One approach to providing a mathematically rich curriculum is to involve young children in mathematical investigations in which they engage in the exploration of meaningful problems, and problem posing. However, there is limited research on how teachers can facilitate young children's learning through investigations. This study explored the difficulties seven-to-eight year old students experienced when they began an investigatory program. We present examples of specific difficulties students confronted in conceptualising and conducting investigations, as well as general difficulties that they experienced which hindered their investigations, such as limited observation skills. Our contention is that mathematical investigations can enhance young children's learning provided that their difficulties are addressed.

Background

The importance of providing students with opportunities to work as mathematicians has held credence for at least the past three decades (e.g., Papert, 1972; Wells, 1985) and has recently been strongly advocated (National Council of Teachers of Mathematics, 1998, 1999). As mathematical investigations are central to the work of mathematicians (e.g., Hoffman, 1998), they are fundamental to children's work as young mathematicians (Baroody & Coslick, 1998; Wells, 1985). Investigations are defined as “something more than solving the problem” in which “there will be questions to ask as well as questions to answer” and that require “speculation and conjecture” coupled with opportunities “to test out ideas and to convince others of their validity” (Jaworski, 1986, p. 3). The cognitive activities fundamental to investigations are consistent with those advocated in reform classrooms. In these mathematics classrooms, students should raise questions, pose and solve problems, participate in constructive dialogue and debate, and explain, clarify, and revise their mathematical ideas and problem constructions (Baroody & Coslick, 1998; Bowers, Cobb, & McClain, 1999; English, 1998). Thus, mathematical investigations are ideal for implementing these practices and supporting the child-centred approach that underpins reform initiatives (Borasi, 1992; Jaworski, 1994; Shifter, 1996).

However, there is an urgent need for classroom-based research that addresses the teaching and learning issues associated with young children undertaking investigations. While classroom-based research on the teaching and learning of children conducting mathematical investigations exists for the upper primary years (e.g., Oliveira, Segurado, da Ponte, & Cunha, 1997), there is limited research in the early primary years. The existing research on young children implementing investigations tends to focus on the implementation of an investigation with an
individual child (e.g., Juraschek & Evans, 1997), and hence, provides scant guidance for implementing investigations with a class. As engaging young children in investigations requires teachers to teach mathematics in new and different ways (Baroody & Coslick, 1998; Skinner, 1999; Taber, 1998), such research is fundamental to the reform vision for improving student achievement (Hiebert, 1999).

Ideally, classroom investigations should parallel real life problems and provide children with opportunities to apply their basic knowledge (Holding, 1991). Such problems might involve making decisions that are influenced by aesthetics, economics, pragmatism or safety. Associated tasks that may involve observation, collecting data, seeking patterns and relationships, characterise original thinking in mathematics and provide authentic circumstances for conjecture, logical thinking and proof, all of which are cornerstones of authentic mathematics (e.g., Greenes, 1996).

Although investigatory tasks for young children need to be commensurate with their interests, experiences, and mathematical capacity, the tasks needs to be relatively challenging to have cognitive benefit (Lappan & Briars, 1995; Stein, Grover, & Henningsen, 1996). Due to the cognitive demand that occurs when students are engaged in challenging tasks, teachers may scaffold students’ problem solving by simplifying tasks or providing hints (e.g., Rosenshine & Meister, 1992). However, even with young children, scaffolding should be used judiciously because when a teacher takes over the challenging aspects of the task, it becomes routinized (Stein et al., 1996) and the cognitive value of the task is reduced (Henningsen & Stein, 1997). Routine investigations in which the “investigation degenerates into an algorithm” have limited cognitive value (Roper, 1999). Thus, while teachers may initially pose and guide children’s investigations (Baroody & Coslick, 1998), children should ultimately develop and implement their own solution plans (Brahier, Kelly, & Swihart, 1999), and pose investigations (Rowan & Bourne, 1994).

A key consideration for facilitating learning is teachers’ pedagogical content knowledge, which includes an understanding of students’ difficulties (Carpenter, Fennema, & Franke, 1996). In this paper, we report on some of the difficulties that confronted young children when they began a program of investigations. This is part of a larger project exploring how young children in the early years of primary school engage in mathematical investigations.

Design and Methods
The research adopts an exploratory case study design (Yin, 1994) in which a teaching experiment was conducted with the goal of supporting the development of investigatory abilities in young children. This study was implemented in class in which one of the researchers (CMD) assumed the role of the teacher while the other researchers provided feedback as a non-participant observer (JJW) and “critical friend” (LDE). Twenty-seven seven to eight-year-old students were selected for the investigations program on the basis of their interest and strength in mathematics from
four class groups within the same school. Students worked as a “class group” and received 90 minutes weekly of investigatory activities over a 14-week period.

This paper reports on the initial five-week phase of the program, which was implemented in the early part of the school year. In this phase, students worked on a series of mathematical investigations involving Smarties¹ (Table 1). The first three investigations were teacher-initiated, although questions posed by students during these investigations were followed up. The fourth investigation was a student-initiated task, which the students undertook with a partner. These investigations are described in detail elsewhere (Diezmann, Watters, & English, 2001).

The case study database comprised video and audio records, classroom artefacts, the teacher’s lesson plans and reflections, and notes by the research team. Four video cameras recorded events during each lesson supplemented by audio taping of selected

individual group interactions. A research assistant made focussed observations that involved an ongoing record of the interactions of particular children. The data also included children’s written work. After each lesson, the video-tapes were reviewed and salient events discussed among the researchers. These discussions permitted the team to analyse behaviours, develop conjectures, and plan strategies. Summaries of discussions were compiled as a diary containing descriptions of events, hypotheses, and reflections about teaching and learning. For this paper, the data were analysed to identify the range of difficulties encountered by students when they were introduced to investigations. Only examples of these difficulties are presented due to space limitations.

Selected Results

In this initial phase of five weeks, the students encountered two types of difficulties. These were Investigation-Specific Difficulties and General Difficulties that impact on other school work in which students engage apart from investigations.

Investigation-Specific Difficulties

Students experienced a range of difficulties when engaged in teacher-initiated and self-initiated investigations. Four examples of these difficulties follow.

1. A lack of understanding of the problem under investigation. For example, in I-4 (Investigation 4) Melissa was asked to explain how to investigate the most popular colour Smartie. Her response suggests that she interpreted the term “popular” to mean the most frequently occurring item instead of a consumer preference. Other students interpreted the term similarly.

   I think you would open all the Smartie jars you had and then, and then put the colours into groups say, purple, yellow pink and different colours and when you are finished putting them into groups well you count them up and (find) ... the colour that has the highest number.

2. Failure to link the findings of an investigation to the answer to the problem. For example, in I-1 students used a variety of tools, including rulers, scales, calculators, and magnifying glasses to investigate “How many Smarties in the Smartie can?” Though they generally used these tools proficiently, most students did not use their measurements in producing their answers. Catherine’s response is typical of students’ responses: “We used the ruler to measure the Smartie Can to see how many Smarties there were.” A couple of students, for example, Caroline, provided further information: “We used the ruler for the height. The height was four and a half centimetres”. Robert was the only student to explicitly link his measurement to his answer. He and his partner weighed a can containing four Smarties and the full can. They then determined how many partially-filled cans were equivalent in mass to the full can. Finally, they multiplied the result of their calculation by four, as there were four Smarties in the partially-filled can. However, they failed to realise that the mass of the partially-filled can should have only been included once in their calculations. They never attempted to weigh an empty can.
We used the scales to measure the can with four Smarties to see how many it weighed to help us find out the answer to the problem...Well, if we weighed the "four can" then we could multiply the four can on the calculator.

3. Difficulty posing a problem to investigate. For example, in I-4 Jason was unable to identify a problem to investigate. He wrote, “Different Smarties go down the slide” (Figure 1). The Smartie slide was a cardboard construction that was used for measuring the speed of Smarties as they travelled down the slide. However, while some students were unable to spontaneously pose their own problems in Phase 1 of the program, other students, such as Tim, clearly articulated a problem: “How long does it take different types of Smarties to go down the Smartie slide?

