and gestures). From the research point of view it would be interesting to better understand the specific role of signs (words and gestures) in the appropriation (or activation) and functioning of the grounding metaphors considered.

**In the case of the search for pivot points how can we distinguish between the three kinds of metaphors described above?**

The very nature of the source domains show important differences between the different metaphors. All of them enter the definition of grounding metaphor quoted in Section 1, but the nature of the evoked everyday experience is not the same in the different cases: again considering the three grounding metaphors surfacing in the research for the pivot points, in the first case we can recognize a reference to an everyday experience concerning crossing of movements. It is interesting to observe that the gestures for the description of this situation are the same that we would use in describing the crossing of two people climbing and descending a staircase. A physical experience concerning ordinary life supports the necessity of a **meeting point**. In the second case, a familiar situation of a necessary crossing of two continuous lines is evoked: the activity of drawing lines on plane surfaces provides the support for the visual necessity of a **common point**. In the third case, an everyday life technological situation is evoked: a technological tool (the balance) provides the physical necessity of an equilibrium point (in fact, the **pivot point**). These remarks suggest the consideration of different kinds of everyday experience, with different relationships between culture and body: an immediate relationship in the first case, a visual culture-mediated relationship in the second case, a technology-mediated relationship in the third case. In other words, we could speak of different culture-mediated necessities for a **pivot point** in the three cases.
Even these remarks suggest some educational implications: a variety of everyday experiences should be recognized and encouraged by the teacher in the classroom as legitimate sources of grounding metaphors for crucial mathematics concepts and situations.

Annexe 1: some excerpts from the first part of an VIII-grade student's solution to the following problem:

Compare the following formulas from an algebraic and a graphical point of view. Make hypotheses about their graphs and motivate them carefully, finally draw a sketch of their graphs. A) \( y = x^2 - 4x + 4 \) B) \( y = -x^2 + 4 \)

"Due to the fact that \( x^2 \), that is \( x \) multiplied by itself, is there, we should get two parabolas. The presence of +4 makes them start from +4 when \( x = 0 \). The first curve will meet twice the second: at +4 (on the y axis) and in another point to be found. The first curve will go down, in the first quadrant, below 4 when the weight of 4x will be greater than \( x^2 \) and will go up again when this situation will be over.

When does the first curve go below +4? Moving from 0 on the right, the first curve will go below +4 till when -4x will balance \( x^2 \), that is they will become equal
The second parabola is a very usual parabola, but it is translated "upwards" by +4 and made negative as an effect of -x^2 which makes everything negative. It will remain over the level 0 for a while, until +4 will remain greater than -x^2. But when will x^2 equilibrate +4? (drawing: again a schematic representation of a balance). When -x^2 will give a number that will annihilate +4, that is -4. When? -2\cdot2+4=-4+4=0 [...]

Annexe 2: a Ph. D. student's solution for the following problem: "To find where xsinx>x^2-1". The student is invited to tell aloud what he thinks.

(from audiorecording and notes taken by the interviewer)
"It is evident that the parabole overcomes the other function when x grows in absolute value, because xsinx cannot be bigger than the absolute value of x. It is a parabole compared with two straight lines coming from the origin and moving upwards (he makes gestures showing the two curves, then he makes a sketch on paper). The problem is what happens near to zero. Indeed if x=0 I see that the parabole is below the other function. But... xsinx... it is a pair function, a symmetric function... Well, I can consider only the positive side of the x axis. Here I imagine... x^2-1 is like x^2 lowered by one (gestures in the air: a parabole then a lower parabole). OK, the other function goes up and down, but definitively it will remain below the parabole... I have already said it (he points to the drawing). Now I must coordinate what happens near to zero and what happens at large (he carefully draws the parabole y=x^2-1, the y=-x and the y=x straight lines). I must be more precise, and see where xsinx meets the x axis (he makes a sign for 1, 2, 3, 4, 5, 6, then he makes a sketch of the graph of xsinx for x>0, saying: "it goes up and down between these two straight lines"). It looks fine. Oh, oh, this sketch is not precise enough - I must find where xsinx meets x... OK, sinx=1, it is here (he makes a sign on the straight line by going up from the value of approx. 1.5 on the x axis, then he draws a more precise graph of y=xsinx between 0 and 3). xsinx=x^2-1 ... no precise solution, but a solution do exist, I see here, one graph goes up steeper and steeper from below and must meet the other which increases and then goes down. But I should get no more than one solution... Let us see: if x=1.5, x^2-1 makes 2.25-1, that is 1.25... bigger than one, but not so bigger... It means that the meeting point is near to 1.5 on the left... OK, my drawing was OK! I can see that x^2-1 overcomes xsinx out of this interval (he rapidly completes the drawing by symmetry on the left, and makes symmetric gestures with the two hands to indicate the two symmetric parts of the x axis, out of the central interval)".
FROM THE DECIMAL NUMBER AS A MEASURE TO THE DECIMAL NUMBER AS A MENTAL OBJECT
Cinzia Bonotto
Department of Pure and Applied Mathematics, University of Padova, Italy

Abstract. We have carried out some explorative studies about introduction of the concept of decimal number, in the upper elementary school. In order to achieve this objective, we have designed a classroom practice that engaged students in a sustained mathematical activity which requires an extensive use of the ruler to accomplish different functions (measuring, drawing segments, ordering and approximating decimal numbers). In this paper we presented an explorative study with fifth-grade children about the role of the ruler as concrete model as well as conceptual model in passing from the decimal number as a measure to the decimal number as a mental object. The emergence, in terms of prospective learning, of some of the properties of the decimal number, and in particular of the property of density on the real number line, is also presented.

Framework
In recent years connections are advocated between mathematical content and the home cultures of learners, as well as between different branches of mathematics, various disciplines in which mathematics is used, historical roots of mathematical content, and connections with the real world and the world of work, see e.g. Civil, 1995. Some considerations are anyway important. Mathematics is a part of students’ social and cultural lives, and the mathematics classroom has its own social and cultural life, see Boaler, 1993. Indeed, “academic” mathematics can also be viewed as a form of ethnomathematics, involving particular cultural practices, see Presmeg, 1998.

The task of connecting students’ everyday contexts to the classroom is not easy. Many educators argue that transferring ideas from one context to another is hard because the two context differ in some significant ways. Just as mathematics practice in and out of school differs, so does mathematics learning. Schliemann, 1995, pointed out that “school learning focuses on individual cognition, pure thought activities, symbol manipulation, and general principles, while out-of-school learning is characterized by shared cognition, tool manipulation, contextualized reasoning, and situation-specific competencies”. In particular in out-of-school mathematics practice, persons may generalize procedures within one given context but be unable to carry these procedures forth to another context since problems tend to be context-specific. Generalization, which is an important goal in school mathematics, is not usually a goal in out-of-school mathematics practice.
The role of cultural artifacts

The critical problem of how to manage at school the relationship between everyday knowledge and school mathematics has been the subject of our studies for some years now. How can we at the same time benefit from what children already know and avoid the limitations that are typical of the everyday mathematical experience? How can we design better opportunities for children to develop mathematical knowledge that is wider than what they would develop outside of school, but that preserves the focus on meaning found in everyday situations (see Schliemann, quot.)? How should we proceed to lead children to develop new understandings about underlying mathematical concepts and structures and their potential generalizability?

Although mathematics learning and practice in and out of school differ in significant ways, we deem that those conditions that often make extra-school learning more effective can and must be re-created, at least partially, in classroom activities. Indeed while some differences between the two contexts may be inherent, many can be narrowed if in the classroom we create and promote learning processes that are closer to the ones that occur in the out-of-school mathematics practices. That can be implemented in a classroom, for example, by encouraging the children to analyze some ‘mathematical facts’ that are embedded in opportune ‘cultural artifacts’ (Saxe, 1991). We are talking here of objects that have relevance for the children and that are meaningful because they are part of the children’s real life experience and refer to concrete situations. This enables children to keep their reasoning processes meaningful, to monitor their inferences. As consequence, they can off-load their cognitive space and free cognitive resources to develop more knowledge (Arcavi, 1994). We can thus make use of the children’s familiarity with the artifacts we have chosen as being objects that belong to the students’ daily experience, and allow the children to express their intuitions and produce their own anticipations, in the sense of “prospective learning” as described by Freudenthal, 1991. These anticipations precede and can be functional to any systematic learning process. Further, if we use the artifacts in a certain way (cf. Basso & Bonotto, 2001, and Bonotto, 2001), we can develop classroom activities of “realistic mathematical modeling, i.e., both real-world based and quantitatively constrained sense-making” (Reusser & Stebler, 1997), and we can overcome the clear limitations of classical word-problems (cf. Verschaffel & De Corte, 1997).

Like in the Realistic Mathematics Education perspective of the Dutch school of taught (cf. Gravemeijer, 1994), we deem that progressive mathematization has to lead a student to algorithms, concepts, and notions that are rooted in the individual’s learning history, a history that starts with informal, experientially real knowledge.

The formal approach to the introduction of decimal numbers in elementary-school classrooms

In previous studies (Bonotto, 1993; 1996), we analyzed the conceptual obstacles 10- and 11-year-old Italian children encounter in ordering decimal numbers. Our findings are consistent with those of classical research studies (Nesher, & Peled, 1986; Resnick, et al., 1989). It was hypothesized that such findings may depend not only on
the inherent difficulties of the subject matter but also on the teachers’ conceptions and educational strategies. Many teachers introduce decimal numbers by extending the place-value convention. They tend to spend little time to let the children understand the meaning of the decimal number symbols and reflect on the decimal number properties and relationships. Efforts to connect decimal numbers and decimal measures are insufficient. As a consequence, children do learn to carry out the required computations, but they have difficulties in mastering the meaning of decimal notation and between fractional and decimal representations, and finally in ordering sequences of decimals.

Measuring activities as an alternative introduction to decimal numbers

According to innovative instructional approaches, we maintain that children’s decimal number understanding can be fostered in rich classroom environments, where learners can transfer their out-of-school knowledge and utilize familiar tools (such as the ruler) to accomplish a recurrent set of mathematical activities, and where they can share some minimal presuppositions about the problem definitions and the goals. “The roots in the student’s reality are expected to foster the meaningfulness and usefulness of the so-developed mathematical knowledge” (Gravemeijer, 1997).

We propose that a set of measuring activities that require an extensive use of the ruler can offer the children good opportunities to move toward the construction of an encompassing numerical structure, which integrates in a consistent whole both the natural and the decimal number systems.

The ruler is a cultural artifact which can offer the children a first approach to the decimal number as the result of a given measurement. On the ruler, “mathematical facts” are represented through its signs: the natural number sequence is visible, and some fractional parts are marked. Therefore, the ruler can offer a “situation-specific imagery” of the additive structure of the written decimal number notation, which supports the child’s progressive understanding. For example in order to draw a 3.15dm segment, the child first draws a 3dm line and marks the final extreme, then she/he adds a 1cm line to it, and finally a 5mm line, and expresses each affixion as ‘plus’, or ‘and’. The child can understand that if there are two decimal digits after the decimal point, then there are units, plus tenths plus hundredths, and that each digit specifies how many parts of a given magnitude are included in the addition. The learner is expected to form images out of her/his actions through the use of the ruler, and to visualize relevant properties. The child can map this visualization onto the decimal number representation to attribute a meaning to the decimal digits after the decimal point; her/his ability to solve ordering problems is enhanced.

As to regard the basic characteristics of the teaching/learning environment that have been designed and implemented in the classroom, a set of activities based on suitable cultural artifacts, in particular the ruler, on interactive teaching methods and on introduction of new sociomathematical, in the sense of Yackel & Cobb, 1996, were combined in an attempt to create a substantially modified teaching/learning environment. This environment focused on fostering a mindful approach toward
realistic mathematical modeling, i.e. both real-world based and quantitatively constrained sense-making, see Reusser & Stebler, 1997.

The research

A previous exploratory study (see Basso, Bonotto, Sorzio, op. cit.) concerned the introduction of the concept of decimal numbers, in the normal classroom curriculum, with third-grade children. In order to achieve this objective, we have designed a classroom practice that engaged students in a sustained mathematical activity which requires an extensive use of the ruler to accomplish different functions (measuring, drawing segments, ordering and approximating decimal numbers). The ruler has been a mediational role in their understanding of the additive structure underlying the standard written decimal notation. The results obtained showed how they correctly measured and expressed lengths with numbers containing only one digit after the decimal point; where numbers with a second digit following the decimal point were concerned, the children had difficulties in distinguishing between the decimal digit value – which represents how many parts of a given magnitude there are – and the meaning to be attributed to each decimal digit position – which represents its magnitude. For example the whole group of digits after the decimal point referred to the decimal unit directly following the main unit that was being measured. The fact of measuring with a ruler, however, did offer the children a concrete anchor and clearly illustrated their errors, allowing them to autocorrect themselves.

Later we decided to carry the study further, to evaluate the influence that the preceding activities with the ruler had had on the children. The same children were thus given problems, in both the fourth and fifth grades, which involved comparing, ordering and approximating decimal numbers. The idea was also to start the children thinking about the structural properties of a line of numbers.

Research objectives: data are gathered and analyzed concerning:

- the children’s understanding of the signs and intervals on the ruler;
- the children’s understanding of the additive structure underlying the standard written decimal notation;
- the children’s process of detachment from the representation on the ruler and from the presence of a given unit of measure;
- the children’s understanding of the relation between different units of measurement;
- the possibility for the children to grasp that the approximation is a limit of the physical instrument;
- the children’s understanding of the density property of the enriched decimal number line;
- the passage from the number as a measure to the number as a mental object.

Subjects: 21 fifth-grade children (aged 10-11 years) in a small school in a village (northeast Italy) participated in this explorative study; they had first started
measurement activities in the second grade. Data were gathered from participant observations and children's written works.

Procedure: Each student was given a sheet that listed three tasks:
1. Write down at least two measurements between 1dm and 2dm.
2. Write down at least two measurements between 1.2dm and 1.3dm.
3. Write down at least two measurements between 1.9dm and 2dm.
Explain how you found these numbers.

Discussion

We briefly present some significant extracts from the written work that show
i) the role of concrete model (characterized by a particular symbolic code-system), as well as the conceptual model of the ruler, in passing from the number as a measure to the number as a mental object;
ii) the emergence, in terms of prospective learning, of some of the properties of the decimal number and, in particular, of the property of density on the real number line.

N.1 (Moreno): 1st answer: 11cm - 12cm - 13cm - 14cm - 15cm - 16cm - 17cm - 18cm - 19cm
The measurements I got without looking at the ruler were all between the 10cm and the 20cm marks.
2nd answer: 1,21dm - 1,23dm
I got them by adding another digit after the decimal point: the millimeters.

N.2 (Daniele): 1st answer: 1,1 - 1,2 - 1,3 - 1,4 - 1,5dm
To get these numbers I thought that between 1dm and 2dm there are the little pieces that are smaller that are centimeters.
2nd answer: 1,21 - 1,22 - 1,23 - 1,24 - 1,25dm
I have to go from 1.2 to 1.3 and all I have to do is add the smaller pieces that is the millimeters.

In these first two protocols (like in about 30% of the class's total), one sees that the students still reason very much along manipulative and procedural lines linked to the image of the ruler.

In fact, numbers/measurements that fit within the required interval, arrived at via mental operations, were clearly thought out placed in the physical spaces of the artifact/instrument. This kind of reasoning highlights some of the characteristics of the ruler as model. Mentally the children refer to the physical act and manipulation of the ruler involved in measuring a segment of, say, 1.21dm: first they draw a 1dm-long segment and mark off the end point; there they add a 2cm segment and then a 1mm one. In this case the physical manipulation they had previously carried out helped them to understand the meaning of a number written with a decimal point and
expressing units of measure, and it helped them to understand the additive structure underlying the standard written decimal notation.

In other protocols (about 50% of the total), the model offered by the ruler proved to be more flexible. Here the ruler no longer served just as a visual and tactile model (as it had in the activities of the preceding years), but as a model that induces thinking in terms of relations between numbers and quantities involved, in a certain sense more “conceptual”. A process had been set off from thinking on the basis of concrete, material objects to thinking on the basis of mental, mathematical objects.

Let us look at the examples given by the following two protocols.

N.3 (Simone): 1st answer: \(1,3\text{dm} - 1,4\text{dm} - 1,5\text{dm} - 1,6\text{dm} - 1,7\text{dm}\)

I went like this: in 1dm there are 10cm. Therefore 14cm is more than 1dm and less than 2dm. Since we’re doing marks in decimeters, I did 1.4dm.

2nd answer: \(1,21\text{dm} - 1,23\text{dm} - 1,24\text{dm} - 1,25\text{dm}\)

I went like this: what’s smaller than centimeters is millimeters. In this case we have to use millimeters because if you add or take away centimeters you don’t get a number between 1.2dm and 1.3dm.

N. 4 (Pamela): 1st answer: \(1,3\text{dm} - 1,5\text{dm} - 1,7\text{dm} - 1,9\text{dm} - 1,06\text{dm}\)

1,32dm - 1,54dm - 1,73dm - 1,99dm - 1,05dm

To get these measurements I didn’t make my brain work very hard, I thought of them, first, thinking of all the possible ones, and then out of these, taking the ones that seemed better to me. For example, 1.3dm equals thirteen centimeters while 1.32dm equals thirteen centimeters plus two-tenths of a centimeter. Therefore one decimeter plus three centimeters makes thirteen centimeters.

2nd answer: \(1,23\text{dm} - 1,24\text{dm} - 1,25\text{dm} - 1,26\text{dm} \quad \text{but also} \quad 1,2321\text{dm}\)

For example 1.23dm consists of one decimeter, two centimeters and 3 tenths of a centimeter. And the same goes for 1.2321dm which means 1dm, 2 centimeters, 3 tenths of a centimeter, 2 hundredths of a centimeter and 1 thousandth of a centimeter, that is 12 centimeters and 321 thousandths of a centimeter.

Pamela carries out transformations going from one unit of measure to another in a meaningful way using fractional expressions. On can see the distinction starting between decimal digit value – which represents how many parts of a given magnitude there are – and the meaning to be attributed to each decimal digit position – which represents its magnitude.

In the following answers, the fact that the subdivisions on the ruler are decimals becomes evident, as does the notion of subdivisions that can go on infinitely, even if one cannot actually see them on the ruler. Thus, the density property of decimal numbers in the number line intuitively emerges. Here are some examples.

N.5 (Selenia): One could go on writing numbers infinitely, because there are always littler spaces that you don’t see on the ruler because it would be impossible to
see them all because they're infinite. Because you only see centimeters and millimeters on the ruler.

N.6 (Veronica): You can have 1,22dm – 1,23dm – 1,24dm – 1,25dm – 1,26dm – 1,27dm – 1,28dm – 1,29dm...
I found them like this. First of all between 1.2dm and 1.3dm there are ten spaces and therefore I can go like this. There aren't only these measurements, but there are infinite ones because every space continues to be divided in 10 parts.

N.7 (Sara): 1st answer: 1,2dm – 1,4dm – 1,6dm – 1,9dm – 1,5dm...
It was very simple to find them I thought what numbers there are between 1dm and 2dm and among so many numbers I chose these, because the interval between one decimeter and two decimeters is decimal and you always divide by ten.

2nd answer: 1,21dm – 1,22dm – 1,263dm – 1,25dm – 1,299dm...
I used the same method as before and if the teachers give me another task like this to do, I'll use the same method again. It's like a cycle that repeats itself... because the spaces inside a centimeter are infinite.

Conclusion and open problems

In this paper we presented an explorative study in the upper elementary school about the role of ruler in passing from the number as a measure to the number as a mental object; the emergence, in terms of prospective learning, of some of the properties of the decimal number, and in particular of the property of density on the real number line is also investigated.

Concerning the first point of our analysis, the results show the passage from mathematics understood as an instrument and incorporated in certain cultural artifacts, like the ruler, and mathematics as an object of study. The use of this cultural artifact first gave meaning to the operations of measuring, to numbers-measures and to decimal number notation in general (cf. Basso, Bonotto, Sorzio, op. cit.); then it favoured integration between acting and thinking in mathematics.

As to regard the second point, and that is the emergence of prospective learning, we hold, in agreement with Freudenthal, that anticipatory intuitions must be encouraged and not stymied: "Prospective learning should not only be allowed but also stimulated, just as retrospective learning should not only be organized by teaching but also activated as a learning habit" (Freudenthal, op. cit.). Mathematics teaching should try to exploit both forms of learning: "prospective" learning (which makes the fullest possible use of the student's intuitions, and to the greatest extent possible encourages anticipation of results), and "retrospective" learning (which makes use of "old" or previously acquired knowledge, revisits it, and re-composes it in new contexts). "Just as prospective and retrospective learning aims at an integration of past and future learning processes, so does intertwining learning strands locally, yet with a view on the involved learning processes as a whole".
There remain some problems that Freudenthal highlighted which still need to be confronted and solved, e.g.,

- how do mental objects develop into concepts?
- what criteria are there by which to judge if the process has taken place?

"I'D BE MORE LIKELY TO TALK IN CLASS IF ...": SOME STUDENTS' IDEAS ABOUT STRATEGIES TO INCREASE MATHEMATICAL PARTICIPATION IN WHOLE CLASS INTERACTIONS

Mark Boylan, Sheffield Hallam University
Peter Lawton, Aston Comprehensive School
Hilary Povey, Sheffield Hallam University

Abstract This paper reports on some exploratory research with a single class of students. They were given the opportunity to express their views on a variety of teacher strategies used in whole class interactions. The students’ responses highlight that developments in the curriculum which support a more problem-based, exploratory approach would be welcomed, particularly if accompanied by opportunities for sharing ideas. This would reduce the shame, public and private, generated by ‘getting it wrong’. Gender and class issues are mentioned but not discussed.

There is considerable interest currently in the UK about the use of whole class teaching in mathematics. This interest has been provoked both by international comparisons (see Jaworski and Phillips 1999) and by government policy (see Brown et al 2000). Previously, there appears to have been an identification of this practice with a traditional, expository approach to learning, with discussion only occurring in the context of small group work (cf Groves and Doig 1998). However, some teachers are re-examining their use of whole class interaction, trying to include in the ensuing talk opportunities both for a more personally dialogic response from students and also for a more equitable one.

As a contribution to this debate and concentrating on the affective dimension, we offer the reflections of some school students on their experience of whole class questioning and what they feel would make their mathematics education a more participatory experience for them. Our concern with increased participation stems not simply from a concern with equity but also because of a belief that participation itself is a defining aspect of learning (Lave and Wenger 1991). We note, however, that the value of increasing participation is dependent on just what it is that is being participated in. Research on the different ‘classroom traditions’ (Cobb et al 1992) or ‘social practices’ (Boaler 1997) that can be found in mathematics classrooms suggests that interactions are not necessarily mathematical. Such research has tended to focus on paradigmatic cases of different types of classrooms. This approach is valuable in highlighting the importance of differences between such types but it is important to recognise the way in which particular classrooms may share features of the different ‘typical cases’. We believe that the evidence presented in this paper tends to support this view.
Analysis of the student experiences we report here reflects that their experience of secondary school mathematics has been predominantly that of exposition plus routine practice, within which mathematics essentially consists of questions to which there is a right or wrong answer. However, the students did report experiences of different types of interaction. We are encouraged that the students, in expressing their desire for greater participation, often focused on those aspects of their experience which are more commonly found in 'inquiry' classrooms (Cobb et al 1992). In reading about the difficulties that the students report, it is important to keep in mind that some of their comments refer to their experience of secondary mathematics teaching in general rather than to their current experience and also to acknowledge that they valued the teaching they were receiving. Their difficulties are despite this.

We choose to represent here the responses of the students themselves for a number of reasons (cf Angier and Povey 1999). Because we are interested in the affective dimension, it seemed to us sensible to work directly with the insights the students were prepared to share since, phenomenologically, they have privileged access to their own feelings. We wished also to be part of a developing tradition that seeks to listen carefully to what school students have to say, inviting them to contribute to the construction of knowledge about schooling. We share the view that... young people are observant, are often capable of analytic and constructive comment, and usually respond well to the responsibility, seriously entrusted to them, of helping to identify aspects of schooling that get in the way of their learning. (Rudduck et al 1996, p8)

The context of the research

The research findings presented here arose out of collaborative work undertaken by a student teacher (Peter) and a researcher (Mark) working together to support Peter in developing reflective aspects to his practice. They were focusing on issues to do with mistake making and teacher questioning in whole class situations. Questioning of pupils, either directly using the grammatical form of a question or by other forms of cued elicitation (Edwards and Mercer 1987), is a prevalent feature of whole class mathematics teaching. A particular interest was in exploring and developing alternatives to 'hands up' as a form of answering.

Peter’s final teaching practice was in an 11-18 school in a semi-rural area on the edge of a large conurbation. The school has a comprehensive intake with respect to gender and class but is almost exclusively white. Results in external examinations are near national averages. This research reports on the views of a class of twelve-year-olds, a 'top set', consisting of 12 girls and 17 boys. The decision to ask the class about their experience of whole class interaction arose from an initial discussion that occurred during one of Peter’s lessons when Mark was present.

Peter introduces the day’s topic – revision of formulas for $n^{th}$ term of a series. He asks the class to spend a moment individually thinking about the topic to see what they can remember and invites those that “have some thoughts” to put there hands up. About four or five hands are raised. He then
asks the students to discuss in pairs. Nearly all students seem to be involved in this and the discussion seems to be centred on the topic.

He now asks again for people to put their hands up if "they have any ideas". There are now perhaps 6 or 7 hands up. Peter comments that lots more should have something to say, he indicates two girls as an example "you were saying some really interesting things". Looks a little perplexed as to why there were not more hands up. I intervene and refer to the implicit question, that "who has some thoughts" also implies "who wants to say something".

Peter picks this up and asks again for hands up but this time saying he won't ask anybody to share, nearly all put their hands up. He asks the class why the difference. One boy responds, his comments include "people don't want to make a mistake, they might look stupid" (Mark's field notes)

An interesting discussion followed which raised a number of issues and it was decided to continue the dialogue with the class about some of them.

Data collection and interpretation

A number of sources provided data for analysis. The story from the earlier lesson was re-told to the students and responses were invited. Peter devised a short questionnaire, completed individually, that focused on the students' willingness to answer questions in class. The students, working in groups, completed an exercise devised by Mark. This involved them in ranking statements about possible strategies a teacher might use after asking the class a question against three criteria: the frequency in which the situations occurred in mathematics lessons; how nervous they felt in the different situations; and how helpful the different means of responding were to their learning. The reasons for using this instrument were twofold. First, students' behaviour in whole class interactions is socially focused and the intention was to reflect this. Second, Mark and Peter wanted to explore the potentially transformative effect of such discussion in helping to develop a community of mathematical practice (Winbourne and Watson 1998).

The students' responses to these sets of data were collated. The answers to the open question in the questionnaire were analysed initially on the basis of an open-coding of meaning units and these generated some more general themes on the basis of which a summary in the form of a class letter was prepared. The results of the sorting exercise were summarised and compared. Following this, seventeen of the students were interviewed in single gender groups about the class' responses. The data collection as a whole attempted to develop a cycle of interpretation in which the pupils' initial responses were interpreted and then this interpretation was the subject of further discussion and validation by the students. Details of the analysis of the questionnaire are presented elsewhere (Boylan and Lawton 2000): here, drawing principally on data from the interviews, we lay out some of the themes which emerged.
Emergent themes

The nature of the curriculum

Much of the discussion reflected the fact that, in the eyes of the students, most whole class interactions centred on questions to which there was a correct answer, already known to the teacher, which they were also expected already to know. This interpretation of what it means to be asked a question in mathematics infuses the interviews with the students so strongly that it might be difficult to imagine teacher or student conceiving interactions in mathematics classrooms differently. The only alternative apparently considered to the right answer being required is that a wrong answer can be helpful too. Although immediately recognisable by mathematics teacher and mathematics student alike, such an outlook does not, of course, permeate the rest of the curriculum.

- Because if you take RE, there’s not like no definite answers for RE questions, like - but in maths there’s - most of them are definite answers, so they might not be as confident if they know that, if they get it wrong, then they’re definitely wrong, kind of (boy interviewed by Peter)

- In other subjects you get it read out, you take the answers from a book, you have it written down in front of you (girl interviewed by Mark)

When, in the questionnaire, the students were asked to choose the part(s) of the lesson in which they felt most involved, the results suggested that they wanted to move beyond the sort of mathematics curriculum which had dominated their previous experience.

These responses were explored in the interviews. Both boys and girls were positive about the effect of ‘puzzles’ on the curriculum. Both groups wanted the puzzles incorporated into the topics they were studying and both made a spontaneous connection between the value of ‘puzzles’ and the fact that they permitted, and indeed provoked, discussion.

- I think [the puzzles] they’ve got to - they’ve got to have some sort of maths in them, and they’ve got - you want to try and get them more related to - if you’re doing like a topic, then try and get them more related to the topic - so you can put a little bit of that in so it’ll help them learn ...  
- Yeah, ‘cause that’s a bit more exciting and you get to have a bit of investigation
You want a variety - you want a variety of sort of things - so you don’t want straight maths all the time - you want puzzle maths - a bit of discussion in there, so - make it easy to learn and more helpful to learn (boys interviewed by Peter)

Did you put ‘puzzles’ [in the questionnaire]?  
- I think it’s mainly because, like, they can have a go at things and if they don’t understand it they can, like, confer with other people and ask the teacher  
- I think they enjoy it more as well  
- It depends which type because, like, if you’re doing one subject that you can’t really have puzzles on them - so it’s, like, better to do questions. But on others - like with sequences - I think it’s better to do puzzles on them  
- I think it’s better to do it on that topic because, if you go onto something else and then you come back to it, you forget all about it (girls interviewed by Peter)

We note two things about these responses. First, the students clearly differentiated between the sort of thinking generated by ‘puzzles’ and what they saw as the demands of ‘questions’ in mathematics lessons. At the same time they found it hard to conceive of an approach to learning in which ‘puzzling’ was the norm and where they were actively engaged in the construction of their knowledge.

What would be better would be to try and help you to be able to see questions a bit more like puzzles, where you have to puzzle it out for yourself?  
- I don’t understand  
- I don’t know  
- Try and puzzle out things? You mean work things out? (boys interviewed by Mark)

Second, the girls, who had not connected ‘discussion’ with personal involvement when answering the questionnaire, nevertheless were motivated by the opportunity to ‘confer’.

‘Discussion’ as part of the lesson

Because previous research had indicated that where an opportunity for talk is part of the students’ experience it is welcomed (for example, Povey and Boylan 1998), we were initially surprised by the girls’ relative lack of enthusiasm for ‘discussion’ as ‘part of the lesson’ in their answers to the questionnaire. However, their responses in the interviews offered a different view. Both groups of girls said that they were keen to discuss their mathematics: they were emphatic about this and returned to the assertion several times even when the interviewers intended to move on.

If you could imagine your maths teaching to be different, how would you make it different?  
- I think I’d make it more discussions  
- I’d make it so you could, like, talk about an answer with your friends and then answer  
- Talk about it before you answer (girls interviewed by Peter)  
- I think it would be better if we could discuss amongst like, in a little group, and be together instead of on your own because some people just don’t know answer (girl interviewed by Mark)
We believe that the girls had interpreted ‘discussion’, in the questionnaire, as a whole class interactive session with dialogue consisting only of public exchanges between individual students and the teacher, with the desired student response confined to offering right answers. Thus the girls' responses in the questionnaire reveal the way in which the discourse of what counts as a discussion has been constructed in their classrooms. As suggested by earlier research (for example, Boaler 1997), the discussion they valued was exploratory, seeking after shared knowledge. What is perhaps less well documented is that this was also the type of discussion described and valued by the boys.

- I prefer to get it discussed and then see what other people think and then see where they’re coming from.
- Yeah, ‘cause if you discuss it with someone then you know that someone else is thinking along the same lines as you after your discussion.
- You’re more confident then.
- You’re more confident.
- You’ve got it right, because more people are thinking (boys discussing with Peter).
- I think it’s better to discuss it.
- More people answer.
- It gives you more ideas so you understand it more fully before you answer.
- Another thing is, like, if you discuss, like, if you don’t understand it then your friend, like, who you’re sat with, knows how you learn and they can, like, explain it in a way that you’d understand it straight away (girls interviewed by Peter).

‘Getting it wrong’

What many of the boys and all of the girls talked to us about was the public shame of getting an answer wrong in the question-response-evaluation context in mathematics lessons.

- ‘Cos they’re, like, kind of embarrassed. If they’re - some people are kind of embarrassed if they get it wrong.
- If you get it wrong in front of the whole group and you’re - when you don’t get the right answer then people think that you’re totally rubbish at maths.
- If you get it wrong, everyone thinks you’re not very good (boys interviewed by Peter).
- I think quite a few questions are asked, but people don’t like to answer if they get it wrong, ‘cause there’s quite a few ways you can do things - and there’s quite a few answers to quite - to some questions. And they don’t like getting it wrong.
- I think if you don’t know the answer and, like, somebody points at you straight away that makes you feel worse than if you do know it and they ask you.
- Well, I wouldn’t put my hand up if I thought it was wrong, or I weren’t, like, totally certain (girls interviewed by Peter).

This links to the theme of security and vulnerability discussed elsewhere (Boylan and Lawton 2000). What we want to point up here is the debilitating experience, also, of private shame, felt by both boys and girls.
- You could talk to the person sitting next to you, and you and your partner could agree on an
  answer and then at least if you're getting it wrong someone else is getting wrong as well, so no
  one can take mick out of just you
- But not everyone takes the mick out of you, some people just feel embarrassed, you might just be
  feeling bad or something
- You feel sick and tired
- There's no one taking the mick out of them, they're just feeling bad about it (boys interviewed by
  Mark)
- Kids think of it in a different way because they don't like being wrong. Like most of them think,
  most of them like being right, but if they put their hand up and get something wrong then they
  don't like it. Not, like, they don't like other people seeing them get it wrong, but they don't like
  it themselves, because it makes them feel as though they don't know anything (girl interviewed
  by Peter)

Unfortunately, there is not room here to discuss two of the gendered aspects of
the students' responses. First that of public shame, experienced by girls much
more than boys as making participation not worth the risk. Second that of
'shouting out' by some of the boys, experienced by the girls as making
participation not worth the battle and as unhelpful by many of the boys (see
Zevenbergen 2000 for an important discussion about this issue related to class).
Nor is there room to discuss the students' unhappiness with the 'top set'
experience and its the associated pace (Boaler 1997; Boaler, Wiliam and Brown
2000) which surfaced strongly despite being outside the researchers' agenda.
But both the themes of 'discussion' and of 'getting it wrong', and also these
themes to which we only have space to allude, can be seen as representing a
desire on the part of the students to have different social practices in the
classroom. In turn, the nature of these social practices influences and is
influenced by, indeed, in part, constitutes, the nature of the mathematics.

Conclusion

With this class of students, we encountered no opposition to whole class interactive
work in itself: indeed, as seen above, group activities as such were not experienced as
engaging. When given the opportunity to discuss their experience of whole class
interactions, the students selected those aspects which allowed them to participate
more fully, both socially and mathematically. The students preferences and suggested
changes to classroom practice point to a community of mathematical practice which
gives time and opportunity for the construction of a more shared knowledge in the
mathematics classroom and for a more 'spacious' pedagogy (Angier and Povey 1999).
The students could point to features of their experience that hinted at the possibility of
such a pedagogy even if this was in the context of a generally transmissive
orientation. This indicates the way in which small changes of practice can begin to
create the space for greater participation and for a different pedagogy to be developed
even within such an orientation. For example, the idea of discussing with someone
next to you before making a public contribution, considered in the sorting exercise,
re-emerged strongly in the interviews. This is a relatively simple practice to arrange in mathematics classrooms. It does not, in itself, make a major change to the epistemology of the classroom but, in a small way, it recognises the legitimacy of mathematical authority for oneself and other learners. These students also say that it means they would be more likely to participate.

SO THAT'S WHAT A CENTIMETRE LOOKS LIKE: STUDENTS' UNDERSTANDINGS OF LINEAR UNITS

Philippa Bragg and Lynne Outhred
Macquarie University, Australia

In this paper the results of a set of tasks designed to investigate student understanding of linear measurement units and the process of measuring length are presented. By Grade 5 the majority of the students were able to use informal paper-clip units to measure length and to identify linear units. However, few students in Grades 1 to 4 showed an understanding of the linear nature of units when they were asked to show a centimetre unit length in a variety of contexts. The results indicate that teachers need to identify units explicitly when they are teaching measurement because many students do not seem to have abstracted this concept in grades where it was assumed they had done so.

INTRODUCTION

In 1976 Carpenter reviewed the research on students' learning of measurement, based largely on the work of Piaget. Carpenter questioned how students might benefit from the information that had been gained because, in his opinion, training on specific concepts of conservation and transitivity seemed to be less important than training in measurement itself. At that time he referred to the lack of direct research relating the results of research to the measurement curriculum. He pointed out that "although research has identified levels of development of measurement concepts and rough age approximations for the development of certain operations, it is not immediately clear what implications this has for the curriculum" (Carpenter, 1976, p.71). Other researchers have queried the idea that concepts such as transitivity and conservation must be learned prior to measurement. Nunes, Light, & Mason (1991) have argued that measuring activities themselves assist in the understanding of transitivity and conservation.

Since that time there have been a number of fundamental studies of how students learn measurement concepts, in particular, Battista, Clements, Arnoff, Battista, K., & Borrow (1998); Hart, Johnson, Brown, Dickson, & Clarkson (1989); Outhred & Mitchelmore (2000); Wilson & Osborne (1988); Wilson & Rowland (1992). The emphasis of these studies is an understanding of how students interpret measurement concepts linked to the mathematics curriculum. However, not only curriculum knowledge is important. Hiebert (1984) has commented that "many children do not connect the mathematical concepts and skills they possess with the symbols and rules they are taught in school" (p. 498). He points out that if learning is to be applicable then students need to connect classroom and real-life experiences with the formal mathematical abstractions.

The first topic primary-school students usually encounter is linear measurement, and their knowledge of length provides the basis for the later development of area and volume concepts, as well as understanding of measurement scales which are...
essential for mass, time and temperature. A useful way of examining the way children think about linear measurement is to use Hiebert's (1986) distinction between the formal symbols, skills and procedures (procedural knowledge) and the intuitions and ideas about how mathematics works (conceptual knowledge). He states that the critical connection between procedural and conceptual knowledge is required when students have to know 'how the system works' to solve tasks or problems.