4. A lack of prerequisite mathematical knowledge to complete an investigation of interest. For example, in I-4 Robert’s initial problem was “What is the chance of the first Smartie out of the box being your favourite colour?” Although Robert recorded the outcomes of his trials and identified the colours that were drawn the most and least times, he was unable to proceed further with his exploration of “chance”. He chose not to present this relatively sophisticated investigation to the class, but presented a simpler investigation designed by his partner. Robert’s sense of self-efficacy might have been diminished because he was unable to complete the initial investigation to his satisfaction. This is an instance of where an investigation requires more advanced mathematics and intervention by the teacher.

It is not surprising that students experienced difficulties with teacher-initiated or self-initiated investigations, as they were novices. The teacher provided students with support to overcome investigation-specific difficulties and addressed these difficulties in subsequent lessons. None of these difficulties was considered sufficiently insurmountable to obviate the benefits of an investigations program.

General Difficulties
In addition to investigation-specific difficulties, students experienced various general difficulties that hindered their investigations. Six of these difficulties are outlined here. The first three difficulties relate to mathematics and the latter three difficulties relate to communication and representation.
1. A failure to detect critical differences. For example, in I-2 students were unable to explain the discrepancy between their prediction and the actual count for the partially filled Can B. After prompting to compare the full Can A with Can B, Robert picked up the cans and explained, “Well this one here (Can B) it’s not as full as this one (Can A)”.

2. A lack of an understanding of what can be added. For example, in I-1 Leanne calculated the number of Smarties in her can to be 24 by combining the can’s mass of “20” with the can’s height of “four” (Figure 2).

3. Difficulty in identifying how to use a tool for a particular purpose. For example, in I-4, Leanne and Libby encountered difficulty in trying to weigh a single giant Smartie on kitchen scales and balance scales. This difficulty was overcome by prompting the students to weigh more than one giant Smartie (Figure 3).

4. Difficulty conveying ideas clearly orally or in writing or in a drawing. Throughout Phase 1, students were frequently asked to clarify and elaborate on their oral and written responses. Additionally, drawing did not appear to be a regular feature of their mathematical thinking or communication. Even when students were instructed to include drawings in their reports, some students failed to complete a drawing or their drawing lacked adequate detail.

5. Difficulty using common mathematical representations. For example, in I-3 many students needed considerable support to produce a simple table and bar graph.

6. A lack of understanding of the correspondence between objects and their symbolic and pictorial representations. For example, in I-3 some students had difficulty understanding that their count of a particular colour Smartie could be written on the table beside the corresponding colour and could also be represented on the bar graph.

These general difficulties highlight the range of knowledge or skills that students utilise in undertaking investigations. Hence, teachers may need to provide individualized and differential support to address particular difficulties that hinder students’ investigatory work. While problematic, these difficulties provide invaluable opportunities for learning within a meaningful context.

Conclusion

The results indicate that young students are capable of planning and implementing investigations but they encounter a range of difficulties in the process. Knowledge of specific difficulties experienced by students enables the teacher to structure an investigations program to pre-empt and address likely difficulties, and provide students with opportunities for success on challenging tasks. Knowledge of the general difficulties that impact on students’ capacity to engage effectively in investigations assists the teacher to determine the preparedness of particular students for investigatory work, and the type of support they may require to successfully engage in investigations. General difficulties experienced by students also provide
teachers with an insight into the students’ capacity to apply previously learnt knowledge or skills within a new and challenging context.

Engaging young students in investigations requires that teachers reconsider their understanding of the nature of mathematics and how mathematics is learnt. Mathematical investigations are one of the few classroom mathematics activities in the early years that require high-level thinking and task commitment. However, investigations provide students with the satisfaction of successfully completing a challenging task and being able to identify and investigate their own problems. Hence, the time and effort invested by teachers in planning and supporting children’s investigatory work can yield worthwhile cognitive and motivational dividends.

References

A modeling approach to problem solving shifts the focus of the learning activity from finding an answer to a particular question to creating a system of relationships that is generalizable and re-usable. In this research paper, we discuss the nature of tasks that can be used to elicit the development of such systems. We present the findings from one classroom-based case study of Australian children and a summary of findings from all U.S. and Australian classes in our studies. Student reasoning about the relationships between and among quantities and their application in related situations is discussed. The case study suggests that students were able to create generalizable and re-usable systems (or models) for selecting and ranking data.

Introduction
Data analysis is increasingly recognized as an important topic within school mathematics and has gained an increasingly visible role in the K-12 curriculum (English, Charles, & Cudmore, 2000; Greer, 2000). The justification of such significance is generally made by an appeal to the usefulness of such skills in everyday life as well as in a wide range of work-related settings. The analysis of data as part of school mathematics is sometimes justified on the basis of contexts which are motivating and of interest to students. In this research, the context is seen as providing a site that is rich for the sense-making activities of learners and that holds the potential for the development of more generalized understandings across a range of contexts. In this paper, we discuss the results of an analysis of a sequence of modeling activities in which middle-school students investigated non-routine problem situations where the core mathematical ideas focused on the creation of ranked quantities, operations and transformations on those ranks, and, finally, the generation of relationships between and among quantities to define explanatory and predictive relationships.

Theoretical Framework
A modeling approach to the teaching and learning of mathematics focuses on the mathematization of realistic situations that are meaningful to the learner. The emphasis on modeling involves three important shifts in the approach to teaching and learning mathematics: (1) the nature of the quantities and operations that are useful, (2) using contexts that will elicit the creation of useful systems (or models), and (3) developing and refining such models in ways that are generalizable. We briefly discuss each of these aspects in turn.

The quantities and operations that are needed to mathematize realistic situations often go beyond what is usually taught in school mathematics (namely quantities such...
as counts, measurements, ratios, rates and proportions, shapes, and the four basic operations of arithmetic. Often in realistic situations, the kinds of quantities that are needed include accumulations, probabilities, frequencies, ranks, and vectors. The operations needed include sorting, weighting, organizing, selecting, and transforming entire data sets rather than single, isolated data points. In solving typical school "word problems," students generally engage in a one- or two-step process of mapping problem information onto arithmetic quantities and operations. In most cases, the problem information has already been carefully mathematized for the student. The student's goal is to unmask the mathematics by mapping the problem information in such a way that an answer can be produced using familiar quantities and basic operations. In modeling tasks, the student's goal is to make sense of the situation so that s/he can mathematize it in ways that are meaningful to her/him. This will involve a cyclic process of selecting relevant quantities, creating meaningful representations, and defining operations that may lead to new quantities (Lesh & Doerr, in press).

A modeling approach to problem situations explicitly uses meaningful contexts that elicit the creation of useful systems (or models). Modeling begins with the elicitation stage, which confronts students with the need to develop a model to describe, explain and predict the behavior of an experienced system. Principles for designing such model-eliciting problems have been put forward by Lesh and colleagues and are described elsewhere (e.g., Lesh, Hoover & Kelly, 1992). Models are systems of elements, operations, relationships and rules that can be used to describe, explain or predict the behavior of some other experienced system. We are particularly interested in those models in which the underlying structure is of mathematical interest. The sequence of data analysis problems (described in more detail below) provide us with a setting in which we can examine the development of students' interpretations of the problem situation, their reasoning about relevant elements of the system, their selection of quantities, operations, and representations, and their multiple cycles of interpretation.

Engaging in this kind of model building is not seen as finding a solution to a given problem but rather as developing generalizations that a learner can use and re-use to find solutions (Bransford, Zech, Schwartz & The Cognition and Technology Group at Vanderbilt University, 1996; Doerr, 1997). To this end, we argue that the students need multiple experiences that will provide them with opportunities to explore the mathematical constructs, to apply their system in new settings, and to extend their model in new ways. Each of these stages of the model development process includes multiple cycles of interpretations, descriptions, conjectures, explanations and justifications that are iteratively refined and re-constructed by the learner, ordinarily interacting with other learners. This view of student's conceptual development through modeling is shaped by earlier research that posits a non-linear, cyclic approach to model building (Doerr, 1997). Generalizing and re-using models are central activities in a modeling approach to learning mathematics. Thus, a modeling
perspective leads to the design of an instructional sequence of activities that begins by engaging students with non-routine problem situations that elicit the development of significant mathematical constructs and then extending, exploring and refining those constructs in other problem situations leading to a generalizable system (or model) that can be used in a range of contexts.

Description of the Study
The model development sequence (described briefly below and elaborated at http://soeweb.syr.edu/mathed/HMDproject/Main.html) was designed by the first author and has been investigated in several middle-school classrooms (students aged 12-13) in the United States. The sequence was later revised by the second author for use in Australian classrooms with students aged 11-12 years. The Australian children addressed here were from a grade 6 class who participated in the sequence of model development activities described below. The activities were implemented in the children's classroom each fortnight over a period of 11 weeks. The children worked in small groups of 3-4 in sessions of approx. 90 minutes duration.

Description of the Modeling Tasks
The overall sequence of model development activities consists of four problem situations centered on the core mathematical ideas of ranking, weighting ranks, and selecting ranked quantities. Since the problem situation is focused on ranking, of necessity the students analyze and transform entire data sets or meaningful portions thereof, rather than single data points. The students had no specific formal exposure or instruction on these ideas prior to the unit. Rather, the unit was designed so that the students could readily engage in meaningful ways with the problem situation and could create, use and modify quantities (e.g., ranks) in ways that would be meaningful to them and in ways that could be shared, generalized, and re-used in new situations. The sequence of problem situations was designed to be completed by a small group of students, thus providing a social setting for the negotiation of conjectures and justifications and for the clarification of explanations. In addition to the sharing which would take place within the small groups, discussion of specific systems created by students provided a forum that could potentially lead to the sharing of either common or multiple systems within the whole class. Each of these tasks is described briefly.

The sequence begins with the Sneakers Problem, which was designed to elicit the notion of ranking in the first place and the multiplicity of factors that would lead to the need for selecting based on ranks. This is followed by two tasks, namely, the Weather Problem and the Summer Camp Problem, which were designed to explore and extend the constructs elicited in the Sneakers Problem. The final task in the sequence, the Crime Problem, provides the opportunity for students to apply the constructs developed in the earlier tasks, to symbolize the systems they have developed, and to refine their notions about weighting factors.
In the Sneakers Problem, the students encounter the notion of multiple factors that could be used in developing a rating system for purchasing sneakers and the notion that not all factors are equally important to all people. Students were asked “What factors are important to you in buying a pair of sneakers?” This generated a list of factors where not all factors were equally important to the students; the students then worked in small groups to determine how to use these factors in deciding which pair of sneakers to purchase. This resulted in different group rankings of the factors. The teacher then posed the problem of how to create a single set of factors that represents the view of the whole class; in other words, the group ranks needed to be aggregated into a single class ranking.

The second problem, the Weather Problem, was designed to extend, explore and refine the idea of ranking, sorting, selecting, and using quantitative and non-quantitative data. The context of the problem is a travel agency that provides a relocation service for clients who specify certain climatic factors that govern their choices of possible destinations. Students are given a table of data on the climatic conditions of various cities, together with letters from two clients (extracts shown below). The students’ task is to develop a generalised rating system for comparing the climates in different places, and to write a letter to the travel agency recommending the first and second best, and worst cities for each client. The students are to explain to the agency how their rating system works and why it is a good one.

Letter from client: Dear Global Travel, My wife and I are retiring in several months and would like to relocate in a warm and sunny area. We don’t care if there is a lot of rain and we definitely don’t want to be too cold. What are some cities we should consider living in? Sincerely, Mr & Mrs Johnson.

The Summer Camp Problem (designed by Lesh and colleagues) is a structural analog to the Weather Problem and asks the students to create a generalized system for selecting teams for track and field events in a summer recreational program. In the Crime Problem, students are presented with crime rates on both violent and property crimes for various cities. They are asked to devise a system that can be used to determine if a particular city (in the present instance, Ipswich) on the list of cities is "safe enough" or warrants increased expenditures for the police budget. Intended in the mathematization of this data set is the notion that although violent crimes against persons have lower overall rates, they would be considered more significant than property crimes.
Data Sources and Analysis

Data sources from both the Australian and American classes included audio- and videotapes of the students’ responses to each of the tasks, together with their work sheets and final reports detailing their models and how they developed the models. Transcripts were analyzed for evidence of students’ mathematical development over the course of the tasks. Field notes and audio-tapes were analyzed for the varying strategies that were developed across classroom settings. The researchers shared their data analyses across the two sites and the analysis is on-going.

Results and Discussion

First, we consider the development of one group of 3 children from the Australian classes (Ben, Erin, and Rose). The group began the Sneaker Problem by listing factors using non-mathematical arguments and decisions that reflected their own experiences in buying sneakers (“I think style then size;” commented Rose, to which Erin replied, “But what if it doesn’t fit them?”). Ben soon realized that they needed to be more objective (“It doesn’t matter!”). This informal negotiating strategy was gradually replaced by a more mathematical one when the group faced the problem of aggregating several group lists into one list. They used a frequency-based strategy (described later) in combining the lists until they faced a difficulty with ranking two of the factors (brand and grip). The girls tried to negotiate here on a subjective basis but Ben rejected this approach and began the shift from subjective negotiating to mathematizing the elements in the lists as mathematical quantities in their own right. He totalled the ranks of each of the two problematic factors and then re-ranked their totals. The group reverted to their earlier frequency-based strategy, however, to complete their aggregation of the lists. Nevertheless, it was interesting to observe Ben’s comments in the subsequent whole-class sharing session. After one group explained, “We put grip [before brand] because there’s two grips there and there’s only one brand at 6” [the student was referring to the sixth place on her list], Ben asked, “What if it was the opposite? What if grip was where brand was, and brand was where grip was. Would you choose grip or brand?” Some children responded in a subjective way (“Use your own opinion”), while one child suggested adding the ranks across the lists and finding the average (although his group had not done so). Ben explained how he solved this dilemma: “I had a bit of trouble so I added up all the brands and got 27 and when I added up grip I got 25, and 25 means it’s, like .... grip before brand.”

On the Weather Problem, which the students completed two weeks after the Sneaker Problem, Ben’s group displayed two major mathematical developments. At the beginning of the Weather Problem, the group appeared focused on finding a generalized system. Rose and Erin recommended using an averaging system, which they had developed independently on a small analogous task at the end of the Sneaker Problem session (this task involved working with data from a McDonalds’ survey of people’s top 5 reasons for coming to McDonalds. Students had to develop a master list that ordered the reasons
from most important to least important). Ben wanted to create his own system, however, his initial ideas were rather unsophisticated ("Why don't we take each city and say what we think of it, like we could say it's pretty cold, pretty hot..."). The girls kept reminding Ben that they had to find a generalized system ("Method, method, because it has to work for all of them."). After some negotiation, the group started to develop their system by ranking cities according to the number of clear days. Rose stated that they should "rank from lowest to highest and then you average it." The group then proceeded to add the data in one of the columns, namely, the number of clear days, and then divided by 9 (there were 9 cities listed in the table). Following Ben’s comment, "If we wanted a perfect city, we should go about getting all the averages for a start," the group found the average of each of the remaining climatic factors in the table of data. After deciding that, if the clients "want a hot one and it's above the average that should mean it's hot" (Ben) and "yeah, if it's below it's cold" (Erin), the group proceeded to draw a table to record those cities that were above or below the average for each climatic factor. In trying to refine the group’s explanation of their system, Ben stressed, "If people want a hot day, you find a city that, hang on, hang on, just listen, you find a city that has over 118 days over 30 degrees," and "you wouldn't look for cities that are the closest to the average." In returning to the clients’ letters, Ben directed the group to list the cities that were above/below the average according to what the client requested. In scanning their list for cities that met the criteria, the group became somewhat bogged down, until Ben decided that the use of an elimination strategy might help: "Write down all nine cities and then cross out the ones we don’t think it is and go right down to the last three." As the group was doing so, Rose was working at a "meta-level," re-focusing the group on the goal of their efforts: "I'm going to re-read the question again...we don't need to look at every single one...we don't really have to worry about rain.....they definitely don't like cold days so we definitely don't want to be cold."