An example of procedural and conceptual knowledge in measurement would be the scale on a ruler. A ruler involves symbols (marks representing the beginning and end of each unit linked with a numeric scale, as well as shorter marks representing subdivisions) and procedures for use (aligning the ruler with the object to be measured and reading off the scale). These involve procedural knowledge. By Grade 5 almost all students can measure the lengths of objects using a ruler, that is they have mastered the "form" of ruler use but they do not understand its construction (Bragg & Outhred, 2000). Making an accurate ruler to measure in informal units (say, paper clips) would seem to involve an "understanding" of how the measurement process works in Hiebert's use of the term.

Hiebert suggests that "Many of children's observed difficulties can be described as a failure to link the understandings they already have with the symbols and rules they are expected to learn. Even though teachers illustrate the symbols and operations with pictures and objects, many children still have trouble establishing important links" (1984, p. 501). An understanding of measurement units would seem to be fundamental to establishing links across different measurement topics. The aim of this paper is to investigate the growth of students' knowledge of linear units across the primary school years. The paper reports the results of five tasks from a larger study of the development of children's understanding of linear measurement.

**METHODOLOGY**

The study was cross-sectional; 120 students from Grades 1-5 (aged 6-10 years) were selected from three state primary schools in a medium to low socio-economic area of Sydney. Each class teacher selected six students: one girl and one boy considered 'above average', 'average', and 'below average' in terms of mathematical concepts. However, in one school twelve students were selected from each grade. The first researcher interviewed individual students towards the end of the school year (September-November). Thus, they had been exposed to a large part of the measurement program for their grades. The interview tasks were designed to elicit information about the students' understanding of length measurement. Five interview tasks, a subset of the larger study, were used to determine what the students understood about the linear nature of units of measure using both informal and formal units. An understanding of measurement units would seem to be a fundamental aspect of learning to measure. Work with informal units is used to help students become familiar with important properties of units and how lengths may be measured and compared (Campbell, 1990). The subset of tasks (see Table 1) was
used to determine how students might represent linear units that are formalised on portable tools such as rulers and tape measures.

The first task (Task 1) required students to apply their knowledge of informal units to construct a ruler, using the length of the paper clips as the unit. The second task (Task 2) was used to establish if students could measure with informal units. Tasks 3, 4 and 5 required students to identify and represent units of linear measure (centimetres). In Tasks 3 and 4 students were asked to either mark the centimetre unit on a printed ruler or on a washable plastic 1cm cube. In Task 5 students were shown a picture of a gesture commonly used to indicate a centimetre (thumb and forefinger opposed to show a gap of approximately one centimetre) and to mark what one centimetre would look like if you could see it.

The tasks were presented in the same order to all students. The paper clip items (Tasks 1 and 2) were presented first followed in order by Tasks 3, 4 and 5. However, the five tasks were separated by other tasks not listed.

RESULTS AND DISCUSSION

The results for Tasks 1 and 2 involving constructing a paper clip ruler and measuring with paper clips are presented in Figure 1 for each grade level. There were 24 students at each grade level.

The results for Task 1 (see Figure 1) show a gradual increase in the construction of an accurate paper clip ruler. No Grade 1 students and only a few Grade 2 (21%) students were successful but, by Grade 5, 75% of the students constructed an accurate ruler. Students were not successful for the following reasons: they used the paper clips as unit markers; they did not maintain a constant-size unit; or they used an arbitrary unit length. There was a very clear distinction between those students who successfully used a paper-clip length as the unit of measure and those who used them as markers. Successful students were observed to mark each unit length carefully and then add the correct numeral.

Figure 1 Number of correct responses for each grade for the tasks involving informal units (Task 1 and Task 2)

The graph for Task 2 (see Figure 1) shows an increase from Grade 1 to Grade 5 with the greatest change between Grade 2 and Grade 3, when there is an emphasis on teaching length measurement. Only a small number of Grade 1 students could measure a length by iterating paper clips and indicate that the result involved a fraction of a paper clip, but by Grade 5 all students could successfully complete this task.

However, when the results of Tasks 1 and 2 are compared with Tasks 3 to 5, it is evident that being able to measure with informal units and to construct an accurate paper clip ruler are not sufficient to show that students understand the linear nature of the units. The results for Tasks 3 to 5 (see Figure 2) indicate that until Grade 5, very few children could show what a centimetre would look like on a ruler (Task 3), between a picture of an opposed finger and thumb (Task 4) or on a cube (or "short") (Task 5). Their responses showed that, in the case of the centimetre on the ruler, students represented the unit either as a space (e.g., by placing their finger on the space) or as a feature of the ruler (e.g., as marks).
Daniel's (Grade 4) remark was typical of many students who had a 'spatial' view: "It's these spaces here, you just count them". His finger fitted the 1cm space on the ruler. He, like many others, coloured in the space between the printed fingers (Task 4) and said that you counted the face of the 'short' (Task 5).

![Figure 2](image.png)

**Figure 2** Number of correct responses for each grade for the tasks involving identification of the linear unit (Task 3, Task 4 and Task 5)

For Task 3, in which students were shown a picture of five seahorses and asked how many. If the answer given was five, the interviewer prompted "five what?" Then the student was asked what the "five" on a ruler represented and if the response was 5 cm, the student was asked to show one centimetre. A number of students represented centimetres as a mark or as marks perpendicular to the length. These students would either say that the measure (5cm) was "Where the line ended", or they would indicate that the 5 centimetres were the five marks: Comments similar to "The lines on the ruler point to the numbers you need." were very common. A large proportion of students (38%) from Grades 3 to 5 made observations such as "...there's nothing at the edge of a ruler anyway, that's where you rule lines." Similar misunderstandings were reflected in the responses to Task 5. In Grades 1 to 4 students usually counted the cubes to measure lengths and most said it was "the flat part" that was used to measure lines. These results suggest that many students have not abstracted the concept of a centimetre as a linear unit from their experiences of measuring length.

Students' different representations of a centimetre unit in Task 4 are shown in Figure 3. The percentage of students who gave each response is shown in Figure 3. There appeared to be four main forms of representations: unrelated to length, area representations; ruler-like representations; and linear representations. Eduardo's response cannot be interpreted as he has transformed the finger-thumb opposition into a "C" cue with a small m inside to remind him of "cm". There is not indication that he has a linear unit in mind when this representation is shown.

The area representations highlight why a response of pointing to a space on a ruler is not sufficient to assume that a student has abstracted the idea of a linear unit. Older students who made this error were more likely to draw a 1cm square whereas the younger ones were more likely to colour in the whole space. Such students may have
a mental representation of a two-dimensional unit in the space between the marks. The confusion with a centimetre cube is evident in the second and third examples (2(b) and 2(c)).

The first two ruler-like representations involve marks to indicate a scale (3(a)), and numbers to indicate a scale (3(b)) between finger and thumb rather than a single 1cm unit. In 3(c) students draw a ruler perhaps because they link rulers and centimetres but they cannot isolate one unit whereas in 3(d) they seem to be indicating the marks delineating a unit (similar to a ruler) but the unit itself could be two-dimensional.

The first and second linear representations (4(a) and 4(b)) suggest that students have no idea of the part of the diagram that is meaningful. Similar responses were found in Task 5 in which students did not know what part of the cube was relevant when measuring length. Only 19% of students in the sample, almost all from Grade 4 and Grade 5, were able to draw an accurate representation of the linear unit. This inability to represent a single linear unit was also found in the other two tasks, the sea horses and the cube.

(1) Unrelated representation (3%):

"I learned how to remember a centimetre this way ‘cause I got mixed up with a metre." Eduardo, Year 4.

(c) 19%
CONCLUSION

According to Kamii & Clark (1997) student performance on National Assessment of Education Performance (NAEP) items remains disappointing. The results of this study suggest possible reasons why performance on measurement items may be disappointing. Although these students were able to manipulate informal units to measure lengths, there is little evidence to show that they have constructed an understanding of the linear nature of the units of measure until Grade 5. While students in Grades 3 and 4 would have had many opportunities to measure using both informal and formal units, few of them were able to identify a cm unit on a ruler, on a cm cube or on a drawing showing a thumb and finger 1 cm apart.

Learning about measuring and the identification of units of measure is very complex (Campbell, 1990) and the dimensionality of the units contributes to this complexity. The analysis of students' drawings of the centimetre unit on a drawing showing a thumb and finger indicated that the majority of the students in Grades 1 to 4 had constructed either a 'spatial' or a 'ruler-feature' concept of a centimetre. Teachers may be unaware of the multiplicity of representations that students construct for this "convention" of showing the size of a centimetre unit.

These results support the theories of Hiebert (1990, 1986, 1984) and Skemp (1979) that many students are learning the "procedures" of mathematics but not the understanding of, or relationships among, the fundamental concepts, linear measurement units in this particular case. Paper and pencil tests and exercises with informal units often assess only student knowledge of routines and procedures and do not reveal if students possess an understanding of units of measure, that length may be represented by a line and that the units of measure are also linear. For example, use of cubes to measure lines may contribute to students' confusion unless teachers make explicit the part of the cube being used as a unit.

The results from this study have shown that, in spite of their facility with informal units, the majority of students have not constructed a clear representation of linear units of measure. Since students rarely establish explicit and unambiguous connections (Hiebert, 1984) researchers and teachers need to work together to investigate how to teach young students to link experiences with informal units with formal measurement, especially the construction of rulers and scales. Students construct "mental images" (Shaw & Cliatt, 1989) and referents that make sense to them from classroom contexts. Incorrect or confused representations may remain undetected if assessment relies on paper and pencil questions and procedural tasks, such as ruling lines or measuring objects. While teachers are encouraged to help students 'make sense' of measurement and not rely on procedures (NCTM, 1989), there has been insufficient research to recommend to teachers how they can best assist students to understand key measurement concepts.

Abstract: This research is part of the project Interaction and Knowledge, whose main aim is to study and promote peer interactions as one of the possible forms of developing pupils' socialisation and positive attitudes towards mathematics, as well as to promote their socio-cognitive development and enhance their school achievement. In this paper we analyse a case that illustrates the role of peer interactions in knowledge appropriation in a statistical task.

Introduction
The curricular reforms implemented in the last few decades have stressed the need to stop considering only aims related to contents and start taking into account the development of attitudes and values, as well as abilities and skills (Abrantes, Serrazina and Oliveira, 1999). These authors claim that “these three aspects (knowledge, abilities and attitudes) are inseparable, not just in the new tasks pupils are presented with but also in the learning process itself” (p. 22).

One of the suggestions most often made in official documents regards turning to group work and giving importance to interactive processes that are present in the didactic relation (NCTM, 1991; van der Linden et al., in press). Abrantes, Serrazina and Oliveira (1999) state that “since pupils are different from one another and build different images and conceptions about the topics under study, the teacher has to value the interactions between pupils and between these and the teacher” (p. 29). This is precisely the main goal of the project Interaction and Knowledge: to study in detail and promote peer interactions as a way of fostering pupils’ full development and their school achievement in Mathematics. At the same time, the intrinsic advantages of a greater link to reality and pupils’ experiences have been highlighted, and Ponte, Matos and Abrantes (1998) have declared that “Statistics and Probabilities are essential themes that allow for a link between school mathematical knowledge and the Maths used in everyday life” (p. 170). This way, when we chose Statistics as a curricular unit for detailed studying in our project, we had in mind that it adapted particularly well to the development of studies of an interactive nature and would encourage exercising a critical and participative citizenship.

The main aim of this report is to analyse the performances of the dyad in tasks related to the concept of mean, stressing the role of peer interactions in the co-construction of solving strategies, in statistical tasks.

1 The project Interaction and Knowledge was partially supported by Instituto de Inovação educacional in 1997 and 1998, and by Centro de Investigação em Educação da Faculdade de Ciências da Universidade de Lisboa since 1996. We deeply thank all teachers and pupils who made this work possible.
Theoretical background

According to Shaughnessy (1992), twenty years ago there was hardly any research in the field of statistical education. In Portugal, despite the topics of Statistics and Probability being a part of the curricula since the 80s, only in the 90s did they begin to be taught by most elementary-level teachers (Ponte, Matos and Abrantes, 1998). The aims of Statistics contents include aspects such as: developing communicational abilities, autonomy and solidarity (including showing a critical and rigorous spirit; trust in one’s reasonings; approaching new situations with interest and initiative; assessing situations and making decisions) or the capacity to use quantitative methods to analyse real-life situations. Reaching this kind of aim is not compatible with teacher centred teaching, neither with solving routine activities, where pupils only have to turn to instrumental knowledge, such as using formulas and algorithms, without needing to interpret the proposed situation (Batanero, 1998, 2000; Carvalho and César, 2000a; César and Silva de Sousa, 2000; Ng and Wong, 1999).

Putting into practice the suggestions of the current curricula and educational policy documents means creating novel tasks, promoting horizontal interactions (pupil/pupil) and not just vertical interactions (teacher/pupil), being able to explore pupils’ reasonings and response strategies, posing stimulating questions that increase their involvement in the tasks. Thus, the didactic contract or the experimental contract established with the pupils or subjects of a certain research is of the utmost importance. These are the (generally implicit) rules that legitimise many of the mutual expectations of the various social partners involved in an interactive process, with which the appropriation of knowledge and the mobilisation of relational competencies are supposed to exist. Therefore, implementing novel classroom practices or experimental activities also involves defining contracts that are novel themselves and that encourage peer interactions (César, 2000a, 2000b, 2000c; Grossen and Py, 1997; Schubauer-Leoni and Perret-Clermont, 1997).

Several investigations have discussed the role of social interactions in cognitive development and in the promotion of pupils’ school achievement, namely in Mathematics (César, 2000b; Perret-Clermont and Nicolet, 1988; Schubauer-Leoni and Perret-Clermont, 1997). In Portugal, the first studies by César (1994) were an attempt to find answers to the challenges brought forth by teachers who wanted to know how to form efficient groups in their daily practices in order to improve pupils’ mathematical knowledge. These studies were contextualised and they allowed us to understand the mechanisms related to peer interactions and their role in the promotion of pupils’ socio-cognitive development and knowledge appropriation. In recent studies (Carvalho and César, 2000c) we showed that working in peers was an effective way of promoting pupils’ cognitive development and better statistical performances. But in order to understand how interactive processes contribute to these progresses we need to undertake an in-depth analysis of the interaction itself.
The contributions of the Vygoskian theory (1962, 1978) were essential in order to understand the difference between actual development and a potential one. This difference leads to the notion of Zone of Proximal Development (ZPD) which is one of the most fruitful constructs arising from this theory and one of the most explored in educational settings (Allal and Ducrey, 2000; Moll, 1990). But in order to work collaboratively pupils need to construct an intersubjectivity (Werstch, 1991) that allows for exchanging ideas and knowledge, i.e., to be able to follow each other’s solving strategies as well as to manage every aspect related to the relational context.

Method
The project Interaction and Knowledge is divided into two different levels: 1) - A micro-analysis level, in which we studied different types of peers, their interactions, the tasks we propose, the mistakes they make and the progress that peer interactions are able to generate in statistical contents (Carvalho and César, 2000a, 2000b, 2000c, in press; César, 2000a); 2) - An action research level, in which some mathematics teachers implemented peer interactions as a daily practice during a school year (César, 1998a, 1998b, 2000a, 2000c; César and Torres, 1998; César and Silva de Sousa, 2000). The data we are going to present are from level 1.

Subjects
The sample was formed by 136 dyads. Subjects attended the 7th grade in two public schools near Lisbon. Their ages were between 11 and 15 years (Average=12.5 and Sd=0.8). The case we are going to analyse is representative of most dyads.

Instruments
The statistical tasks used in peer work sessions were “unusual” ones according to teachers’ statements and to our previous observations of their classes (Carvalho and César, 2000c; César, 2000a). They corresponded to more open and innovative tasks.

Procedure
In this research pupils had three sessions in which we promoted collaborative work. Pupils were grouped in dyads and the interactions were audio taped only in the second session of peer work. The episode we are going to analyse is related to one of the tasks presented in the second session. The working instructions that were given asked them to discuss before writing their answers and to explain everything they thought. Each dyad only had an answering sheet.

Results
The task that pupils were solving in these episodes is the following one: “The mean of four numbers is 25. Three of those numbers are 15, 25 and 50. Which is the missing number?”
Case 1 - Co-constructing statistical knowledge in an asymmetric dyad

14 A - First we must sum up 15 + 25 + 50.
15 C - 15 + 25 + 50 is 90 [She uses the calculator]. If this was the mean of 90, 90 dividing by three would be 30.
16 A - Let's try with 94 divided by four. It must be an integer number. So, adding four doesn't make it right.
17 C - 90 plus what? 6? Wait a moment, I'll do it. [She uses the calculator] 25 isn't right either
18 A - So, how do you calculate the mean? When you calculate the mean you sum up all this [she points to the values] and you divide by a number.
19 C - How many they are?
20 A - 4. So, what you should do is this, 15 + 25 + 50 + X and divide by 4 which equals 25.
21 C - How much is the X?
22 A - It's the result of 15 + 25 + 50 + X divided by four which was 25.
23 C - It's 6.
24 A - It can't be. In order to solve this equation you have to do 25 times 4.
25 C - Wait a moment!
26 A - Let me do it. 25 times 4 is 100, eh! Delete it [C is doing the computations with the calculator]. Now try to do 100 dividing by four to see whether... [C finishes her computations and she agrees moving her head] it's 25. Then, it has to be 10. It's 10.
27 C - 15 + 25 + 50 + 10 is 100.
28 A - Now, if you do 100 dividing by four, which is the total of the data. Do it: 100 dividing by 4 is...
29 C - 100 dividing by four is 25 [She writes down]
30 A - Equals four, how dumb! Equals 10, because 25 times 4 is 100 and then... If we had 100 to 90 there's 10 left. Let's move on to the next one.

In this episode A.'s leadership is clear although, according to the rules of the experimental contract we established, she always explains everything she is thinking to C. and takes care to check if C. is following her solving procedures for the proposed task. So, C.'s first phrase is to show A. she knows how to calculate the mean. However, this phrase does not show a solving strategy for the problem, for C. just says what the mean of the 3 numbers on the sheet would be. The fact that classroom practices usually stick to applying algorithms and procedures (Batanero, 2000; Carvalho and Cesar, 2000a; Shaughnessy, 1992; Skemp, 1979) may explain why this pupil associates solving this problem with merely applying an algorithm, regardless of this leading or not to the solution of the problem. This way, C. would dominate what Skemp (1979) calls instrumental knowledge but, if she worked individually, she wouldn't manage to reach a relational knowledge.

As the mean is 30 instead of 25, A. realises that the missing number mustn't be very high. So she decides to start applying a trial-and-error strategy, which Cesar (1994) considers to adapt well to problems of a medium complexity, but in this case
her attempt fails from the start. However, we can see that despite C. having the calculator, it is A. who controls the credibility of the results: "It must be an integer number". So she is the one who understands, through the result on the calculator, that her hypothesis isn’t the result they want, for the number is not an integer.

C., who is having more calculation difficulties, doesn’t want to leave the solution of the problem to A. alone. Therefore repeatedly she tells her "Wait a moment", which not only shows that she acknowledges that she works at a slower rhythm than her peer but also that work should be carried out in dyads and she intends to contribute to it, however slow she is. Curiously, the several temporal expressions present in this dialogue have a well defined role: for C., they mean to tell A. that she needs more time to think, so A. doesn’t answer just yet. So they serve to put the brake on the speed of the solution. For A., who starts several times by saying "Now...", they serve to accelerate the rhythm, make suggestions or even give orders, so C. can collaborate but not put the task solution at risk. This is also visible in the last phrase of the episode, when A. wraps up the task solution, adding, "Let’s move on to the next one".

On the other hand, since C. has less knowledge that is necessary for the task solution, the pauses she imposes are also a way of negotiating in the relational context – the appropriation of the knowledge in question in the task solution. This probably explains how C. progressed, between pre- and post-test (see Carvalho and Cesar, 2000c for more details) in cognitive terms and in terms of her level of performance in statistical tasks. Besides, this kind of attitude also shows she understood and stood by the proposed experimental contract, since it suggested they only write down an answer when both agreed with it and when both had collaborated in the task solution.

These rules of the didactic contract give rise to a few words of a pedagogic nature, on behalf of the more competent peers: "So, how do you calculate the mean? When you calculate the mean you sum up all this [she pointed out to the values] and you divide by a number". This way, we may state that the rules of the experimental contract play a very important role in the type of interaction that pupils establish, as several authors stress (Cesar, 1994; Schubauer-Leoni and Perret-Clermont, 1997).

As soon as A. realises that through trial and error she is not reaching the result she wants, she drops this tactic and changes to an algebraic strategy, typical of pupils who already have access to formal reasoning (Cesar, 1994; Perret-Clermont and Nicolet, 1988). She easily verbalises the translation of the problem on the sheet in an equation: "15 + 25 + 50 + X dividing by 4 equals 25", which means A. does not only master Statistics contents. In this part of the interaction the difference between the operatory level of each of the subjects is clear: for A., the value X really represents an unknown quantity and does not need to be immediately replaced with the value it represents; C., who is on a less advanced operatory level, needs to ask "How much is the X?", for she needs to materialise this value. Actually, it is funny that C. seems to
adopt A.’s initial strategy for a moment, for she still tries to see whether X can be
replaced with 6, before calculating its value by solving the equation A. formulated.

Another very interesting point is the understanding A. gains through C.’s
difficulties. When she realises C. has difficulty in reasoning in formal terms, she
abandons the equation solution that had been her second suggestion and chooses an
arithmetic strategy: 25 times 4 is 100; the previous numbers had summed 90. So, the
missing number is 10. This way A. does not drop the leadership of the problem
solution but adapts her speed and solving strategies to the difficulties revealed by C.
They are able to construct something that Werstch (1991) calls an intersubjectivity,
whereby both contribute to find an adequate solving strategy. This capacity to
simultaneously deal with the cognitive as well as the relational aspects of the task is
what enables them to work in their ZPD, which, according to Vygotsky (1962, 1978),
promotes cognitive development. This is what happened to the less competent peer,
who progressed to performances that are typical of the formal stage.

Regarding the relational aspect for a moment more, it seems important to us that
there is an opposition between A.’s patience and the type of vocabulary she uses
when C. has difficulties or makes a mistake, and the way she reacts when she makes a
mistake herself. Only one expression with a negative connotation is used in this last
case: “How dumb!”. This means that A. has a true concern in supporting C., in
contributing so that she gains confidence in her competencies and mobilises them
more easily. When it comes to judging herself, A. becomes a harsher evaluator,
probably because she doesn’t feel her competency threatened by the fact.

It seems clear to us that for either one of the elements of this pair, it is the fact that
they work collaboratively and with certain rules of the experimental contract that
allows them to develop a relational knowledge. The fact that they have to explain
everything they do, discuss several solution hypotheses, experiment with several
possible strategies, makes the level of appropriate statistical knowledge more
complex, for they discuss the inherent context of the proposed task between each
other, enriching the meaning they are capable of giving it.

As for statistical performances, in both cases they had better results in the post-test
than in the pre-test, which is in accordance with results reached by several pupils,
namely in Portuguese investigations (Carvalho and César, 2000c, in press; César
(1962, 1978) believed, it is not just the less competent peer who benefits from the
interactive process. Peer interactions have shown to be a powerful mediator in
knowledge appropriation and in the mobilisation of competencies on behalf of the
pupils. Therefore, when we promote peer interactions in the Maths class we are
facilitating pupils’ full development and their school achievement in this subject, for
on a post-test level, which is already solved individually, subjects are often capable of
using solving and reasoning strategies that we saw them developing for the first time during the collaborative working sessions.

Statistical tasks adapt particularly well to collaborative work, as long as teachers use open tasks that stimulate the use of varied strategies and the development of a critical spirit (Carvalho and César, 2000a). In this case, more positive attitudes towards Maths are also promoted, besides contributing to the development of an academic self-esteem on behalf of the pupils who usually have difficulty in reaching good performances. Thus, as we see in the example we presented, pupils show their intent in solving tasks instead of abandoning or rejecting them. Hearing and talking to a colleague forces them to express their doubts and solving processes clearly, and this contributes to them being able to appropriate more knowledge and do so in a relational way instead of a merely instrumental way (Skemp, 1979). This is in conformity with the aims suggested in the educational policy documents.

**Final Remarks**

Attributing a meaning is a fundamental step in solving a mathematical task and for knowledge appropriation and the mobilisation of competencies. As Vygotsky (1962, 1978) stressed, pupils need to de-contextualise and re-contextualise knowledge so that it goes from being external and social to being internal and personal. Facilitating the attribution of meaning is essential in order to promote school achievement and numeracy, so the nature of the tasks we propose to pupils must be taken into account. Besides this, social interactions, namely peer interactions, play a truly relevant role in the facilitation of meaning attribution, so the implementation of a novel didactic or experimental contract is also a very important element to take into account if we intend to reach the aims of current curricula and educational policy documents.

In order to promote school achievement in Maths, namely in Statistics contents, we need to facilitate the possibility of pupils going from an instrumental knowledge to a relational knowledge. But for this to become a reality and not just an intention, we need to learn to observe pupils' solving strategies and reasonings in detail. Only this way can we, as researchers and teachers, promote practices that allow pupils to work in their zone of proximal development, as several authors suggest.

The recommendations of several official documents point to the need to value social interactions in the Maths classroom, particularly if we consider, as Abrantes, Serrazina and Oliveira (1999) state, that “Maths education may contribute, in a significant and irreplaceable way, to help pupils become individuals who are not dependent but, on the contrary, competent, critical and confident in the essential aspects in which their lives relate to Maths” (p. 18). However, we feel this aim will only be fully reached if we know how to implement rich and fruitful social interactions in the classroom.

ARITHMETIC AND ALGEBRA, CONTINUITY OR COGNITIVE BREAK?
THE CASE OF FRANCESCA

Michele Cerulli & Maria Alessandra Mariotti
Dipartimento di Matematica – Università di Pisa

Abstract. Taking the 'operational/structural' perspective, as introduced by Sfard, this paper analyses the passage from computing with numbers and computing with letters. The discussion is based on a case study, taken from long term research project, still in progress. A key aspect, characterizing the transition from the two types of computation, will be highlighted: the change of role of operation properties.

Introduction
High school Algebra activities are often characterized by the use of symbolic manipulation. According to the Italian tradition, symbolic manipulation constitute a basic element of secondary school curriculum and in school practice. Usually, students are introduced to the manipulation of algebraic expressions only after experiencing large amounts of computation of numerical expressions: therefore the problem of transition from numerical to algebraic computation arises. Analysing the connection between Algebra and Arithmetic, Lee & Wheeler (1989) showed that the relationship between calculation with numbers and calculations with letters is not so direct and transparent. They argue that, in spite of the use of common operation signs, the activities of writing and manipulating expressions in algebra and in arithmetic are quite different.

In this paper we shall point out and discuss some aspects characterizing the difference between calculating in Algebra and in Arithmetic; the following analysis will be carried out in terms of Sfard’s operational-structural theory (Sfard, 1994).

Both the necessity and the difficulty of achieving such a duality is clearly expressed by the author:

"The formula, with its operational aspect (it contains 'prompts' for actions in form of operators) must be also interpreted as the product of the process it represents."

"[...] our intuition rebels against the operation – structural duality of algebraic symbols, at least initially."

(Sfard, 1994, p.199)

The operational character of pupils' conceptions related to algebraic formula and expressions tends to persist; at the same time, although symbolic manipulations of algebraic expressions is largely present in school practice, the absence of "structural conceptions" appears evident (Kieran, 1992, p. 397).

This paper aims at analysing the relationship between the two levels of computation:
computation with numbers and computation with letters. We will argue that, contrary to
what books and teachers usually state, the transition from computing with numbers and
computing with letters is not so smooth and in fact, it may present a cognitive break: as
suggested by Francesca: "Our teacher says that with letters it [computing] is the same
as with numbers, but to me it doesn't look the same, it looks very different [It: non mi
sembra la stessa cosa]".

Methodology
The results we are going to discuss are part of a long term project (Cerulli & Mariotti,
2000) concerning the introduction of pupils (aged 14-15 years) to algebra and in
particular to symbolic manipulation. A 9th grade class was split into two separate
groups, one following the project, the other following a traditional approach to algebra.
Comparison between the groups is interesting because the pupils have the very similar
school experiences: apart from the class of mathematics, and they share the same
courses for all the other subjects.

The following discussion concerns only some results related to the exemplary case of
Francesca, a medium-high level student who attended the traditional course.

1 Before the algebra course
At the beginning of the teaching experiment, before splitting the class, a test was
submitted to the students. Some answers given by Francesca are analysed. The first item
of the test concerned the correctness of some equalities between numerical expressions.

T1 Observe the following statements, for each of them explain why you think it is
correct or why you think it is wrong.

Let us consider the following answers given by Francesca:

T1.2 \[ 17 + (6 + 9) = (17 + 6) + 9 \]
This statement is correct because of the associative property.

T1.5 \[ 8 + 9 \cdot (3 + 2) - 17 = 8 + 27 + 18 - 17 \]
This is not right because one can't get rid of the brackets and compute 9\cdot3 and
9\cdot2 and then add [the terms] because the result changes.

T1.8 \[ 3 + 6 \cdot 73 + 6 \cdot 8 + 13 = 3 + 6 \cdot (73 + 8) + 13 \]
It is right because adding few numbers, which are multiplied by the same number,
or multiplying them by the previously defined [common] number the equivalence
remains unchanged.

Unlike other students, Francesca seems to tackle the problem within a structural, instead
of a operational approach (Sfard, 1994). Both aspects actually seem to be present: on the
one hand the operations properties are considered rules which determine whether or not
it is possible to pass from one expression to another ("...keeps the equivalence
unchanged"); on the other hand, they are considered equivalent relationships between
computing procedures. Answers to items 5 and 8 are clearly in contrast but both
justifications have the same nature: Francesca is so strongly convinced about the
acceptability of the transformation rule, that she performs no computations to check the equality statements.

Thus the rules known by Francesca are instructions which make it possible to move from one expression to another, from one computing procedure to another; the sign “=” is interpreted according to a fixed direction (from left to right) and this peculiarity may affect the acceptability of reversible transformations of algebraic expressions.

In conclusion, as concerns the operations properties, both the structural and procedural aspects can be found in Francesca’s answers, but they do not seem to be stable and merged together.

2 After a traditional algebra course

After one year of activities within a traditional framework concerning algebra and symbolic manipulation, a number of interviews were designed, aimed at investigating the relationship between computation with numbers and computation with letters. In other words, we were interested in studying the evolution of the conception of “computing, taking into account the fact that in Italian a unique word "calcolo") includes both symbolic and numerical computations.

2.1 What is the meaning of “calcolo”?

When asked what she intends by the word “calcolo”, Francesca refers to the primitive model of computation related to the four operations, natural numbers and eventually fractions; the meaning of “computing” ("calcolare") is “finding something unknown [qualcosa che non si conosce]”, she says. Changes occur when letters are introduced; consider the following excerpt of Francesca’s interview.

30.A. Listen, and after these computations… are there any others?
31.F. With letters
32.A. With letters they are even more difficult, aren’t they?
33.F. (Laughs) Yes.
34.A. Let’s write a computation (calcolo) with letters, but a very difficult one …
35.F. (She thinks and writes) Mmm …something…how was it? (while producing the expression she tries to remember some “prodotti notevoli”1, then she writes a cube) Yes this one \((a + b)^4 \cdot (a^2 - b^2)\) (the cube) that I could never work out, then the other one with fractions (she writes the fraction line and denominator)

The construction of the example seems to be inspired by a strong model of computing with letters: the expression is obtained combining various “prodotti notevoli”; within

---

1 A “prodotto notevole” is a standard equivalence statement used to speed up computations with letters, an example is \((a+b)(a-b)=a^2-b^2\).
this model, success in computing depends on whether one knows/remembers the formula associated with computing chunks (35).

In the case of Francesca, this model contrasts with the original model of computing numerical expressions, based on the idea of “finding something”, i.e. finding a result.

The common aspects shared by the two models are evident. Furthermore, the teacher states that they “are the same thing”, but Francesca in convinced that computing with letters is quite different from computing with numbers, and she says:

64.F. Well, I know that...also the teacher always tells me that computing with letters is the same thing as computing with numbers, but to me it is not the same. Because if I am given 10+3 whilst...[ if you give me] a*b+c+d I get stuck... (laughs) I can't work it out. With numbers we are back to something real, well ... for me numbers are not real, but they are still more real than letters in mathematics.

65.A. O.K. so the teacher said that it is the same.

66.F. Yes.

67.A. And you say “to me it is not the same”, let’s start from this point. Why isn’t it not the same for you? That’s what I am interested in.

68.F. Because!...because if you do 10+13 times, 25+3, you find it [the results], but if you do a+b you can’t do it, if you have to do it, for example (she writes a numerical expression and a literal expression)...here we put a minus (she changes 25+3 into 25-3), if you do this, you get a number, but if you do that, you find “a square minus b square” (she writes the "result" of the "prodotto notevole").

\[
\begin{align*}
(10 + 13) \cdot (25 + 3) \\
(a + b) \cdot (a - b)
\end{align*}
\]

Francesca’s words clearly show that the meaning of numerical computation is consolidated and based on concrete models, whereas “to find something” has a specific stable meaning, but this meaning cannot fit the case of letters. Francesca knows quite well how to cope with algebraic expressions, and knows how to transform them using standard formulas, but she still can’t accept the supposed similarity between the two ways of manipulating expressions: the model of computing with letters is not derived from an evolution of the model related to numerical computations. As a consequence she feels a break between the two situations; in other terms we can recognise a break between the two meanings of "calcolo". The next part of the interview shows clearly where such a break occurs.
2.2 Computation with numbers and computation with letters
Francesca tries to compare the two kinds of computations, and in order to express her uneasiness she starts to compute the expressions she has produced. In the numerical case, she first computes the sums in brackets, then multiplies the numbers obtained and finally obtains the result which is 506. In the case of the expression with letters, Francesca has already produced a result “a^2-b^2”, thus she makes explicit the intermediate computation steps, previously skipped: she multiplies the two sums in brackets term by term, and finally sums the similar terms. At this point the interviewer asks:

74. Did you perform the same operations (with numbers and with letters)?
75. F. No I didn’t
76. A. in this case and in that case (she points to the two expressions)?
77. F. No...well, yes, I multiplied, here [expression with letters] I multiplied everything, while here first I have to add, first I calculate the parts in brackets
78. A. And here, (pointing to the numerical expression) could you multiply everything or couldn’t you? Is it forbidden?
79. F. You mean multiply 10 times 25, as I did here [in the case of letters]?
80. F. I never tried to!
81. A. Fine; it’s ok that you never tried; do you think you would get 506? I mean do you think you would get the same result...or not?
82. F. I don’t know...I don’t think so...I don’t know. (she doesn’t seem to be sure at all, she is curious, and starts to compute)...250...13×25...
83. F. Aha! It is the same!
84. A. Is this a surprise for you? 250 – 30 + 325 – 39 = 545 – 39
85. F. Yes!(laughs) 506
86. A. Well, you never tried: is it true?
87. (She nods)
88. A. And now are you convinced...that it would be always the same, if you had done ...because this is a specific case, you might have been lucky...do you think it would always work; or not?
89. I don’t know. How can I ...? I didn’t know the rule that if you do so you always get the same result, it is not as if it were an axiom that tells you that it is always the same, I thought it was just a case, and not a rule.
90. A. Bah!, you wouldn’t trust it. So, here, this way to compute (points to the literal expression) why... are you sure that this is correct?
91. F. Yes I do
A. And why do you trust it here?

F. Because I was taught to do so (*laughs*)

A. Because you were taught, and does that make any sense?

F. The sense is that of not writing such a long computation, and to write only those two numbers (*points to* $a^2 - b^2$), but there is...

It is surprising to see how astonished Francesca is when she realizes that the result obtained by applying the rules of symbolic manipulation to a numerical expression is the same as that obtained previously by computing sums and multiplications. Furthermore it is surprising that, even after having verified such a phenomenon by executing computations, she is still not convinced of it’s generality. It looks as if no link has been established between the two kinds of computations and the acceptability of the rules is strongly influenced by school practice: when pupils are required to transform an algebraic expression into another one, the validity of the transformation depends on the external control of the teacher (“I was taught to do so” 93). Nevertheless, Francesca is able to establish a link between numerical and algebraic expressions:

A. [...] what is the relationship between the expression $(a+b) - (a-b)$ and the expression $a^2 - b^2$? What is the relationship...

[...]

F. The result...well, if you put numbers instead of $a$ and $b$, if you do this with 3 and 2, you get a number which is equal to...if you perform the other computations, there...

A. If I put numbers I get that result.

F. Yes

100. A. So, why don’t you trust the fact that if you had a numerical expression it wouldn’t...

101. F. I don’t know...because I was never told...thus (*she smiles embarrassed*)...well if I think it would have, well...if it was that, well...anyway everyone tends to shorten [*computations*] and do things as quickly as possible, but then I don’t understand anything anymore...

Francesca knows that two expressions are equivalent when they have the same value if letters are substituted with numbers; but this equivalence relationship, in terms of “values of the expressions”, is conceived considering the two expressions as autonomous entities. The equivalence relationship of this type does not concern the symbolic manipulation which transforms one expression into another. In Francesca's view, two algebraic expressions $[(a-b)(a+b)$ and $a^2 - b^2]$ are two completely independent calculation procedures, which can be accomplished only by substituting letters with numbers. This shows that Francesca is conceiving the two expression according to a dual meaning (Sfard, 1994): both as calculation procedure and as two
single entities that can be compared. Nevertheless she seems not to have related the two kinds of computation: "computing with numbers and "computing with letters"

This represents a rupture between the two meanings of computing ("calcolo"): the two procedures (for number on the one hand and for letters on the other) follow different rules which in Francesca's view have nothing in common. As a consequence, it is possible to accept the idea of equivalence in terms of values of expressions, but not to accept or believe that calculating with numbers "is the same as" calculating with letters.

3. Properties of the operations as instruments for symbolic manipulation

The case of Francesca is particularly interesting because it clearly shows the complexity of the relationship between the two meanings of 'computing' ("calcolo"). It shows that it is possible to access some key aspects of this relationship, such as a structural and operational conception of operation properties and algebraic expressions, equivalence between computing procedures, but still lack (CONTROLLARE) a comprehensive meaning of computing including both the case of numbers and that of letters.