The group used the same "mean-split" system in working the Crime Problem. They found the average of the violent data of all cities listed in the given table and then repeated this for the property data. The group compared these two overall averages with Ipswich’s rate for property and its rate for violence to make a decision on whether Ipswich is a safe place to live. They then decided to make a more fine-grained analysis by considering the individual components of property and violence for Ipswich, and explained, "We added down every one of them [the columns of data] and murder is about average, and assault's better than average, and robbery's better than average, and burglary is better than average. All of them is better than average. But the overall trend (for Ipswich) is up (the 5-yearly trends for each of the cities were listed in the table). Ben added, "We found Ipswich is good against other cities but bad against itself." With minimal intervention, Ben’s group had developed a generalizable and re-useable system for selecting and ranking data; this sophisticated system was developed across three different problem contexts.
We now report the range of systems that we have found across all of the classes in our studies. In analyzing the aggregation of the ranked sneaker data, we have identified five distinct systems that students have developed. Similar to the development shown by the small group discussed above, these systems are further developed by the students as they progress through the modeling sequence. Here, we are summarizing just the variations in models that occur in the first task. In general, we have found that at least three of these systems will emerge in most classrooms.

The first system to determine an aggregated class rank is a frequency-based strategy. The factor with the greatest number of one's becomes the first ranked and so on for the second and third factors. The students were easily able to identify the highest and the lowest ranking factors by this system as well. What became problematic with this system was the selection and identification of a rank for the factors in the middle; this was the problem encountered by Ben's group, above. These middle factors were often assigned ranks using an estimation strategy that yielded a "close enough" rank from the perspective of the students. An alternative strategy, such as what Ben proposed, that is occasionally used is to use successive pairwise comparisons. So if two factors are competing for the same rank on the list, these two factors are compared in terms of the relative order in which they appear on all the original lists. The factor with the greater number of higher rankings is then ranked higher. We note that this notion of pairwise comparisons is mathematically powerful and useful. However, it does not become a strategy that persists across the sequence of tasks. Finally, we note that the difficulty in resolving the problematic issue of the middle ranks often precipitates a rejection of this model and a move to one of the other systems below. Hence, in most cases, this frequency-based model is an early way of thinking about the problem that is later abandoned as the students strive to accommodate all the data into their system.

A second system developed by students is to arithmetically average the ranks of each factor and then to explicitly re-rank those averages. Significantly, this system indicates a shift from seeing the ranks as labels or as positions on a list to seeing them as quantities that can be operated on by averaging. The factors now have explicit numerical values, rather than implicit places in a list. In turn, the newly constructed quantities of the average rank are assigned explicit numerical ranks. In one instance, we found that the occurrence of a tie in ranks led to a refinement of the system. The tied factors were assigned a common rank, and the next rank was skipped. At the time, we were surprised at this solution, since to the best of our knowledge students had not had any formal instruction in methods to resolve ties. In subsequent reflection, we surmised that the students may have had experience with this solution from sporting events in which this solution is a common strategy.

A third system developed by students is to simply total the ranks of each factor and then to explicitly re-rank those totals. This system reflects the same shift in thinking
about the ranks as does the "averaging" system above. However, it would appear that
the students are focusing on the meaning of the quantities in a slightly different way.
Occasionally students will express the total as "the number of points" attributed to the
factor.

A fourth system that is devised explicitly ranks the initial data so that a factor that
is "highest" on the list (i.e. is ranked number one) receives the greatest number of
"points." Similarly a factor that is "lowest" on the list is given the least number of
"points," namely one. We see the students in this case explicitly shifting from a label
or position on a list to a rank quantity ("points") that measures the relative merits of
the factor. These ranks are then summed (similarly to the third system) and these
totals are re-ranked in reverse order so as to keep the "best" factor in the first position,
with the greatest number of points.

A fifth system used to determine an aggregated class rank simply ignores the group
data and resorts to a "voting" strategy. This occurred in a classroom where the
discussion of how to combine the lists was initiated not in the small groups, but in a
whole class discussion. Hence, a salient feature of the ranks became the values
given by each individual class member, rather than by the groups. Some students argued
that this strategy was "fairer" than using the group data since it took into account the
opinion of everyone in the class.

Concluding Points

The above five systems reflect the thinking of various groups of students about the
task of aggregating data that are in ranked lists. These are the initial models that are
elicited by the context of the task and importantly, are later developed by the students
with minimal intervention from the teacher. As we saw in our case study, Ben's group
progressed from an initial frequency-based and at times, subjective strategy, to
mathematizing elements in lists by totalling ranks, and then to a sophisticated "mean-
split" system that was generalizable across tasks.

UNPACKING A CASE STUDY: UNDERSTANDING TEACHER EDUCATORS AS THEY UNDERSTAND THEIR PRE-SERVICE SECONDARY TEACHERS

Helen M. Doerr and Joanna O. Masingila
Syracuse University

The challenges facing those who seek to prepare mathematics teachers are well established in the literature. Most of the research to date has focused on the perceptions and understandings of pre-service teachers, but not on the perceptions and understandings of teacher educators. In this study, we explore how teacher educators understand their pre-service teachers as these pre-service teachers attempt to make sense of teaching through the investigation of a multimedia case study of practice. We found that in using the case study, teacher educators elicited pre-service teachers' thinking about the complexities of the teacher's role in small group work, about the limits of their abilities to extend lesson ideas, and about the value of revealing teacher's reflections.

Introduction

Mathematics teacher educators face several practical problems in their work with pre-service teachers: finding sufficient high quality classrooms for placements, developing robust understandings of mathematics among pre-service teachers, supporting their reflections on students' mathematical thinking, and developing images of practice that go beyond "telling clearly." The number and intricacy of theories attempting to model mathematics teaching has increased substantially over the last two decades (Koehler & Grouws, 1992). However, it is only recently (e.g., Cooney, 1999; Cooney, Shealy & Arvold, 1998; Simon, 1995) that theories of teacher development are beginning to emerge that go beyond theories that describe models of effective teaching to theories that explain the nature and the development of teachers' knowledge.

Such theoretical work appears to hold promise for informing the practical work of teacher educators. Yet much of the current research focuses primarily on pre-service teachers' mathematical content knowledge, their beliefs, and their pedagogical content knowledge. There is very little research on the teacher educators who work with these pre-service teachers. This study intends to contribute to the emerging theories of teacher development by examining the work of teacher educators as they understand the development of their pre-service secondary teachers. In this study, we investigated the nature of the implementation of a classroom-based, multimedia case study that was used by teacher educators as part of the professional preparation program of pre-service teachers. We seek to understand how teacher educators understand their pre-service teachers as these pre-service teachers attempt to make sense of teaching through the investigation of a multimedia case study of practice.
Theoretical Framework

Our theoretical framework is grounded in two areas of research related to teachers' professional development. The first area involves research regarding the complexity of classroom environments while the second involves research regarding the use of case studies in supporting the development of effective practices within such complex settings. The complexity of classroom environments presents particular problems for the novice teacher whose limited experience and knowledge make it difficult to effectively observe the complexity of interactions that occur, often with great rapidity, in a typical classroom. Beginning teachers are often concerned with issues of classroom management and the planning of lessons as important priorities. They may not focus on the subtleties of understanding student thinking or the nuances of facilitating group work and class discussion or the tradeoffs inherent in teachers’ decisions.

The complexity of these interrelated issues is addressed by Simon (1995) as he describes mathematics teaching as the cyclic interrelationships of teacher knowledge, thinking, decision making, and mathematical activities, all of which are influenced by the teacher's understanding and evolving hypotheses about students' learning. Cooney (1999) notes the importance of examining the contexts through which teachers develop and use their knowledge. He states that "whatever lens we use to describe teachers' knowledge, that lens must account for the way in which knowledge is held and the ability of the teacher to use that knowledge in a reflective, adaptive way" (p. 171). Teacher educators are faced with the challenging task of simultaneously meeting the practical needs and concerns of their pre-service teachers while supporting their professional development along lines that will deepen their mathematical knowledge, develop their understanding of children's reasoning, and enhance their ability to reflect upon their decisions and actions in the classroom.

The second perspective that is brought to this study is the notion of the case study as a vehicle for understanding complex practices such as law, medicine, engineering, and (more recently) education (Barnett, 1998; Merseth, 1991). In developing approaches for using case studies in the professional preparation and development of teachers, broad and varying appeals are made to the potential of case studies. These appeals range from the potential for providing paradigmatic exemplars of practice to providing a means of understanding theoretical principles, while bridging the gap between theory and practice (Sykes & Bird, 1992). Others have suggested that the primary purpose of case studies is to support the development of critical analysis and informed decision making. A key characteristic of a case study is that it is embedded in the context of teaching (and schooling) with all its concomitant complexity, ambiguity, and incomplete information. As Feltovich, Spiro and Coulson (1997) have argued, the knowledge base of teaching is an ill-structured domain and as such is best learned by a criss-crossing of the landscape through the study of cases of practice. It is precisely within the complex, ambiguous, and partially understood context of practice that teachers have to make reasoned
judgments and decisions for action. Learning through cases studies, it is argued, promotes teachers' understanding of the complexities of practice and of the need to become more analytical about the data of classroom practice (Wassermann, 1993). It is this paradigm—that case studies are a site for reflection and analysis by those preparing to become teachers—that guides the analysis in this study. We wish to examine how teacher educators understand the thinking of pre-service teachers as they reflect on and analyze a case study of practice.

Methodology and Data Analysis

This qualitative case study is part of a larger research project on the use of multimedia case studies by mathematics teacher educators to support the professional growth and development of pre-service secondary mathematics teachers. The teacher educators participating in this study were all experienced faculty, one at a small college and two at mid-sized universities. For purposes of anonymity, all results are reported in a single gender. The pre-service teachers were graduate and undergraduate students in the final stages of their preparation for full-time student teaching. Most were involved in classroom observations and had some limited teaching experiences. All of the participants in this study had a copy of the CD-ROM "Ranking Data to Make Decisions: The Case of the Sneakers Purchase" (Bowers, Doerr, Masingila & McClain, 1999). These multimedia materials were intended to capture the artifacts of practice in a 7th grade class of 23 students in an urban public school over the course of a one and a half day lesson.

The purpose of the case study lesson was to engage middle school students in the collaborative analysis of real world data in an effort to make a mathematically viable group decision about the most important factors to consider when purchasing a pair of sneakers. The problem first involved identifying criteria that might be used when deciding on a pair of sneakers to be purchased. The students were then asked to rank order the criteria from most important to the least important. After each of the six groups ranked the list of eight criteria, students were challenged to develop a system to aggregate all of the groups' lists into one final, ordered list of criteria. The case study teacher then called upon groups of students to present their ranking systems to the class. The case study materials included background information on the school, the teacher's lesson plans, the teacher's anticipations of the lesson and her reflections after the lesson, video of the whole class discussions and small group interactions, a scrolling transcript that was linked to the video, copies of student work, and related mathematical activities.

The teacher educators had a facilitator's guide that suggested some ways that the case study could be used and contained a set of discussion questions that organized the issues of teaching and learning mathematics around four themes: planning, facilitating group work and whole class discussion, understanding student thinking, and mathematical content and context. These four themes were intended to guide and support the reflection and analysis by the pre-service teachers without overly constraining or dictating how the case study would be used by the teacher.
educators. Each teacher educator used the materials for a minimum of three to four class hours over at least a two week period.

Both the teacher educators and the pre-service teachers completed questionnaires that were designed to understand (a) how the case study was used and the goals of the teacher educator, (b) the background and experiences of the pre-service teachers, and (c) the salient issues in the case study for the teacher educator and the pre-service teachers. In addition, we conducted semi-structured interviews with the teacher educators to probe the issues that were raised through the use of the case study materials and to better understand how the teacher educator perceived the relationship of those issues to the professional growth and development of the pre-service teachers. The pre-service teachers completed several written assignments based on study questions from the facilitator’s guide and an essay on the characteristics of effective teaching. The questionnaires, interviews, assignments and essays constituted the data corpus for this study.

The analysis of this data was conducted in three phases, using inductive qualitative methods. In the first phase, we coded the responses of the teacher educator and pre-service teachers to the open-ended questions on their respective questionnaires (e.g., “For me, the most valuable part(s) of this case study investigation was . . .”) to identify emerging themes for the pre-service teachers. In the second phase, we analyzed the students’ written assignments and essays for instances of these themes and other possible themes that may not have been addressed in the responses on the questionnaires. We also analyzed the teacher educators’ interviews, seeking elaborations and instances of these themes and identifying key issues from the teacher educators’ perspectives. In the third phase of our analysis, we compiled profiles on the use of the case study by each of the teacher educators and identified those themes and issues that were critical for the teacher educator or for the pre-service teacher. These profiles then became the basis for interpreting each perspective in light of the analysis done in the first two stages.

Results

We report the results of our analysis in terms of the issues that emerged from the use of the case study by each of the teacher educators. In the first teacher educator’s investigations with the multimedia case study, she was very open-ended in her approach to the case study. She described her pre-service teachers as very "autonomous" learners and simply directed them to "use it how you want to but if I were you I wouldn’t watch the follow up reflection yet, today at all, until later when we’re using this." This teacher educator gave her students these materials as a case for them to investigate from their own perspectives, with only the suggestion that they refrain from looking at the case study teacher’s reflections until after they have discussed the lesson in the case. Two central issues emerged for this group of pre-service teachers. First, the pre-service teachers expressed concerns over the case-study teacher’s interactions with one of the small groups of students. The pre-service teachers felt that the teacher did not understand what the group was doing and needed
to spend more time with that group. They felt that the teacher did not probe deeply enough into their thinking, as she did with some other groups. Furthermore, they found that this lack of probing was a mismatch with the teacher's professed belief in the value of listening to students in order to move the lesson forward.

The second issue that emerged for this group of pre-service teachers was related to the judgements that they were forming about the case teacher's decisions. These pre-service teachers became somewhat more tentative in their judgements about the teacher as their analysis of the case progressed. They wanted to see all the other groups, not just the three selected for the case study; they wanted to know more about what happens next; they expressed a need to have "the whole picture." They noted that "she has so much to do" and that "it is hard to run a classroom in that way." The teacher educator saw these responses in terms of how the pre-service students were beginning to "see the complexities" of the classroom.

The second teacher educator intended to "emphasize the value and importance of anticipating students' thinking" with her pre-service teachers. In this teacher educator's class, the two central issues that emerged were related to anticipating children's thinking and on the interactions between the teacher and the students. For the first issue, the teacher educator directly encountered the difficulties that pre-service teachers have in anticipating children's thinking. The teacher educator had spent a class session focusing on the mathematics of the case study and found that her pre-service teachers had difficulty "thinking about how else middle school kids might solve" this problem. Later, since the case study was only a one and a half day lesson, the teacher educator involved her students in developing the mathematical lessons that would follow, in order to bring out the ideas of "weighted averages." The teacher educator felt that the mathematics of this concept was significant content that her pre-service teachers needed to understand both mathematically and pedagogically. The activity of developing a next lesson revealed to the teacher educator the pre-service teachers' "beliefs in action." She found that they would suggest, for example, that the lessons needed to mix different modes of instruction or types of assessment, but that they could not articulate why this should be done. The pre-service teachers could not articulate "the criteria that they should use to decide what kinds of activities they should use" to develop the mathematical ideas. The teacher educator reflected that she had not anticipated how revealing of the pre-service teacher's thinking this activity would be, that it was very valuable for her to see them engage in this type of planning, and that she was then thinking about how to bring this in as a component in the methods course.