As a matter of fact, grasping the link between computing with numbers and with letters, requires a radical change of perspective, of which the operation properties are the core.

According to Sfard's hypothesis, when computing with algebraic expressions a new operational level must be achieved, but this must be achieved without breaking the link with the previous one. The analysis of Francesca's case shows that not only must the reification of an expression be accomplished (expressions can be acted upon as new objects), not only must the structural level be consolidated (equivalence between expressions must be stated in terms of their values), but also a relation between the two 'computing procedures' ("calcoli") must be constructed explicitly.

The key-point is that properties of the operations have to become rules of transformation, i.e. "instruments" of computation, and in order to do so, they must assume a dual meaning (structural and operational): properties state the basic equivalence relations and function as instruments for symbolic manipulation, i.e. instruments by means of which any symbolic transformation is derived.

Within the numerical context, operation properties do not play an operative role; they simply express the equivalence of computing procedures, but they are not necessary, and thus not usually employed for computation.

Within the algebraic context, operation properties must assume an operative role and must become the instruments for transforming expressions.
Such a change of role is not made explicit in school practice and focusing of attention on memorisation of particular shortcut procedures such as algebraic formulas ("prodotti notevoli") may definitely hide it. In conclusion, it seems reasonable to take the hypothesis that this change of role becomes a first goal in introducing pupils to symbolic manipulation.

UNDERSTANDING HIGH SCHOOL MATHEMATICS TEACHER GROWTH
Olive Chapman
University of Calgary

This paper reports on a study of the professional growth of four inservice high school mathematics teachers who made fundamental changes to their teaching over their teaching career. The analysis focused on the nature of the teachers' belief structure for mathematics and the relationship between it and changes in their teaching. The findings indicated that belief structure played a key role in when and how changes occurred in the participants' teaching in terms of creating pedagogical tensions and as generative metaphor, which were important to facilitate the generation of new perceptions, explanations and behaviours in their teaching. The findings highlight the possible significance of consciously attending to these factors to assist mathematics teachers in achieving desired changes and choices in their teaching.

Background
Change seems to be a significant challenge for mathematics teachers. Even teachers who are interested in change do not necessarily succeed at making substantive or fundamental shifts in their teaching. In the last decade, the mathematics education literature has reflected a growing emphasis on beliefs as playing a key role on if, when or how change occurs because of their apparent relationship to behaviour. Ernest (1989), for e.g., argued that beliefs are a primary regulator for mathematics teachers’ behaviours in the classroom. Although it is not clear that beliefs by themselves can account for mathematics teachers’ classroom behaviours, studies do suggest that there is a strong and important influence (e.g., Cooney et al 1998; Chapman, 1997; Lloyd and Wilson, 1998; Pehkonen, 1994; Raymond, 1997; Thompson, 1992). The relationship to change, for the most part, has been deduced from such studies and others which have demonstrated or implied that shifts in beliefs accompanied shifts in teaching for inservice teachers participating in innovative approaches to professional development (e.g., Chapman, 1999; Cobbs et al, 1990; Simon & Schifter, 1991). The literature, however, seems to lack studies with an explicit focus on the relationship between belief structure and inservice mathematics teachers’ growth. This relationship deserves attention given the ongoing importance of understanding the mathematics teacher and helping them to make fundamental changes in their teaching to reflect current reform recommendations in mathematics education. This paper reports on a study that investigated this relationship for inservice high school mathematics teachers who have changed their practice on their own from a teacher-centered to a student-centered perspective. Specifically, the focus

This paper is based on information from a project funded by the Social Sciences and Humanities Research Council of Canada.
is on the nature of the belief structure (how the beliefs are held) for mathematics and the relationship between it and changes in their teaching over their teaching career.

Belief Structure

Green’s (1971) metaphorical analysis of belief structures provides one way of interpreting the ways beliefs are held. Green described 3 dimensions of belief systems: (1) primary or derivative (i.e., the quasi-logical relation between beliefs), (2) central or peripheral (i.e., the relations between beliefs having to do with their spatial order or their psychological strength), and (3) isolated clusters (i.e., beliefs are held in clusters, more or less in isolation for other clusters and protected from any relationship with other sets of beliefs). Beliefs are also held evidentially or non-evidentially. Green (1971) explained that the importance of a belief to the believer is determined by whether it is psychologically central. Thus, the question of which beliefs are amenable to change may have to do with their being primary or derivative, but with the strength with which they are held. For e.g., a teacher who holds a psychologically central belief that mathematics is a collection of facts may be less likely to change it regardless of whether it is primary or derivative. Change can also be restricted when, as Green (1971) explained, isolation of belief clusters occur to facilitate contradictory beliefs developed in contexts in which beliefs are not explicitly compared or when beliefs are held from a non-evidential perspective, a perspective immune from rational criticism.

Research Method

The participants of the study were 4 experienced (16 to 33 years) high school mathematics teachers (pseudonyms Linda, Elise, Mark, and Rose) who were known in the school system as excellent teachers. They were very articulate and open about their thinking and experiences in teaching mathematics. Data collection and analysis followed a humanistic approach (Chapman, 1999; Creswell, 1998). Data collection involved open-ended interviews, role-play, and classroom observations. The interviews focused on paradigmatic and narrative accounts (Bruner, 1986) of the teachers’ past, present, and possible future teaching behaviours and their thinking in relation to mathematics pedagogy. Paradigmatic accounts, triggered in a variety of ways, highlighted the teachers’ theories about a situation (e.g., problem solving). Narrative accounts highlighted the teachers’ lived experiences and consisted of stories that described the experiences as they occurred, e.g., stories of lessons they taught that (i) were memorable, (ii) they liked, and (iii) they did not like. Classroom observations focused on recording what the teachers said and did and to identify scenarios for the teacher to talk about or role-play. All interviews and classroom talk were audio taped and transcribed.

The data were scrutinized for situations indicating change in teaching approach and for beliefs related to teaching mathematics. Beliefs were identified in terms of significant statements and actions that reflected, for e.g., personal judgements, intentions, expectations, and values of the participants in the context in which they
were described. Belief about mathematics emerged as the most dominant belief in the teachers' story of change and was made the focus of the study. The nature of the belief structure and the relationship to the teachers' growth in teaching mathematics were determined by examining the beliefs in the contexts in which they occurred and the relationships among contexts. An abbreviated account of the findings follows.

Belief Structure for Mathematics

The dominant beliefs the participants held about mathematics were mathematics is play/game (Elise), mathematics is shared experience (Mark), and mathematics is language (Linda and Rose). The beliefs emerged from and were supported by the participants' personal experiences. For Elise and Rose, the beliefs emerged from their experience as students of mathematics. Elise explained,

As a student in the classroom, I just thought it [math] was a blast... something that you absolutely love to do for no other reason. ... I mean, I just loved the thrill of the chase. I loved proof. You know, it's the, it's a game, like it's just play, and it has a set of rules but it doesn't really have a set of rules.

Rose's experience as a student involved a lot of small-group discussions about mathematics that framed her view of mathematics as language, i.e., "something you speak, do and use to number the world."

Mark and Linda's beliefs emerged from their experiences as teachers. Mark's experience using manipulatives and small-group work when he started teaching elementary school mathematics along with his high school teaching framed his view of mathematics. He pointed out,

Math to me is an experience. That's the way, that's how I started to see it with the elementary [school] kids.

Linda's experience working through mathematics problems in her own way in planning a mathematics course she was teaching for the first time framed her view of mathematics as language – "a tool used to understand our world."

There were two significant ways in which these beliefs were held – in terms of Green's (1971) belief structure and as metaphors. The way the participants held their beliefs about mathematics seemed to be primary, evidential and central (Green, 1971). The beliefs were primary because they were not explicitly based on other beliefs and evidential in that the teachers' lived experiences provided the primary evidence for them. Thus, they were amenable to change if these experiences changed. The beliefs seemed to be central, i.e., psychologically strong, because of the passion and conviction the participants displayed for them and their resistance to change. For example, each participant was very critical of any thinking or actions of teachers that was not consistent with her/his belief. He/she was very judgemental of her/his own teaching when in conflict with the belief and not vice versa. The belief also remained stable in that while there were extensions in its interpretation, it did not change conceptually/philosophically since it was constructed. The psychological strength of the beliefs was further validated and reinforced by current reform recommendations.
about mathematics adopted in the revised mathematics curriculum of the teachers' province. The humanistic perspective of mathematics embodied in the beliefs resonated positively with this orientation of the reform recommendations.

In addition to the preceding belief structure, another way in which the participants' beliefs about mathematics were held was as metaphors. Mathematics is play, experience and language can be viewed as descriptive metaphors from the teachers' perspective in that mathematics was being described and understood in terms of characteristics directly appropriate for some other domain. In the context of their stories, however, there were times when the beliefs also seemed to become generative metaphors (Schön, 1979) and helped to facilitate change as discussed later.

Relationship Between Belief Structure and Change in Teaching

The preceding structure of the participants' beliefs of mathematics played an important role in when and how changes occurred in their teaching. These roles are discussed in terms of pedagogical tensions and generative metaphor.

Pedagogical Tensions

Substantive changes in the participants' teaching were preceded by pedagogical tensions and a desire to resolve them. Both of these conditions seemed to be influenced by the psychological strength of their beliefs about mathematics. Fundamental shifts in the teachers' teaching were generally directed, often unconsciously, to eliminate or reduce tensions between their teaching and their beliefs about mathematics that created a state of disequilibrium for them. This tension was triggered by situations in their classroom experiences that made their teaching not feel right or students' learning seem to not meet their expectations. The tensions were resolved by extending the interpretation of doing mathematics without changing the primary belief of mathematics and modifying the teaching approach. Thus, belief about mathematics seemed to be held with more dominance, and had a stronger influence, than belief about teaching, in that, regardless of how the latter was held, e.g., central or peripheral, the change was to make actions reflect belief about mathematics. Elise's case will be used to illustrate these tensions and corresponding changes in teaching.

As a beginning teacher, Elise's expectation was that she would be able to teach to reflect mathematics as play even though she did not have a clear conception of what teaching looked like to realize this. This expectation was quickly smothered when Elise started her practice. She was told by her experienced colleagues that their approach (which Elise described as "stand and deliver") was the only realistic way to teach high school mathematics. There was nothing play-like about high school mathematics and she should abandon any thoughts of wanting to make it that. Not sure of what else to do, Elise reluctantly adopted her colleagues teaching approach and started to experience her first significant pedagogical tension. In order to deal with this conflict, instead of changing her belief about mathematics, she developed a position to protect it. She explained:
You know, that’s the time when I separated mathematics from teaching mathematics. That’s when ... it became internalized to me that there must be a difference between teaching mathematics and doing mathematics. But those aren’t the same thing and they can never be the same thing. And that to this day frustrates me because I don’t want that to be the way it is.

With this ongoing desire to resolve the tension, Elise continued to think of how to make high school mathematics be play for her students. When she no longer felt under the influence of her experienced colleagues, since what she was doing lacked fun, she decided that if she added some fun activities, students might start to experience mathematics as play. These special activities, however, did not resolve the tension between what Elise believed about mathematics and how she was teaching it. They were “fun” in an isolated way and did not give her a feeling of play or a sense of the students engaging in play in terms of the mathematics being taught/learnt or mathematics in general.

After a few years, Elise realized that those “fun” activities did very little to foster her beliefs about mathematics in her classroom. They were too detached from the core content being taught and served more of a recreational purpose in the transition from one unit to the next. Elise also felt that, for the most part, the students were simply mimicking her instead of engaging in play or being problem solvers. As she focused on how to help them to become problem solvers, she eventually made a connection between game and problem solving, in particular, viewing problems as games and emphasizing the importance of strategies. She explained,

I thought, if I'm going to be a good problem solver, I have ...to think about what strategies to try. And I really firmly believe as a learner, what I need to do is look at them [problems] as a game. When I play monopoly, I know the rules but it's a dynamic, it changes. When I solve a problem, I have my strategies that colours the rules, but it's a dynamic situation, and so sometimes I use this strategy, sometimes I use that strategy, but I'm more relaxed because it's a game

Elise’s interpretation of strategy included a way of thinking, seeing patterns, making connections, and reasoning and was seen as relevant to all areas of mathematics. For her, strategies were not just techniques to solve problems, but a way of viewing and learning mathematics. They were also “something you must see for yourself”. This perspective of strategies provided a way for Elise to think of high school mathematics and her teaching of it differently. For her, in addition to fun, high school mathematics and doing mathematics became being and focusing on strategies, respectively, and consistent with her belief of mathematics as play/game. With this, Elise’s teaching shifted from being “stand and deliver” to being more student-centered, but teacher guided. She tried to guide students to seeing strategies, e.g., looking for patterns in developing a procedure for themselves. She started to use more questioning and less telling. She followed the textbook less and selected or developed activities in which students could discover strategies through discussion. Students worked in small-
groups to figure out strategies and shared them in whole-class discussions. However, Elise often intervened in the groups with questions to guide them to a strategy or led interactive, whole-class discussion to do so. This strategy-based approach created for Elise an acceptable level of harmony between her belief about mathematics as play and her teaching. The primary beliefs about mathematics remained unchanged while teaching behaviour was modified to an acceptable level of harmony.

The next significant pedagogical tension arose when Elise’s view, that her approach of focusing on mathematics in terms of strategy was helping students to think for themselves, was challenged by her students’ performance on the grade 12 provincial diploma examination (required for graduation in mathematics). In the mid-90’s, this exam was revised to include genuine problem-solving items and Elise was surprised when even her best students did not perform at the level she expected. In trying to resolve this new tension, Elise eventually concluded that guiding students to see strategies was not enough for them to be good problem solvers. They must be able to think for themselves to be successful. Elise decided to facilitate this by getting students to think about their thinking through writing and self-questioning. She noted,

I’ve focused much more the past 5 years on reflective thought for each person, each individual, and trying to not only encourage but in many ways force kids to do it. … Reflecting on what it is that you know and what does it mean to understand the remainder theorem [for e.g.] is very important. …

The reflective process Elise added to her teaching was, for her, both a strategy and a way of making sense of strategies. It also increased the level of harmony she was developing between her belief about mathematics as play/game and her teaching.

At the time of the study, Elise’s teaching had evolved from a “straight stand and deliver” at the beginning of her practice to a combination of teacher-guided and teacher-facilitated situations. Her pedagogical tensions were resolved by modifying her teaching approach within the primary belief of mathematics as play/game. This belief did not change, but her understanding of it broadened (i.e., as fun, strategies, and reflection) in response to resolving the tensions and resulted in significant shifts in her teaching.

Elise’s pedagogical tensions were unique to her but the underlying process of dealing with them was representative of that of the other participants. Mark, Rose and Linda had their own tensions that corresponded to significant turning points in their teaching. For example, in Mark’s case, his teaching shifted from lecturing, which was in conflict with his belief of mathematics as experience, to teacher-guided/facilitated situations to correspond to his broadened interpretation of experience as communication, connection, and problem solving, each of which resulted from trying to resolve a pedagogical tension.

Generative Metaphor

While the preceding section highlighted the relationship between pedagogical tensions associated with the psychological strength of the participants’ beliefs about
mathematics and change, this section highlights the relationship between the metaphorical structure of these beliefs and change. One way of understanding the process of change in the participants' thinking and teaching is in terms of viewing the way the belief about mathematics was held, i.e., as play, experience and language, as a generative metaphor. Generative metaphor (Schön, 1979) or structural metaphor (Lakoff and Johnson, 1980) facilitates learning through a process that involves generating or structuring one concept in terms of another. As Schön (1979) noted,

Metaphor refers to a certain kind of product ... and to a certain kind of process, a process by which new perspectives on the world come into existence [p 254].

The latter situation refers to the generative quality of metaphor in terms of helping an individual to generate new perceptions, explanations and inventions to understand and deal with his/her world. This generative quality seemed to underlie the way in which the participants broadened their perspective of mathematics within the primary beliefs of play, experience and language and made changes to their teaching. The generative process was triggered by the pedagogical tensions as a way of resolving them. From the perspective of metaphor, these tensions occurred when the two domains of the metaphor seemed incompatible in relation to teaching high school mathematics, e.g., high school mathematics (first domain) as play (second domain) for Elise, or experience for Mark, was difficult for them to relate to their teaching. The generative process allowed for the elaboration of the interpretation of the second domain and corresponding changes in the first domain and their teaching. For continuity, Elise's case will be used as representative of the other participants' situation to illustrate the following five stages that seemed to constitute this process.

(i) **Hold belief as a metaphor:** This stage involved holding and articulating the belief about mathematics as a metaphor. Elise was able to do this at the beginning of her practice. Concrete, personal experiences were important to the creation and articulation of the metaphor.

(ii) **Experience pedagogical tension:** The generative process was triggered by these tensions described earlier.

(iii) **Elaborate assumptions/characteristics:** This stage involved becoming aware of and articulating assumptions/characteristics flowing out of the phenomenon providing the context of the metaphor (i.e., play for Elise) based on personal experience of the phenomenon. The first characteristic elaborated by Elise was fun.

(iv) **Connect two domains of metaphor:** The two domains of the metaphor were connected through the characteristics identified in stage (iii). For Elise, fun was mapped to high school mathematics.

(v) **Revise perception:** The mapping led to a revision of perception of both domains of the metaphors. Elise extended her understandings of high school mathematics, interpreting it as fun activities. Mathematics as play could now be seen in the context of high school mathematics and consequently the teaching of it. Change in Elise's teaching was then accomplished to reflect these ways of viewing mathematics.
Stages (ii) to (v) were repeated when the conflict in stage (ii) was not completely resolved or a new conflict arose. In repeating these stages, Elise generated strategies and reflection as further articulation of characteristics of play. These were accompanied by corresponding changes to her teaching. Thus, in the context of the generative process, only after further articulation of the nature of play was Elise able to expand her interpretation of high school mathematics and make substantive changes to her teaching.

Conclusion

The study suggests that the belief structure about mathematics and experiential/concrete contexts for generating and interpreting pedagogical tensions related to the belief about mathematics are important factors that determine when and how changes in teaching occur. The belief structure in the form of metaphor could help to facilitate teachers’ generation of new perceptions, explanations, and inventions in their teaching of mathematics. Thus, the study brings to light the possible importance of generative metaphors that may underlie mathematics teachers’ personal story of growth and the possible significance of consciously attending to such metaphors to assist teachers in achieving desired changes and choices in their teaching.

Developing Formal Mathematical Concepts over Time

Erh-Tsung Chin & David Tall

Mathematics Education Research Centre
University of Warwick, UK
e-mail: E-T.Chin@warwick.ac.uk, David.Tall@warwick.ac.uk

This paper investigates the development of university students' understanding on ‘equivalence relations & partitions’ over a period of time. Although these ideas are taught in the same topic, they have quite different cognitive properties. We find that, although the concept of ‘relation’ can be visualised, an ‘equivalence relation’ is more subtle. A partition, however, is more easily visualised than remembered formally. Our focus is on if and how these different properties influence students’ concept development.

Introduction

Chin & Tall (2000) focused on a theory in which informal mathematics becomes formalised by introducing definitions, proving theorems and compressing formal concepts into cognitive units appropriate for powerful formal thinking. The theory was tested by a questionnaire filled in by 36 students after 6 weeks studying the formal theory of equivalence relations and partitions. It was found that:

Less than half gave formal responses in terms of definitions or theorems. [...] This confirms a picture in which the majority of students following a formal course at a highly rated university responded at an informal level after several weeks’ experience of formalism. At the same time, two able students worked in a different way using the compressed concept that encompassed both equivalence relation and partition.

Chin & Tall, 2000, p. 183

In this paper we follow the development over a longer time period to gain further insight into the students’ constructions. We focus on fifteen students, of whom ten were tutored by the first author for an hour per week during the first two terms and on into the second year. Data was collected through audio-taping tutorials and in-depth interviews, with a second application of the questionnaire to determine long-term changes in conceptions.

An evaluation of the Foundations course by the students at its conclusion in the first year revealed that the students considered ‘relations’ to be the most difficult topic—a comment that had been repeated for several previous years of assessment. Summarising the perceptions of the students, the annual report commented that ‘Euclid’s algorithm and symbolic logic were well understood, basic set theory and functions generally required extra work, but the topic on relations was often poorly understood.’ On an average, only about 20% of students declared that they understood relations well with nearly a third of students claiming that, even after extra study, they only understood the topic poorly. It was this observation that drew us to study the topic of ‘equivalence relations and partitions’. We considered that an understanding of students’ difficulties in this topic that they found most problematic might shed light into wider difficulties in the understanding of formal mathematics. In particular, why do the students claim to have such difficulty with ‘relations’? We now focus on the longer-term development from the first to second year of the course.
Analysis and comparison

The subjects are 15 second year mathematics students following a course in the highest ranked pure mathematics department in the whole of the UK. Their marks for the first year are widely distributed—three are over 80, four between 70 to 79, four between 60 to 69, one between 50 to 59, three between 40 to 49. They answered the same questionnaire on the topic of ‘equivalence relations & partitions’ that they have already learnt for about a whole year and were interviewed during the first term in their second year.

The formal definition of equivalence relation

The formal definition of equivalence relation in terms of being ‘symmetric, reflexive, transitive’ proves to be relatively easy for students to learn and reproduce, though the precise use of quantifiers in each part of the definition is a little more subtle. Table 1 shows that 14 out of the 15 students reproduced a definition although only 5 of these gave the full quantified definition, 4 gave the formal definition without quantifiers and 5 gave an informal response in terms of the three words ‘reflexive, symmetric, transitive’.

Table 1: Responses to ‘equivalence relations’

Only one student—whom we shall call ‘Arthur’—did not give the formal definition in the first year. He explained later that he could not remember the definition at the time; instead he attempted to explain the notion of equivalence classes in terms of a partition:

An equivalence relation generates a subset of elements that are all related to each other, and divides the set into partitions.

Note the imprecision of the language here, for example ‘generates a subset’ and ‘divides the set into partitions’. Arthur obtained 50% in the end of year examination and had to resit one of his courses. Nevertheless, even he was able to give a formal detailed response in the second year. This gives us our first major piece of evidence: all of the students could reproduce the definition of equivalence relation; 9 out of 15 gave a complete version, the other 6 at least remembered ‘reflexive, symmetric, and transitive’.

This was reflected in responses to an informal question asking if the relation ‘has the same surname as’ is an equivalence relation on the set of students in the class (Table 2).
Table 2: Responses to the informal 'surnames' question

Both the students giving informal responses in the second year were able to give a full formal response in interview. Both thought the question too trivial to merit a detailed response in writing. For instance, John (whose response was classified as 'other') wrote:

\textit{Since the relation is to do with "equality" of the surname, it must be an equivalence relation.}

He was a talented student with a mark of 68% in the first year examination who showed his understanding to be definition-based on all his assignments and in tutorials. Thus all fifteen students were capable of a formal definition response by the second year.

Table 3 shows the responses to the following question:

A relation on a set of sets is obtained by saying that a set $X$ is related to a set $Y$ if there is a bijection $f : X \rightarrow Y$. Is this relation an equivalence relation?

Table 3: Responses to the formal 'bijection' question

This data shows that after being given a period of time to digest what they had been taught, whilst only 3 were theorem-based in the first year test, 12 are able to upgrade their understanding to the theorem-based level in the second. This is consistent with the successive move from definition-based conceptions to theorem-based conceptions over a time in which the ideas are being used formally.

\textbf{The definition of equivalence relation on a set $S$ as a subset of $S \times S$}

When responding to the notion of equivalence relation, none of the selected fifteen students used the general notion of relation as a set of ordered pairs in their definition. Only one student (Nathan) in the first year alluded to the idea as follows:
Even here the notion is an afterthought following the definition in terms of the notation \( apb \), for the relation \( \rho \) rather than the notation \((a,b) \in \rho \) which was given initially in the lectures. Notice that even here Nathan used the notation \( \{ a,b \} \) (used in the course for unordered pairs) rather than the correct notation \((a,b)\).

In the second year, only one student (Simon, the most successful with a mark of 85%) referred to a relation as ‘a subset of \( A \times A \)’ in his response to the meaning of ‘equivalence relation’. He also was the only student to give a satisfactory answer to the following:

\[
A = \{(x, y) \in R^2 \mid 10 \leq x \leq 10, 0 \leq y \leq 10\}. \text{ Is } A \text{ an equivalence relation on } R?
\]

In the first year no student responded positively to this question. Several wrote explicitly that they did not understand what the question meant:

\[
A = \{(x, y) \in R^2 \mid 0 \leq x \leq 10, 0 \leq y \leq 10\}. \text{ Is } A \text{ an equivalence relation on } R? \\
\text{Answer (yes or no or don't know): Don't know.} \\
\text{Full Explanation: A defines points in the plane } x-y \\
\text{where } 0 \leq x \leq 10 \text{ and } 0 \leq y \leq 10. \text{ But don't understand the relation.}
\]

In the second year, Simon responded as follows:

He described an equivalence relation as ‘a subset of \( A \times A \)’ with reflexive, symmetric and transitive properties that can divide a set into a partition. He also offered the formal definition with all the detail. He therefore had a conception of equivalence relation and partition as a rich cognitive unit.

We therefore obtain our second major piece of evidence: all but one of the students did not relate the notion of relation as a set of ordered pairs with the notion of equivalence relation.

**The gap between relations and equivalence relations**

We see that all fifteen students could work with the notion of equivalence relation using the notation \( a \sim b \), but only one evoked the notion of relation on a set \( S \) as a subset \( R \) of \( S \times S \). On reflection, one can see that the notion of ‘equivalence relation’ on a set \( S \) does
not have an easy visual image. Seen as a subset $R$ of $S \times S$, the reflexive law can be pictured by saying that the diagonal elements $(x,x)$ are all in $R$, the symmetric law can be seen in terms of reflection of the element $(a,b) \in R$ in the diagonal to also give $(b,a) \in R$, but the transitive law $(a,b), (b,c) \in R$ implies $(a,c) \in R$ is a little more sophisticated. (The transitive law moves horizontally from $(a,b)$—maintaining the second coordinate $b$—to the diagonal then vertically to the point $(b, c)$, completing the rectangle to give the third point $(a,c)$.) (Figure 1).

![Figure 1: Visual representations of the three axioms for an equivalence relation $R$ on a set $S$.]

The complexity of the visual representation is such that it was not taught in the course. Thus, although the notion of relation on a set $S$ is given in terms of a subset of $S \times S$, it is never represented as a visual picture. In this way there is a complete dichotomy between the notion of relation (interpreted as a subset of $S \times S$) represented by pictures and the notion of equivalence relation which is not.

Furthermore, the topic of ‘relations’ also includes order relations. We hypothesise that the typical student will find it difficult to give a coherent overall meaning to the notion of ‘relation’ that encompasses both order relations and equivalence relations. Partial support for this hypothesis is the students almost total failure to respond to the equivalence relation defined as a set of ordered pairs compared with almost total success with questions using the form $a-b$.

After interviewing 10 of the 15 students, the authors find that these students learnt the definition of relation on a set formally as: “a subset of the cartesian product of the set itself”. But they learnt the definition of ‘equivalence relations’ focused on the three properties of reflexive, symmetric and transitive. The following conversation recorded in an interview with two students (whom we name Jack and Nathan, respectively) offers some evidence. Jack and Nathan were being asked about the question in which the relation $A$ is defined as the subset $A = \{(x,y) \in R^2 \mid 10 \leq x \leq 10, 0 \leq y \leq 10\}$ of $R^2$.

Jack: Sorry! I can’t understand what this question means?
Interviewer: O. K. Nathan, can you understand it?
Nathan: Well, umm... (Pondering for a while.) No, I don’t think so.
I: Can you think of the formal definition of ‘relations’ first?
They started trying to recall their memory of 'relations'.
N: I think it's a sort of ordered pairs, isn't it?
I: Yes. You are right. Can you say it more formally?
J: Let me think. It's ages ago, I don't think I can remember it.
I: How about you, Nathan?
N: (Shaking his head.)
I: O.K. Let me write it down on the board.
The interviewer wrote the definition (Stewart & Tall, p.69) on the board and explained it to them.
J: Yes. I see. That should be what we learnt in the lecture a long time ago.
I: O.K. Now, can you try to answer this question again?
Nathan immediately made the whole deduction, answering 'yes' after checking the three conditions although he did not include the quantifier in 'reflexivity'. Jack still seemed confused.

\[ A = \{(x,y) \in \mathbb{R}^2 \mid 0 \leq x \leq 10, 0 \leq y \leq 10\}. \text{ Is } A \text{ an equivalence relation in } \mathbb{R}? \]

Answer (yes or no or don't know)...YEA...

Full Explanation:
\[
\begin{align*}
&\forall x \in A \quad (x,y) \in A \quad (x,y) \in R \\
&\forall x \in A \quad (x,x) \in R \\
&\forall x,y \in A \\
&\text{because } (x,y) \in R \\
&\text{because } A \text{ is a square} \\
&\Rightarrow y = x \\
&\forall x,y \in A \\
&\Rightarrow (y,x) \in R \\
&\Rightarrow (y,z) \in R \\
&\Rightarrow 0 \leq z \leq 10, 0 \leq y \leq 10, 0 \leq x \leq 10 \\
&\Rightarrow (y,z) \in R.
\end{align*}
\]

J: I still can't see how to check A is an equivalence relation in R.
I: You can understand the definition of 'relations' we just reviewed, can't you?
J: Yes. I think so.
I: 'Equivalence relation' is just a kind of 'relation' but with some more properties, isn't it?
J: Yes.
I: Just add the three properties to the definition of 'relation', then try to answer this question again. Jack was stuck checking 'reflexivity'.
J: I'm getting confused. What's the point of checking 'reflexive'?
I: Nathan has finished his deduction. Let's have a look at his answer then I'll answer you, Jack. Do you think Nathan's answer is correct?
J: mmm... (Pondering for a while.) Yes, I think so.
I: O.K. Let's have a careful look at 'reflexivity'. What is the quantifier for it?
N: For all the elements in A?
I: What do you think, Jack?
J: Should be 'for all the elements in R'.
I: Do you agree with Jack, Nathan?
N: mmm...Yes. Yes. I think he's right.
I: So, do you think A is 'reflexive' now?
J: I see. No. Because A doesn't cover the whole plane, so it won't be 'reflexive'.
N: mmm... So the answer should be 'no'.
I: I think you both get the point. Now can you check if A is 'symmetric' or 'transitive'?
N: Yes, both of them. I think I used the wrong notations. They should be A, not R.
I: Well done! Jack, could you make a conclusion of this question?
J: You mean A is not an equivalence relation because it is symmetric and transitive but not reflexive.

2 - 246

PME25 2001
This data seems to suggest that even students who do not have a formal concept image of a former idea (like the idea of 'relations') can still build up their understanding of the next relevant idea without having much particular difficulty (like the idea of 'equivalence relations') if the two definitions are not directly related.

### Partitions

The development of the notion of partition also improved over the year (table 4).

**Table 4: Responses to 'partitions'**

The number of detailed formal definitions increases from 2 to 8 and the overall definitions increase from 8 to 11. However, 4 students fail to give a definition for partition when all can give a definition for 'equivalence relation'. Looking closely at the responses reveals that the majority of students tried to use *their own language* to interpret the definition of 'partitions' so that their answers were highly varied.

Interestingly, all ten students interviewed said they had a mental picture of a partition. Nine of them thought they understood 'partitions' better than 'equivalence relations'. The exception, Jack, explained that although he could picture partitions, he still did not know the formal definition and was happier handling the formal definition of equivalence relation. Of the other nine, Arthur was typical in saying that he felt he understood 'partitions' better than 'equivalence relations' because he could visualise 'partitions' but not 'equivalence relations'.

When asked to give examples of partitions, twelve out of fifteen gave satisfactory answers. The other three revealed an interesting misconception. Jack wrote:

*Write down two different partitions of the set with four elements, X={a,b,c,d}. For the first of these, please write down the equivalence relation that it determines.*

\[
P_1 = \{a, z\}, \quad P_2 = \{b, c, d\}
\]

\[
a \sim a, \quad a \sim b, \quad a \sim c, \quad a \sim d, \quad b \sim c \sim d.
\]

At first sight this may seem as if Jack has written down one correct partition. However, in interview, he explained that he thought that his two partitions were \(P_1\) and \(P_2\). All three of the students giving unsatisfactory responses shared the same misconception: that the term 'partition' referred to each individual subset, not to the collection of all subsets.
In this way we see that the class as a whole retain their understanding of ‘equivalence relation’ at the definition level and apparently shift their perception of partition to the theorem-level, whilst some are still having difficulty with the definition of partition.

Conclusion

In this paper we have been considering the development of ‘equivalence relations’ and ‘partitions’ a year after the students first met the concepts in the Foundations course. During this time they would have met the ideas in other courses and revised for the end of year examinations. We questioned why the students claimed that the notion of ‘relation’ was the most difficult in the whole of the Foundations course. We found that, after a year, although all 15 students could give the definition of equivalence relation using the notation \( a \sim b \), only one could respond to a question where an equivalence relation was given in terms of a subset of the cartesian product. We showed that, although the notion of relation is easily visualised, the notion of equivalence relation is difficult to visualise but easy to remember as a verbal definition. We also hypothesised that the introduction of the very different notion of order relations at the same time gives little common ground amongst the examples of relation to allow a coherent link to be made between the examples and the general concept.

We note that nine out of ten students interviewed claimed that they felt they understood partition better than equivalence relation, whereas in fact their performance on the test showed that they were able to handle equivalence relation better than partition. This is accompanied by the observation that they say they can visualise a partition, but not an equivalence relation. We consider this to be consistent with the notion of ‘embodied mathematics’ (Lakoff & Johnson, 1999; Lakoff & Nunez, 2000) giving a deeper human sense of meaning. Thus the development of the formal thinking characteristic of the ‘rigour prefix’ (Alcock & Simpson, 1999) is here underpinned by the embodied concept-image and formal concept-use in the sense of Moore (1994).

Over the year there is a general shift from ‘definition-based’ deduction referring specifically to the formal definition to ‘theorem-based’ deduction, using already proven theorems. One student clearly had the composite notion of equivalence relation and partition as a rich cognitive unit. The investigation of whether others have such a cognitive structure is more likely to arise in interview rather than standard written questions. This remains a topic of our current research.

VALUE-LOADED ACTIVITIES IN MATHEMATICS CLASSROOM

Chien Chin and Fou-Lai Lin
Department of Mathematics, National Taiwan Normal University

ABSTRACT

This paper describes a form of value-loaded activities emerged in teaching and learning of mathematical induction in which the value of pleasure is shared by an expert teacher and his students. Using case study method, values are explored with classroom observation, teacher and student interview, and questionnaire survey. Conceiving identity theory from the pedagogical aspect, values are identified in terms of the significant value statements attached to and reflected by teacher and student's pedagogical identities. In consequence, implications about the teaching of pedagogical values and the need for more research on pedagogical values are suggested.

INTRODUCTION

S₁ (whole class replies): Oh! No, you are cheating ---.
S₃ (single student replies): My goodness! What if I do ---.

Why the students above would react like that? We will show in this paper that these reactions have to do with the value-loaded activity that the students engage. Goals of the school mathematics curriculum in many countries indicate explicitly desirable values, for example 'pleasure' and 'appreciation' in Australian curriculum statements (AEC, 1991). There were considerable discussions of the link between affective and cognitive elements, in particular the role of values in mathematics teaching, in the PME conferences. For example, at the 1993 conference in Japan the overall theme was “How to link affective and cognitive aspects in mathematics education”, and there was also substantial exchange of implicit values in various sessions at the 1998 conference in South Africa. There is a strong concern both to question and to challenge the values currently being taught in mathematics classroom. And yet, the school curriculum following these goal-initiated values, for example the values of happy and knowledge for learning that the new Taiwanese curriculum statements “happy to learn” and “knowing how to learn” underline (ME, 2000, p.135), say little about their practice, particularly in the teaching of such values. Although there are several levels of values transmission (e.g., Bishop, 1988) but we are still lack of the relevant researches looking particularly at the form of teacher-student values interaction in mathematics classroom. To conceptualize values about mathematics and pedagogy, we have to consider carefully the question of ‘What implicit values could classroom teaching convey and through what kind of teaching activities could such values be taught?’

Values have been conceived as personal experiences, objects of thought, or
psychological phenomena (Frondizi, 1970), as individuals’ feelings (Meinong, 1894) or objects to be desired (Scheler, 1954), as individual principles of selection and judgment (Samuel, 1937), as ideas or concepts concerning the worth of something (Swadener & Soedjadi, 1988). In this case, they are personal preferences concerning individuals’ standards for considering the importance or worthwhile of something for themselves to think and act. A domain of research relevant to values is beliefs. Mathematics teachers may hold various pedagogical beliefs, which differ in forms as mathematical or pedagogical, or in levels as enacted or espoused. Nevertheless, beliefs have to do with an individual’s propositions about mathematics and pedagogy, and values are more about personal principles or standards of thinking and action across such propositions. Rokeach (1973) in studying the nature of human values suggests that values are prescriptive or proscriptive beliefs wherein some means or end of action is judged to be desirable or undesirable. Allport (1961) further contends that a value is a belief upon which a person acts by preference. These arguments conceive value as a preference, a desirable mode of conduct, or a desirable end-state of existence, concerning the conception of something that is importance and worthwhile of thinking and doing for the person (Rokeach, 1973). Therefore, beliefs are more about “the nature of propositions about phenomena” (Bishop, 2001), however, values are likely to be the key substances underlying such propositions for people to think and act.