The second issue for these pre-service teachers and their teacher educator was the focus on the interactions between the case-study teacher and the seventh grade students. The same incident of the teacher's interactions with one group emerged as significant. The pre-service teachers sensed that the case-study teacher was more passive in her actions with that group and that she did not pursue or continue with questions. This led the pre-service teachers to speculate as to why that might be. As
with the first teacher educator, this group was not able to come to any definitive conclusion as to the reasons why the case study teacher acted as she did. This then led to a discussion of "what role the teacher might have in the interacting with the students, what kind of information maybe teachers should be keeping in mind and in relationship to her lesson plan." In this way, the teacher educator acted to encourage a level of analysis of the role and the thinking of the case study teacher among her pre-service teachers thereby supporting their development as practitioners who will analyze and reflect upon their decisions.

In the third teacher educator's classroom, the first issue that emerged was that the pre-service teachers were struck by the reflections of the case study teacher. The teacher educator noted that her pre-service teachers found the reflections "very focused and purposeful." One of the pre-service teachers observed that the case study "gave me a more general but paradoxically more specific idea of what goes into effective teaching practices." The teacher reflections in other video-based materials that this teacher educator had used were "generic comments" and "almost in the order of endorsements." In contrast, the reflections in this case study showed reflective, careful planning and the teacher's thinking about what she thought her students were doing. The teacher educator commented: "We teach them [pre-service teachers] about teaching, but we don't actually show them teachers practicing, reflecting, and evaluating." In other words, the artifacts of the teacher's plans and her reflections went beyond what the pre-service teachers had found in other video materials, observation experiences, and readings. For the pre-service teachers, the reflections appeared to provide an important link to the relationship between the planning and anticipation and the actual outcomes of a lesson. As one pre-service teacher wrote: "She provided insights on what she had expected and what actually happened." Another observed that the reflections "let you know what the teacher was trying to do and what the teacher accomplished. It gave you insights into the lesson." Analyzing the teachers' reflections supported the pre-service teachers in understanding how the case study teacher's planning affected the actual lesson.

The second issue that emerged for this teacher educator and her pre-service teachers focused on the complexities of managing small group instruction. The teacher educator expressed the pre-service teachers' recognition of the complexities and their desire to learn more in one student's comment that "I'm going to try to find somebody that knows how to do that so I can watch it more because it looks pretty complicated." The teacher educator found that the case study helped her to reveal the role of the teacher in interacting with small groups. The pre-service teachers came to recognize that the teacher's interactions were purposeful and that this as an explicit role of the teacher: "They sensed that that was a very purposeful thing on the part of the teacher that was made possible because of the careful preparation in which the teacher thought about what she wanted the students to do and thought about the kinds of expectations." At the same time, the teacher educator found that the pre-service teachers were "anxious [because] they didn't know enough yet to do anything more
than appreciate it [the teacher's role]." The teacher educator felt that her students had a greater appreciation of the teacher's role, but since they didn't know enough yet to construct a plan and implement it themselves, many hoped to work in their student teaching with a teacher who did.

In addition to these two issues, the teacher educator reported on the distinctive quality of engagement of the pre-service teachers with the multimedia materials. In addition to the immediacy and the reality of the context, the teacher educator commented that the case study had "incredible depth" and noted that "it takes a long time to unpack it as information and then you have to repackage it into your own thinking for professional training." She anticipated having even better results with her students now that she has experienced the depth of the case study.

**Discussion and Conclusions**

In each of these three cases, the teacher educators and their pre-service teachers focused on elements in the teacher-student interactions in the group situations. With the first group of pre-service teachers, this was accompanied by more tentative judgments about teaching. With the second group, the pre-service teachers began to analyze why the case teacher might be interacting with the students in this particular way. The shift towards tentativeness in judgment on the part of the pre-service teachers and the awareness that their perspective is limited suggest that these pre-service teachers are beginning to appreciate the complexity and difficulty in understanding classroom interactions. With the third group, the pre-service teachers focused explicitly on the complexity of the role of the teacher and the relationship between her plans and purposes and her subsequent interactions with students. The teacher educator in this instance seemed satisfied that an important step had been taken by her students in appreciating the planning, knowledge and skills that enter into effective interactions with groups. However, she also recognized, as did her pre-service teachers, that the analysis of the case study alone had not prepared them to plan and implement effective group interactions. Overall, we see these responses to the case study materials as leading to an appreciation of the difficulties of a teacher's interactions with groups of students and insights into the complexities of the classroom.

The second group of pre-service teachers and their teacher educator focused on the mathematics of the case. The teacher educator found that the pre-service teachers had difficulty in anticipating middle school student's responses and that their own planning for follow up actions was revealing of the limits of their beliefs about teaching. In this instance, the pre-service teachers were not able to move beyond their own actions to articulate rationales for pedagogical strategies. The third group of pre-service teachers and their teacher educator focused on the case-study teacher's reflections. The case study teacher appeared to provide reflections that were more focused and purposeful to the pre-service teachers, moving beyond general reflections. The analysis of the case study supported the pre-service teachers in the recognition and perhaps valuing of reflections tied to specific teaching. The case
study teacher's reflection revealed the link between the teacher's plans and anticipations and the actual outcomes of the lesson.

We make no claims that the analysis of the reflections helped the pre-service teachers become more reflective in their own subsequent practice. Rather, we argue that these instances of analyzing and reflecting on the practice of the case study teacher provided an opportunity for the teacher educator to support the development of pre-service teachers' reasoning about the complexities of practice. The analyses on the part of the pre-service teachers provided the teacher educators with insights into their students' thinking. The case study materials appear to be effective as a resource that provides a site for pre-service teachers to analyze practice while revealing the strengths and limitations of their analyses to teacher educators.

THE CONSTRUCTION OF ABSTRACT KNOWLEDGE IN INTERACTION

Tommy Dreyfus, Holon Academic Institute of Technology, Israel
Rina Hershkowitz, Weizmann Institute of Science, Rehovot, Israel
Baruch Schwarz, Hebrew University, Jerusalem, Israel

We take abstraction to be an activity of vertically reorganising previously constructed mathematical knowledge into a new structure. Abstraction is thus a context dependent process. During group work, peer interaction is an important component of the context. In a previous publication, we proposed a model for processes of abstraction. The model is operational in that its components are observable epistemic actions. Here we use the model to analyse an interview with a pair of grade seven boys collaboratively constructing an algebraic proof. The analysis of the interview reveals subtle links between the abstraction process and the peer interaction.

Abstraction is a central process in learning mathematics; however, it is notoriously difficult to observe. In a previous paper (Hershkowitz, Schwarz & Dreyfus, 2001, referred to below as HSD), we have proposed a model for abstraction that is operational in the sense that its components are three observable epistemic actions. The model considers abstraction as a process occurring in context. Although our outlook is theoretical, our thinking about abstraction has emerged from the analysis of experimental data from the CompuMath curriculum development project (Hershkowitz & Schwarz, 1997). Group work in a computer-rich environment is a prominent feature of CompuMath and thus part of the context for the processes of abstraction we observe. In this paper, we briefly review our definition and model of abstraction (see HSD for a more detailed description), and illustrate them by means of processes of abstraction by an interacting pair of students working on an algebra problem with a spreadsheet.

Mathematics educators have proposed that abstraction consist in focusing on some distinguished properties and relationships of a set of objects rather than on the objects themselves. Abstraction is thus a process of decontextualization. According to Davydov (1972/1990), on the other hand, abstraction starts from an initial, undeveloped form and ends with a consistent and elaborate final form. Similarly, Ohlsson and Lehtinen (1997) see the cognitive mechanism of abstraction as the assembly of existing ideas into more complex ones. Noss and Hoyles (1996) go even further. They situate abstraction in relation to the conceptual resources students have at their disposal and see it as attuning practices from previous contexts to new ones. Therefore, according to Noss and Hoyles, students do not detach from concrete referents at all. Leaning on ideas of these and other authors, we define abstraction as an activity of vertically reorganising previously constructed mathematical knowledge into a new structure. The use of the term activity in our definition of abstraction is intentional. The term is directly borrowed from Activity Theory (Leont’ev, 1981) and emphasises that actions occur in a social and historical context. The reorganisation of knowledge is achieved by means of actions on mental (or material) objects. Such
reorganisation is called vertical (Treffers and Goffree, 1985), if new connections are established, thus integrating the knowledge and making it more profound.

According to this definition, abstraction is not an objective, universal process but depends strongly on context, on the history of the participants, on their interactions, and on artefacts available to them. As abstraction is an activity consisting of actions, our research included the identification of actions involved in abstraction. We focussed on epistemic actions, that is actions relating to the acquisition of knowledge (Pontecorvo & Girardet, 1993). In many social contexts, such as small group problem solving, participants' verbalisations may attest to epistemic actions thus making them observable. The three epistemic actions we identified as related to processes of abstraction are Recognising, Building-With and Constructing, or RBC.

Constructing is the central step of abstraction. It consists of assembling knowledge artefacts to produce a new structure to which the participants become acquainted. Recognising a familiar mathematical structure occurs when a student realises that the structure is inherent in a given mathematical situation. The process of recognising involves appeal to an outcome of a previous action and expressing that it is similar (by analogy), or that it fits (by specialisation). Building-With consists of combining existing artefacts in order to satisfy a goal such as solving a problem or justifying a statement. The same task may thus lead to building-with by one student but to constructing by another, depending on the student's personal history, and more specifically on whether or not the required artefacts are at the student's disposal. Another important difference between constructing and building-with lies in the relationship of the action to the motive driving the activity: In building-with structures, the goal is attained by using knowledge that was previously acquired or constructed. In constructing, the process itself, namely the construction or restructuring of knowledge is often the goal of the activity; and even if it is not, it is indispensable for attaining the goal. The goals students have (or are given) thus strongly influence whether they build-with or construct.

The three epistemic actions are the elements of a model, called the dynamically nested RBC model of abstraction. According to this model, constructing incorporates the other two epistemic actions in such a way that building-with actions are nested in constructing actions and recognising actions are nested in building-with actions and in constructing actions. The genesis of an abstraction passes through (a) a need for a new structure; (b) the construction of a new abstract entity; (c) the consolidation of the abstract entity through repeated recognition of the new structure and building-with it in further activities with increasing ease. We have argued in HSD that this model fits the genesis of abstract scientific concepts acquired in activities designed for the special purpose of learning. In such activities the participants create a new structure that gives a different perspective on previous knowledge. The model is operational: It allows the researchers to identify processes of abstraction by observing the epistemic actions and the manner in which they are nested within each other.
In the remainder of this paper, we will illustrate the model and its use for studying processes of abstraction by an interacting pair of students. For this purpose, we focus on a pair of grade 7 boys who will be identified as Yo and Ra, or collectively as Yo&Ra. These students’ CompuMath algebra curriculum consisted of a sequence of activities, most of them with a spreadsheet, in which they learned to use algebra and the spreadsheet to express generality. On the other hand, they were not asked to justify general properties by using algebraic manipulation. The students usually worked in pairs. In an interview situation, Yo&Ra were presented with an activity that presented a definite potential for abstraction to them. The activity was designed for students from whom the use of algebra for proving properties could possibly be expected but who had never actually done it. The activity was intended to lead students into a situation, in which they felt the need to justify a property whose proof requires algebraic manipulation. Students were asked to investigate properties of rectangles of same type as the following ones:

<table>
<thead>
<tr>
<th>7</th>
<th>13</th>
</tr>
</thead>
<tbody>
<tr>
<td>9</td>
<td>15</td>
</tr>
</tbody>
</table>

After creating (in the spreadsheet) a ‘seal’ that generates such rectangles upon input of any number into the upper left cell, and after discovering and investigating properties of such rectangles, students’ attention was drawn to the difference between the products of the diagonals. When they claimed that this difference equals 12 for all such rectangles (the diagonal product property or DPP), they were asked to justify their claim. The easiest way of justifying the DPP is to use algebraic manipulation and compare \(X(X+8)\) (the expression for the main diagonal) to \((X+6)(X+2)\) (the expression for the secondary diagonal). While reorganising their knowledge so as to arrive at a proof of the DPP, this activity presented two opportunities for abstraction to the students. The first such opportunity is the construction of the extended distributive law \((a+b)(c+d)=ac+ad+bc+bd\): The students had never used that law yet but needed it in the present activity to transform the expression for the secondary diagonal. The second opportunity for abstraction more global in that it concerns the entire proof task, namely the establishment of the general perspective that algebra can serve as a tool for the justification of general properties.

In order to study abstraction by interacting pairs of students one needs to study simultaneous cognitive and social processes: For this purpose, we videotaped and transcribed Yo&Ra's work on the seals activity and then carried out two analyses of the interview protocols, one that analyses the cognition and one that analyses the interaction. Our aim was not to give precedence to either of these analyses, but to carry them out as independently from each other as feasible, and then to compare the resulting patterns.

We first produced a coarse segmentation of the protocol into cognitive segments. Next, we proceeded to two independent analyses. On the one hand, we identified
interaction patterns between the peers. We categorised the students' conversational moves according to their function into six categories to be discussed below. On the other hand, we closely followed the methodology we used in HSD for the identification of the students' epistemic actions. For pairs of students, this identification poses problems, which were not present in the previous study. Because of the subjectivity of the epistemic actions, what is constructing for one student may be building-with or recognising for the other. We classified such cases as constructing for the pair.

Yo&Ra began by generalising the pattern of the seal so that the spreadsheet produces the entire seal from the left upper cell. When asked to find properties of the seal, they found many simple ones and some more complex ones. In particular, they found the DPP and verified it inductively by substituting numbers in the left upper cell of the generalised seal. When asked to justify the DPP, they produced, after some difficulties, the algebraic expressions $X(X+8)$ and $(X+2)(X+6)$ for the diagonal products. They were unable to progress further because they faced the algebraic obstacle of comparing these expressions. The interviewer's suggestion to end the interview triggered the segment Y263-R290, transcribed below, and three more segments, which together constitute a justification of the DPP.

Yo263  *Oh, I know: You can do the distributive law here.*
Int264  *Yes.*
Yo265  *X times 8 plus X times X ...*
Int266  *Yes.*
Yo267  *Here one can do ...*
Int268  *Here I'll write X times 8 ...*
Yo269  *Yes, plus ...*
Int270  *Plus X times X, yes?*
Yo271  *Now, here one can do X times X ...*
Ra272  *...plus X times ...*
Yo273  *... plus X times 6 plus 2 times X plus 2 times 6.*
Ra274  *Why? You are using too many factors!*
Yo275  *No, it's OK.*
Int276  *Yes [writes], don't you agree?*
Ra277  *No, there are too many factors!*
Yo278  *It's correct!*
Ra279  *We already used the ..., I don't understand what the 8 is for, first of all*
Int280  *This?*
Ra281  *Yes!*
Int282  *Ah, yes!*
Ra283  *We have X times X ...*
Int284  *Yes!*
Ra285  *plus X times 6, and then the normal continuation will be X times 2.*
Int286  *X times 2, OK!*
Yo287  *Why X times 2?*
Ra288  *Because I go according to how you do it, then this is X times X, X times 6, X times 2...*
Yo289  *No, this is X plus 2. Look, you do, this is the distributive law, and you do X times X plus X times 6; now you pass to the 2; 2 times X and 2 times 6.*
Ra290  *Ah, logical! I got it.*

Because of space limitations, we analyse only this segment in the present paper, although some of the conclusions we will draw will be partially based on other segments as well. Our main tools of analysis are presented in the following figure:
The analysis will be presented in three stages: Interaction patterns, epistemic actions, and relationships between them.

*Interaction patterns:* At the beginning of the interview Yo and Ra both have the mathematical curiosity and the drive to complete the mathematical activity. In addition, each of them is conscious about his mathematical potential, and likes it to be seen by the other and by the interviewer and even the future video observers. At the same time each of them is quite aware of his friend’s mathematical ability. Both students are assertive and try to convince the other from time to time.