The Value In Mathematics Teaching (VIMT) project funded by the Taiwanese National Science Council (NSC, 1997-2000) aimed to: explore mathematics teachers’ values about mathematics and pedagogy; examine and increase the extent to which mathematics teachers’ can clarify their own pedagogical values; and investigate students’ values about mathematics and mathematics learning, and the values interaction activity in the classroom between teacher and student. Based on a portion of VIMT results (Chin & Lin, 2000a; Chin & Lin, 2000b), this paper aims to describe an activity observed in the teaching and learning of mathematical induction in which the value of pleasure was loaded, and through which a teacher and his students interacted overtly. Other values can be found in Chin and Lin (2001, submitted)

THEORETICAL BACKGROUNDS

The Value of Pleasure in Mathematics Teaching

The analog/unconscious mathematics (Davis & Hersh, 1981) is related to the idea of intuition and feeling, in which sense making and free thought are the two important elements. It is our belief that the more efforts that we make for students to learn mathematics through understanding the better they would appreciate the value of pleasure. The statement, “The thing that is important is that doing math is fun. That’s what I try to put across to the kids --- What I try to do is to tell math to kids on the basis that it’s fun” (ibid, 1981, p.272), may convey “Learning mathematics is interesting and doing it is a pleasant thing” undrelining the value of pleasure in pursuit of having fun in the teaching and learning of mathematics. The
analytic/conscious aspects conceive mathematics from the other way round as a
combination of forms, rules, and proofs. This is to addresses the concept of
mathematical induction as a formalized subject for learning through a step-by-step
mechanical process of proofs. As a result, these effects may create the value of
un-pleasure. In discussion of the emotional influences on learning school
mathematics, Skemp (1989) proposed a model of conceptualizing affective responses
such as pleasure and un-pleasure in terms of the orientations towards goal state or
away from the goal state. Pleasure signal changes towards a goal state, and leaving
from the goal state creates un-pleasure. The goal state here depends on the implicit
learning orientations about mathematical induction that individual students stand.

Values Statement as Carrier of Values

We conceive a statement of values as the carrier that contextualizes
individual pedagogical values into a concise sentence, representing his/her core
principle for thinking and action. A value carrier thus contains a set of values that the
teacher endorses. A values statement, as Taylor (2000) pointed out, is a goal-directed
description indicating the values by which the school intends its practices to be
guided, and setting out the values the school intends to promote and which it intends
to demonstrate through all aspects of its life. An example of a secondary teacher’s
values statement is “We want our school to be caring and Christian, disciplining,
encouraging, happy” (ibid, p.157). This statement includes the values of care,
discipline, encouragement and happiness that secondary school is expected to address
across the curriculum. Values, in the light of this view, are situated in and entertained
with the propositional statements of teacher and student conceptions about
mathematics and pedagogy (e.g., Haydon, 2000).

The Pedagogical Aspect of Identity and Its Relationship to Value

Values are conceived here as a sort of individual identities concerning
mathematics and pedagogy. Fereshteh’s (1996) definition of teaching, as an
intellectual activity requiring varied abilities in educating students certain knowledge,
as guiding and evaluating students’ learning processes, and as an artistic and
scientific activity, seem to suggest that the underlying pedagogical values for such an
activity are intellectual and knowledge acquisition, guidance and evaluation of
learning process, and artistically scientific discovery. In pursuit of such values, a
teacher is expected to play as a manager, creating and organizing the lessons, as a
motivator, fulfilling the student needs, and as a professional, enjoying and developing
their career. To accomplish these roles, a teacher identifies him/herself with the
professional identities of a manager whose classroom teaching reveals some role
specifics. This aspect of identity seems to shift its sociological nature into a
pedagogical realm, reflecting how and in what ways a teacher should think and act
‘as if’ he/she is a person accompanying with such identity. In an article of reporting
the role of values in pedagogical content knowledge (PCK) from four experienced
English and History teachers, Gudmundsdottir (1990) concluded that values, as
implicit personal curricula, are integral part of teachers’ excellence in teaching
influencing several aspects of PCK, such as choice of pedagogical strategies and
perception of the students' needs. These elements, reflecting a teacher's excellence in teaching, play an integral part of his/her pedagogical identities. In discussion of a continual development of values from early youth to old age, Erikson (1963) indicated that the value systems properly reflected those features of the development of eight identity stages. In Rokeach's (1973) researches, values are integral to self-identity that people strive to be authentic, moral beings by acting on the basis of values tied to their desired self-conceptions. Therefore, pedagogical identities seem to tie to the values of individuals.

RESEARCH METHODS

The case study method, including questionnaire survey, interviews, and classroom observations, was used as the major approach of inquiry to explore an expert teacher (Ming) and his students' pedagogical values: Ming had a master degree in mathematics and taught mathematics in a public senior high school for 21 consecutive years. We used critical teaching events as probes for post-lesson interviews. Another teacher, Yuh who taught mathematics in the same school, participated in each interview. Four teaching topics were videotaped and transcribed during 1997-1999 including mathematical induction. A senior secondary mathematics teacher acted as an independent checker to examine the reliability of the observational data. A questionnaire was used for all students, designed to uncover students' preferences on selecting two of the six problems relating to the topic taught and to collect students' reasons of doing so. First part of this questionnaire consists of six open-ended problems designed by Ming based on his core pedagogical values, and the second part has several items for students to express their agreements on each statement, concerning the reasons of doing and not doing so. The second questionnaire consisted of 20 questions, using a five-point Likert format. It asked students to express their views on each statement according to two different contexts, test scores taken for grading or not to be taken. The 6 sample students were selected according to their mathematical performance in the first questionnaire and willingness to talk, and the representative of the student class. These questionnaires were piloted and revised with Yuh's students.

RESULTS

A Value-loaded Teaching Activity

According to the school curriculum, the topic should be taught in duration of five 50 minutes lessons. Usually teachers, for example Yuh, would take less than ten minutes to introduce the format of mathematical induction, and the rest for exercises. Ming spent 15 minutes in the activity of Hanoi tower to develop student ideas of 'potential infinity'. Although the activity is well known, however; Ming re-framed it to address student manipulation and teacher-student dialogue. Two critical questions used by him to guide the student thinking were: 'Can you do it?' and 'Do you believe
that if \( N=3 \) is possible then \( N=4 \) will also be possible?' Ming told the rules first followed by student manipulations and teacher-student dialogue. Finally, he showed the solution. A brief snapshot of the activity after three students manipulated was:

Ming: Let me show how I solve it. First of all, can you do it if the number is 3?
S; (whole class replies): Yes, of course we can.
Ming: If it is 4, could I pack it up as a unit and move the package from A to B?
S; It is okay.
Ming: Then, I move the fourth one to C, is it okay?
S; Yes.
Ming: Then, if I move again this package from B to C, can I do it?
S: Oh! No, you are cheating.
S; (single student replies): My goodness! What if I do it the way that you just showed us by packing up the case of 4 to solve the case of 5, and then to solve the case of 6, and so on?
Ming: Are you sure?
S; Why not?
Ming: Excellent (he smiles expressively), are you convinced that I didn’t cheat you?
S; Yes! There should not be any problem.
(a recursive procedure of potential infinity through teacher-student dialogues)
S; It can also be done by the same way. There will not be any problem.
Ming: Therefore, we can do it all the way through in the same method?
S; Yes, why not.
Ming: Are you convinced that for any counting number we can always do it this way?
S; Yes, we can do it by counting up.

The expressions “Oh! No, you are cheating” and “My goodness! What if ---”, referring to the freshness and power of interpreting mathematical knowledge, are related to the value of pleasure, which will be discussed later. The subsequent dialogues, in which a recursive procedure of step-by-step reasoning format is introduced, develops meanwhile the ideas of potential infinity that the values of infinite and reasoning underlay (see Chin & Lin, 2001, submitted).

The Underlying Teacher's Pedagogical Values

The activity of Hanoi Tower was used to inculcate the value of pleasure. As Ming said that “the idea of ‘infinite reasoning’ underlying the ‘empirically counting truth’ conviction, should play the significant role to encourage students to do mathematical investigations in which enjoyment of knowledge are of paramount importance”. In particular, he concerns the affective aspect of learning and teaching school mathematics as “I really hope that all of my students will feel happiness, enjoyment, and pleasure in their own processes of investigating mathematical knowledge in these activities. They are the affective and humanistic concerns that I have been trying very hard to express in my teaching, such as mathematical induction”. Referring to the pre-lesson planning of the activity, Ming professed that “I intended to develop activities in which my students would feel that mathematics could be very interesting and they might in this case be eager to attend the subsequent lessons. The Hanoi Tower activity was just designed to initiate such student motivation through learning the concept of mathematical induction”. He explained further “Most students are not happy in the mathematics lessons --- they don't feel that the knowledge is useful or practical in their life. Therefore, most of them feel
panic and anxiety when learning mathematics. This is the reason I have been trying so hard to motivate them to learn mathematics through enjoyment, pleasure, and anticipation using investigative games or activities, and focusing on the nature of the knowledge---".

The acceptance of such a value of Ming for the students will be further examined in terms of the data collected from the student phase.

The Attainable Students’ Pedagogical Values

One question in the first questionnaire, “Suppose that the concept of human is well defined, and the life in the earth has gone through about 4 billions year. Prove that there is a human being whose mother is not a human (called Genesis)”, was used to examine student understanding and the ability of application from an unconscious/analog aspects and meanwhile loading specifically with the value of pleasure. The implicit pedagogical values that Ming intends to pass to the students are then contextualised into 6 tasks in assessment, including Genesis, for students to select and solve. It was supposed that in the process of selection that the values of students would become explicitly.

When we asked ‘Why did you choose Genesis rather than other questions?’ S1 said “Because I felt that these two questions ask me to elaborate and the context of the problem make sense to me”. The text and situation of Genesis was much easier for him to get access. They created motives of pleasure such as interesting and fun, and he was eager to solve the problem since “These are questions that I have not seen before. They are new for me. But, I am quite familiar with the other questions that I am not so interested. They are so boring because I have already known the answer of the questions and the procedure of solving them”. This value encouraged curiosity and willingness for the student to solve individually, for “The questions raise my curiosity to solve them and I like to find out myself. I really like to know whether if I can solve a totally new problem like this on my own”. Routine questions could not create any pleasure for him, as he said that “There is no pleasure for me at all to face a mathematical question which has no practical use or not realistic. I don’t know what could be of interest if you have already known the answer or method of solving the question?” Another student S2 also claimed for searching an unfamiliar question to solve, as “I would have got bored if a mathematical question were solved easily according to certain familiar steps. It is no fun at all for doing or answering a question like that”. Therefore, it was the pleasure of reasoning that encouraged him to solve Genesis. Because, “I like to solve the question through my own efforts. There are lots of pleasant during the processes of solving such questions” and “I am now telling you that I hope all mathematical will like this, encouraging me to think and reason freely according to the ways whatever I like, fulfilling my curiosity, and being full of pleasure in the process of solving them”. These statements indicate the crucial role that affect played in the mathematics learning concerning the value of pleasure.

Therefore, the mathematical ideas of infinite reasoning/potential infinity and its accompanied affective element of pleasure are interwoven within the process of teaching and learning of the Hanoi tower.

DISCUSSIONS

A foreseeable relationship between pedagogical values, value statements, and identities is become clear. Value statement as carrier of pedagogical values portrays
teacher and student principles of evaluation on teaching incidents and learning tasks. A text like this has its syntactical structure of wordings in which certain values are embedded implicitly. The key words included in a value sentence may represent different pedagogical values. Values are in this sense represented and embodied in words or a combination of words, underlying the connected value statements to which they apply. Peoples, who agree or identify oneself with a particular value statement, are conceived as carrying the underlying fundamental elements of the statement, that is, the pedagogical values that the statement portrays. This is to conceive and analyze pedagogical values from human discourse in terms of a syntactical and psychological analysis of talks and words. It is this process of pedagogical identification that reflects a person's preferences to aspects of teaching. These preferences are in connection to the teacher and student's pedagogical identities. In the light of this, values are integral to self-identity and that teacher and student strive to be authentic (Rokeach, 1973). Australian researchers also referred values to the pedagogical aspect of personal identity as in "The values taught, whether explicitly or more like implicitly, seems to depend heavily on one's personal set of values as a person and as a teacher" (Bishop, Clarkson, FitzSimon, & Seah, 2000, p.148). Halstead (1996, p.5) used the concept of identity to define values, as he put it "The term values --- which act as general guides to behaviors or as points of reference in decision-making or the evaluation of beliefs or action and which are closely connected to personal integrity and personal identity".

To inform classroom practices, the practitioners need more supports on learning and constructing value-loaded activities that might be useful, and also the framework for developing and elaborating on pedagogical values for different subject matters. This is an area that Tomlinson and Quinton (1986) called "De facto implemented curriculum" and Bishop (2001) claimed "the Meso classroom level" in which means of planning and enacting values are the foci. Researches on this line are urgent. It is also important for mathematics teacher educators to try to develop and examine plausible ways of inculcating specific pedagogical values at "the Macro curriculum level" (Bishop, 2001) of pedagogical value education for mathematics teachers. Therefore, we need to know more about the processes of valuing and value clarification from both teachers and students that may in turn contribute to the development of values education curriculum for them.

Acknowledgements: Thanks are given to the two participant teachers Ming and Yuh, who were kind and open in sharing their ideas with us. We thank Miss J.R. Lin who is a senior high school mathematics teacher for evaluating the observational system and also our assistant Miss J.C. Huang who did a great job on the audio-video tape transcriptions. We are grateful to NSC for funding the VIMT project. The opinions expressed do not necessarily reflect the views of NSC.

DEVELOPMENTAL VERSUS DIFFERENCE APPROACHES TO SELF-EFFICACY BELIEFS OF MATHEMATICS TEACHERS

Constantinos Christou, George Philippou, & Omiros Dionysiou
Department of Education, University of Cyprus

Abstract: The developmental approach to efficacy beliefs of mathematics teachers is based on the view that comparisons between experienced and beginner teachers at the beginning of their career should indicate no substantive differences in the structure of their efficacy beliefs towards mathematics teaching. In contrast, the difference approach states that such comparisons will often reveal major deficits in efficacy beliefs. As far as we know there are no research studies discussing the developmental and difference approaches to self-efficacy. We argue that aspects of the conceptual and methodological foundations on the theory of developmental and difference approach are important for any effort to change efficacy beliefs. A paradigm based on regression analysis is recommended as the starting point for further theoretical and methodological work in the area.

Self-efficacy influences several aspects of behavior that are important to teaching and learning. Teachers' efficacy beliefs have been related to student achievement, student motivation, teachers' adoption of innovations, teachers' management strategies, and teachers' strategies in instruction (Christou & Philippou, 1998; Cooney, Shealy, & Arvold; Kyriakides, 1998; Pajares, & Miller, 1995; Woolfolk, Rossoff, & Hoy, 1990). In these studies, with a few exceptions (Pajares, & Miller, 1995), efficacy was generally assumed to be the independent variable. In this paper, we consider teachers' efficacy beliefs as the dependent variable and we propose both a theoretical and a methodological model linking teachers' efficacy beliefs with teaching experience. The proposed theoretical model reconciles two competing conceptual strands found in the literature: The first strand assumes a developmental approach to teaching efficacy, while the second one emphasizes the differences found among teachers. The methodological model refers to a new design based on the regression analysis through which both the developmental and the difference approaches can be discussed.

THEORETICAL BACKGROUND

The Concept of Teaching Efficacy: The conceptualization of teacher efficacy is based on the theoretical framework of self-efficacy developed by Bandura (1997). Bandura (1997) defined perceived self-efficacy as "beliefs in one's capabilities to organize and execute the courses of action required to produce given attainments" (p. 3). In the same sense, teaching efficacy, which is a form of self-efficacy beliefs, can be defined as teachers' beliefs in their abilities to organize effective teaching-learning environments and have positive effects on student learning.
Recently, Soodak and Podell (1996) found that teacher efficacy is comprised of three factors labeled as Personal Efficacy (PE), Outcome Efficacy (OE), and Teaching Efficacy (TE). PE refers to teachers’ beliefs that they have the skills to bring changes in students’ behavior and performance, while OE refers to the belief that, when teachers implement those skills, they can achieve desirable outcomes. The TE factor refers to teachers’ beliefs that teaching in general can lead to students’ successful performance overcoming influences outside the classroom which affect learning, including children’s home environment.

**The Developmental - Difference Theory in Teaching Efficacy:** The developmental and difference theory, as proposed in the present study, has its roots in the psychology literature (Cole, 1998). One of the purposes of the present study is to apply the developmental and difference theory in the field of teaching efficacy. In the following paragraph, we first explain the terms of internal and external factors, which are used throughout the study, and then we briefly discuss the developmental and difference theory as it may apply to teaching efficacy.

The internal variables refer to the extent to which teachers feel equipped with the tools needed to teach the classroom mathematics (Ross, Cousins, & Gadalla, 1996). By internal variables we mean all those variables that are closely related to teachers’ attitudes and most importantly to teachers’ feelings of being well prepared. By external variables, we mean all those variables called by Ross et al. (1996) as between variables such as the teaching experience, the age, and the gender of teachers or other environmental factors as described by Bandura (1997). In this study, we examine the developmental-difference theory with respect to only one external factor, the teaching experience of teachers. However, the results and conclusions of the present study can be replicated in such a way as to include a number of other external factors.

**The developmental Theory:** According to Bandura (1997) efficacy beliefs among teachers may be best conceptualized as following a developmental sequence. The concept of developmental sequence, in the context of the present study, assumes that teachers in their early years of experience have the opportunity to develop a sense of efficacy as professionals in the field. It is also assumed that teachers during their career constantly develop teaching efficacy beliefs, but the basic structure of their beliefs does not substantially differ from the beliefs they demonstrate throughout the years in the profession. We advocate that the continuity in the efficacy beliefs of teachers of mathematics holds true provided that teachers are equated on internal factors. The matching of teachers on internal factors provides a more complete picture of teachers’ development of self-efficacy, because the internal factors are more salient in shaping efficacy beliefs especially when teachers lack experience (Tschannen-Moran, Hoy, and Hoy, 1998). Thus, the first proposition of the developmental
approach to efficacy beliefs states that if teachers of mathematics equated on internal factors have a similar pattern of teaching efficacy irrespectively of external variables. This is the notion of the similar-structure hypothesis put forward in the framework of the developmental models in conjunction with the similar sequence hypothesis. The similar sequence hypothesis predicts that experienced and inexperienced teachers pass through the same phases of teaching efficacy development, differing only in the rate at which they progress and the ultimate ceiling they attain. The similar structure hypothesis involves the view that experienced and inexperienced teachers have similar processes underlying their teaching. There is also a second proposition contained in the developmental theory and it is subsidiary to the first. This second proposition states that if there are differences between internal-matched groups of teachers with regard to teaching efficacy, then these differences are likely to relate to exogenous factors such as motivation, adjustment, personality, and other background factors associated with environmental variables.

The difference theory. In contrast to the developmental theory, the difference theory states that comparisons between teachers with different external factors, often reveal major differences in teaching efficacy, irrespective of the internal variables. The difference position, in other words, states that even when teachers of mathematics are equated on internal factors, there would be differences in their teaching efficacy. The difference approach supports the view that any pattern of deficits in teaching efficacy is related to external factors such as experience, cultural factors and gender. Much of the research provides evidence that teaching efficacy is at an inferior level in inexperienced teachers compared with experienced teachers (Sanders, Borko, & Lockar, 1993). In addition, the aim of those who support the difference model is to show that the relationships between external factors and teaching efficacy are essentially different in teachers with or without long experience. Difference theorists may reject the assumptions of the developmental theory. They may point out that teachers with different external factors demonstrate quite different feelings of teaching efficacy. Sanders, et al. (1993), for example, claimed that inexperienced teachers perform at substantially lower levels on key measures of teaching efficacy than experienced teachers, because they have difficulties in selecting appropriate examples and activities for their students. In the same way, Saber, Cushing, and Berliner (1991) found that experience levels are crucial for explaining teachers' differences in teaching efficacy, because beginning or inexperienced teachers were not able to interpret adequately instructional strategies and hypothesize reasons for different student behaviors.

Much of the research revealed contradictory findings about experienced and inexperienced teachers’ efficacy. Two patterns of results emerged: Fisrt, a number of studies indicated that teaching efficacy increases with experience (Dempo & Gibson,
1985), and thus teaching efficacy in experienced teachers is higher than in inexperienced teachers (Lin & Tsai, 2000). On the other hand, Ross et al. (1996) reported that novice teachers had strong sense of teaching efficacy. There are several reasons of this conflict. Lin and Tsai (2000) referred to different measurement tools, to cultural differences and variation in the sample groupings. Besides those justifications, there are also some important theoretical and methodological issues.

THE AIMS AND HYPOTHESES OF THE PRESENT STUDY

Comparing the means of experienced and inexperienced teachers in teaching efficacy scales is the prevalent research paradigm adopted by almost all studies purporting to make comparisons between the groups of individuals with and without long experience in teaching. In the present study a different approach was applied in discussing the developmental and difference debate in experienced and inexperienced teachers. Specifically, according to developmental theory, the relationship between teaching efficacy, and attitudes and preparatory programs is the same in both the experienced and inexperienced teachers, despite the fact that, in some cases, the inexperienced group may demonstrate a lower level on measures of teaching efficacy. On the other hand, the difference theorists may state that the relationship of teaching efficacy and internal factors of experienced teachers is substantially different from that of the inexperienced. In this respect, the following two related hypotheses were stated:

(a) The teaching efficacy of inexperienced teachers is comparable to that of experienced teachers matched on internal factors, and
(b) The relationship between teaching efficacy and internal factors is the same for both experienced and inexperienced teachers.

METHOD

Subjects and Procedure: Data were obtained from 94 secondary mathematics teachers who participated in the TIMSS-R. These teachers taught 8th graders during the school year 1998-99. Thirty-five of them were males and 59 females. The sample was representative of the population of mathematics teachers in Cyprus with regard to experience and gender. The sample selection as well as the procedures for the questionnaire completion followed the guidelines provided by TIMSS-R.

Instruments: Data were collected using parts of the TIMSS-R teacher questionnaire, and the teaching efficacy questionnaire, which was developed by the authors. The following is a brief description of the variables used in the present study for measuring the internal factors and the teaching efficacy of teachers.

Internal Factors: In the present study we considered as internal factors the attitudes of teachers towards mathematics, their content knowledge and their pedagogical content knowledge. To measure teachers' attitudes 9 items were selected from
TIMSS-R teacher questionnaire. These items elicit information about teachers' conceptions of mathematics on the nature of mathematics, and the on process of teaching and learning mathematics. The content knowledge preparation of mathematics teachers was also represented by the total score of teachers’ responses to 12 items in which they were asked to indicate the extent to which they feel well prepared to teach the curriculum content of mathematics in the 8th class. The pedagogical knowledge was measured using 20 items from the TIMSS questionnaire which provide information about the way teachers organize their classes, the type of questions and exercises they assign to students, the way they deal with students’ problems, the type of homework they assign, and the weight teachers give to different types of assessment. The measures of teaching efficacy were obtained through a questionnaire specifically designed for the purposes of the present study. Respondents used a 6-point agree/disagree scale to respond to 13 statements which measured TE, 11 which measured PE, and 10 which measured OE. Three composite scores (TE, PE, and OE) were produced by adding the scores of the individual statements comprising each one. TE, PE and OE were the dependent variables for the subsequent analysis.

RESULTS

The main assumption of the study was that experienced and inexperienced teachers matched on internal factors such as attitudes towards mathematics, content apprehension and pedagogical preparation do not differ substantially on their teaching efficacy beliefs. Therefore, it is important, first, to present the situation of teachers on these matched tasks, and then their feelings about TE, PE and OE. To this end, we conducted a repeated measures analysis, which showed that there were no statistically significant differences between the two groups on the tasks of internal factors (attitudes, content knowledge and pedagogical preparation). This result leads to the conclusion that both the experienced and inexperienced teachers, involved in the study, were matched on all internal tasks under consideration. The matching of both groups of teachers on the internal factors can be explained by the fact that mathematics teachers in Cyprus form a homogeneous group with respect to their qualifications, since the great majority of them are graduates of Greek universities, which mostly follow the same programs.

Following developmental theory’s assumptions, we would expect that inexperienced teachers when matched to teachers of equivalent internal factor levels should perform equally well as experienced teachers on efficacy tasks. The results showed, however, that teachers in the two groups, although matched on internal factors, performed equally well on two of the three efficacy tasks, i.e. on the PE and OE efficacy beliefs but differed significantly on the TE. Non-experienced teachers (X=15.36) seem to believe that they are more successful on TE than experienced
teachers (\(\bar{x} = 14.28\)). The latter difference is not sufficient to provide support for either the developmental or the difference theory.

Figure 1: The Regression of TE, OE, and PE of Experienced and Inexperienced Teachers on Internal Factors.

What is of greater importance is the relationship between efficacy and internal factors and not the disparity in the mean levels of TE, PE or OE, which in some cases can be explained by differences in other variables such as motivation, school system and climate, organizational structures, etc. According to difference models, the relationships between efficacy and internal factors are essentially different in the two groups. The developmental theory posits that the relationship of efficacy and internal factors in experienced and non-experienced teachers is not different from that observed for teachers in general. Therefore, the second hypothesis of this study refers to these relationships, which are explored through the regression analysis.

According to the design, the efficacy effect is a linear combination of parameter values of internal factors. To test this model multiple regression was used. Figure 1 presents the plots of the observed and predicted values for both groups of teachers. The regressions of efficacy beliefs on internal factors for teachers as a whole and the
two groups (experienced and non-experienced) separately are indicated by the straight bold line and the dotted lines, respectively. As can be seen from Figure 1, the regression lines seem to coincide in the case of PE, while in the case of OE the regression lines of the two groups are almost parallel and very close to the line for total sample of teachers. The regression line of TE shows that non-experienced teachers reported higher feelings of TE than experienced teachers, reaffirming the results of multivariate analysis. This result is not in contrast with the notion of development and thus, it can not be considered as supporting the difference model. However, in order to provide support to the developmental theory in this case, we need to examine whether the regression lines are homogeneous for both groups in TE, PE, and OE. The t-values for the difference between the line slopes of the two groups of teachers were quite smaller than the critical values in the t-distribution, leading to the conclusion that the slopes do not differ significantly. Thus the pattern of efficacy beliefs is homogeneous in experienced and non experienced teachers even in the case of TE where the means of the two groups of teachers differed significantly.

CONCLUSIONS

In the present study we advocated for a different methodological approach to conceptual issues of teaching efficacy in the context of a new theoretical framework, that of developmental and difference theory. At present most of the studies placed excessive reliance on testing for group differences between experienced and inexperienced teachers’ teaching efficacy. This study suggests a shift from group means to relationships among internal factors and teaching efficacy at specified experience levels. The main view expressed in this paper is that the line of regression should be the test for the developmental or difference models. If discrepant relationships between teaching efficacy and internal factors were apparent in comparisons between groups designated experienced and non experienced teachers, then support for the difference theory would be indicated. In the present study the comparisons of the slopes of the lines of experienced and inexperienced teachers demonstrated that TE, PE and OE beliefs develop in a similar continuous way, and thus the data provide support for the developmental theory.

The developmental theory of teaching efficacy implies that experience does not alone constitute a decisive factor that influences teaching efficacy. The role of experience is moderated by internal factors. Thus, the development of TE, PE, and OE was similar in both groups of teachers. However, differences between beginning and experienced teachers may exist, but the emphasis is on the relationships among the factors that contribute to teacher efficacy. Thus in the present study we first equated teachers on the internal factors, and we advocated that when teachers are matched on internal factors then the structure of teaching efficacy follows in an equivalent manner.

The Role of Mathematical Beliefs in the Problem Solving Actions of College Algebra Students

Victor V. Cifarelli
Department of Mathematics
University of North Carolina at Charlotte

Tracy Goodson-Espy
School of Education
University of Alabama at Huntsville

This paper reports on the results of a study of the beliefs of College Algebra students. Subjects came from College Algebra classes at two universities in the southern United States. A total of 115 subjects participated in the study. Data sources included both a mathematical beliefs and attitudes survey instrument and on-going individual interviews conducted with 25 of the students. Drawing from the episodes of two students, Brad and Carrie, the analysis demonstrates and explains how the students' mathematical beliefs about formal algebraic concepts influence and sustain their problem solving actions.

Introduction. Among four-year universities, the number of students required to enroll in College Algebra classes forms a critical mass that presents unique challenges for the mathematics faculty whose mission it is to provide quality instruction. The large numbers of College Algebra students enrolled in these classes can be traced back to the 1970s, when remedial enrollments increased 72% as non-science academic programs such as Nursing and Business looked to mathematics departments to provide the necessary mathematics preparation for their students (Leitzel, 1987). In the most recent survey of the mathematics preparation of incoming students, the National Center for Education Statistics reported that 34% of entering freshmen at two-year public colleges were required to take remedial coursework in mathematics as were 18% of the freshmen enrolling at public four-year institutions (NCES, 1995). Other sources have placed similar figures much higher (Watkins, 1993). Because College Algebra serves as the core mathematics requirement for many majors, both universities and community colleges are looking for innovative ways to address the needs of College Algebra students.

The research conducted on the College Algebra population includes studies which surveyed the mathematical beliefs of these students (see for example the work of Peskoff, 1998), studies which have documented the fragmented conceptual understandings that many of these students possess (Carlson (1997), and studies which examined the effectiveness of specific instructional strategies (Underwood Gregg and Yackel, 2000; Yackel and Underwood, 1998). However, there have been no studies examining how the mathematical beliefs and conceptions of these students influence the ways they conceptualize mathematical situations and pose mathematics problems to solve. The role of mathematical beliefs in the evolution of mathematical activity needs to be documented and explored.

Purpose and Theory. The purpose of the study was to examine the beliefs and conceptions of College Algebra students, with the view that their mathematical conceptions and beliefs interact to influence their cognitive actions in mathematical
learning situations. Drawing from the work of Cooney, Shealy, and Arvold (1998), we focus on the learner’s beliefs as mental structures which aid his/her interpretations in mathematical situations. According to Schoenfeld (1985), the mathematical beliefs of students help constitute their “mathematical world view” (Schoenfeld, 1985, p. 157), and hence play a crucial role in the ways they “see” the mathematical problems they face. This view is compatible with Vergnaud’s (1984) notion that exists a formal connection between the learner’s mathematical beliefs and conceptual actions; he asserted that problem solvers often demonstrate their “mathematical beliefs-in-action” as they solve problems, and that these beliefs serve them as conceptual models upon which they can develop successful solution strategies (1984, p.7). Given these theoretical underpinnings, the study examined the role played by the students’ mathematical beliefs in the evolution of their mathematical problem solving activity.

**Methods.** Subjects came from College Algebra classes at two universities in the southern United States. A total of 115 subjects completed a mathematics beliefs and attitudes survey developed by Yackel (1984). While the survey would yield a snapshot of sorts of the students’ mathematical beliefs, we wanted to observe the reasoning activity of individual students as they solved mathematics problems. Hence, 25 of the students participated in a series of individual teaching interviews, which occurred bi-weekly and lasted about 40 minutes each. Each interview included approximately 20 minutes where the students solved algebra tasks given by the researchers; during the remaining time, the students introduced their own problems and questions.

**Analysis.** The analysis proceeded as follows. First, the survey of beliefs and attitudes was compared with students’ activities in the interviews. Next, the interview data were examined through protocol analysis. The video-taped recordings were examined to identify instances where significant conceptual structuring activity appeared to occur. This enabled the researchers to focus on episodes of novel activity, and make inferences about the constructive role played by the subject’s mathematical beliefs in the evolution of their conceptual knowledge. In addition to the video protocols, transcripts of the videos, paper-and-pencil records, the researchers’ field notes, and the subjects’ written tests were examined and used to develop case studies.

Given the space limitations here, we will only mention highlights of the analysis of the survey data, and then devote the remainder of the paper to episodes from the student interviews. Briefly, our survey results are consistent with what other researchers have found regarding the nature of mathematical beliefs and its impact on performance (Frank, 1986; Sackur and Drouhard, 1997; Schoenfeld, 1985). For example, 90% of the students demonstrating high-level achievement in the classes demonstrated flexible mathematical beliefs, viewing mathematics as a tool of their reasoning that is supposed to make sense to them, and that the teacher’s way of solving math problems represents only one of many possible solutions. In contrast, 88% of the students demonstrating low-level achievement in the classes appeared to
have more rigid beliefs about mathematics, viewing mathematics as a collection of rules and tricks, where the teacher determines what is correct and the student’s goal is to imitate the actions of the teacher.

In this paper we focus on the mathematical activity of two subjects by examining episodes that illustrate the significant interplay between the students’ beliefs, their conceptions, and their demonstration of mathematical structure through their problem-solving activities. We will discuss these episodes in terms of 1) how the students conceived of and interpreted their problems initially; 2) the complexities of their mathematical ideas; and 3) how they worked through the dilemmas and difficulties they faced as they solved their problems.

An Interview with Brad: Brad was a first-year Business major who had taken College Algebra the previous semester and earned a grade of D. He was repeating the class, a practice common among College Algebra students, because he needed a grade of C to satisfy his academic major.

During the first interview, Brad worked a series of tasks that involved simplifying radicals and applying the laws of exponents. After completing the tasks, Brad asked a question from the current homework on radicals. Brad had tried to simplify the expression \( 2\sqrt{50} + 12\sqrt{8} \) using the laws of radicals, and he was concerned that his answer, \( 34 \), did not agree with the answer given in the book, \( 34\sqrt{2} \). The interviewer asked Brad to re-work the problem at the blackboard.

Brad: I’ve worked it out twice but I didn’t get the answer that’s in the back of the book. First thing I do is look at radicals and see if I can simplify anything, just to drop one of the radicals. And um ..., you can’t break these down into terms that can’t so ... 50 will break down into 2 and 25, which are both perfect squares (sic), so that’s what I went ahead and did. (Writes \( 2\sqrt{25} \times 2 \)) Some people like to break them up I’ll keep them together. And 8 is not a perfect square either, but I know that 2 and 4 are (sic), which are factors of 8, so I went ahead and wrote that down (Writes \( 12\sqrt{2} \times 4 \)) (Re-writes entire expression)

\[
2\sqrt{50} + 12\sqrt{8} = 2\sqrt{25} \times 2 + 12\sqrt{2} \times 4
\]

Brad’s retrospective reporting of how he tried to solve the problem demonstrated an overall understanding of the task -- that he could both recapitulate and monitor his prior activity in an objective manner. In addition, while Brad invoked an appropriate strategy, his problem involved making sense of a discrepancy between his answer and that given in the back of the book.

Brad: And from here I just go ahead and take the square root of this 25, which would bring the 5 out front, which would leave me ...2.5 and go ahead and bring the 2 out which would be 1, right ? ... or now it’d just be a 2, right ?...(stares in space, rolls eyes)... and then plus 12 then ... that that’ll just be 1 and bring out a 4, which will be 2, and we multiply by 2, ... 2 x 5 will be 10, and 12 x 2 will be 24, which will leave you with 34, but that’s not what the book got.
Brad’s solution is summarized below (#1-4). Step #3 includes Brad’s erroneous action, $\sqrt{2} = 1$.

**Brad's Solution**

1. $2\sqrt{50} + 12\sqrt{8}$
2. $2\sqrt{25 \cdot 2} + 12\sqrt{2 \cdot 4}$
3. $2x5x1 + 12x1x2$
4. $10 + 24 = 34$

Brad’s hesitation in asserting that he could simplify $\sqrt{2} = 1$ ("go ahead and bring the 2 out which would be 1, right?") indicated that he was becoming aware of the probable source of his problem, that $\sqrt{2}$ may not simplify to 1 as he had previously thought.

**Brad**: The book got $34\sqrt{2}$. I can’t figure where $\sqrt{2}$ is?

**Interviewer**: It looks awfully close, only thing is the $\sqrt{2}$ there in the answer. Why don’t you look back at an earlier step and see if there’s some place where there could’ve been a $\sqrt{2}$ and maybe it got lost in the shuffle when you reduced things. Where do you think the $\sqrt{2}$ might be?

**Brad**: (reflects) ... There and there. (points to $\sqrt{25 \cdot 2}$ and $12\sqrt{2 \cdot 4}$)

**Interviewer**: So, what did you do at that point in the process?

**Brad**: I just took the square root of 25, which was 5 and the square root of 2, ... (long reflection here) ... that’s not perfect! ..., yes, it’s perfect, ... yeah for some reason, I cannot ... (realizes he has a problem here, but tries to work it out)

**Interviewer**: So the question is, is $\sqrt{2}$ perfect?

**Brad**: ... no, it’s not, is it. You know what I was getting confused with? ... is because that (writes $\frac{1}{2}$) and for some reason I thought I could cancel (cancels 2s in expression $\sqrt{2}$, e.g., $\frac{1}{2}$). Maybe that’s where I got lost, that has to be it, because there’s no other place.

**Interviewer**: So why don’t you fix it from this point on?

**Brad**: OK, so just go from this line? (goes back to his board work and starts with $2\sqrt{25 \cdot 2} + 12\sqrt{2 \cdot 4}$) Um. $2 \cdot 5\sqrt{2}$. Still gonna keep the $\sqrt{2}$ and it’s gonna be plus 12, um $\sqrt{4}$ is 2, still have $\sqrt{2}$ there. Then we go ahead and multiply that to be $\sqrt{2}$, $5 \cdot 2\sqrt{2}$ plus $12 \cdot 2\sqrt{2}$, that stays there. (writes $10\sqrt{2} + 24\sqrt{2}$).
Brad: (several seconds of reflection) I guess this is just like $10X + 24X$, the $X$ stays the same and you just go ahead and bring down the radical. Then 24 and 10 is 34 (writes $34\sqrt{2}$) O.K. That’s what I was doing. That’s the kind of mental lapse I’ll have, that right there. ... that’s crazy, for some reason it didn’t register with me on the homework. And that’s the kind of crazy thing I do ... crazy little careless mistakes like that. It kills me on the test. I usually catch it on the homework, I checked it twice.

We believe that Brad’s episode is noteworthy for the following reasons. First, Brad was able to distance himself from his prior activity and objectively review, monitor, and then report results to the interviewer. College Algebra students are seldom able to engage in such retrospective analysis of their actions. That Brad was able to demonstrate such a grasp over his actions indicates both the robust nature of his conceptions (his knowledge of what he needed to do) and the strength of his convictions about how these types of problems are to be solved. He systematically set about to simplify the radicals (#2-3) and never wavered from his belief that his overall reasoning was sound -- he knew what he needed to do to solve the problem with the radicals and could carry out and evaluate the efficacy of his actions. Second, Brad’s inability to self-diagnose and correct his erroneous idea about cancellation of radicals ($\sqrt{2} = 1$), suggests that his misunderstandings were deep-rooted within his flow of continuous action. While Brad could “see” an overall structure of appropriate solution activity to carry out, he had great difficulty isolating the source of error even after repeated attempts. It was only with the intervention of the interviewer’s questions that Brad became aware of the error and set about to correct his solution accordingly.

An Interview with Carrie Carrie was a 2nd year student whose performance in the class was consistently in the B to upper C range. Carrie’s responses on the beliefs survey indicated that she believed mathematics to be difficult because in order for one to be successful solving problems, one must remember many rules and procedures. She indicated that she thought mathematics was important for many careers but that she personally took mathematics courses only because they were required. She also indicated that she thought some people were naturally better at mathematics than others but she strongly disagreed when asked if mathematical ability was determined by gender. During the latter part of the first interview, Carrie introduced a rather difficult complex fraction problem from homework that had puzzled her. Her solution is summarized below as a series of simplifications (#1-5) of the original problem.

Summary of activity. Carrie began her work on this problem by factoring $m^2-4$ (#2). Immediately thereafter, Carrie came to her first major decision - was this a division problem? Initially, Carrie stated that she did not know what to do with the denominator, $1/(m+2)$. In describing her source of indecision, it appeared that the numerator posed the more immediate problem for her. Carrie stated that she wanted to work on the numerator using the least common denominator which she identified very quickly as $(m+2)(m-2)$. While Carrie had some difficulty describing what she wanted to do, her actions indicated that she understood the process for combining rational expressions. She correctly combined the terms in the numerator (#3); however, she also altered the denominator from $1/(m+2)$ to $m+2$. The interviewer intervened with a question and the subsequent episode served as a second major decision point for Carrie as she solved her problem.

*Interviewer: How did you get this in the denominator (points to m+2)?*

*Carrie: Do I apply the same LCD to this part or do I do it separately? Basically I get the LCD which is that [points to (m-2)(m+2)] and so all it is going to be is 1. (m+2), it's already there, so it's like..one.*

*Interviewer: You keep saying one, I'm not sure what you mean. [The interviewer inferred that Carrie was mentally dividing out (m+2)].*

*Carrie: (pause) O.K. see my LCD for this part, 1/(m+2)?*

*Interviewer: Yes, what are you going to do with it?*

*Carrie: (pause) Here it is simplified?*

*Interviewer: Yes.*

*Carrie: Should I leave it as it is?*

*Interviewer: Yes. What should you do now?*

*Carrie: Well, you don't want to mark it out (Indicates cancellation in the numerator). So I want to multiply it out.*

The interviewer's interpretation of Carrie's activity was that she had confused the two common methods for simplifying complex fractions and was trying to apply both methods simultaneously. In her first attempt (#3), Carrie appeared to be trying to mentally multiply both the numerator and denominator with the LCD, $(m+2)(m-2)$. In the subsequent attempt, she considered the denominator separately and determined that her simplification of the denominator was incorrect. Carrie then returned to the numerator and addressed the issue of how to multiply $m(m-2)(m+2)$. She noted that she understood how to apply the "FOIL method" but she wasn’t sure if she should multiply by the $m$ first.

---

1 The FOIL method refers to a memory device used by algebra students in the U.S. to remind them how to multiply together a pair of binomials -- First, Outer, Inner Last.
After the interviewer suggested that she could multiply in any order that she wished, Carrie wrote: \((m^3 - 4m - 1)/(m-2)(m+2)\) (#4) and then mused as to how this answer should be written in relation to the rest of the problem. At this time, Carrie reached the third major decision point of her problem solving process, when she again reflected as to the kind of problem she was faced with. She immediately declared that it was a division problem and began to work on it using the invert and multiply method. Carrie hesitated for a moment as she considered whether or not she should try to factor \(m^3 - 4m - 1\). After deciding against factoring, she divided out the common factor of \(m+ 2\) and wrote her final answer, \(m^3- 4m - 1/m-2\).

Carrie’s activity indicated that she had possession of some basic mathematical tools that many students at this level have not yet mastered. Carrie could factor polynomials, combine rational expressions, and simplify algebraic expressions. However, on the basis of her survey responses and interview data, we claim that her “mathematical world view” (Schoenfeld, 1985, p. 157) is procedurally based. For example, in utilizing her rules to simplify the complex fraction, she demonstrated solution activity that ultimately led to results that did not make sense to her. In order for her to resolve the confusion regarding what she perceived as similar solution paths, she was unable to mentally coordinate the two methods, one against the other, and determine which one to apply. Rather, she needed to choose one of the paths and physically carry out the process. She appeared unable to mentally carry out a process and evaluate the results it would yield. Finally, we noted that while Carrie immersed herself within the problem, she sometimes became lost inside the details of specific sub-tasks. We contend that one reason for this is that Carrie does not see mathematics as a world of connected mathematical ideas. Survey data revealed that she believes that “mathematics consists of many unrelated topics” (Yackel, 1984).

Conclusions. We posit that the experiences of Brad and Carrie are somewhat typical of College Algebra students. Such students enter college with a collection of mathematical rules, procedures and rigid expectations concerning what it means to do mathematics. As a result, the mental structures they invoke to help them organize and direct their mathematical actions are often fragmented. For example, memorizing the definition of a linear equation may help students recognize when they have a linear equation; however, it does not ensure that they will be able to mentally reflect upon, critically examine, and choose from among potential solution strategies. While memorizing definitions and rules is an important part of learning mathematics, it is not sufficient for the development of such reflective activity. For students such as Brad and Carrie, instructional practices that merely review and reinforce procedural tasks are not likely to benefit their mathematical development. Rather, these students need to face mathematical tasks that present dilemmas for them, the resolution of which contributes to their evolving awareness of algebraic concepts and, hence, to their evolving mathematical knowledge. Our continued work in this area is directed at developing instructional activities of this nature.

Composition of Geometric Figures

Douglas H. Clements
Julie Sarama
David C. Wilson

State University of New York at Buffalo

The purpose of this research is to chart the mathematical actions-on-objects young children use to compose geometric shapes. We designed a hypothesized learning trajectory based on previous research and an instrument to assess levels of this trajectory. We tested both the trajectory and the instrument with extensive case studies of 60 children, ages 3 to 7. Our research reveals that children move through levels of thinking in the composition and decomposition of 2-D figures. From lack of competence in composing geometric shapes, they gain abilities to combine shapes into pictures, then synthesize combinations of shapes into new shapes (composite shapes), eventually operating on and iterating those composite shapes.

The ability to define, use, and visualize the effects of composing (putting together) and decomposing (taking apart) geometric forms is a major conceptual field and set of competencies in the domain of geometry. This domain is significant in that the concepts and actions of creating and then iterating units and higher-order units in the context of constructing patterns, measuring, and computing are established bases for mathematical understanding and analysis (Clements, Battista, Sarama, & Swaminathan, 1997; Reynolds & Wheatley, 1996; Steffe & Cobb, 1988). There is empirical support that this type of composition corresponds with, and supports, children's ability to compose and decompose numbers (Clements, Sarama, Battista, & Swaminathan, 1996). Although there is limited research on children's thinking about geometric composition, there is a lack of research detailing specific learning trajectories. The purpose of this research is to chart the mathematical actions-on-objects young children use to compose geometric shapes.

The genesis of the study was in observations we made of children using Shapes software (Sarama, Clements, & Vukelic, 1996) to compose shapes. Shapes is a computer manipulative, a software version of pattern blocks, that extends what children can do with these shapes. Children create as many copies of each shape as

1 Time to prepare this material was partially provided by the National Science Foundation, grant number REC-9903409, "Technology-Enhanced Learning of Geometry in Elementary Schools" and grant number ESI-9730804, "Building Blocks—Foundations for Mathematical Thinking, Pre-Kindergarten to Grade 2: Research-based Materials Development." Any opinions, findings, and conclusions or recommendations expressed in this publication are those of the authors and do not necessarily reflect the views of the National Science Foundation.
they want and use computer tools to move, combine (compose and decompose) and duplicate these shapes to make pictures and designs and to solve problems. We noticed that several of our case-study students followed a similar progression in choosing and combining shapes (e.g., rhombi or equilateral triangles) to make another shape (e.g., to fill a hexagonal frame). At first, children merely appreciated the relationship between pattern blocks, how one pattern block could be made using other pattern blocks, but their efforts to fill a hexagonal frame with other pattern blocks was by trial-and-error. Second, they could fill the hexagon with 2 trapezoids. Then they followed a sequence of filling the hexagon with 6 triangles, the trapezoid with 3 triangles, the trapezoid with 1 rhombus and 1 triangle, and the hexagon with 3 rhombi. To ascertain whether this sequence was a valid indicator of developing competencies in composing shapes, we conducted a series of studies; we report on one here.

Theoretical Framework

Our theoretical assumption is that to solve composition tasks such as ours effectively and efficiently, children must build an image of a shape, then match that image to the goal shape by superposition (of both components and shapes), performing mental rotations as necessary to match these images. We wished to ascertain what features made certain composition tasks more or less difficult. In brief, the literature indicates that possibilities include: a horizontal or vertical side in the frame or component shape (Fisher, 1978; Hemphill, 1987; Ibbotson & Bryant, 1976), few component shapes (Vurpillot, 1976), symmetric components (Bremner & Taylor, 1982; Vurpillot, 1976), components which are symmetric halves of the frame (Clements & Battista, 1992), components that match a maximum number of the frames components (sides and angles), and presence or lack of mental rotation (Kail, Pellegrino, & Carter, 1980; Presmeg, 1991; Rosser, 1994; Shepard & Metzler, 1971). It is important to note that we are drawing indirect inferences from most of these studies in which the actual tasks were related to Piagetian horizontality and verticality tasks or disembedding tasks, not composition tasks in which we were interested.

We created a hypothetical learning trajectory from the existing research on shape composition, including our own research and intuitions generated from our work with children (Clements, in press). Hypothesized learning trajectories (Cobb & McClain, in press; Gravemeijer, 1999; Simon, 1995) ideally include “the learning goal, the learning activities, and the thinking and learning in which the students might engage” (Simon, 1995, p. 133). Unlike other approaches (Gravemeijer, 1994), we believe that existing research should be a primary means of constructing the first draft of these learning trajectories (which may, in turn, ameliorate the difficulty many development teams appear to have incorporating the research of others). The following levels constitute our hypothesized learning trajectory for the composition of shapes.

1. Pre-Composer. Manipulates shapes as individuals, but is unable to combine them to compose a larger shape.
2. Piece Assembler. Similar to step 1, but can concatenate shapes to form pictures. In free-form “make a picture” tasks, for example, each shape used represents a unique role, or function in the picture. Can fill simple frames using trial and error (Mansfield & Scott, 1990; Sales, 1994). Uses turns or flips to do so, but again by trial and error; cannot use motions to see shapes from different perspectives (Sarama et al., 1996). Thus, children at steps 1 and 2 view shapes only as wholes and see no geometric relationship between shapes or between parts of shapes (i.e., a property of the shape).

3. Picture Maker. Can concatenate shapes to form pictures in which several shapes play a single role, but uses trial and error and does not anticipate creation of a new geometric shape. Chooses shapes using gestalt configuration or one component such as side length (Sarama et al., 1996). If several sides of the existing arrangement form a partial boundary of a shape (instantiating a schema for it), the child can find and place that shape. If such cues are not present, the child matches by a side length. The child may attempt to match corners, but does not possess angle as a quantitative entity, so will try to match shapes into corners of existing arrangements in which their angles do not fit. Rotating and flipping are used, usually by trial-and-error, to try different arrangements (a “picking and discarding” strategy). Thus, can complete a frame that suggests that placement of the individual shapes but in which several shapes together may play a single semantic role in the picture.

4. Shape Composer. Combines shapes to make new shapes or fill frames, with growing intentionality and anticipation (“I know what will fit”). Chooses shapes using angles as well as side lengths. Eventually considers several alternative shapes with angles equal to the existing arrangement. Rotation and flipping are used intentionally (and mentally, i.e., with anticipation) to select and place shapes (Sarama et al., 1996). Can fill complex frames (Sales, 1994) or cover regions (Mansfield & Scott, 1990). Imagery and systematicity grow within this and the next levels. In summary, there is intentionality and anticipation, based on shapes’ attributes, and thus, the child has imagery of the component shapes, although imagery of the composite shape develops within this level (and throughout the next levels).

5. Substitution Composer. Deliberately forms composite units of shapes (Clements et al., 1997) and recognizes and uses substitution relationships among these shapes (e.g., two pattern block trapezoids can make a hexagon).

6. Shape Composite Iterator. Constructs and operates on composite units intentionally. Can continue a pattern of shapes that leads to a “good covering,” but without coordinating units of units.

We had two research goals, to evaluate (a) the geometric composing instrument and (b) the validity of the hypothesized levels of thinking in the domain of composing geometric figures.
Method

Based on this model of students' learning, we created an instrument to measure each of the first five levels of thinking. The following are examples of two items on the instrument.

On the first, children are given pattern blocks and a frame of a "man" and asked to "Use pattern blocks to fill this puzzle." We categorized children as follows. **Pre-Composer:** Cannot match even well-defined, simple frame, such as the "feet." **Piece Assembler:** Can fill simple frames (e.g., "feet" only) using trial and error. **Picture Maker:** Fills frames with trial-and-error, matching shapes by boundary or matching side lengths. **Shape Composer:** Completes entire frame with deliberate choices of shapes; to do so, matches configurations, sides, or angles. **Substitution Composer:** Deliberately replaces a group of shapes (e.g., two triangles) with one shape (e.g., blue rhombus) or vice versa. **Shape Composite Iterator.** Deliberately, systematically iterates a composite group of shapes to fill a region.

A second example asks children, in three separate questions, to determine how many yellow hexagons, red trapezoids, and green triangles they would need the cover the puzzle (given a limited number of the latter shapes).

We categorized children for the **Piece Assembler** to **Shape Composer** levels in ways similar to the first example, but this item was designed especially to target **Substitution Composer:** The deliberate recognition and use of the relationships between the hexagons, the trapezoids, and the triangles (e.g. 2 trapezoids = 1 hexagon).

Participants were 60 children from 4 classrooms selected at random from all children who completed a human subjects permission letter. All children were interviewed individually by one of two graduate research assistants following a protocol for administering the composition instrument. The researchers also asked questions of children, as in a clinical interview, whenever they believed that such questions would clarify the nature of children’s thinking.

Each session was videotaped. These tapes were partially transcribed, coded, and analyzed, both to complete the scoring of the instrument for each child and to identify additional themes.

We compared the results of applying the scoring rubric to the qualitative analysis of each child’s response to each item with the intent of determining, for each item, if (a) the item elicited the types of thinking we wished to observe and (b) the scoring rubric accurately encapsulated the type of thinking that the qualitative analysis revealed. We then used the results of both the scoring rubric and the qualitative analyses to determine whether (a) items designed to measure the same level of thinking elicited similar responses, providing information as to the reliability of the
items and the coherence of the hypothesized levels of thinking, (b) the levels form an invariant sequence. For example, each student’s scores were entered into a spreadsheet divided into categories based on the hypothesized trajectories; each item was classified according to the level it was designed to measure. The resultant spreadsheet was examined visually to answer the research questions. In addition, the proportion of items providing evidence of attainment of each level of thinking were computed. This allowed us to examine the percentage of children whose scores followed a pattern consistent with the hypothesized trajectory (e.g., if half of the items indicated thinking at level $n$, more than half should reliably indicate mastery of thinking at level $n-1$, etc.). Qualitative analyses were also used to ascertain whether the levels evince “incorporation”; that is, if thinking and actions of an earlier level are incorporated in the next level. Thus, we were assessing the main developmental criteria of constancy and integration (across a period, there is a type of thinking that forms an integrated whole), invariant sequence, and incorporation (Steffe & Cobb, 1988).

**Findings and Discussion**

Findings generally supported the hypothesis that children demonstrate the various levels of thinking when given tasks involving the composition and decomposition of 2-D figures, and that older children, and those with previous experience in geometry, tend to evince higher levels of thinking.

The most intensive work was in the qualitative analysis of children’s responses. We found that the levels of thinking could be reliably differentiated, and that children could be reliably assigned to a level of development (including those in the process of developing the next level). Here we can discuss only a few examples.

Mary, a preschool (4.3 years) child, exhibited actions that typified the behaviors of our early level of composition: the Piece Assembler. When Mary began working on the above described puzzle man, she tried (correctly) to place a trapezoid in the foot as shown. The trapezoid was $180^\circ$ opposite of the orientation needed to fill the frame and Mary, through her minor rotations in each direction, was unable to arrive at the requisite orientation and thus rejected the piece. Moments later, she uses the trapezoid to fill the arm, this time successfully rotating the shape to match the frame.

After similarly filling the other arm, Mary returned to the legs and concatenated 4 squares to (incorrectly) cover one leg, and two to cover the other before deciding to move on to another item. Using squares inappropriately shows that Mary was not attending to angle, a behavior typical of all of the children categorized as Piece Assemblers.
Kevin, a grade 1 student (6.0 years) demonstrated the actions used frequently by children at the Picture Maker level. The “picking and discarding” strategy that typifies this level can be observed repeatedly as Kevin attempts to fill the dog puzzle item. As Kevin tries to fill the puzzle, shapes are selected and “tried out” for a fit through placement and manipulation of the shape directly on the puzzle; there is a notable lack of the construction of a mental image of the shape and its relationship to the puzzle frame. The accompanying figure displays the puzzle nearly completed. Kevin attempted to fit a rhombus into the open space, then a square, and eventually, unable to fill the open frame, he rejected the arrangement and cleared away the shapes in the head. He then placed a trapezoid along the left side of the head and similarly on the right, thereby creating two simple frames that did allow him to complete the puzzle.

The Picture Maker level of thinking evinced by Kevin precedes the Shape Composer level which is exemplified in the work of Alice, a grade 2 (7.4 years) student. In this level we no longer observe the random selection of pieces, but rather deliberate selections are made as the child creates a mental image of how the shape may fill the frame. In addition, the process of completing a puzzle often becomes systematized. As Alice worked on the puzzle man she first placed a trapezoid on one arm, then the other, followed by a rhombus on each arm. Similarly, Alice carefully considered how to fill the leg as she looked back and forth from the shapes to the puzzle prior to making her selection. Once she filled one leg with two trapezoids, she was able to think of the concatenated pieces as a whole and simply duplicated the process on the other leg. She filled the body of the puzzle man in a similarly systematic way with the finished puzzle reflecting this nicely.

Across all 60 children, examination of the items indicating attainment of each level similarly confirmed the hypotheses. If a child evinced a level of thinking on one item, they were more likely than not to attain it on the other items measuring that level. Most exceptions involved the highest level the child had attained; many children, unsurprisingly, were in the process of developing that level of thinking, so that scores were mixed. With few exceptions, once a higher level was reached, children had mastered the vast majority of items at each lower level. Quantitative summaries supported these conclusions. Computing the percentage of children whose scores followed a pattern consistent with the hypothesized trajectory, we found that 84% of the children followed the pattern exactly. Of the 16% that did not, all but one broke the pattern in the same way: they scored slightly higher on the Substitution Composer than the Shape Composer level. Older children, and those with previous experience in geometry, tend to evince higher levels of thinking. Total scores for PreK, K, 1, and 2 were 3.28, 9.91, 12.3, and 12.5.
Conclusions and Future Research

Our research reveals that children move through levels in the composition and decomposition of 2-D figures. From lack of competence in composing geometric shapes, they gain abilities to combine shapes into pictures, then synthesize combinations of shapes into new shapes (composite shapes), eventually operating on and iterating those composite shapes.

The next phase of this research is to evaluate the usefulness of the present findings for instruction and to assess children longitudinally in teaching experiments. We have created a sequence of activities aligned with the learning trajectory and will engage children from preschool to second grade in these activities, charting their development through the learning trajectory.

LISTENING: A CASE STUDY OF TEACHER CHANGE

Alf Coles

Kingsfield School, South Gloucestershire, UK and University of Bristol, Graduate School of Education, UK

The data for this study is taken from a current research project [1] looking into the development in year 7 students (aged 11-12) of a 'need for algebra' (Brown and Coles, 1999) in four teacher's secondary classrooms in the UK. For this case study I introduce the notions of evaluative, interpretive and transformative listening, (adapted from Davis, 1996), to analyse three transcripts taken from the lessons of one teacher on the project. The project design and case study were informed by ideas of enactivist research (Varela, 1999, Reid, 1996, Brown and Coles, 1999, 2000). A significant change occurred in Teacher A’s classroom, as shown in the transcripts, and the listening of both students and teacher became transformative. There is evidence that specific teaching strategies were linked to this change in listening and that once the change occurred the students started asking their own questions within the mathematics.

BACKGROUND

In the summary of findings (Coles, 2000) from a one year teacher-research grant (awarded by the UK’s Teacher Training Agency (TTA)) I identified teaching strategies that were effective in establishing a ‘need for algebra’ (Brown and Coles, 1999) in a year 7 class (students aged 11-12 years) whom I taught. ‘Algebraic activity’ in this project was interpreted as being synonymous with ‘thinking mathematically’ (see Brown and Coles, 1999). Evidence for students finding a ‘need for algebra’ was that they were able to ask their own questions about complex mathematical situations and structure their approach to working on these questions.

The results of the TTA research formed part of the background to a current research project [1], funded by the Economic and Social Research Council (ESRC). This project involved three other teachers, who had all been part of a steering group on the TTA research, and wanted to work at developing a ‘need for algebra’ in their own year 7 classes (the first year of secondary school in the UK).

Since a ‘need for algebra’ was linked to students asking their own questions, whole class discussions in which students developed these questions were seen by all the teachers on the project as being a vital component of their lessons. If discussions amongst a whole class (around twenty six students for each teacher) are to be effective in allowing students to develop their own ideas, then the quality of listening of the students is a key factor. Before presenting a case study of the changing practice in Teacher A’s classroom in relation to the listening that took place, I need to set out what I mean by listening and by different types of listening.

LISTENING AND HEARING

The dictionary definitions of listening and hearing are as follows:

hearing is; ‘the action of the faculty or sense by which sound is perceived ... the action of listening ... knowledge by being told’

PME25 2001 783 2 - 281
listening is; ‘the action or act of listening ... to hear attentively ... to give ear to ... to pay attention to ... to make an effort to hear something’ (Little et al, 1973)

There is an overlap in these definitions in that both can be used to mean ‘the action of listening’. The different aspects of the definitions of listening all share this active component; ‘to give ear to’, ‘to pay attention to’ and in each phrase I take listening to involve an act of will or decision on the part of the listener ‘to make an effort ...’. This sense of listening involving the will is echoed both in research in psychology: ‘Listening is a process that is triggered by our attention.’ (Rost, 1994 p.2) and in mathematics education: ‘The act of listening ... requires a full and conscious effort to tune into the how and the what of the students’ idea’ (Wassermann, quoted in Nicol, 1999 p.57).

The definitions of hearing, in contrast, I take to refer to two different phenomena. The ‘faculty ... by which sound is received’ (Little et al, 1973) seems to refer to the mechanical aspect of perceiving sound. However, the last definition of hearing in the quotation above: ‘knowledge by being told’ (ibid) does not fit with this ‘mechanical’ meaning. ‘Knowledge by being told’ implies that when I hear, something happens internally. I may be attending to whether what was said agreed or conflicted with my previous knowledge or whether what I heard extends the ideas I previously held.

There is an implied distinction here between a listening that is active but where no connection is felt with what is said and times where there is a connection made and where the hearer is changed by what they hear. I have found this distinction useful in thinking about classroom discussions but, in analysing lesson dialogue, I needed a finer grained and observable categorisation. The definitions that follow are based on Davis’ (1996) notions of the evaluative, interpretive and hermeneutic listening of teachers, which I adapt for analysing the listening of students as well as teachers.

THREE FORMS OF LISTENING

(1) Evaluative listening
If a teacher is listening in an evaluative manner then they will characteristically have a ‘detached, evaluative stance’ (Davis, 1996 p.52) and they will deviate ‘little from intended plans’ (ibid). For such a teacher: student contributions are judged as either right or wrong ... listening is primarily the responsibility of the learner’ (ibid). The teacher makes assumptions based on a supposed ‘knowledge of the other’s subjectivity’ (ibid) or rather the assumption is the students have knowledge of the teacher’s subjectivity - hence it is the student’s responsibility to listen and learn from the unproblematic access they will thus have to the teacher’s thinking.

If students or teacher are listening in an evaluative manner then they would see what others say in terms of right or wrong, and see listening as the others’ responsibility. This is indicated by, for example, someone responding immediately to another’s suggestion with a judgement that it is incorrect (or correct).
(2) Interpretive listening

Interpretive listening is characterised by an awareness of the ‘fallibility of the sense being made’ (Davis, 1996 p.53). If I hear someone while listening in an interpretive manner then along with whatever connection I make, or any idea that arises, or whatever meaning I take from the words, I am aware that this may not be the connection, idea or meaning the speaker intended. There is a recognition that listening requires: ‘an active interpretation - a sort of reaching out rather than taking in’ (ibid). A response might offer feedback to the speaker not by evaluating what is said but e.g. by offering an interpretation and asking for clarification.

(3) Transformative listening

What distinguishes transformative listening from the previous category, interpretive listening, is that the interpretive listener is still ‘standing back’ from the speaker. There is an attempt to interpret and make sense of what the speaker says, but always from the point of view of the listener.

When I listen in a transformative mode, then as well as an awareness that what I hear may not be what the speaker intended (characteristic of the hearing of interpretive listening) I am open to the interrogation of assumptions I am making, e.g. that allow me to believe communication is possible at all.

I have again drawn on Davis’ (1996) categories of listening. He defines his third form of listening (which he labelled ‘hermeneutic’) as:

... an imaginative participation in the formation and the transformation of experience through an ongoing interrogation of the taken-for-granted and the prejudices that frame these perceptions and actions. (Davis, 1996 p.53)

The notion of the ‘transformation of experience’ links this form of listening to traditions of Buddhist mindfulness, in which knowledge is seen as ‘equivocal’ and ‘open to question or revision’ (Claxton, 1997 p.219).

Evidence of transformative listening and mindfulness in a classroom includes a willingness to alter ideas in a discussion, to engage in dialogue, to entertain other points of view, and hold them as valid, independent of whether they are accepted or not. If a student makes a connection to a previous piece of work or links something that has been said before, this would indicate the transformation of experience, the re-structuring of categories. Similarly, if a student creates a new categorisation, this indicates a mindful attention to what is happening: the seeing of ‘a new world’ (Thera, 1996 p.32). This sense of re-structuring previous categories or ideas, seeing a ‘new world’ is indicative of learning.

CASE STUDY - TEACHER A

With these distinctions I have been able to analyse the listening in teachers’ classrooms across the project. After a brief description of the methodology and
methods of the study, I present three transcripts (see Appendix 1) to illustrate how the listening changed in Teacher A’s classroom over a period of four months.

Methodology

There are four researchers on the ESRC project (one of whom is myself), each responsible for a different strand of analysis (e.g. teaching strategies, algebra).

The whole project design has been informed by ideas of enactivist research (Varela, 1999, Reid, 1996, Brown and Coles, 1999, 2000) and a key component of the research process has been that we take multiple views of a wide range of data. This is ensured by the different strands of the researchers. We will often look at one piece of data, e.g. a short piece of a videotape of a lesson, and discuss what we see from each of our perspectives.

We also tell stories of the changes that are happening over time for the students, teachers and researchers on the project. The three transcripts that I use in this paper are part of a story about learning and about teacher change. All four researchers have written about an expanded version of the last transcript (Brown et al, 2000) weaving a different story to the one I present here.

There is no sense of there being a ‘best’ theory for our work or, for example, of the perspective of listening in this paper being ‘better’ than a previous analysis of the same data. An explicit part of the project is that we see ‘research about learning as a form of learning’ (Reid, 1996 p.208). From an enactivist viewpoint learning is the telling of multiple stories and the awareness of ever finer grained distinctions.

Methods used for this case study

There were four teachers on the project who were videotaped in each of the six half-terms that make up an academic year. The camera was fixed at the back of the classroom - focused on the board but with around half the students in view. The data for this study is taken entirely from the videotapes of one teacher, Teacher A (TA). I was looking at times during the lesson of whole class discussion, i.e. when there was a single conversation occurring in the room. I initially watched the videotapes and noted - at 5 second intervals - whether a student or the teacher was speaking. This record helped me identify times when students responded directly to each other or when there was significant interaction between teacher and students. I then transcribed those sections of dialogue from the video recording. I chose Teacher A for the study because, of the four teachers on the project, there was the clearest evidence of a change in listening on the videotapes of his lessons.

Analysis

The dialogue in Transcript 1 shows evidence of evaluative listening. After the comments of both S1 and S2, Teacher A says ‘they do’ thus evaluating and confirming the students’ contributions. S3’s comment is greeted with a ‘thank you’ which the other comments were not, suggesting to me that this is the comment that the teacher
wanted (although the comment is unclear, from Teacher A’s response I interpret S₃ as saying something about the first and last digits of the three numbers under consideration). Further evidence for the teacher having a pre-given idea of what he wanted the students to say is that having started with the general question: ‘Any comments about those three numbers’, Teacher A then asks: ‘what can you tell me about the first and the last?’. Having started with an open question, since the students were not offering what was wanted, the teacher directs their attention to a specific aspect of the problem.

It seems possible here to pick out sentences and analyse them using the categories of listening. However, in viewing more videotapes this rapidly became problematic. In looking at transcripts of sections of dialogue to decide what type of listening was being displayed I needed, in most cases, to take into account the wider context of what was happening in the lesson. For example, in a different lesson a student said to his neighbour: ‘You are wrong’. On the surface this seems typical of evaluative listening. However if this comment was the start of an interaction in which the students began to explore their differences, the listening would be interpretive or transformative. It therefore made more sense to characterise whole lessons or sections of lessons as evaluative, interpretive, etc.

In fact, when I analysed longer sections of the lesson transcribed above the listening was more interpretive. In general Teacher A does not evaluate the students’ contributions as right or wrong. However, the task for the students is to fit their comments and suggestions to the teacher’s plan. Teacher A interprets the students’ comments and gives feedback in relation to the idea he has chosen to focus upon.

I believe the listening in Transcript 2 moves from interpretive to transformative. A student makes a suggestion: ‘It’s got six lines of symmetry’, which is dealt with in a different manner to the ones just before. Rather than continuing the interpretive listening pattern of repeating each student’s contribution and asking for other comments, Teacher A says: ‘Where’s your lines of symmetry then?’. The teacher cannot know where S₁’s lines of symmetry are, hence he is genuinely involved in making meaning of the comment.

Teacher A then asks for the rest of the class’ opinion: ‘Who thinks it’s a line of symmetry? Hands up’. After S₅’s comment, Teacher A gets an A4 piece of paper and starts folding it the ways S₅ and then other students suggest. The teacher responds directly to suggestions from students. The task for the class (in this case deciding what is a line of symmetry and how many there are on a rectangle) emerges from the interaction of students and teacher. I read Teacher A’s comment at the start of the transcript: ‘right, we’re talking symmetry’ - which was said with a slightly higher tone of voice, as further evidence that he had not anticipated dealing with issues of symmetry. There is a feel of collaboration and participation in the dialogue - characteristic of transformative listening.
The participatory nature of discussion is even more evident in Transcript 3 (taken from later in the same lesson as Transcript 2) in which the listening is also transformative. The teacher here is not running the discussion (e.g. by posing questions for the students to respond to). It is the students who are asking questions: 'What about 100?', 'What would just a straight line be?'. Students are now talking directly to each other and extending each other's ideas e.g. 'S: And a quarter times 48 is twelve'.

The transcripts provide evidence that there was a significant change in the listening in Teacher A's classroom. The listening in videotapes of lessons up to Transcript 2 was interpretive or evaluative and in all later videotaped discussion the listening was transformative, so the change appears to have been a lasting one.

TEACHING STRATEGIES

It is beyond the scope of this paper to deal with what factors have contributed to the change in listening in Teacher A's classroom, however it is striking that there are a number of teaching strategies in evidence in Transcript 2 (and later discussions) that were not being used in Transcript 1. These strategies include:

- the teacher asking a question they do not know the answer to. Teacher A says: 'Where's your line of symmetry then?' Having made this comment there is immediately the possibility for other students to engage with S, in dialogue.

- responding to students' suggestions. There is evidence of this particularly in the sequence when Teacher A gets a piece of paper and starts folding it.

- asking for feedback from the whole class. Teacher A asks for 'Hands up' in response to the question 'Who thinks it's a line of symmetry then?'. Feedback from this response allows the teacher to use the next strategy.

- asking a student to explain their idea to the class.

These strategies can all be seen as 'slowing down and opening up discussion'. They are strategies that encourage and allow different students to engage in dialogue with each other. In Transcripts 2 and 3 over a quarter of the class speak in a period of a few minutes. Another way of characterising the strategies is that they all depend on the teacher's contingency upon the responses of the students. It is important to note that this does not imply the teacher will do anything the students suggest but only that students' voices can be heard and can play a part in the creation of the lesson focus.

There is evidence from other teacher's lessons on the project of the teaching strategies above being used during times of transformative listening.

It is striking that in Transcript 3 it is not the teacher who is 'asking a question they do not know the answer to', or 'responding to students' suggestions', but the students themselves. It seems that students are taking over some of the roles in discussion previously performed by the teacher - a culture of transformative listening is becoming established in the classroom. In Transcript 3, for the first time on any of
Teacher A’s videotapes, students raise their own questions, which they could work on, related to the mathematical activity.

CONCLUSION

The description in this paper of different types of listening has provided a tool for analysing classroom dialogue. The evidence of this study is that teaching strategies based on the teacher’s contingency to the responses of the students allow the opening up and slowing down of class discussions, which seems necessary for the development of transformative listening. There is evidence that in discussions in which the listening of students and teacher is transformative, students exhibit behaviour associated with these teaching strategies in responding to each other. In such discussions, there is the opportunity for students to ask and work on their own questions, which for the ESRC project is linked to them having a ‘need for algebra’.

I would like to give especial thanks to the headteacher, governors and staff of Kingsfield School for their unfailing support and encouragement of this research.

REFERENCES

**APPENDIX 1**

[NB The numbering of students in each transcript is done independently.]

**Transcript 1: September 1999**

TA: Any comments about those three numbers? [The numbers referred to are: 92101, 29810, 54321]

S1: They all have two in them.

TA: They all have two in them [pause] they do [pause] anything else?

S2: They all have one in them.

TA: They do [Two more students offer suggestions, which Teacher A responds to.]

TA: Now remember what we were saying ... when we were looking at four digits we were comparing the first and the last, we were comparing the two middle ones. What can you tell me about the first and the last with those ones ... what can you tell me about the first and the last?

S3: [unclear]

TA: Thank you S3: nine is bigger than one, two is bigger than zero, five is bigger than one.

**Transcript 2: March 2000**

S6: It's got four sides

TA: It's got four sides, okay, very good, anything else?

S7: It's got four equal angles

TA: Four equal angles, yes

S1: It's got six lines of symmetry

TA: Six lines of symmetry, right, we're talking symmetry. Where's your lines of symmetry then?

S1: Across the right hand top corner to the bottom left hand corner

TA: This is a line of symmetry? [TA holds up a ruler along a diagonal of the rectangle] [pause] he's unsure. Who thinks it's a line of symmetry? Hands up [pause] a couple of you. [pause] Who thinks it's not a line of symmetry? [lots of hands go up] Oooh, okay, S3, convince those that think it is why is it not a line of symmetry do you think?

S3: You can only have diagonals in a square

TA: Oh right, okay

S4: Or a circle

TA: Why is that one not a line of symmetry though? S5

S5: Well, if you get like a A4 paper, that's a rectangle, you can fold it diagonally so that it goes all [unclear]

**Transcript 3: March 2000**

TA: Excellent. Oh, lovely. Well done. [Students applaud] So, 3 times 4 is 12, 2 times 6 is twelve, 1 times 12 is twelve and a half times 24 is also 12...

S3: And a quarter times 48 is twelve

TA: And a quarter times 48 ...

S3: And an eighth times ...

S4: Three quarters.

TA: And an eighth times ...

S: I'm not saying.

S: You can actually go on.

TA: ... We could carry on forever couldn't we?

Ss: What about 100? How could you draw it though?

TA: Well, it would be a sixth of a unit. Very small.

S: If you drew it really big so one square was 6

S: Sir, what would just a straight line be?
AN INVESTIGATION OF PRESERVICE ELEMENTARY TEACHERS' SOLUTION PROCESSES TO PROBLEMATIC STORY PROBLEMS INVOLVING DIVISION OF FRACTIONS AND THEIR INTERPRETATIONS OF SOLUTIONS

Jose N. Contreras
The University of Southern Mississippi, USA
Jose.Contreras@usm.edu

Armando M. Martínez-Cruz
California State University, Fullerton, USA
Amartinez-Cruz@fullerton.edu

In this study, we examine 68 preservice elementary teachers' solution processes to a problematic story problem involving division of fractions. The problem was problematic in the sense that the numerical answer to the division does not necessarily provide the appropriate solution to the problem, at least if one takes into consideration the realities of the situation embedded in the context of the word problem. It was found that the sample of prospective elementary teachers did not always base their responses on realistic considerations of the context situation. In fact, only 19 (28%) of the participants' responses contained a realistic solution to the given problem. In addition, only 4 (6%) participants provided an explanation for their solutions. None of the participants made any comments about the problematic nature of the problem. It was also found that other factors contributed, at least in part, to students' unrealistic solutions: inappropriate mathematical models and mistakes on the execution of the mathematical procedures.

Story problems play a fundamental role in school mathematics because of several reasons. First, they intent to offer examples of where mathematics can be applied in "real-life" contexts. Second, they offer students opportunities to make connections between mathematics procedures or formulas and real-world situations. Third, they offer opportunities for students to practice mathematical procedures and formulas. However, in many cases the "stereotyped" nature (Nesher, 1980) of word problems leads students to apply mathematical procedures in an instrumental way, without realizing the inappropriateness of their actions. As an example, consider the following problem:

What will be the temperature of water in a container if you pour 1 jug of water at 80°F and 1 jug of water at 40°F into it? (Nesher, 1980, p. 46). Verschaffel, De Corte, and Lasure (1994) used this item with 75 fifth graders in Flanders. They reported that only 13 (17%) students provided a realistic response to the problem. Other studies (e.g., Contreras, 2000; Reusser & Stebler, 1997; Silver, Shapiro, & Deutsch, 1993) further illustrate that many students fail to activate their real-world knowledge or to use realistic considerations to solve problematic word problems.

This study is part of a larger project whose main purpose is to understand prospective teachers' knowledge of the meaning of quotients and reminders when solving story problems involving division. The purpose of the present paper is threefold. First, we examine prospective elementary teachers' solution processes and their use (or lack of) of realistic considerations to solve problematic story problems involving division of fractions. Second, we examine the extent to which prospective elementary teachers explicitly interpret the solution to mathematical procedures. Third, we also examine the extent to which the participants' solutions support or refute a referential-and-semantic-processing model proposed by previous research (Silver et al., 1992, 1993).
THEORETICAL AND EMPIRICAL BACKGROUND

Word problems also provide students with experiences about the process of mathematization, especially mathematical modeling. We define mathematization as the representation of aspects of reality by means of mathematical procedures. The process of mathematization involves the application of mathematical ideas and procedures to solve real-world problems. We will adopt Silver et al.'s (1992, 1993) model of mathematization for the story problems presented to the participants of the present study. Figure 1 displays Silver and colleagues' model.

![Diagram of Silver et al.'s model](image_url)

Figure 1: Silver et al.'s (1992, 1993) referential-and-semantic-processing model

According to this model, students' understanding of the structure of the problem might enhance their abilities to represent its solution through a mathematical operation or procedure. That is, students would map from the story text (the problem) to an appropriate mathematical model. Students then perform the required computations. Next, students should interpret the results of the computation using their real-world knowledge about the story text or story situation in the "real world." In other words, students need to map the computational result back to the story problem or to the implied "real-world" situation. If students fail to perform any of those three activities of the process of mathematization, they may not be able to provide a realistic response to the problem posed. While Silver et al. (1992, 1993) focused on students' lack of mapping from the numerical answer of the mathematical model to either the story problem or story situation, we hypothesized that students' range of solutions to the problem could be explained more completely by paying attention not only to the semantic processing feature of the model (mapping from the computation of the mathematical model to the story text or story situation) but also to the mapping from the story text to the mathematical model and to the execution of the mathematical procedures. Our hypothesis was based mainly on our teaching experience that suggests that problems involving division fractions are cognitively more complex than division of whole numbers. Our hypothesis
turn out to be reasonable. We will refer to the Silver et al.'s model as *referential-and-semantic-processing model* to distinguish it from their emphasis on the semantic feature of the model.

The story problem examined in the present study involve division of fractions in which the quotient does not represent the solution to the problem, at least if one takes into account some realistic considerations of the story context or story situation in the "real world". Such problems are called problematic division problems. One of the first sources to document students' solutions to problematic problems involving division is the Third National Assessment of Educational Progress (Carpenter, Lindquist, Matthews, & Silver, 1983). It was reported that only about 24% of the students who took such test gave a correct solution to the problem: "An army bus holds 36 soldiers. If 1,128 soldiers are being bused to their training site, how many buses are needed?"

Other studies (e.g., Cai & Silver, 1995; Ruwisch, 1999; Silver, Mukhopadhyay, & Gabriele, 1992; Silver, Shapiro, and Deutsch, 1993) have investigated students' solutions processes and responses to problematic division problems. In their study, Silver, Shapiro, and Deutsch (1993) examined 195 middle school students' solution processes and their interpretation of solutions to a division problem involving remainders. The problem read as follows:

The Clearview Little League is going to a Pirates game. There are 540 people, including players, coaches, and parents. They will travel by bus, and each bus holds 40 people. How many buses will they need to get to the game?

The researchers administered three versions of this problem. The different versions differed in the amount of people going to the game (532, 540, and 554) so that the decimal part of the numerical quotient were less than .5, .5, and greater than .5. The researchers had hypothesized that the size of the remainder could influence students' responses. They reported that over 60% of the students who used an appropriate procedure to find the solution executed their procedures correctly, but only 43% of the total number of participants provided 14 as their solution to the problem. The researchers also found that the size of the reminder did not influence students' responses. The authors concluded that the semantic feature of their model (Fig. 1) provides a solid explanation about students' lack of sense making or "suspension of sense-making" (Schoenfeld, 1991) when solving problematic story problems. In this paper we extend Silver and colleagues' research to a new content domain (fractions) and to a different population (preservice elementary teachers).

**METHOD**

Sixty eight prospective teachers participated in the study. A paper-and-pencil test was constructed consisting of five items involving division of fractions and decimals. As stated above, our original purpose was to examine prospective elementary teachers' understanding of the
meaning of quotients and remainders of division with fractions or division with decimals. In this paper we report the results of the first problem which was stated as follows,

Lida is making muffins that require \( \frac{3}{8} \) of a cup of flour each. If she has 10 cups of flour, how many muffins can Lida make? (The muffins problem)

The prospective elementary teachers were enrolled in two sections of a mathematics course for elementary majors at a southeastern state university in the USA. The test was given to students during regular class and they were told orally that they would have enough time to complete it. Students were not allowed to use calculators. Written instructions asked students to explain each of their solutions and to write down any questions, comments, or concerns that they might have about each problem.

ANALYSIS AND RESULTS

Students' written responses to the problem were examined to detect four features of their solution processes (a) mathematical model, (b) execution of the procedures, (c) solution to the problem, and (d) explicit interpretation of the solution to the mathematical model. The mathematical model refers to the mathematical operation or procedures that students used to represent and obtain the solution to the problem. Execution of the procedure referred to the set of steps or actions that students took to obtain the solution represented with a mathematical operation or procedure. The solution to the problem referred to the solution that students provided to the story problem presented to them. Finally, the explicit interpretation of the solution provided by the mathematical model referred to the explanation that students provided to justify their solution to the word problem. Table 1 presents the distribution of the mathematical operations or procedures (mathematical model) that students used to represent and obtain the solution to the word problem.

A procedure was judged appropriate if it could potentially produce the correct solution to the problem. As indicated in Table 1, less than 70% of the students used an appropriate procedure. In particular, nearly 6% used a proportion, about 3% used multiplication, and nearly 3% used the concept of unit rate and then multiplied by 10. Table 1 also shows that about 29.5% of the students used procedures that were judged as inappropriate. Specifically, about 17.5% multiplied the two given number, 4.5% used reverse division \((3/8 + 10)\), and nearly 7.5% used other procedures such as estimation, incorrect concrete models, etc. Only the appropriate procedures were examined for correctness of execution. Out of the 47 students who set up an appropriate procedure, 40 executed the procedure correctly, 5 incorrectly, and 2 did not show work. As we can see, only forty students were able to set up an appropriate procedure, execute it correctly, and showed work.

Table 2 exhibits a categorization of students' solutions and the percentage of the students providing each solution. A solution was coded as realistic (RS) if it was 26, 27 or any other solution with an appropriate justification. Nearly 28% of the solutions were categorized as RSs. A solution was categorized as reasonable unrealistic solution (RUS) if it was the result of an appropriate procedure executed correctly and it was different from 26. About 37% of the solutions were categorized as RUSs. A solution was categorized as incorrect reasonable unrealistic solution (nearly 6%) if it was the result of an appropriate procedure executed incorrectly. Finally, underestimated solutions close to 3 (3 and 3 3/4) or 23 (23.1 and 23) and overestimated solutions (28, 35, 375) were classified as unreasonable unrealistic responses (about 28%).

We also examined students' interpretations of the solutions to their procedures. An interpretation was defined as the written explanations provided by the students to justify the solution to the problem based on the execution of the procedure. An appropriate interpretation was one in which...
the student gave a meaningful interpretation to both the integer and fractional parts of the solution produced by the mathematical model. Only two students provided appropriate interpretations. An interpretation was judged inappropriate when the student's interpretation of either the integer or fractional part of the solution to the mathematical model was incorrect. Two students gave inappropriate interpretations. For example, one of them said "Lida can make 26 muffins with 2/3 cup of flour left over." The other student wrote a similar statement. Sixty three (about 93%) students did not provide an interpretation to the solution produced by the mathematical model. In particular, 10 students wrote procedural explanations that described the procedure followed to get the answer to the problem, 36 reported a solution to the problem equal to the solution produced by the mathematical model (and hence they did not probably see the need to justify their solutions), and 17 did not explain why their solution to the problem was different from the solution produced by the mathematical model.

Finally, we also gather evidence to support or refute aspects of the referential-and-semantic-processing model proposed by Silver et al. (1992, 1993). About 78% of the responses provided direct evidence to support the model. Specifically, nearly 6% of the responses provided an appropriate justification to support a realistic solution and 72% contained information that explained, at least in part, why some students failed to obtain a realistic solution. The 6% of the realistic solutions supporting the model contained the numerical solution of 26 and also an appropriate interpretation of 26. Out of the 72% of the unrealistic solutions, about 26.5% contained an inappropriate mathematical model, 4.5% a procedure executed incorrectly, and about 39.5% contained a reasonable unrealistic solution that was the result of an appropriate procedure executed correctly but there was not an interpretation of the result produced by the mathematical model.

About 16% of the responses contained indirect evidence to support the referential-and-semantic-processing model. These responses contained the solution of 26 to the problem but failed to include an appropriate interpretation or justification about why the solution to the problem was different from the result produced by the mathematical model. Nearly 6% of the responses were judged as containing counter-evidence for the model. These responses contained the realistic solution of 26 but also contained flaws either on the selection of an appropriate mathematical model or on the execution of the mathematical model. In other words, those students managed to obtain the realistic solution without a correct mathematization of the problem.

To examine the influence of students' lack of semantic processing on their final solutions to the given problem, we focused on the 48 responses that contained realistic solutions or reasonable unrealistic solutions. That is, responses that contained or potentially could have contained realistic solutions. We found that 29 (about 60.5%) of those responses were unrealistic because students failed to map from the computation produced by the mathematical model to the story problem or story situation in the "real world". 

\[ 796 \]
DISCUSSION

One of the major goals of this study was to better understand some of the contributing factors to prospective elementary teachers' solutions to a problematic story problem involving division of fractions. Silver et al.'s (1992, 1993) referential-and-semantic-processing model provided with some solid explanations of students' failure to offer a realistic solution to the problem. The model includes three important actions that successful problem solvers might take to assure a realistic solution: set up an appropriate mathematical model, correctly execute the procedural features or steps called upon by the mathematical model, and interpret the numerical solution produced by the mathematical model. About 72% of the solutions were categorized as unsuccessful solutions. In particular, nearly 1.5% of the responses contained no work, about 26.5% involved an inappropriate mathematical operation, nearly 4.5% had flaws on the execution of the procedure, and about 39.5% did not include a semantic interpretation of the result produced by the mathematical model. About 28% of the responses contained a successful (realistic) solution to the problem. In particular, only about 6% of the responses explicitly included a semantic interpretation to the numerical answer produced by the mathematical model, and over 16% reported a realistic solution without a written explanation or justification for their response. However, nearly 6% of the responses included a realistic response but contained either inappropriate mathematical models or flaws in the execution of procedures. This finding suggests that some students sometimes use non-mathematical means to solve mathematical problems. These responses were considered as evidence to refute the referential-and-semantic processing model. The other responses were judged as supporting either directly or indirectly the referential-and-semantic processing model.

Although the majority of prospective elementary teachers set up an appropriate procedure to solve the given problem, a high percentage of students failed to do so. In fact, about 30% of the students set up the problem incorrectly. The most common inappropriate procedure was multiplication (10 x 3/8). Given that the students had already posed and solved word problems involving multiplication and division of fractions, this finding seems somewhat unexpected and discouraging. On one side, instruction did not have the desirable effect; on the other, some of those prospective teachers might teach fractions without having a good understanding of modeling situations for which division or multiplication of fraction is an appropriate operation. As to execution of procedures, prospective elementary teachers had, in general, little difficulty in performing the computation procedures successfully.

We recognize that the muffins problem is problematic since it potentially admits multiple solutions or interpretations depending on the context but that was the whole point of the problem. The same division expression (in this case 10 ÷ 3/8) can represent different problem situations. We asked students to solve the muffins problem because we wanted to confront them with a problematic problem involving division of fractions for which the solution could be either the
integer part of the quotient (26) or one more than the integer part of the quotient (27) depending on aspects of the situational context. In the muffins problem, we could argue that a realistic solution is 26 because each muffins requires \( \frac{3}{8} \) of a cup of flour and there is not enough flour to make another one. However, in another situational context some students might argue that Lida could make another muffin which would use \( \frac{1}{4} \) (\( \frac{2}{3} \) of \( \frac{3}{8} \)) of a cup of flour. In this case the answer would be 27 muffins. While we did not expect all students to provide realistic reactions or comments to the problematic situations, it was surprising to find that only 4 (about 6%) students provided an explicit explanation for their solution, even though they were asked to explain their answers and to write down any questions or concerns that they might have about each problem.

We suspect that a factor that contributed to a great extent to students' failure to react realistically to the problems was students' impoverished experiences with standard problems in which the solution can be obtained by the straightforward application of one or more simple arithmetic operations with the given numbers. Further empirical research is needed to enhance our understanding of prospective elementary teachers' lack of semantic interpretation of solutions to problematic word problems.

THE CONCEPT OF DEFINITE INTEGRAL: COORDINATION OF TWO
SCHEMAS
Bronislaw Czarnocha, Hostos Community College, CUNY
Sergio Loch, Grand View College
Vrunda Prabhu, William Woods University
Draga Vidakovic, Georgia State University

This is a report of a study examining students' understanding of the concept of definite integral. Using APOS, a specific framework for research and curriculum development in collegiate mathematics education, as a guide in investigation, we analyze and interpret students' responses to the interview questions. The analyses of the interviews and the results of other studies indicate that the coordination between the visual schema of the Riemann sum and the schema of the limit of the numerical sequence is necessary for developing a good understanding of the concept of definite integral. Consequently, we give suggestions for didactic and curricular changes when teaching the concept.

In communicating mathematics to students, the professor presents concepts as a combination of (a) his or her understanding (b) the understanding established by the mathematical community, and (c) the pedagogical values the professor incorporates into his or her teaching. Communication however is a two-way process, and hence an important question arises: does the communication initiated by the professor achieve its objective? In particular, in the realm of the definite integral, do students indeed think along the lines defined by the classroom instruction? Is there a lack of understanding of some key concepts? Do modifications need to be made to our communication, our sequencing of topics that lead to the definite integral? What can we incorporate into our teaching that we learn from our current students thinking?

The definite integral is the composition of two distinct constructions: (1) the geometrical one, ultimately based on the principle of exhaustion, and (2) the numerical one of the infinite converging sequences and their limits. The problems encountered in the understanding of the sequences and their limits are quite widely investigated, the understanding of the definite integral has received much less attention, while the combination of sequences and limits leading up to the definite integral has received the least attention. Because of the dependence of the definite integral on the notion of the limit of the sequence, one can suspect that the problems in understanding the limit of a sequence will create difficulties in the understanding of the definite integral as well. One of the main goals of our paper is to demonstrate how this suspicion bears out. Thus, we report in this article, our findings of student understanding of the Riemann sum as revealed in the interviews, the need for a more intensive treatment

---

\(^1\) Our appreciation goes to Ed Dubinsky for his helpful suggestions during numerous conversations.
of sequences and limits of sequences prior to the treatment of Riemann sums and the justification for this suggestion.

As stated earlier, inspite of being one of the essential concepts developed during the first two semesters of college mathematics, there are comparatively few articles investigating the understanding of the definite integral by students. One of the most interesting works is the article by Orton who points out students' difficulties in using the limit process for their understanding of the concept of the definite integral. The analysis of our data expands and builds upon Orton's findings, presents the evidence of students' successes and difficulties and offers suggestions concerning significant changes in the instruction design.

**Literature review**

Two articles that deal with pedagogy as relates to the definite integral are by Orton [1983], and Davis and Vinner [1986]. Articles that shed light on student understanding of sequences and limits of sequences and functions are by Sierpiska [1987], Williams [1991], and Cornu [1992].

One of the interesting tools of analysis in mathematics education is that of a cognitive obstacle. According to Cornu [1992] there are the following types of cognitive obstacles: genetic, didactical and epistemological. A cognitive obstacle helps to identify the difficulties encountered by students in the learning process, and to determine appropriate strategies for teaching. Genetic and psychological obstacles arise as a result of the personal development of the student, didactical obstacles arise as a result of the nature of teaching and epistemological obstacles arise as a result of the nature of mathematical concepts themselves. It is equally interesting that according to Cornu, the concept of the limit has been fraught with several major epistemological obstacles in the course of history of which we mention two that are of significance to our work: a) the failure to link the geometry with numbers; and b) the difficulties with the last term, can one reach it or not?

Davis and Vinner [1986] report on a special 2-year Calculus course, in which they included a brief treatment of sequences and limits of sequences. Sierpiska’s [1987] study was intended to explore the possibilities of elaborating didactical situations that would help students overcome epistemological obstacles related to limits. She lists several epistemological obstacles encountered by students, related to limits, obstacles that maybe due to a lack of rigor, due to incomplete induction, due to notions that limits only amount to approximating, etc. Orton [1983] reports on a study investigating students' understanding of integration and differentiation. He thinks it would be very unlikely that the introduction of integration can be made easy.
He feels that the topic of limits is one of the most neglected topics at the school level, which in turn does not help the introduction of integration.

Framework

The study reported in this article, used APOS [Asiala, M., Brown, A., DeVries, D. J., Dubinsky, E., Mathews, D., & Thomas, K., 1996], a specific framework for research and curriculum development in collegiate mathematics education, as a guide to investigating students' understanding of the definite integral. The premise of this framework is that educators can develop knowledge about students' learning of mathematical concepts by going through a cycle of theoretical analysis, instructional treatment, and observations and assessment of student learning. The initial step in our approach, which we refer to as theoretical analysis, is to hypothesize about mental constructions that a student might make when learning a specific mathematical concept. We refer to this structured set of mental constructions as a genetic decomposition. The researcher's own understanding of mathematics along with her or his learning and teaching experiences are the most important components for this step of the framework. Subsequent iterations of the framework lead to an evolving genetic decomposition of the concept and an instructional treatment.

The present study is at the point of analyzing data collected during and after the instructional treatment in the first iteration of the teaching cycle. In the process of analyzing data and answering our research questions, we describe our observations in terms of actions, processes and objects [Asiala, M. et. al., 1996]. Figure 1 shown below represents the initial genetic decomposition of definite integral that was hypothesized by the instructor/researcher and used in developing instructional treatment and interview questions. This genetic decomposition assumed that students would have an object level understanding of functions, partitions, and would develop their understanding of Riemann sums by the usual approach of an action, process and object level progression. It ended by assuming that students would apply a limit schema to obtain a number. It was not clear at that point how this particular limit schema would enfold, and how it would affect the development of the entire Riemann sum schema. Thus, it seems that this particular development in the instruction would have to be determined by the enfolding illustrated by the students.

1. Object level of function
2. Object level of partition
3. Action on a function and a partition.
   Construct one Riemann sum of one function with one partition.
   Coordinate the process of a function and the process of a partition via the Riemann sum formula
5. Object conception of Riemann sum
   Encapsulate 4.
   Variations of the sum (Left, Right, Trap, Mid)
   Dependence on n.
6. Action on Riemann sum
   Compare with an area or a solution to a differential equation.
   This is done on a vague, pictorial, intuitive level.
   Improve the approximation.
7. Process on Riemann sum
   Interiorization of 6.
8. Apply limit schema to obtain a number.
   At this point, very few students will have a strong limit schema so it is unclear how the
   concept of definite integral will grow for them. It needs study.

Figure 1: Initial genetic decomposition of definite integral

The setting and data gathering
Data for this research were collected during the fall semester of 1992. The participants were 32 engineering, science and mathematics students who had, during the previous year, taken two semesters of single variable calculus at a large midwestern university. The interview consisted of 10 questions about the concept of integral. On the average, each interview lasted for approximately one hour. The interviews were audio taped and tapes were transcribed by paid student aides.

In this paper we attempt to answer the following three research questions: What is the relationship between the preliminary genetic decomposition and the students' mental constructions of the definite integral? What are the mental constructions that were not made by students? What should the modified genetic decomposition be to accommodate for the possibility of making the required mental constructions?

To answer the above research questions, we will analyze the responses to Questions 4, 6, 7, 9, and 10 from the interviews. Analysis of the remaining items will be presented in other studies. Below are the interview questions on which this study is based.

**Interview Question 4.** What is the mathematical meaning of \( \int_{a}^{b} \frac{1}{x^2} \, dx \).

**Interview Question 6.** Suppose that an object moves in a straight line at a velocity which is a function of time, \( v = v(t) \). Write a formula for the net distance which the object moves starting at time \( t = t_0 \) and ending at time \( t = t_f \).
**Interview Question 7.** Explain why your formula gives the distance.

**Interview Question 9.** Suppose now that you have a region $S$ in space which is a body of density $\rho$ which has a different value at different points in the region. Write a formula for the mass of this body.

**Interview Question 10.** Explain why your formula gives the mass.

Initially the students were given the opportunity to answer each question without prompting. Based on their response the interviewer asked additional questions or provided hints or clarification. The interviewer encouraged any kind of student's response (verbal, written, graphical) that might help to explain her or his ideas.

**Data Analysis**

In the excerpts of student interviews, we see instances of student thinking that follow the steps outlined in the genetic decomposition, viz., in achieving an object level of function and partition, an action and process level of Riemann sum. The next step students would need to make is to have an object level understanding of the Riemann sum. A student with an object level understanding of the Riemann sums should be able to talk and think about a Riemann sum on a partition of size 2, 3, 4... and be able to realize that the size of the partition needs necessarily to be finite. However, it is in demonstrating an object level of the Riemann sum that we notice difficulties that are principally related to the limit concept in the following two ways:

1. The limit of the Riemann sum is seen as the infinite sum of the rectangles of small width.

2. The limit of the Riemann sum is seen as the sum of lines, i.e., as the infinite sum of rectangles of zero width. (i.e., rather than the limit of the sum of the areas of $n$ rectangles, students state it as the sum of the limit of the areas of the rectangles.)

The student Kenard reveals the first difficulty. When questioned about what is being done to the Riemann sums in order to make it basically equivalent to the definite integral, he states:

$S$: For instance if you are using Riemann sums, you take infinity number of rectangles, you will get almost exactly the same thing because there won't be as much error.

Jernau when questioned about how he reconciles the two different meanings mentioned earlier, states

$S$: Right. Um... well, the Riemann sum breaks this up into $n$, an infinite number of rectangles. And, it's difficult to use the theory behind it. It is difficult for me.

Dadgaron reveals the second difficulty in response to the question of how one goes from the Riemann sum to make it equal 2/3, he replies
S: By making these rectangles infinitesimally small...smaller and smaller, I mean almost until they are a line they are a unit... and then you are just adding up these units and like, the smaller this empty area is the more exact the estimation until you get to a point where there is no empty space to be accounted for and that will give you an exact number.

In both of the above difficulties demonstrated by students, they (students) sense a correct need for fitting their intuitive tools, be it rectangles or lines, in the region under the curve, which can be pictorially seen as the area under the curve, however, they are unable to connect that area to the numerical sequence of partial sums. The best example of the absence of connection to the concept of the sequence is the following fragment of an A student (Jasax):

S: Um, well the integral is, is um, basically the sum of f(x) for i in this case -3 < i < -1 – not necessarily integers but every number, every single point between -3 and -1 is going to have an f(x) value...
I: Okay.
S: ...and if you add all of these together...
I: Um-hum.
S: ...you should get the area under the curve, ...

Clearly the student sees area as all the parallel lines contained in it, but in the next sentence where he notices his mistake in the formula he wrote, he immediately moves to the Riemann approach, without however anywhere indicating the presence of the sequence of which that limit is the limit of.

S: ... and the integral is just, um, actually it's f(x_{i+1}) - , okay it's f(x) times x(i+1)-x(i). Okay so now you have got, you've got a height which is f(x) times i, which is somewhere between x(i) and x(i+1).
I: Um-hum.
S: And so that would be your height and then your width would be x(i+1) - x(i), and so if you multiply those together you're gonna get some kind of little area...
I: Um-hum.
S: ...within that section. So if you sum up all of the little areas between -3 and -1 you should get a certain value. Now when you take the integral of that same function, it's still f(x^*) if you want to say that, and the x(i+1) - x(i) the integral makes it get --- takes the limit as, takes the limit of that sum as x(i+1) - x(i) goes to zero.

One might then suspect that an integrated approach which from the start correlates the pictorial representation with the numerical sequence of partial Riemann sums, would provide an answer to students difficulties. Such an integrated approach was investigated by Orton. In his work, Orton identified several key ingredients of the conceptual (or structural) problems students have with the definite integral. One of them was the difficulty "students have with the power of the limiting process in
mathematics" and in particular in calculus. The majority of students, who in one of Orton's investigational tasks, obtained initial 5 terms of the sequence Riemann Sums - which were understood as the approximations to the area under the curve $f(x) = x^2$, on the interval $[0, 1]$, appeared to grasp that this sequence consisted of better and better approximations and that it was possible to continue improving them. They were asked whether that sequence could be used to obtain the exact area under the curve. However, he states that the students "quite rightly pointed out that such a procedure would never produce the correct answer, and were unable to state that the limit would provide the answer." We see then that such an integrated approach still does not solve the students' difficulty, it has the effect of allowing students to construct the first few terms of the sequence without being able to see how the sequence could ever converge to the number which is the exact area under the curve.

This is in direct opposition to our students who can see the limit without having access to the sequence that converges to the limit.

Both difficulties appear to be grounded in the same inability to separate the concept of a limit from the last term of the sequence. Our group influenced by the pictorial image of the area would like to take the infinite sum which fits under the given curve, Orton's group on the other hand which also sees the area under the curve as the last term to reach, cannot get to it due to the infinite number of steps required to reach there. Therefore it seems essential to take the precise e-n mathematical definition of the limit of a sequence as a base foundation on which to build the notion of the limit of a sequence and of the definite integral as the limit of partial sums, which bypasses the issue of reaching or not reaching the limit and instead focuses on a process of approach [Sierpinska].

Refining theory with pedagogical implications

Based on the data analysis we suggest that the preliminary genetic decomposition (Figure 1) should be modified as follows:

2. Object level of sequence
9. Schema of the limit of a sequence
   The distance between the term and the limit of the sequence;
   The notion of the measure of the distance
10. Schema of the Riemann sum
11. Coordination between the schema of the Riemann sum and the schema of the limit of the sequence

The numbers in front of the new items added to the initial genetic decomposition denote the position of the entries in the initial genetic decomposition illustrated in Figure 1. We wish to emphasize that the requirement of an 'object level
of sequences' is a major change from the existing curriculum in the order of the concepts necessary to understand the definite integral as a limit of the Riemann sum. Currently, in a typical calculus course, the topic of sequences is studied in detail after the concept of the definite integral is studied extensively. Our proposed genetic decomposition requires a certain rearrangement of the order of the topics, with other emphasis as suggested above.

Our article emphasizes the pictorial understanding of the limit of the sequence of Riemann sums while Orton's emphasized understanding of the limit of a numerical sequence. The results of both studies point to difficulties by students when only one of them is seen separately. We conclude that there must be a coordination between the visual schema of the Riemann sum and the schema of the limit of the sequence. The source of students' difficulties can well be in the didactic and curriculum which a) doesn't develop the connection between the two in the design of the curriculum, and b) does not propose an alternative to the second by eliminating the precise definition eps-N of the limit of the sequence. This definition, the Weierstarss definition of the limit of the sequence was created especially to bypass the problem of reaching or not reaching the limit, as Sierpinska points out. Hence the absence of the instruction of the formal definition is leaving our students on the pre-modern level.

We detail one young woman’s journey in a 16 week mathematics content course for pre-service teachers. We analyse her initial efforts at problem solving in groups, and her ability to see and recall explicitly connections that were inherent in the instructor’s conceptions of the problems. Using her writing during the course, we compare her memories with those of other students of differing achievement, and infer that she made remarkable strides in coming to terms with the language of and ideas of mathematics, and understanding how engaging with those can help her be a better teacher.

Correct answers and mathematical connections

Pre-service elementary teachers want to get mathematical answers right. They want to know which formulas to use, and how to get the correct answer. A typical comment about their perceptions of mathematics on entering a mathematics content class is: “Coming into this class, I was under the impression that finding a formula to solve a problem was, in reality, the answer to the problem.”

This is where many of them stop in their understanding of mathematics. A strict utilitarian perspective often limits their mathematical vision. We are concerned when pre-service teachers figure the answer to $9+3\frac{5}{8}$ by reducing the problem to one of “how many eighths?” We are frustrated when they justify their answer that there are 16 ways of building towers of height 4 using blocks of 2 colors with the statement: “I know I have found all possible towers because every other group in the classroom got the exact same answer as us.”

Changing what students value in mathematics is frequently a much harder challenge than teaching them mathematical procedures and application of formulas. We need an antidote to a severely procedural orientation to mathematics focused on ‘correct answers’ that prospective teachers have learned to value above all. How can we explicitly emphasize connections, and assist students to construct relationships between parts of mathematics that they see as different?

We addressed this issue with a class of pre-service elementary teachers at Harper College, Illinois (www.harper.cc.il.us), during the Fall 2000 semester. The two authors co-taught the first three weeks of a 16 week course on mathematical content for pre-service elementary teachers. Differences between this and previous classes of the second author are in the explicit and intensive focus on building connections in the early part of the course. The emphasis in
the first three weeks of the course was on making connections between different combinatorial problems and on multiple ways of interpreting answers.

**Theoretical background**

We wanted to know whether the problems we set could promote the formation of useful long-term mathematical memories. We followed the model of Davis, Hill and Smith (2000) in assisting students to make their implicit, procedural memories declarative (Squire, 1994). The latter are memories we are capable of expressing in words, drawings or gestures. They are to be distinguished from *implicit*, or non-declarative, memories that assist us to carry out routine procedures and habits. There are three major types of declarative memories relevant to mathematics. Two of these are familiar from everyday memory, whilst the third is more commonly seen in its full form in mathematics and science.

*Episodic memory* is the system of memory that allows us to explicitly recall events in time or place in which we were personally involved. (Tulving, 1983; Tulving & Craik, 2000, and references). *Semantic memory* is the memory system that deals with our knowledge of facts and concepts, including names and terms of language. (Tulving, 1972, p. 386; Tulving, 1983; Tulving & Craik, 2000, and references). *Explanative memory* is that part of declarative memory dealing with explanations for facts. Davis, Hill, Simpson, & Smith (2000) present a case that explanatory memory is a separate memory system, linked to, but different from episodic or semantic memory.

Most psychological studies of memory are oriented to memory for language. Studies in memory for mathematics are much less common. A semantic memory such as *Paris is the capital of France* has quite different content to one such as *the number of prime numbers less than n is asymptotically n/log(n)*. The first is a linguistic convention, the other expresses a deep, non-obvious fact. Our experience with student mathematical writing and verbal recall suggests that there are, at least, the following distinctions in memory for mathematical facts:

1. **Memories of labels, customs, and conventions.** For example: *A prime number is a whole number with exactly 2 factors.* This sets up *prime number* as a conventional term. We refer to these memories as *semantic labels*.

2. **Factual memories of things sensed, or done.** For example: *The proportion of prime numbers less than 500 is 19%*. One might recall this as a fact from having done a series of calculations: the recollection is of the fact, not the episode of calculation. We refer to these as *semantic actions*.

3. **Memories of things believed.** For example: *There are infinitely many prime numbers: one recalls this from a book on number theory*. We refer to these as *semantic beliefs*.
Memories of explanations. For example: A proof that there are infinitely many prime numbers: one recalls an explanation. We refer to these as explanatory memories.

Method

We set a number of connected problems in the first three weeks of the course. These were specifically designed to set up strong episodic memories as a result of students discussing their solutions in class. For example, after students had attempted the problem of finding how many towers of heights 4 and 5 they could build using blocks of 2 colors, they were shown, and discussed, a video clip of three grade 4 students attempting the same problem. This problem and its connections with algebra, which we utilized, has been reported on by Maher & Speiser (1997). For a detailed description of these, and other problems set in the course, see: www.soton.ac.uk/~plr199/algebra.html

The combinatorial problems we set for the students in the first three weeks were connected in our minds: they all deal with different aspects and representations of a systematic counting problem related to binary choices. We focused on students’ written expressions of memories of the course. The reason for this is that long-term declarative memories are mediated by protein formation, following gene expression, to stimulate novel neuronal connections (Squire and Kandell, 2000). The relevance of this neurological fact is that long-term memory formation is an energetic, committed process for an individual. Long-term memories - certainly those sustained over two months - are therefore a good indicator of what a student values.

Students worked on the problems in groups. After completing the sequence of problems, they explained connections as a homework exercise. We asked them to write reflectively after each of the combinatorial problem sessions, and re-writes were encouraged. Opportunities for making connections with their earlier work were provided during the semester in questions on three group and two individual exams students hadn’t seen previously. Students also wrote mid-term and end-of course self-evaluations. Twenty-two students began the course and nineteen completed. Their writings provided us with a great deal of data for analysis. We present a preliminary analysis of some of that data by focussing on the development of one student: Jennifer. For fuller details of these and other student’s written statements see: www.soton.ac.uk/~plr199/algebra.html

Results and analysis

We begin by placing Jennifer in the class in terms of her initial and final test scores. Table 1 shows the initial and final test results for Jennifer and two other selected students as well as the shift statistic, defined, as follows:

$$shift = \frac{(final\ test\ % - initial\ test\ %)}{(100 - initial\ test\ %)}$$
We interpret shift as how much a student has moved from their initial test result to their final test result. Of course, a student who has a relatively high initial test score does not have as much room for improvement as a student with a low initial test score. The other two students - Allison and Rebecca - we use to compare with Jennifer were chosen to be representative of students with a middle and low shift value, respectively.

Building towers and the grade 4 video clip

Jennifer focused on building towers of height 4 by swapping colors, a strategy used commonly by pre-service elementary teachers. They refer to this as "being systematic": when challenged as to why they have all possible towers they commonly reply that they systematically swapped colors. Every group in the current study used this strategy.

"We began with combinations of 3 red and 1 blue. We then altered the placing of the one blue cube which resulted in 4 different combinations. Second, we alternated the colors and made 4 combinations of 3 blue and 1 red cube, which gave us 4 combinations. Third, we made two groups of cubes, alternating between red and blue with a total of 4 in each tower. ... After building several towers, we realized that each tower had an opposite."

Working in her group she came up with a formula based on opposites that did not, however, extend to the case of towers of height 5

"... if you multiplied the number of blocks in a tower by the number of options, you would have the number of combinations possible. Then you would double that number because each combination has an opposite: Ex: 4 high x 2 = 8; 8 x 2 = 16. However, this formula does not hold up for 5-high towers."

Jennifer realized that the number of towers had something to do with doubling. She gave no reason or explanation, other than empirical evidence, as to why this might be so:
"It appears that you are doubling the possibilities when adding a cube to each tower. The formula we discussed in class appears to make sense where when you add a level to each tower, the possibilities double. 1 level = 2 possible; 2 levels = 4 possible; 3 high = 8 possible; 4 high = 16 possible; 5 high = 32 possible, etc."

She recognized some system in the grade 4 students’ explanations, but she did not relate this precisely to her group’s approach and she was – mistakenly – under the impression that she solved the problem as Stephanie did in the video clip:

"... I now realize that there are several patterns and options to solving this type of problem. Each of us in class recognized patterns, but not one formula could clearly explain or define our cases. When building my towers, I looked for patterns similar to the way Stephanie did. My pattern differed in that I grouped my towers by building towers with one blue, and then built those with one red. I continually built towers and followed them with their opposites."

After building towers and watching the grade 4 students argue why they found all towers of a given height Jennifer stuck to her belief that building opposites is a key to systematically building towers. From our perspective the pre-service teachers were uniformly unsystematic in their attempts to build towers and to explain why they had built all possible and not repeated any. Jennifer was not alone in expressing the sentiment that since they did not know how to tackle this problem “mathematically” they would approach it through common sense:

"Instead of looking at it as a math problem, I was looking at it as a building exercise. I first attempted the problem by guessing and testing. Tony and I first attempted the problem of four high by creating combinations of four that would design an obvious pattern."

Seeing and valuing connections

Jennifer did not immediately see connections between the problems set in the first 3 weeks of the course. Some of those connections she learned about through class discussions, following insights of other students. At the time of writing these reflections, however, she was able to articulate a common vision of “algebra” in all the problems. Not the algebra she initially imagined, namely $2^n$ as the formula for the number of towers of height $n$, but algebra based on multiple interpretations. The algebraic expansion worksheet showed $(a+b)^2 = a^2 + 2ab + b^2$ and asked students to similarly expand $(a+b)^3$ and $(a+b)^4$. Only one student in the class (not Jennifer) could do this problem. The tunnels problem was to figure how many ways there are to run through a series of 4 tunnels if each could be black or white.

"The algebraic expansion worksheet threw everyone off at first. We really were not sure how it related to the first three exercises. What we did not see was that the “towers” were actually algebraic expansion. If two different color cubes can make 16 different towers four high, how do you mathematically write this out? Answer: $2^4$. Let’s say that the cubes are the colors black and white...then the formula would be written $(w + b)^2$. This is how exercise one and
Exercise four relate. Tunnel travel led us to a new discovery. A student can look at the problem and sketch the different possibilities just as he/she did with the tower building exercise or they can apply the algebraic expansion \((w + b)^4\) where \(w = \text{white}; b = \text{black}, 4 = \text{number of tunnels}\) and \((w+b)^4 = w^4 + 4w^3b + 6w^2b^2 + 4wb^3 + b^4\).

Jennifer was able to use her insights to help her solve two further problems: (a) how many pizzas can be made from 8 toppings, and (b) how many towers of a given height can be built using at most 3 colors?

(a) “This situation is similar to the former exercises of building towers, the committee vote exercise, the grid walk problem, and the tunnel exercise with Mork. The “‘with” or “without” question resembles the two color combination for the tower building exercises, the “yes” or “no” vote of the committee members, the “up” or “right” direction for the grid walk and the alternating pattern of the tunnels. ... The “with” or “without” strongly indicated powers of two as in the tower exercise. We extrapolated this to apply to the Pascalini’s dilemma, so we figured that \(2^8 = 256\), therefore, there are 256 combinations for pizza made of 8 toppings.”

(b) “\(3^4 = 81\), \(n = \# \text{ of cubes high}; x = \# \text{ of color choices}; \text{formula: } x^n\) There are 81 towers that can be built. This is similar to white and black (2 colors) as we did in class. In class we built towers of four and five high with the combination of two colors (two choices). We also worked on committee votes of YES or NO (two choices). ... This problem also relates to the pizza problem. Instead of 8 choices of toppings you would use 3. They differ in their number of choices.”

Jennifer valued the insights she gained by seeing connections. At the conclusion of the course she articulated a different vision of mathematics:

“When I joined this class in August, I thought of math as a series of formulas, each of which should be followed in order to find an “answer”. It was working on the tower building investigation and traveling through tunnels that I discovered how each relates... My original approach to the tower building revealed that instead of looking at the small picture (i.e., What do I really have in front of me? What is it I’m trying to solve?), I just dove in expecting multiple patterns. When our class finally concluded that the towers, tunnels, grids and Pascal’s Triangle were all about “choices”, everything seemed to fall into place. ... my perspective of mathematics changed over this semester. The changes occurred due to learning that my mathematical understanding was instrumental and not relational. I had to re-learn basic math in order to eventually teach it to children.”

Memory types

Table 2, below shows the number of different types of memory statements made by the 7 students for whom we currently have transcribed data. For these students the shift statistic correlates moderately well with the total number of semantic statements (semantic action + semantic belief + semantic label; \(r^2 = 0.77, p < 0.0001\)). Whether this correlation holds more generally we do not yet know.
Table 2: The number of statements according to memory type in 7 student's written work.
Note that the classification of memory types has not yet been subject to marker reliability.

For this group of students the number of semantic labels correlates almost as well with the shift statistic: $r^2 = 0.71, p < 0.02$. Recall that semantic labels are memories of conventional facts: their mathematical depth is negligible. Some examples given by Jennifer are listed below. Bear in mind that these statements may also contain connotations of other types of memory (episodic, for example).

- "All problems assigned present two choices or a binomial." Jennifer illustrates here that she knows the meaning of the conventional term ‘binomial’.
- "...place value as we know it today is also known as the Hindu-Arabic numeration system." She shows that she knows another conventional name for the place value system.
- A number is considered a factor of another when it can divide that number without a remainder. This shows that Jennifer has a meaning for the term ‘factors’.
- We used proof by exhaustion when working with a finite set of numbers; listing all of the possible cases. Here she is able to explain ‘proof by exhaustion’ in other terms.

Examples such as these are significant: they show that Jennifer is coming to terms with the language of mathematics, that she is able to interpret and use conventional mathematical terms. They show, we believe, that she has accepted her entry into the mathematical community and now feels part of it; perhaps a small part, but a part nonetheless. Compare this with part of her final written reflection, at the end of the course:

“One issue I have always had problems with in mathematics is definitions. I can physically work through a math problem, but to try to put my efforts into words is a challenge. Definitions in mathematics play a vital role in building a solid base of one's knowledge and abilities. It is the basis of your criteria. The mistakes our class made in defining even numbers were (a) we assumed that we were working in base ten and (b) we tried to define even numbers by using the word “even”! If definitions are the base of our mathematical foundation, then algorithms are the brick in the bridge of our mathematical path...an algorithm is a systematic procedure that one follows to find the answer to a computation.” (Our italics).
Conclusion

Jennifer made a significant change in her understanding of mathematics. She began, as many pre-service elementary teachers do, expecting to apply formulas and get correct answers in order to be "mathematical". By the end of the 16 week course Jennifer expressed a different view of mathematics: one that she herself characterized as more relational. She established manifold long-term memories of mathematics: factual, episodic, and relating to the conventional use of mathematical language. Her tests score improved from not satisfactory to excellent.

How important were the experiences of the first 3 weeks in setting Jennifer on a path to seeing and valuing connections, and establishing lasting useful mathematical memories? In her words:

"I feel this was the most productive experience I have ever had in my educational career. I deeply feel that I will be a better educator because of it."

The beautiful phrase: "If definitions are the base of our mathematical foundation, then algorithms are the brick in the bridge of our mathematical path," is a sharp illustration of how well she assimilated the mathematical experiences of the semester, and how these assisted in deepening her understanding of and competence in mathematics.

SECONDARY SCHOOL PUPILS' IMPROPER PROPORTIONAL REASONING: AN IN-DEPTH STUDY OF THE NATURE AND PERSISTENCE OF PUPILS' ERRORS

Dirk De Bock¹ ², Wim Van Dooren¹, Lieven Verschaffel¹ and Dirk Janssens¹
¹University of Leuven and ²EHSAL, Brussels; Belgium

Abstract. This paper describes an in-depth investigation (through individual interviews) of the problem-solving processes of 12–16-year old pupils who improperly apply linear models when solving problems involving lengths, areas and volumes of similar plane figures and solids. The results showed that the linear model was used in a spontaneous and self-confident way by almost all pupils, and that these pupils were almost insensible to the confrontation with conflicting data. Furthermore, it was shown that the poor results were due to a bad understanding of the principles governing the enlargement (or reduction) of geometrical figures, to pupils' inadaptive beliefs about and attitudes towards mathematical problem-solving, and to their poor use of heuristics and of metacognitive strategies.

1. Theoretical and empirical background

Pupils' tendency to apply proportional or linear reasoning in non-proportional problem situations was already exemplarily described in several mathematical domains, such as elementary arithmetic, algebra, probability and geometry. Best-known in the domain of geometry and measurement is pupils' improper application of linearity in problems about the relationships between the lengths and the area and/or volume of similarly enlarged or reduced figures. In the NCTM Standards, for instance, it is stated that “... most students in grades 5–8 incorrectly believe that if the sides of a figure are doubled to produce a similar figure, the area and volume also will be doubled.” (NCTM, 1989, pp. 114–115). Gaining insight in the quadratic, respectively, cubic growth rates of areas and volumes, appears to be a slow and difficult process, and, therefore, it deserves our close attention, both from a phenomenological and a didactical point of view. According to Freudenthal (1983, p. 401), “this principle deserves (...) priority above algorithmic computations and applications of formulæ because it deepens the insight and the rich context in the naive, scientific and social reality where it operates.”

Recently, several studies have shown that – in the context of enlargements or reductions of plane figures and solids – the “illusion of proportionality” (or linearity) is a widespread and almost irresistible tendency among pupils (see, e.g., De Bock, Verschaffel & Janssens, 1998; De Bock, Verschaffel, Janssens & Claes, 2000). In these studies, large groups of 12–16-year old pupils were
administered (under different experimental conditions) a written test consisting of proportional and non-proportional word problems about lengths, areas and/or volumes of different types of regular and irregular figures. The majority of the pupils in these studies failed on the non-proportional problems because of their alarmingly strong tendency to apply proportional reasoning "everywhere". Even with considerable support (such as the provision of drawings, of metacognitive stimuli in the form of an introductory item accompanied with both a correct and an incorrect solution, or embedding the problems in an authentic problem context), only very few pupils appeared to make the shift to the correct non-proportional reasoning.

Despite our rather extensive knowledge about the phenomenon of the "illusion of linearity" in this domain, the research method used so far, namely administering a collective test of large groups of pupils under different experimental conditions, did not yield adequate information on the problem-solving processes underlying improper proportional responses. This is one of the main reasons that the data could not provide a satisfying answer to the question why and how so many pupils fell into the "proportionality trap". Therefore, we made a shift in our methodology by having exploratory in-depth interviews with individual pupils who fall into the "proportionality trap".

2. Method

To obtain in-depth information about pupils' problem-solving processes, semi-standardized individual interviews were performed with eighteen 12–13-year olds and twenty-three 15–16-year olds. During Phase 1 of the interview, each pupil had to solve one non-proportional word problem from a set of problems involving irregular plane figures or solids. Previous research had shown that the vast majority of pupils from these age groups solves these problems in a proportional way. Below, we give two examples of such problems.

<table>
<thead>
<tr>
<th>Problem with irregular plane figure</th>
<th>Problem with irregular solid</th>
</tr>
</thead>
<tbody>
<tr>
<td>A publicity painter needs 5 ml paint to make a drawing of a 40 cm high Santa Claus on a store window. How much paint does he need to make a drawing of a Santa Claus with the same shape, but a height of 120 cm?</td>
<td>In a perfume store, bottles of “Eau Fraîche” are sold. The bottles have a height of 8 cm and contain 10 cl perfume. In the store window, a publicity bottle is shown with the same shape, but enlarged, and also filled with “Eau Fraîche”. This bottle has a height of 24 cm. How much perfume will this large bottle contain?</td>
</tr>
</tbody>
</table>

By asking each pupil to “think aloud” (Ginsburg, Kossan, Schwartz & Swanson, 1982) while solving the problem, we could retrieve (parts of) the solution process. The interviewer also asked well-specified questions to make (parts of) the reasoning process more transparent. The pupil was asked how (s)he exactly
calculated the answer, why (s)he thought his or her answer was correct, and how sure (s)he was about the correctness (using a five-point scale from “certainly wrong” to “certainly correct”).

In Phase 2, we tried to raise a first, weak form of cognitive conflict by confronting the proportional reasoning pupils with a fictitious frequency table of the answers given by a group of peers. There were two major answer categories in this fictitious frequency table: 41% of the peers gave an incorrect, linear answer (i.e., respectively 15 ml and 30 cl in the examples given above), but another 41% gave the correct, non-linear answer (i.e., respectively, 45 ml and 270 cl). Then, the pupil was asked to re-evaluate his or her own initial answer.

If the pupil did not change his or her answer, a stronger conflict was elicited in Phase 3 by giving the argumentation of a fictitious peer from the 41% who answered the problem correctly (e.g. in the first example: “one pupil told me that if the Santa Claus becomes three times as high but keeps the same shape, not only his height is multiplied by 3, also the width has to be multiplied by 3, so that you have to multiply by 9”). Again, the pupil was asked to re-evaluate his or her own answer. Pupils who had exchanged their original linear answer for the correct non-linear one in Phase 2 or 3, were interrogated at the end of the interview about the origin of their initial wrong answer.

3. Results

The table below presents the (cumulative) number of pupils who chose the correct answer in each phase. The tendency to give a linear answer was strongly present in both age groups. All pupils spontaneously gave the wrong linear answer. Even in Phase 2, only one pupil realised that his original answer was wrong. In Phase 3, finally, only another nine pupils changed their answer to the correct one, so that in sum only ten pupils (24%) accepted the non-linear answer as the correct one. Most of these pupils belonged to the older age group. We now will look at each phase in more detail.

Phase 1: Solving the word problem

The mean response time after the first confrontation with the word problem was one minute. During this minute, none of the pupils made a drawing or any other kind of external representation involving more than the three given numbers. They mainly read and re-read the problem, wrote down the numerical data, and performed calculations on these numbers to obtain the answer. Hereby, thirty-seven pupils calculated the ratio of the given lengths of the two figures, and thought that the ratios of the areas or the volumes (or their indirect parameters: paint or content) should be the same. Four pupils applied formally the so-called “rule of three”: first calculating “the amount of paint (or the content of the
bottle) needed for 1 cm", and then multiplying the result with the height of the large figure. The use of one of these strategies led all pupils to an improper linear answer, as expected on the basis of earlier studies by De Bock et al. (1998, 2000).

Most pupils had great difficulties explaining why their method was the correct one. After insisting, most pupils (a) referred to the fact that their solution is the most logical one, (b) explained that they solved the problem as they had learned to do at school or (c) simply repeated how they carried out their computations. These superficial answers seem to indicate that pupils do not spontaneously check whether a model is applicable in a given situation or not. Pupils do not seem to have clear arguments justifying its use, or do not realise there are other possible models too. It seems that the linear model is used in an implicit, routine and mindless way.

Despite this difficulty in justifying the correctness of their answers, most pupils were very or quite sure they were correct. Twenty-one pupils said their answer was “certainly correct”, fifteen said it was “probably correct” and only five “had no idea”. The alternatives “probably wrong” and “certainly wrong” were never chosen. If pupils had reasons to doubt about their solutions, these reasons were mainly superficial and general (e.g., “word problems are difficult”, “I am not good in math”, “I might have made a calculation mistake”). None of the argumentations expressed any doubt about the correctness of the applied model.

**Phase 2: Reactions to a weak form of cognitive conflict**

For the majority of the pupils, the confrontation with the frequency table really induced a cognitive conflict: they started wondering where the alternative frequently-chosen answer could come from. However, the search for its origin was done – again – in a very superficial way. The single pupil who made a drawing of the small and large figure in this phase, chose the correct answer, but all other pupils limited themselves to “randomly” trying out several combinations with the basic arithmetical operations (+, −, ×, ÷) and the given numbers to obtain the other answer, regardless of their contextual meaning (e.g., some pupils added 40 cm and 5 cl to obtain the alternative answer 45). Only in very rare cases, we observed pupils re-evaluating their own strategy, searching for the meaning of the alternative answer or representing the problem. The superficial strategies used by most pupils were not very helpful. All pupils (except for one of the oldest group) persisted in their original linear solution.

A further deduction from the fact that the pupils did not immediately change their incorrect answer is that the mistake was not simply caused by an underestimation of the difficulty level of the word problem. In the latter case, the correct solution (strategy) would have been a sufficient scaffold to choose the correct answer.
Phase 3: Reactions to a strong form of cognitive conflict

In the third phase, another nine pupils (three of the youngest and six of the oldest age group) changed their incorrect answer into the correct one. Apparently, the given argumentation provided them the insight that, to maintain the same shape a figure has to be enlarged in all dimensions. The nine pupils who changed their answer were asked to explain why they originally gave the wrong linear solution. Their explanations referred to the fact that (1) they did not solve the problem in a reflective manner but immediately (a pupil called it “instinctively”) started calculating or (2) they had made no real mental representation of the problem, but just were fixating on the formulation of the word problem (which only referred to the height).

The thirty-one pupils who still chose to withhold their original answer after the argumentation of the fictitious peer, made serious efforts to justify their choice. Their reactions were diverse, but can be grouped into three different categories (each covering about one third of the reactions).

A first group of pupils justified their answer by referring to the implicit rules for solving school mathematics word problems. Often a simplistic view was shown, assuming that all word problems can be solved using simple mathematical calculations, and that real-world knowledge should not be involved in the solution process. Some examples are: “I think you don’t have to use such a complex solution to solve a word problem”, “you have to calculate only with the data that are given”, “if they wanted you to calculate the width too, they should have explicated that in the problem statement”.

A second group of pupils violated the mathematical principles relevant to this problem. The first principle that is ignored or not understood is that if a figure is enlarged (or reduced) but maintains its shape, all dimensions (height, width and depth) are enlarged (or reduced) by the same factor. Some pupils reacted that “if you only know the height, you can’t know the width”, “height and with are not that much related to each other”, or “the width and depth will change too, but you cannot know how much”, and used these arguments to simply ignore that the width (and depth) also change and determine the solution. The second principle pupils seemed to struggle with is that if the linear measurements of a figure are enlarged (or reduced) by a factor k, its area is enlarged (or reduced) by \(k^2\) (and its volume by \(k^3\)). Typical examples are: “the width is already incorporated in the small one, so it isn’t necessary to calculate it in for the big one again”, “the Santa Claus is not a spatial object where you have to calculate the volume, it is flat; consequently, only the height plays a role”, “I think 270 cl actually is quite a lot”.

After being confronted with the argumentation for the correct solution, a third group of pupils tried to give an alternative interpretation to the word problem. As already said earlier, most pupils did not construct any mental representation about the problem before the third stage of the interview. Once they were confronted with an argumentation rejecting their answer, many pupils looked for
an alternative interpretation in which their incorrect solution still would make
sense: "the figure is stretched, only the height changes and the rest remains the
same", "if you make it higher, that doesn't mean it becomes wider", "it says
with the same shape, so it only is a higher one, not wider or deeper". We cannot
absolutely exclude that some pupils may have held this alternative interpretation
of the problem situation already earlier during the interview, but our data
indicate that they form only a small minority. Moreover, when the interviewer
confronted pupils with the concrete consequences of their alternative
interpretation (by means of a drawing or a description) most pupils admitted the
strangeness of it (e.g. a very high but narrow Santa Claus, a copy of a perfume
bottle that isn't really a copy with the same design). Analogous defensive
reactions of students, who try to withhold an original erroneous answer, even if
they realise this answer is untenable, have also been observed in other studies.
E.g. Verschaffel, De Corte and Vierstraete report that pupils "tirelessly came up
with contextual considerations in which their unrealistic response would still
hold. (...) These far-fetched context-based considerations were (...) only made
during the whole class discussions by pupils who became aware their group had
answered the problem in an uncritical, stereotyped manner" (Verschaffel, De

4. Conclusions and discussion

The interviews provided a lot of information about the actual process of
problem-solving from pupils falling into the "proportionality trap" and the
mechanisms behind it.

First of all, several possible causes were rejected by the research data. From the
collective tests (De Bock et al., 1998, 2000), it was impossible to find out (1)
whether pupils gave the wrong linear answer reluctantly by lack of a better
alternative or (2) whether pupils gave the wrong linear answer because of the
expectation that the test would contain routine tasks only. We think both
possible explanations can be refuted, the first one because most pupils declared
to be sure about their initial incorrect answer, the second one since the
confrontation with the correct solution (even with an accompanying
explanation) was not sufficient to make them change their answer.

Second, there is a parallel between the problem-solving processes observed in
the first phase of the interview and the "intuitive rules" theory developed by
Tirosh and Stavy (1999). These authors claim that there are some common,
intuitive rules that come in action when students solve problems in mathematics
and sciences. These rules appear to be self-evident (i.e. true without a need for
further justification), receive great confidence, and are persistent despite formal
learning. All these characteristics seem to apply to the incorrect reasonings of
the interviewed pupils too. More specifically, Tirosh and Stavy have
distinguished two schemes that (whether correct or not) frequently come in
action in an intuitive way: "Same A – same B" (while in fact $A_1 = A_2$, but
sometimes $B_1 \neq B_2$) and “More $A$ – more $B$” (while in fact $A_1 < A_2$, but sometimes $B_1 \geq B_2$). In our case, pupils seem to apply first the “More $A$ – more $B$” rule (which is correct for this problem: the more height, the more area/volume). The mistake happens, however, during the intuitive quantification when applying the “Same $A$ – same $B$” rule: pupils reason that the figures share the same shape, so all measures (length, area and/or volume) enlarge by the same factor. This is illustrated in the following quotations: “I knew it was enlarged, but not how much, so I calculated $180 : 60$ and then I knew the multiplier”, “because the picture becomes larger, you need more paint, so you have to multiply by $3$”, “it has the same shape, but is enlarged, so you have to multiply the content by the same number”. The specific connection between the “illusion of linearity” and the “intuitive rules” theory certainly needs further investigation.

Third, we found that many pupils (as well the younger as the older ones) struggled with the principles behind the enlargement of figures/objects and the relationship between length and area/volume. They had already learned these principles in school, but nevertheless they seemed to have a bad or weak understanding of them, or at least they were not able to apply them correctly. Further research should determine whether the struggling really is a cause of the mistakes or rather that pupils post hoc violate the principles in a self-defensive attempt to save their original answer. The same goes for the alternative interpretations some pupils gave to the word problem after they heard the interpretation for the correct answer. Some pupils may have had it in advance, but most of them had made no real representation of the problem until the third phase.

We want to argue that the described findings are also related to the fact (supported by a vast amount of research, see, e.g., Verschaffel, Greer & De Corte, 2000; Wyndhamn & Säljö, 1997) that many pupils have inadaptive beliefs and attitudes towards mathematical problem-solving, and have a poor use of heuristics and metacognitive strategies. The intuitive reasoning in the first phase and the small impact of the conflict in the second and third phase only could occur because the pupils approached the word problem in a superficial way, only looking at the numbers without making a clear and realistic problem representation, assuming that all application problems can be solved with some simple mathematical operations on the given numbers, and without any control of the correctness of their answer afterwards. Further research will have to evidence if stimulating realistic modelling in pupils has a beneficial impact on overcoming the “illusion of linearity”.

---

1 We found some evidence for this supposition since we asked several pupils – after the interviews were finished – to make a drawing for the word problem. At that moment, nearly all of them then really “discovered” that a figure with the same shape must enlarge in all dimensions, so that the area/volume enlarge by a larger factor.
A final remark concerns the educational value of the cognitive conflict to enhance pupils’ metacognitive awareness or to provoke cognitive change (see, e.g., Forman & Cazden, 1985). Our experiences show that it is very difficult to induce an effective cognitive conflict in pupils if they have no minimum metacognitive awareness about their problem solving process.

DO INTUITIVE RULES HAVE PREDICTIVE POWER?
A REPLICATION AND ELABORATION STUDY ON THE IMPACT OF 'MORE A–MORE B' AND 'SAME A–SAME B'

Dirk De Bock, Lieven Verschaffel and Dave Weyers
University of Leuven and EHSAL, Brussels; Belgium

Abstract. In recent years, the intuitive rules theory has received growing attention in the mathematics and science education research community because of its capacity to explain and predict various kinds of responses of students to a wide variety of tasks from scientifically different content domains. Two major intuitive rules show up in comparison tasks: 'More A–more B' and 'Same A–same B'. Although these two rules have been extensively studied by Israeli researchers, the relation between these rules and their gradual impact on students from countries with different traditions in mathematics and science education require further research. In this paper, we describe two consecutive studies aimed at re-examining the predictive power of 'More A–more B' and 'Same A–same B' in situations wherein both rules lead to different erroneous judgements.

Theoretical and empirical background
Building on the pioneering work of Fischbein (1987) about the role of intuitive thinking in mathematics and science, Israeli researchers recently established the intuitive rules theory (Stavy & Tirosh, 2000; Tirosh & Stavy, 1999a; 1999b). According to this theory, students’ responses to various conceptually unrelated tasks in mathematics and science can be explained and predicted by several common, intuitive rules that are activated by some salient, external features of a task. Two such rules show up in comparison tasks. The first is called 'More A–more B': students comparing two objects differing with respect to a certain salient quantity A ($A_1 > A_2$), intuitively argue with respect to another quantity B that $B_1 > B_2$. In many everyday life and scientific situations, such an intuitive reaction leads to conclusions that are accurate (e.g. squares with a larger perimeter have a larger area), but students of different ages strongly tend to use this rule also beyond its range of applicability (e.g. plane figures with a larger perimeter always have a larger area). The second rule is called 'Same A–same B': students comparing two objects being equal with respect to a certain salient quantity A ($A_1 = A_2$), intuitively argue with respect to another quantity B that $B_1 = B_2$. Clearly, this intuitive rule can also lead to both correct (e.g. squares with the same perimeter have the same area) and incorrect responses (e.g. plane figures with the same perimeter always have the same area). Stavy and Tirosh
provided a variety of examples of students' erroneous and correct responses that are in line with these intuitive rules. Furthermore, they collected an impressive amount of research data demonstrating how strongly students of different age groups and study streams are influenced by these basic rules.

Although the intuitive rules theory is widely known in the international mathematics education community nowadays, replications of the results obtained by Stavy and Tirosh in other countries with different cultural and educational traditions, are quite rare. Furthermore, we need more convincing evidence that the reasoning process of students who respond 'in line with' a given intuitive rule, is actually affected by that rule. Especially for older students, who can generate a particular answer by simply applying an intuitive rule, but also by relying on a more advanced mathematical notion or strategy learned at school, this point needs to be clarified. Finally, connections between these intuitive rules and other misconceptions and systematic errors known from the mathematics education research literature (see, e.g., Davis, 1989; De Bock, Verschaffel & Janssens, 1998), has to be examined more thoroughly.

**Study 1**

We set up a first study to arrive at a better understanding of the nature and predictive power of the intuitive rules 'More $A$–more $B$' and 'Same $A$–same $B$'. More specifically, we aimed at providing answers to the following research questions: (1) do Flemish students react in a similar way as Israeli students to comparison tasks eliciting the intuitive rules, (2) do students' explanations contain explicit references to 'More $A$–more $B$' or 'Same $A$–same $B$', and (3) do their answers and/or explanations yield evidence for other erroneous strategies or misconceptions known form the literature. Because both 'More $A$–more $B$' and 'Same $A$–same $B$' were targeted, we looked for tasks wherein both rules lead to a different but inaccurate answer.

Seventy students of grade 10 (15–16-year olds) of a Flemish secondary school participated in Study 1. All participants were divided in three equivalent subgroups and each subgroup was confronted with two problems. All problems were variants of a geometrical problem about the ratio between the surface area and volume of differently-sized cubes, – a task introduced by Livne (1996), and mentioned in several publications of Tirsoh and Stavy (see, e.g., Stavy & Tirosh, 2000; Tirosh & Stavy, 1999a) (see Figure 1). The first group (Group I) received Livne's original problem about cubes and its two-dimensional variant about the ratio perimeter/area of differently-sized squares. The second group (Group II) was confronted with conceptually the same two problems, but formulated with spheres and circles. Also in the third group (Group III), students received two mathematically equivalent problems, but formulated with irregular two- and three-dimensional figures (maps and bottles, respectively). The problems were
formulated in a multiple-choice format with three alternatives. One alternative proposed an incorrect answer in line with the rule ‘More A—more B’ (the larger figure has the larger ratio). A second (also incorrect) alternative was in line with ‘Same A—same B’ (‘same shape, same ratio’). The third alternative, which did not involve one of these two intuitive rules, was the correct one. Students were not only instructed to select one of the three alternatives (larger than, equal to, or smaller than), but also to explain their choice. As in Livne’s study, drawings of the geometrical figures were given.

Cube problem. Consider two differently-sized cubes. Is the ratio between the surface area and volume of Cube 1 smaller than/equal to/or larger than/the ratio between the surface area and volume of Cube 2? Explain your answer.

Livne (1996), who confronted biology majors in grade 10, 11, and 12 (15–18-year old students) with this problem, reported the following results: (1) Substantial percentages of students in grades 10, 11, and 12 (41%, 45%, and 55% respectively) incorrectly argued that the ratio surface area/volume is the same in both cubes. Typical explanations were: ‘Cube 1 and Cube 2 have the same geometrical shape, hence the ratio surface area to volume is the same regardless of their size’; ‘The surface area and the volume in Cube 1 are proportionally smaller than in Cube 2 and therefore the ratio is constant’. (2) Only 24%, 19%, and 24% of the students in grades 10, 11, and 12 respectively claimed that the ratio surface area/volume is larger in Cube 2 than in Cube 1.

Table I gives an overview of the results of our study.
These quantitative data do not reveal a clear trend: the student answers seem to be more or less uniformly distributed. For plane figures, most students tended to select the alternative in line with ‘Same A–same B’, but this tendency was not confirmed for the solids. With respect to the geometrical figure involved, most correct answers were given for the items about squares and cubes (Groups I) and for the items about irregular figures (Group III) (39% and 49%, respectively); least correct answers were given for the items about circles and spheres (Group II) (17%). Remarkably, 43% of the students selected a different answer for task 1 than for task 2. Probably, as a result of the ‘experimental contract’ (Greer, 1997), many students expected different answers for two tasks given in the same test.

A qualitative analysis revealed that 24% of the explanations contained an explicit reference to proportional reasoning. Although ‘k times A, k times B’ (with k > 1) can be seen as a straightforward quantification of ‘More A–more B’, students’ response sheets contained no empirical evidence that students’ misuse of proportionality was the direct result of a prior ‘More A–more B’ judgement. Above all, this finding confirms students’ tendency to apply proportional reasoning ‘everywhere’ (see, e.g., De Bock, Verschaffel & Janssens, 1998), – a misconception that seems to be affected by students’ instructional histories rather than by their general intuitions. Only 3% of the students referred explicitly to shape or shape similarity and not a single student reportedly reasoned that ‘the larger figure must have the larger surface/volume ratio’. Apparently, Flemish students do not readily verbalise the ‘Same A–same B’ or ‘More A–more B’ rule. If these rules affected students’ reasoning, it seems they were not aware of it.

In conclusion, the strong ‘Same A–same B’-tendency reported by Livne (1996), was not confirmed for the different geometrical shapes included in our study. With respect to the tasks involving solids, the global percentage of responses in line with ‘Same A–same B’ was even below chance level! This finding seems to question the predictive power of ‘Same A–same B’ for that kind of geometrical problems. But also students’ explanations, especially those explicitly referring to shape or to shape-similarity, qualified as being ‘typical’ in the Livne-study, proved to be quite rare in our first study.
Study 2

Because (1) the quantitative data of Study 1, especially the ‘total scores’ did not show a convincing trend and (2) very few of students’ explanations explicitly referred to the intuitive rules that, according to the theory of Stavy and Tirosh, would have affected their (erroneous) answers, we decided to set up a follow-up study on a larger scale.

In this study, fifty-eight, fifty-eight and fifty-six students of, respectively, grades 10, 11, and 12 were confronted with a written multiple-choice test consisting of five problems from different mathematical subdomains. As in Study 1, each problem was accompanied by three alternative responses. One alternative proposed an incorrect answer in line with the rule ‘Same A–same B’. A second alternative (not necessarily in this order) was also incorrect, but was in line with ‘More A–more B’. The third alternative, which did not involve one of these two intuitive rules, was the correct one. Students were instructed to explain their choice on their answer sheet. They were given 50 minutes to complete the test and were not allowed to use calculators.

Two of the five test items functioned as ‘anchor items’, allowing a straightforward comparison of our results with those obtained in Israel: the Cube problem that was already used in Study 1 (cf. Figure 1) and the ‘Carmel problem’ (see, e.g., Tirosh & Stavy, 1999b; Stavy & Tirosh, 2000) given in Figure 2. We completed these two items with three self-made tasks, which are also listed in Figure 2, together with an indication how the distinct alternatives are linked to the intuitive rules.

**Carmel problem.** The Carmel family has two children, and the Levin family has four children. Is the probability that the Carmels have one son and one daughter larger than/equal to/smaller than/ the probability that the Levins have two sons and two daughters?

- ‘Equal to’ is in line with the rule ‘Same A–same B’ (‘same ratios \( \frac{2}{4} = \frac{1}{2} = \frac{1}{2} \), same probability’).
- ‘Smaller than’ is in line with ‘More A–more B’: the larger family has a larger probability.

**Cake problem** (inspired by Lin, 1991). On Wednesday afternoon, Els and her father are baking together a cake. Both cakes have the same height. The diameter of Els’ cake is 15 cm, the diameter of the cake of her father is 30 cm. Els adds 150 gram sugar to her batter, her father adds 300 gram sugar to his batter. Is the cake of her father less sweet than/as sweet as/or sweeter than/ the cake of Els?

(This problem was accompanied by drawings of the two cakes, having a cylinder form.)

- ‘As sweet as’ is in line with the rule ‘Same A–same B’ (‘same ratio \( \frac{15}{150} = \frac{30}{300} \), same sweetness’).
- ‘Sweeter than’ is in line with ‘More A–more B’: the cake with more sugar is sweeter.
**Root problem.** Is $\sqrt{10}$ larger than/equal to/or smaller than $\sqrt{15}$?

'Equal to' is in line with 'Same A–same B' ("same ratio $\frac{2}{10} = \frac{3}{15}$, same expression').

'Smaller than' is in line with 'More A–more B': $15 > 10$ and/or $3 > 2$.

**Physics problem.** The gravitational pull on a mass $m$ at a distance $s$ metres from the centre of the earth is given by a formula of the form: $F = c \frac{m}{s^2}$ (in which $c$ is a constant).

Suppose a mass $A$ is twice as heavy as a mass $B$ and the distance of $A$ to the centre of the earth is twice the distance of $B$ to the centre of the earth. Is the gravitational pull on mass $B$ smaller than/larger than/or equal to the gravitational pull on mass $A$?

'Equal to' is in line with 'Same A–same B' ('same ratio $\frac{m_A}{s_A} = \frac{m_B}{s_B}$, same gravitational pull').

'Smaller than' is in line with 'More A–more B': $m_A > m_B$ and/or $s_A > s_B$.

**Table II.** Distribution (in %) of the answers by grade and by problem in Study 2

For five problems and the three grades together, 55% of the students selected the correct alternative. Responses in line with 'Same A–same B' and 'More A–more B' were below chance level (31% and 13%, respectively). For the five tasks together, the percentages of correct responses slightly increased with age: 52%, 55%, and 59% correct responses in grades 10, 11, and 12). The Root, the Carmel, and the Physics problem proved to be the easiest tasks (for the three grades together, respectively, 74%, 63%, and 54% correct responses). For these problems, the percentages of responses in line with each of the intuitive rules were not above chance level for all three grades. For the Cake and the Cube problem, the percentages of correct responses and those in line with 'Same A–
same $B'$ were more or less the same (between 41% and 44%), whereas the number of responses in line with ‘More $A$–more $B'$ were far below chance level.

Although it is problematic to compare test results form different countries on the basis of a rather small and not carefully matched sample of students, it seems that students in Flanders are less affected by the ‘Same $A$–same $B'$ intuitive rule than their Israeli peers. For the Cube problem, 41%, 45%, and 55% of Israeli students in, respectively, grade 10, 11, and 12 responded in line with this rule; in Flanders we found (slightly) lower percentages in all grades, respectively, 40%, 43%, and 39%. For the Carmel problem, the results in both countries diverge completely. In Israel, where about forty students in each grade were confronted with this task, an increasing percentage of students (57%, 50%, and 62% in grade 10, 11, and 12, respectively) responded in line with ‘Same $A$–same $B'$, incorrectly arguing ‘the ratio is the same, therefore the probability is the same’ (see, e.g., Tirosh & Stavy, 1999b); in Flanders, such an increasing trend could not be established and the corresponding percentages were much lower, respectively, 33%, 24%, and 36%. Correspondingly, the percentages of correct responses in Flanders (64%, 67%, and 59% for grades 10, 11, and 12) were significantly higher than in Israel (24%, 42%, and 30%). This last finding does, however, not necessarily mean that the Flemish students displayed a higher quality of probabilistic reasoning. A closer look at the response sheets of the Flemish students revealed that the majority selected the correct answer on the basis of another erroneous reasoning process! Some students misinterpreted the statements ‘one son, one daughter’ and ‘two sons, two daughters’ as, respectively, ‘first a son, then a daughter’ and ‘first two sons, then two daughters’, which leads to, respectively, the probabilities of 1/4 and 1/16. However, the majority of the participants that selected the correct response proved to suffer highly from the so-called equiprobability bias (see, e.g., Lecoutre, 1992), according to which all events were thought as equally likely. So, in the Carmel family, there are three possible events (‘two sons’, ‘one son, one daughter’, and ‘two daughters’), each having a probability of 1/3; in the Levin family, there are five possibilities (‘four sons’, ‘three sons, one daughter’, ‘two sons, two daughters’, ‘one son, three daughters’, and ‘four daughters’), each having a probability of 1/5.

Discussion

The results of two Flemish studies on the intuitive rules ‘Same $A$–same $B'$ and ‘More $A$–more $B'$ did not provide a strong confirmation of the predictive power of these intuitive rules. In both studies, percentages of responses in line with these rules never exceeded 50% and were mostly below chance level. In the explanations accompanying their answers, students seldom referred explicitly to these rules.
In our view, two points need further investigation. First, a more detailed and systematic picture of problem types and characteristics that elicit the intuitive rules is required. In this picture, there should be room for intercultural differences. Indeed, it seems that the intuitive rules and how they affect students' mathematical problem solving compete with alternative conceptions and strategies – both correct and incorrect ones – that are shaped by culturally bound instructional traditions. Second, there is a need of more fine-grained, process-oriented research that tries to unravel in which stage of the problem-solving process intuitive rules show up, and to detect under what internal and external conditions this intuitive thinking is replaced by more advanced mathematical reasoning. A possible research approach could be to administer individual interviews in which a student has to respond instantly to a comparison situation, and is then encouraged to reconsider his initial judgement.

Abstract

From different perspectives we have analysed an episode of two children working together on a mathematical task. Integration of our analyses brings to the fore authentic dilemmas and paradoxes, which are also experienced by students and teachers during collaborative work. We will present some examples.

Introduction

In the past, analyses of student learning have considered learning from cognitive, social or motivational aspects in isolation. Now in contrast to this earlier view, an interest exists in developing a "multidimensional framework for understanding mathematical learning" (Pintrich, 2000, p. 221). This is an approach that we have taken in collaborating in analyses of an episode of two children working together on a mathematical task. We will first describe the different perspectives we use in research and then explain our recent work--a multiple analysis of learning events (Dekker, Elshout-Mohr, & Wood, in press). Although we differ in our perspectives, a common goal for research is to develop ways to describe events in students learning as they are occurring in classroom situations. In this case learning is defined as conceptual understanding and mathematical level raising.

THEORETICAL ORIENTATIONS

A Process Model for Mathematical Level Raising

Dekker and Elshout-Mohr (1996, 1998) developed a process model for interaction and mathematical level raising based on empirical analysis of students learning working in small groups while solving mathematical problems (Dekker, 1991). The problems are specifically developed to stimulate mathematical level raising among students (cf., Dekker & Elshout-Mohr, 1999). In the process model three types of activities are incorporated; they are key activities in the learning process; regulating activities; and mental activities. Each of these is further discussed below.
Key Activities

Dekker and Elshout-Mohr (1996, 1998) deem four key activities are primary conceptual level raising. Whenever these key activities occur, we speak of learning events. The key activities are:

- to show one's work
- to explain one's work
- to justify one's work
- to reconstruct one's work

The process model is presented in Table 1 with the key activities indicated in bold print. Dekker and Elshout-Mohr (1996, 1998) assume that the conjunction of these activities leads to the desired type of learning (i.e. conceptual level raising). The four key activities have the following characteristics:

a) They can be demonstrated by students who work individually, but more so by students who communicate with each other during their work;

b) They are easily observed;

c) They have a function in the learning process and contribute to mathematical understanding;

d) They can be influenced by didactic factors, such as the nature of problems and by teaching actions.

Regulating Activities

The process model further captures regulating activities, which elicit key activities, and mental activities, which concur with key activities. Table 1 shows the regulating activities identified in italics. Students asking for explanations, justifications, or transformations are described as regulating activities. For instance, when students are working together and show each other what they are doing and thinking, they may become aware that different participants have different knowledge about a central concept, and they may start thinking about these differences. They may also ask each other to show and explain their work, or to justify or transform it. In principle, a student who works alone can perform all the key activities, but it takes a great deal of self-regulation. However, by communicating with other students, the key activities will take place in a more natural way. Therefore, the process model also contains interactive and communicative activities that we call regulating activities.
Mental Activities

While key activities and regulating activities can be observed externally, mental activities occur which are not observable. Mental activities involve those activities which ‘go along’ with key activities. For instance, to show one’s work includes the mental activity of becoming aware of one’s own work. It has the effect that a focus on task-progress is temporarily replaced by taking a look at the work from the outside. To explain one’s work means that one has to think about one’s own work. It leads to elaboration of one’s task-related conceptual knowledge. Attempts to justify one’s work may include reinforcing prior knowledge or questioning it, and a prerequisite to reconstruct one’s work is to criticise one’s own work. Table 1 shows the process model of these mental activities in standard print.

Social Interaction and Learning Mathematics

The theoretical perspective taken by Wood (1996, 1999) in analysis of student learning is to consider the very social nature of children’s learning and the fact that rich social interactions with others substantially contribute to children’s opportunities for learning. Therefore, Wood claims that there is a need to consider an analysis of educational settings that attends to the social cognitive processes involved in learning as well as the cognitive processes (Wood & Turner-Vorbeck, in press).

This perspective is influenced by the view of Bruner (1990) and others that children need to adapt to a social existence and to develop a system of shared meanings in order to participate as members of their culture. Sociologists interested in the human need to adapt to social existence and develop a system of shared meanings provide insights into the importance of social structure in the lives of humans. Both Garfinkel (1967) and Goffman (1959) contend that the social structures in everyday life consist of normative patterns of interaction and discourse. Once established, these patterns become the reliable routines found in interactive situations. Individuals, when they participate, come to anticipate certain behaviours for themselves and for others so that much of what happens "goes without saying" (Garfinkel, 1967).

Several researchers argue that the social structures that are created in the classroom influence the ‘mathematics’ a child learns. They claim that the everyday patterns of interaction and the norms that are constituted contribute to children’s beliefs about the nature of mathematical knowledge and the ways in which one learns and uses mathematics in everyday life (e.g., Carraher, Carraher, & Schliemann, 1985; Cobb, Wood, Yackel, and McNeal, 1992). In order to understand the children’s mathematical learning we need to examine the social situations that teachers establish with their students. The norms (expectations for self and others behaviour) underlie the social interaction that reveals the ‘practice’ of mathematics in the classroom.

Moreover, it is thought that learning that is conceptual can benefit considerably from dialogue and collaboration with others (Yackel, Cobb, & Wood, 1991). Although social norms are initiated and established by the classroom teacher, the children’s ability and commitment to adhere to the shared expectations is equally important. Kieran and Dreyfus (1998) provide evidence that the social cognitive facility of negotiation of meaning influences individual learning.

Using a qualitative research paradigm, drawing on microethnographic procedures developed by Voigt (1990), analysis of learning situations is conducted using a line-by-line examination of the dialogue and interaction. This provides detailed description of the events that occur. Through this process interpretation can be made of the meanings held by students during collaborative problem solving classroom situations.
DATA SOURCE AND ANALYSIS

The multiple analysis is best explained in contrast to the approach that we followed to construct the above-mentioned process model. In the process model, we incorporate three types of activities: key activities in the learning process, regulating activities, and mental activities. The key activities are given the central place in the process model, whereas other activities are merely presented in so far as they are directly connected to the key activities. Thus, employment of the process model produced a coherent description of learning events in terms of the elements of the process model. In addition, a focus on social interaction provides information on the social conditions for learning including the influence of the teacher. The aim of the analysis is to reveal how the social norms established in the class affect the collaborative work of students and how these expectations actually provide the space for learning.

Towards Multiple Analyses and Integration

In the multiple analysis approach, however, we did not give priority to the elements of the process model or social interaction. Instead, we began by performing three separate analyses on one protocol of a student collaborative session wherein two primary-aged (8 year old) students worked together to solve a mathematical task. The mathematical task was developed to encourage students’ conceptual understanding of multiplication beyond their intuitive notions of multiplication as repeated addition.

The first analysis of the episode was guided by theory about the role of key activities in achieving mathematical level raising. The second was guided by theory about social cognitive processes and the role of social interaction in learning, and the third was guided by theory about the role of time on task in learning outcomes. Once completed, the results of the three analyses were integrated in ways that allowed each perspective to be represented.

In the integrative stage, which we are currently in the process of conducting, preliminary findings reveal the complexity of multiple effects on students' learning activities. For instance, an activity that is evaluated positively from a social perspective on learning mathematics does not necessarily contribute to the occurrence of key activities, nor is it necessarily evaluated positively from a time on task perspective on learning. In the presentation, examples will be given that show how the methodology of multiple analyses brings to the fore authentic dilemmas and paradoxes that are also experienced by students and teachers during collaborative work in classrooms. One example is the fact that the social norm of collaboration leads to a lowering of level of one of the students, which conflicts with the aim of level raising. We will discuss this example in detail.
It was in 1988 at ICME 6 in Budapest where we first met. Dekker (1988) gave a presentation about her classroom observations. Inspired by the ideas of Freudenthal (1978) about learning of mathematics in small heterogeneous groups and the Van Hiele’s (1986) level theory, Dekker showed learning materials specifically developed for mathematical level raising and observations of small groups working with those materials. Wood was in the audience and expressed similar research interests. It was nine years later at the CIEAEM 49 in Setúbal where we met again, both giving plenary lectures on interactions in the mathematics classroom. Wood’s focus was on the role of the teacher and the influence of the social norms on the learning opportunities for students (Wood, 1998). Together with Elshout-Mohr and Pijls, Dekker presented a process model for the analysis of interaction and mathematical level raising (Dekker, Elshout-Mohr, & Pijls, 1998). We again discussed our common interest albeit with different perspectives and decided to conduct a joint analysis of a classroom event.

The episode is from the project, Recreating Teaching Mathematics in the Elementary School, supported by the National Science Foundation under award RED 9254939. All opinions expressed are those of the authors.

PUPIL PARTICIPATION IN 'INTERACTIVE WHOLE CLASS TEACHING'

Hazel Denvir, Mike Askew, Margaret Brown, Valerie Rhodes
King's College, University of London

One particular result of recent policy and practice changes in mathematics teaching in English primary (elementary) schools, is that pupils are increasingly involved in 'interactive whole class teaching'. Longitudinal case study data are informing our examination of the different ways that pupils engage in such sessions and manage their participation. Drawing on observations of three children we develop the argument, that within whole class sessions, pupils are becoming skilled at presenting themselves in ways that enable them to appear to be engaged with the mathematics in the way that the teacher expects them to be, while in actual fact they are engaged in other ways and for reasons other than interest in the mathematics.

INTRODUCTION

The English National Numeracy Strategy (NNS), officially introduced from the September 1999 has begun to affect the teaching of primary mathematics profoundly. It is rare now to find primary mathematics lessons that do not follow the form and content set out in the NNS document 'Framework for Teaching Mathematics'.

A central tenet of the NNS is the need for increased emphasis on 'interactive whole class teaching'. All mathematics lessons are expected to begin with a ten minute 'oral and mental' starter, where the whole class joins in activities that often either require everyone to show answers (through, for example, use of digit cards or individual white boards) or have the expectation that individuals may be called upon to respond to questions posed. The end of each lesson is also expected to have a whole class 'plenary' which may also involve question and answer interactions about the lesson.

Our observation of some 150 lessons over the past year indicate that these interactive whole class sessions have become the norm. Moreover as recommended, the main part of lessons, between 'starter' and 'plenary', also frequently including a substantial element of 'public' answering of questions in order to prepare for a period of group or individual work. Indeed, the use of questioning is promoted as a major teaching tactic with resources, equipment and 'exemplary' videos supplied to school to encourage this.

There is also strong encouragement for lessons to have 'pace' and much of the whole class work that we have observed places emphasis on speed as well as correctness.
Thus a strong 'performative' element, viz. being seen to take part and being able to produce correct answers to closed questions and appropriate answers to questions inviting explanation is entering into English primary mathematics lessons. The strategies that children develop in order to be seen to participate in such sessions are likely to affect learning outcomes and is the focus of this paper.

THEORETICAL BACKGROUND

Our theoretical starting point for examining the sort of learning that might arise through such whole class sessions is analysis of pupils 'participation in sociocultural activities' (Rogoff, 1994). Working together in the whole class 'mental and oral starter' provides a microcosm 'community of practice' (Rogoff, 1994). Similarly, Coffield (1999), discussing post 16 education and arguing for a social theory of learning sees learning as located in social participation and dialogue as well as the heads of individuals; and it shifts the focus from a concentration on individual cognitive processes to the social relationships and arrangements which shape, for instance, positive and negative 'learner identities... (p. 493)

But while all pupils are, in a sense, participating collectively in such sessions, in that the teachers set up activities to involve everyone and monitor participation, the ways in which particular pupils manage their involvement and what motivates them to engage with the activities will vary from individual to individual. A shift in attention away from the individual to the collective might also be accompanied by decreased focus on innate ability. As Claxton (1999) points out, the ability to learn in a flexible way in our current age of uncertainty needs to emphasise the importance of engagement rather than 'ability'. But, as the examples that follow demonstrate, the reasons that children engage with activities may be far removed from enthusiasm to engage with the mathematics.

Rogoff (1994) argues that 'adult run models of instruction' problematise children's conceptual engagement. Pollard and Triggs, et al. (2000) provide an example of this in their case study of four to seven year olds found that:

children had only a vague idea of teachers' instructional objectives. Rather than engaging in some synergetic process between teacher and pupil to extend existing understanding, most children were simply concerned to do what they needed to do to avoid being embarrassed or told off or having to do the work again. We found that children felt pressured by classroom constraints to develop task engagement. (p. 302-303)

Pollard also finds that it is 'necessary to facilitate emotional engagement as well as intellectual challenge' (Pollard with Filer, 1996), an issue explored in detail by Goleman (1996). Part of the emotional engagement will rest upon maintaining a successful 'presentation of self' (Goffman 1959) and may well be a 'necessary precondition of stable engagement with learning’ (Pollard with Filer, ibid. p310.)
**DATASOURCES**

The Leverhulme Numeracy Research Programme (LNRP) is a longitudinal study of the teaching and learning of numeracy investigating factors leading to low attainment in primary (elementary) numeracy in English schools, and testing out ways of raising attainment. Two cohorts of children, one starting in Reception (four and five year-olds) and one in Year 4 (eight and nine year-olds), are being tracked through five years of schooling. Pupil data are being collected at several different levels ranging from large scale, twice yearly, assessments on each of the two cohorts (some 1700 children in each cohort) through to detailed case studies of six children from each cohort in five schools, each of whom are observed for two weeks of mathematics teaching each year of the programme (Brown, Denvir, Rhodes, Askew, Wiliam, & Ranson, 2000). While the large scale assessment data provides insights into pupil progress at a general level, the case study data enables us to gain insights into how individual children respond to specific teaching. To explore more deeply our notions of participation we draw on data for three case study children now aged seven years: George, Meg and Oscar.

Through this case study data we seek to elaborate the notion of participation and, in particular, to ask:

- how do pupils present themselves during whole class sessions?
- what motivates pupils' to take part?
- is it fruitful in terms of mathematical learning?

**MEG**

**Episode 1.**

As part of a whole class session, the teacher is working on halving numbers. Each child has an individual white board and marker pen with which to display answers.

**Teacher:** Half of 36?

Meg starts to lift her board up to show the teacher. She has written '15', but before she shows it she notices that others around her have '18'. She quickly changes it; the teacher does not notice and says, 'Well done, Meg.'

**Teacher:** Half of 72

Meg puts on an act. She takes the top off her pen, pushes it back again and looks puzzled. She appears to be counting - her lips are moving but it is not clear what she is saying. She turns round and sees what George has written then turns back again and wrinkles her face (as if to say, 'I'm concentrating hard'). Then she looks around at several boards and see what answer others have got. Next she closes her eyes and screws up her face. After a time her face lights up as if she's just made a big discovery and she writes down '36'.

PME25 2001
Episode 2.

The teacher is using a counting stick (metre length rod, with ten divisions but no number marked) to count on from zero in 10s, 5s, 2s going up to 100, 50 or 20 respectively. The children each have a number fan to show their answers. From the way that Meg looks at the rod and nods her head, it seems that she relies a lot with the higher multiples on counting from zero (as opposed to, say, knowing that when counting in 5s the other end is 50, so the ninth mark must designate 45). She is often still searching for the two digits on her fan with which to show her answer when the teacher has moved on to the next question.

After two counting on in 10s questions (where Meg was not quick enough to show her answer) the teacher changes to counting in 2s. She points to the 8th division and asks for its value.

Meg, again, repeats her nodding and looking at the divisions from zero, notices that the boy sitting next to her has set his fan to show 16. She stops counting on and puts out 16.

The teacher then points to the 9th division. Meg nodding and counting from zero, puts out 18 on her fan, the teacher asks her how she got the answer.

Meg: You count in ones to nine and then go backwards and then its like double again.

Teacher: Meg is using what we did last week, like doubling and halving.

While it is possible that Meg was multiplying by 2 her actions suggested otherwise. Once she had counted along to the number she went straight to showing it on her fan, that is that she arrived at the answer by counting on in twos. There was little suggestion that she was carrying out any operation on a number such as counting along to nine and doubling it. If she had realised that she could get an answer quicker by doubling it is not clear why she talked about "counting in ones to 9" or "going back".

It seems that Meg is not trying to explain her method but only striving to take part in the ‘game’ of providing an explanation. Time and again, we have observed Meg produce post hoc explanations which do not match what she did but are sometimes not even mathematically correct (add on 9 by adding on 10 and taking off 6). She can do it with great conviction, and even present it in a way that covers up the nonsense.

It is not that she is not capable of invoking a learning orientation. On those occasions where she has been encouraged to slow down and think about the mathematics rather than investing her energy to convince others that she knows it all her delight at succeeding is palpable. She often resists admitting that she might need help on. In another incident when she was attempting to shade one quarter of various rectilinear shapes drawn in her book she protested that questions from the researcher were making her terribly confused, rather than saying that she wasn't sure about the work. But when asked if she would welcome some help she looked both pleased and
interested, listened carefully and seemed to take on board intelligently the suggestions offered.

What motivates Meg when she is relating to the teacher, here and in other examples, is her status. Throughout the four years that we have been observing Meg, her teachers say she is able, hardworking and reliable. Meg strives to continue to appear like this to the teacher. In relation to other children, Meg behaves differently, enjoying having power and some control over them. In one incident, having been entrusted with a set of cards for a fraction game for her group, she insisted they all sit still and quiet while she, playing ‘teacher’, took her time choosing who she would allow to set them out.

GEORGE

Episode 1

*The teacher and the class are playing a game where the teacher has a hidden shape and the children have to ask questions with a yes/no answer to figure out what it is.*

Teacher: It's a shape. You're going to have to guess what shape. It might be a solid 3-d shape or a 2-d shape. Put your hands down (they've already got their hands up, presumably to guess) and I'll tell you some clues first.

Teacher: It's got, 6 faces, all square
George: (immediately, calling out, not loudly but still quite clearly): cube
Teacher: It's got 8 vertices, 12 edges which are all the same length.
George: (Putting hand up this time) Is it a cube?
Teacher repeats all this information. There are now 6 hands up.
Teacher: Lenny?
Lenny: (who is sitting next to George) A cube.
Teacher: See if that is right.
She pulls out the cube from under the puppet's body.
George: You gave too many clues.

Episode 2

*The class are all on the mat, playing the guess the number game: the teacher has a glove puppet that is hiding a numeral and nods yes or no to children's questions.*

George takes a lead role in this. He listens to the other information and uses this to frame his questions. Questions he asks include:

*Is it a three digit number?*
*Is it under 300?*
*Is the second digit number 3?*
Is it 444 (this shortly after someone has asked if all three digits are even (perhaps George is interpreting ‘even’ as all the same?) and knowing that it is between 400 and 450)

Somebody gives the correct answer of 428

George: Someone already said that.

In these examples George is engaged with the mathematics and is seeking to engage with the teacher and the class by using his mathematical insight. His motivation to engage comes from his interest in the mathematics as well as a desire to maintain his position as a clever, articulate boy. He appears to dislike behaving in a way that would make him appear the same as all the other children and frequently stands out by being seen to be doing something different. It is also possible that some of his responses are a challenge to the teacher to keep up with him, or to provoke more serious intellectual challenges being offered to him. Pollard (1996, p. 311) quotes a 1984 study by Doyle and Carter which observed how pupils and teacher collude to reduce the intellectual level of tasks by making them more routine. Perhaps George's habitual behaviour could be a response to his frustration at such routinisation.

OSCAR

Episode 1

The teacher is asking children to double and halve various numbers. Each time they write down their answers on a white board and show it to the teacher.

Oscar gets all of the answers correct. I can’t see how he is doing them, whether he is doing them by himself or copying.

Teacher: Half of 36?

Teacher: Oscar how did you get 18?

Oscar: I don’t know.

The teacher asks someone else.

Later in the same lesson the teacher is using a disk of card folded into four segments to stand for a cake:

Teacher: This one is cut into 4, into quarters. X comes along and eats a quarter. How much is left? Write it down on your boards.

Oscar writes 1/3

Teacher sees the researcher looking and looks herself.

She says, 'Oscar, How many is it cut into?'

Oscar: 'Umm, three, .., no four.'

Teacher: 4. So that's the number at the bottom. The other number goes at the top.
Oscar changes his $1/3$ to $3/4$.

**Episode 2**

**Oscar's contributions to the whole class guess the number game.**

Oscar: Is it lower than 100?

George: Is it a three digit number?

Yes

Teacher to Oscar: So is it lower than a hundred?

Oscar: Is it above 400?

Oscar: Is it below 450?

The teacher, after the number has been found, picks up on this and says that the questions were good until they knew that the number was between 400 and 450, and asks what might have further asked.

Oscar: Is it above 410?

Teacher: Or is it between 410 and 430?

As children leave the carpeted area to go to text book tasks, Oscar tell me he is in blue group and that he and George are best at maths in that group and ahead even of Harry.

Unlike George, Oscar seems to like being fairly unobtrusive in the classroom and keeps a low profile, offering 'safe' answers and, unlike Meg, sticking with 'Don't know' rather than risking an incorrect response when asked to describe his strategy. Initially he was identified by his teacher as 'average' in mathematical attainment. He used to work quite slowly, taking his time, capable and proficient. Now he works in the same group as George, identified as higher attaining throughout. George and Oscar now spend time together as a pair both inside and outside the classroom. The friendship with George is very important to Oscar and this maybe the reason for the culture of speed and competitiveness which is creeping into his work and which prompts him to fall back on getting the answers from George. His desire to maintain his position in the class as George's friend seems to compete with his inclinations to work slowly and steadily.

**DISCUSSION**

As Pollard (1996) notes, children who are ‘the most ‘effective learners’ are likely to be those children who can manage their classroom identities so that they derive support from both their teacher and other pupils’ (p. 310). The examples presented here show how children are in different ways simultaneously both learning and establishing or protecting their identities in the public forum of class ‘question and answer’ activity.
These examples support the idea that when children participate in whole class interactive teaching in mathematics they may not be participating in the mathematical thinking which is intended. This arises from other motivations than the desire to learn.

The emphasis on whole class interactive teaching does seem to be connected with the notion that all children should participate in shared discussions of mathematical ideas. A major concern is that the strong "performative" element referred to above prompts children to adopt classroom behaviours which mitigate against them developing good habits as learners. Pollard (2000 p.293) in discussing how children develop a "learning disposition" quotes the New Labour election manifesto of 1997, *Because Britain Deserves Better*:

> Primary schools are the key to mastering the basics and developing in every child an eagerness to learn throughout life.

Certainly behaviours that are identified here especially Meg's need to maintain her image and George's experience of inadequate challenge seem unlikely to foster that "eagerness to learn".

A STUDY OF CHILDREN'S VISUAL IMAGERY IN SOLVING PROBLEMS WITH FRACTIONS

Adrian M. DeWindt-King
Cumberland County College
Vineland, New Jersey, USA

Gerald A. Goldin
Rutgers University
New Brunswick, New Jersey, USA

We describe some contrasting aspects of the internal, visual imagistic representations of two elementary-school children, inferred from fine-grained analysis of their problem solving during a pair of carefully scripted, videotaped task-based clinical interviews 16 months apart. The problems involve conceptual interpretation and use of fractions. We look for and find concrete/pictorial, pattern, and dynamic imagery, based on set (discrete quantity) and spatial extent (continuous quantity) models, and memory images of formal notation. We also infer internal operations on and transformations of imagery, and discuss our interpretations.

This study considers in some detail the internal, visual imagistic representations of two children as they solve some problems involving rational numbers (fractions). We acknowledge at the outset important limitations to the methodology of inferring internal representational configurations from observed external statements, behaviors, or productions. Internal representation involves ambiguity, and inferences about it entail context-dependent interpretations. In this exploratory and descriptive "status study," our goal is not (yet) to commit to a definitive, reliable or generalizable coding scheme, but to make as explicit as possible the bases for our inferences, improving task-based interview methodology as we explore individual children's imagery.

Various researchers investigate and discuss imagistic representation generally, and visual imagery in particular, as a fundamental system of cognitive representation for mathematical problem solving (Bishop, 1989; English, 1997; Goldin, 1982, 1987, 1998; Goldin & Kaput, 1996; Owens, 1993; Presmeg, 1985, 1986, 1998; Thomas & Mulligan, 1995). We shall focus here on concrete/pictorial imagery, pattern imagery, memory images of symbolic notation, dynamic imagery, and mental operations on or transformations of images. These characteristics are not mutually exclusive; e.g., pattern imagery may be dynamic, and transformed via mental operations.

We use definitions (consistent with those of Owens and of Presmeg) as follows. Concrete/pictorial imagery is spoken of or gestured at as if it were a picture or a
physical object. The image may be given a name referencing what it resembles in real life. Presmeg (1985) found pictorial imagery to be the predominant form during problem solving; Owens also found it to occur frequently, especially during the orientation phase of problem solving and again as a kind of retrospective, global check. In pattern imagery the image abstracts and/or generalizes mathematical relationships. Presmeg (1985, p.175) notes “such imagery may be vague or vivid but its essential feature is that it is pattern-like and stripped of concrete details.” Krutetskii (1976) calls pattern imagery a graphic scheme where the problem’s terms and relations are represented in a visually schematic way. Memory images of symbolic notation refer to the visualization of formal mathematical expressions, as Presmeg reports students who describe “seeing” a mental picture of a formula and “reading” the image. In dynamic imagery there is active movement or change in all or part of the image (Thomas & Mulligan, 1995). Mental operations or transformations refer here to visualized purposeful acts by the imager that modify or transform the image, suggesting but not requiring dynamic imagery (as they can also be visualized as a succession of static images). Presmeg also uses the term “kinaesthetic imagery” because of associated physical actions; Owens’ term is “action imagery.”

As our study of imagery is centered in the domain of fractions (Behr, Lesh, Post, & Silver, 1983; Behr, Wachsmuth, & Post, 1988), we consider the children’s imagery in relation to various possible conceptual models: e.g. discrete (set) vs. continuous quantity or spatial extent (area or volume, sometimes termed “region”) models; part/whole vs. comparison or ratio relationships; mental operations such as partition. We also focus on understandings of fractional symbolic notation through visual imagery.

Research questions and design of the study

The following questions motivated our analysis. (1) Inferring internal imagery. Can we create explicit criteria for inferring from hand gestures, body movements, paper and pen or marker diagrams, pictures, and charts, and physical manipulations of concrete materials, the five characteristics of visual imagery discussed above? Do we find consistency among these in the individual child? (2) Relation between internal and external imagistic representation. What relationship can be discerned between the child’s internal visual representational capability and her facility in constructing external imagistic representations? How does the use of paper and pencil or marker to draw pictures, diagrams, and/or create charts, or the use of concrete manipulative materials, assist in or influence the visual imagery used in the problem solving? (3) Relation between internal visual imagery and strategy. Heuristic strategies of interest include drawing diagrams, working backward, solving simpler or similar problems, guess and check, subproblem decomposition, etc. How does the child’s internal imagery interact with or influence strategy use? (4) Relation between internal imagery and inference of mathematical patterns. How is the child’s facility in constructing or recognizing a mathematical pattern influenced by her imagery. Which imagery characteristics are important here? (5) Internal imagistic representation and
mathematical conceptual development. Is there a relation between the child’s internal imagery and the development of her conception of a fraction over time?

In a longitudinal study of individual children’s mathematical development, whose design has been described in greater detail elsewhere (Goldin, DeBellis, DeWindt-King, Passantino, & Zang, 1993; Goldin, 1997), 22 children ages 8 to 10 years at the outset were selected to participate in five highly structured task-based interviews over three school years. Interviews #2 and #5 involved non-routine problems about and with fractions. A broad, cognitive analysis with respect to fraction representations and strategies of all 20 children who participated in these two interviews has been completed (Passantino, 1997; see also Goldin & Passantino, 1996). The present report is part of a study focusing in greater depth on the visual imagery of a cross-sectional subset of four children. Below we discuss brief excerpts from interviews with two of them, Marcia and Londa, inferring some contrasting representational characteristics.

The interview scripts were developed at Rutgers by a team of experienced teachers that included the clinicians, and revised after rehearsal and pilot testing to incorporate many different contingencies. Free problem solving is encouraged throughout--after posing a question, the clinician allows for spontaneous response before questioning to explore the child’s answer or request an external representation. If the child is not engaged or seems at impasse, planned suggestions/hints are offered. The clinicians are not to impose their methods or correct or confirm the child’s solution, as it is not the goal here to teach rational number concepts. At certain points, decided in advance and described in the interview script, the children are guided toward particular understandings essential for subsequent questions to be meaningful. Two video-cameras operated simultaneously during each interview, one focusing on the child’s work and the other showing the interaction of the clinician with the child. Outlined below are elements of the two interview scripts needed for the discussion; the complete scripts are in Passantino (1997), or available from the authors.

In task-based interview #2, materials placed before the child include a pad, pencil, markers, and red and black chips (checkers). Some preliminary, non-mathematical questions precede a sequence of mathematical questions posed by the clinician. For each one, the follow-up includes, as appropriate, “Can you help me understand that better?” “Why?” and/or “Are there any other ways to take one half (one third)?)” [The first such questions are:] “When you think of one half, what comes to mind?” “When you think of one third, what comes to mind?” “Suppose you had twelve apples. How would you take one half? ... one third?” [Cutouts are presented in succession: a square, a circle, a 6-petal flower. For each the child is asked:] “Here is a shape. How would you take one half? ... one third?” “What was on your mind when you were answering the questions up to this point?” and if no image is described, “Did you have a picture in your mind while you were answering any of the questions?” with follow-up. [The interview continues:] “Can you write the fraction one half?” “What does this fraction mean to you?” (similarly for one third) The clinician then goes on with more complicated exploratory
activities that involve taking one half and one third of an array, and visualizing the cutting of a cube into fractional parts. At the end of the interview retrospective questions again address the child's visual imagery.

Task-based interview #5 re-explores specific topics from interview #2, and extends to further rational number problems. Materials at the outset include red and white chips, paper circles, squares, and triangles, markers, pencil and paper, a calculator, a ruler, ribbon, scissors, and other items specific to later questions. The follow-up for each question includes, as appropriate, "Why?" "Why not?" "Can you show me what you mean?" "Can you show me [using] the materials?" [The main questions begin:] • "When you think of a fraction, what comes to mind?" • [Bold-face printed expressions in vertical format for five fractions, 1/2, 1/3, 2/3, 3/4, and 4/6, are presented on a sheet of paper:] "What fractions do you see here?" • "Can you explain ... what one of these fractions means?" • "Why is it written this way?" • ... • [Several main questions later, the clinician asks:] "Imagine a big birthday cake shaped like a rectangle. Can you imagine what it looks like?" • "Describe what it looks like." • "Now imagine that there are 12 people coming to the birthday party and they each want a piece of cake. Your job is to cut the cake so that each person gets the same size piece. How will you cut the cake?" • ... • "Are there any other ways to cut it?" • "Now think about the icing. Suppose the cake has icing on the top and side." • ... • At the end of the interview further retrospective questions address visual imagery.

Observations and inferences: Londa

At the time of interview #2 Londa was 9 yrs. 8 mos. old, in the 4th grade of a school in a low-income, urban district. Her spontaneous representations of "one half" and "one third" are verbal: "a cookie, split in half" "... and then when you split it in half, it's two ... Two smaller pieces," and "Half of our classroom, kids in our classroom," "... we have 19 kids in our classroom so half of that would be 9 ... no, we have 18, half of that would be 9," followed by "box cut in threes ... because I think a box would be easy to picture," "one-third of an orange," and "one-third of an apple. Really one-third of anything." All these phrases suggest 3-dimensional, concrete/pictorial imagistic representation, drawn from familiar real-life contexts, with interpretation of the fraction based on a mental operation of partition of a whole into equal parts. All but the second provide a "spatial extent" or continuous quantity model. The "kids in our classroom" can be characterized as a "set" or discrete quantity model. Asked to take one-half of 12 apples, she replies, "Split all of the apples in half." Showing with checkers, "Well, take 12 of these" [takes 6 red, 6 black] "I would split them all in half. So then there'd be 24" [she counts the 12 checkers, assigning a value of two to each] "Cause you cut this in half this would be two ... four, six, eight" [she continues to 24]. When asked to take one-third, "Cut them all into threes" [she counts by threes with the 12 checkers, to 36]. Londa never explicitly states what would be one-third. Her external representations to this point suggest mental operations visualized through a succession of static, 3-dimensional concrete/pictorial image-configurations, using exclusively a continuous quantity model for "fraction."
She does not come back to a “set” model; having acted to transform her image from 12 apples into 24 pieces, she does not seem to treat the latter as equivalent elements but retains the pairing derived from the apple at which they originated.

Asked to write the fractions one-half and one-third, Londa does so correctly in a vertical format, symbolic notation. Interpreting what she wrote, she explains, “This [the 2] means that you have two parts, and this [the 1] being one whole. One whole and two parts.” She explains one-third as “one whole, three parts.” [Clinician:] “Is there any other way you can think of what those fractions mean?” [Londa:] “Either that or three wholes and one part.” She explains, “if I had one cookie, two cookies, three cookies” [draws three circles], “and I take one cut, part out of each of them” [makes a small wedge at the top of each circle]. Londa translates consistently but with some instability among verbal expressions, pictorial images with mental operations, and memory images of symbolic notation. Her interpretation of the numerator as representing the whole and the denominator as the number of parts is consistent with her first answers, and with her method of taking one-half and one-third of twelve apples. She does not show evidence of a ratio or comparison model for fractions.

At the time of interview #5 Londa was 11 yrs. 0 mos. old, in the 5th grade in the same school. Her initial statement of what comes to mind for a fraction is, “I think about how the denominator means that it’s the whole and the numerator means how many parts are out of it.” ... “Like two thirds, the three is the denominator, that means the whole thing; and two means how many, um, two pieces out of the three whole.” [Clinician:] “Could you show me using some of these materials perhaps?” [Londa:] “Okay, this is two, [picks up two yellow cutout circles] this is the two-thirds, and then you have three on the bottom, you have three all together [puts a third circle with the others] and then you have this is two [indicates the two circles] and then you have one left over [indicates the third circle]. So, well, like, if you say two-thirds minus, um, one-third you have two-third, no, two-thirds minus one-third you have one third and that’s it.” [without further action with the circles] Londa’s first words suggest a memory image of symbolic notation related directly to part-whole imagery. Her use of the circles makes no further reference to “pieces of the whole,” but suggests a possible relation to a set model, even the genesis of a ratio model, but with additive imagery. She evidences a memory image of an algorithmic procedure for fractions.

Later, asked to visualize the rectangular birthday cake, Londa describes it, explains that “Since it’s a rectangle you can divide it into equal parts,” shows its height with the ruler perpendicular to the table, “It’s about two inches thick,” and draws a rectangle with two rows and six columns to show exactly how to cut it in 12 equal pieces. Asked if there are other ways, she replies, “I don’t think so because that’s the way we cut my birthday cake. I, [shakes her head] I don’t think so.” Asked how many, and then what fraction, of her pieces would have icing on exactly two sides and the top, she (correctly) explains “Just the four, because ... you can’t put icing on the inside of a cake ...” and “one-third, well, four-twelfths you can reduce it, four-twelfths can be reduced by four and it’d be one-third.” Her verbal and external
pictorial representations of how she cut the cake, and her way of determining the number of pieces with icing on exactly two sides and the top, suggest static, internal 3-dimensional, real-life pictorial imagery, with operations of partition and counting closely embedded in the context. Londa uses her imagistic part-whole model and an internal algorithm to obtain the desired fraction of the pieces.

Observations and inferences: Marcia

At the time of interview #2 Marcia was 10 yrs. 4 mos. old, in the 5th grade in a small, lower middle income school district. Her spontaneous, verbal representations of “one half” and “one third” are “a half of a circle,” “a half of a triangle,” and “a third of a circle.” These suggest possible internal pattern or pictorial imagery with a region model for the fraction. Asked about the 12 apples, Marcia replies, “Count ’em. Well if you know there’s 12, and 6 ... and since 6 and 6 is 12, take 6 of them if you want half.” [arranging 12 red checkers in two rows of 6, and counting them] “... you know that 6 and 6 is 12 you could just take half of them away and you would have half.” [She pushes the 6 checkers from the top row into a casual irregular group. Clinician:] “Why is it one half?” [Marcia:] “Because, well, if you place it like this and you add the 12 to your 6 here” [she arranges the two rows of 6 again, indicating that taking the bottom row of checkers is equivalent to taking the top row, and counts] “... it’s the same amount the other way.” For one-third of twelve apples Marcia replies, “if you knew 4 times 3 was 12, you could take 4 away and you would know it was a third ... because 4 and 4 is 8 and then another 4 is 12.” [pushes 4 checkers to the right, then separates the remaining 8 into two groups of 4, maintaining the row and column structure] Marcia’s external representations suggest memory images of notation, and additive and multiplicative structures for part-whole relation in a “set” model. She focuses on the numbers of apples, doing some mental computation; importantly, her physical manipulation of the checkers suggests an internal pattern image that includes operational one-to-one correspondence between items in parallel rows.

Later Marcia correctly writes the fractions one-half and one-third in vertical-format symbolic notation, explaining, “well, I can tell that it’s one-half because like this is a two [points to denominator] and it’s a one [points to numerator] and if you add one and one it would equal two,” and “if you could times one times three or one and one and one is three so it would be one-third” Her repeated addition of the numerator to reach the denominator value is suggestive of her earlier pattern imagery.

At the time of interview #5 Marcia was 11 yrs. 8 mos. old, in the 6th grade in the same community. She now describes a fraction in quite general terms, “like a part of a whole of something” [writes the fraction three-fifths] and explains, “like three-fifths it’s like the five-fifths is the whole, and it’s like that’s part of the whole of whatever the thing is.” To us this suggests not just internal memory images of notation, but also a level of abstraction that includes a pattern image of a fraction as an operator.

Marcia initially responds to the birthday cake question verbally, kinesthetically, and with a drawing: “Well, um, it’s like this [tries to indicate with her hands how the cake
would look, then draws a triangle] like, a, uh, oh a rectangle” [draws a long, thin vertical rectangle]. After some dialogue she measures and redraws a horizontal rectangle 4 inches long. “... and like you would divide the four into half... which is at two [draws a vertical line at 2 inches, dividing the rectangle in half] and then you would divide each of these into halves [draws vertical lines dividing each section in half]... so you’d have four pieces ... and then you divide these, which is at the half an inch, 'cause the other one was at the inch to divide ... and then you have to divide these which is at a fourth of an inch” [counts 16 pieces]. “... But there's more than twelve so ...” Prompted to redraw freehand, Marcia suggests, “it would depend on like how big the cake is 'cause like if the cake is, like, um, 24 inches long then you would have to divide them each into two inches” “So, it depends how long the cake is.” Further encouraged to redraw freehand, Marcia again considers halving, “... there would be 16 ... since there's 8 now ... so it would double it so like you ...” [Clinician:] “Yeah, could you do it?” [Marcia:] “… would have to divide the cake into thirds” [draws a long horizontal rectangle, with vertical lines dividing it in thirds] “... and then divide these so then there’s 6 [draws vertical lines dividing each of the 3 sections in half] and then you divide these into half [draws additional vertical lines dividing each of the six sections in half] which would make that 12 pieces.” Marcia does not think of other ways to cut the birthday cake into 12 equal pieces. Asked how many, and then what fraction, of her pieces would have icing on exactly two sides and the top, she answers (correctly), “there would be 10, 'cause there, it would be on the top here [points to interior of the rectangle] and then it would be on this side and this side [points to the upper and lower horizontal edges] but you can't count these sides [points to the right and left vertical edges] 'cause there would be three since there's the edges.” She continues, “10 out of 12, or five-sixths,” explaining, “you divide the 10 and the 12 by two and you get five-sixths.” Space permits no further detail, but from this and other evidence we infer internal visual and kinesthetic pattern imagery based on linear and region models, interacting with the “trial and evaluate” halving strategy. We think her linear model stems from her measurement process.

**Comparison and conclusion**

We infer a close relation between the children’s internal imagery and their conceptual development of fraction, based not only on the presented excerpts but on our analyses of the full interviews. Londa’s imagery is predominantly pictorial, centered in familiar concrete objects. She consistently connects her memory images of symbolic notation with just a part/whole conceptual model for fractions, relating each problem directly to a real-life embodiment. Her use of pattern imagery, which might help her abstract and connect different ideas or metaphors of fraction, is not well developed. In contrast, Marcia evidences predominantly pattern imagery, connected with memory images of symbolic notation. She uses part/whole, operator, additive, multiplicative, and linear conceptual models for fractions, and is not “stuck” in particular contexts. Her frequent pattern imagery and her wider range of conceptual models suggest that for her symbolic notation is more flexibly representational of her imagery. Both children show consistent visual imagery characteristics from the first interview to the
second, with evidence of developing memory images of symbolic notation and school-taught algorithms between the two interviews.

While initial verbal responses usually allow us to infer some imagery, the planned prompts for additional external representational forms yield evidence of different internal imagery, not easily discernible from the purely verbal descriptions. Throughout the interviews Londa’s and Marcia’s drawn pictures and physical manipulations of concrete materials suggest concrete/pictorial and/or pattern imagery; their hand gestures and body movements suggest dynamic imagery and/or mental operations; and their notations suggest memory images of symbols and algorithmic operations.