Details of the interaction patterns in this segment are coded in the central part of Figure 1. They show an interaction pattern that is very typical for Yo&Ra. Although the “seen interaction” indicates mostly individual work done by each student, the conclusions are at the end agreed on by both of them. A thorough analysis suggests a quite intensive type of interaction between them: In 263, Yo makes a proposal (category 1) that he elaborates step by step (category 2), while Ra is silent but follows very carefully the proposal and the elaboration. Then (274) Ra starts his elaboration of the same proposal by opposing it (category 4). This opposition expresses his struggle to understand the elaboration, which Yo just completed. Only then Ra elaborates it at his own speed. He completes this process by expressing his agreement with the process (290). During Ra’s elaboration Yo is silent. Each of them has the need to elaborate a given idea in his own way. By remaining silent for a while, each student respects his peer’s need. But both of them reach a point where they refer explicitly to the other’s elaboration and criticise it, until they reach an agreement (category 5). This agreement appears within a collaborative explanation (category 3) of the original claim (Y263, as elaborated in Y273).

*Epistemic actions of abstraction:* In HSD we showed that constructing is a combination of the three epistemic actions where recognising actions are nested in the two others, and building-with actions are nested in constructing actions. Here, we show that the nested model is even more intricate. The constructing action may be quite long and contain shorter segments, which themselves are constructing actions. For example, in the case of Yo&Ra the main constructing action (which we will name C₁) occurs along the entire justification process, and includes the construction of the extended distributive law (which we will name C₂, see the right side of the Figure). C₂ is nested in C₁. Building-with and recognising actions are nested in C₁ as well as in C₂. In other words, constructing actions, like building-with and recognising actions, may be nested in a more global constructing action.

The Figure (right hand side) describes the model for our segment. Level 1 represents the whole process of C₁ (only part of it can be seen in this segment), in which the epistemic actions of level 2 are nested. In the present segment, all level 2 actions are constructing actions (C₂). In other segments, building-with and recognising actions also occur at level 2.
The construction of the extended distributive law starts with Yo's breakthrough suggestion to use the distributive law. The students both recognise the structure of the expression $X(X+8)$ as appropriate to apply the (simple) distributive law. Yo then builds with the elements of $(X+6)(X+2)$ and obtains the correct expansion ($Y_{273}$); in other words, he constructs the expanded distributive law. Although he makes no explicit reference to the simple law, we surmise that the immediately preceding use of the simple law has guided him in building the more complex expression. Now Ra takes over. After being momentarily confused by the many addends, he goes through the same constructing process Yo went through, step by step building up the expanded law with the elements of the expression $(X+6)(X+2)$. This lower level ($C_2$) construction does not occur in the void but as a crucial part of the justification of the DPP. It is therefore nested in the higher-level ($C_1$) construction of the algebraic justification of the DPP.

From the beginning of their struggle to construct the DPP justification, the students are at the level of the $C_1$ construction. On this $C_1$ level their progress is controlled and monitored by their awareness and their need to accomplish the DPP justification. During this process, they face algebraic obstacles, which are quite unfamiliar to them. Overcoming these obstacles necessitates the construction of new mathematical structures, which are the $C_2$ level constructions. These $C_2$ constructions are controlled only indirectly by the motive of the $C_1$ construction. The students enter these $C_2$ level “adventures” without any knowledge about the needed mathematical structures, and they have to discover as well as to construct them. The $C_2$ constructions thus make the $C_1$ level into a deep holistic construction, which goes beyond the specific construction of the DPP justification, and in which the constructions of unfamiliar algebraic structures are nested. In this sense $C_1$ is an activity of vertically reorganising previously constructed mathematical knowledge into a new mathematical structure, which fits our definition of abstraction.

Relationships between epistemic actions and interaction patterns: The Yo&Ra interview is a case of collaboration between the two students. This collaboration finds its expression in the students' cognitive RBC actions on one hand and in their pattern of interaction on the other hand. The RBC flow and the flow of the interaction patterns are developing in parallel. There are no clear causal relationships between the two of them. It rather seems that both of them are different “indications” of the single collaborative process revealed in the interview. Our understanding of this process is dependent on our understanding of both, the RBC flow and the interaction patterns, as well as the relationships between them. In the following we will try to throw some light on these relationships.

Globally, Yo&Ra share the activity, because they share the motives of searching for the mathematical properties of the “seals” and of justifying these properties; they also share the justification processes themselves, as well as their conclusions. We claim that the students constructed a global structure of meaning for algebraic justification (the $C_1$ action, which can be seen only partially in this paper). From the
interaction perspective, there are long-range control (category 1) and explanation (category 3) arrows that can be considered as the "glue" that ties this justification process together. The diagram of the entire process reveals that these long-range interaction arrows are connected to the beginning and/or end of the main cognitive segments. The part of the diagram in the figure of this paper shows a category 1 arrow emanating from the beginning of the segment to an earlier segment, and a category 3 arrow concluding this segment.

Hence, long-range interactions occur between statements that are milestones in the RBC flow. In this sense the interaction pattern has nesting characteristics similar to the RBC flow, where various patterns of interaction are nested in the overall global collaboration. And the cutting edges of the interaction patterns are those that at the same time define the different segments of the RBC flow. In other words, the cognitive segmentation we started out from fits the interaction as well.

REFERENCES

Abstract

The study that is presented here concerns the learning of algebra in a computer algebra environment and, more specific, the concept of parameter. Students of 14 – 15 years old used a TI-89 symbolic calculator during a five week period. They studied the parameter in different roles such as placeholder, changing quantity and generalizer. The results indicate that using parameters in the computer algebra environment requires a clear view on the roles of the different letters. Also, the reification of a formula seems to be important for an appropriate instrumentation.

The research project

The study presented here is part of an ongoing research project called ‘The learning of algebra in a computer algebra environment’. The general research question of this project is:

How can the use of computer algebra promote the insight in algebraic operations and concepts?

This question is specified in two sub-questions:

1. How can the use of a computer algebra system contribute to a higher level understanding of parameters as they appear in algebraic expressions and functions?

2. How does instrumentation of computer algebra take place and what is the role of the relation between machine technique and mathematical conception?

Why parameters?

A reconsideration of algebra education is currently taking place in the Netherlands as well as in many other countries. The transition from the informal, reality-bound algebra at the lower secondary level (students of 12 – 15 years old) to the more formal and abstract algebraic skills that are required at the upper secondary level is difficult for many students in the Netherlands.

The conception of the parameter can be a suitable topic to try to bridge this gap. Variables and parameters are in the heart of algebra. The parameter is an ‘extra’ variable in an algebraic expression or function that generalizes over a class of
expressions, over a family of functions, over a sheaf of graphs. The parameter can be considered as a meta-variable: the \( a \) in \( y = a.x + b \) can play the same roles as an 'ordinary' variable, such as placeholder, unknown or changing quantity, but it acts on a higher level than is the case for a variable. For example, a change of the parameter value does not affect one single point locally, but the complete graph globally. The different roles of the variable are resurfaced, but now at a higher level, and the generic function becomes the object of study. The concept of parameter, therefore, is adequate for enhancing the abstraction of concrete situations, so that the more formal and general algebraic representation can become a natural part of the students' mathematical world.

Why computer algebra?

Taking into account the affordances of technology in general, and the algebraic capacities of computer algebra in particular, it seems obvious to use a computer algebra system (CAS) for the purpose mentioned above. It can serve as a powerful and open algebra environment that allows students to concentrate on the concepts and the problem solving strategy. We conjecture that performing procedures in the computer algebra environment contributes to the development of insight in algebraic operations and concepts such as substitution and the distinction of the different roles of letters. Using the machine, the students don’t have to worry about the calculations and this may enhance a more global conception of the problem solving procedures.

On the other hand, however, computer algebra can be demanding in its use. Guin and Trouche (1999, p. 205) pointed out that an adequate use of computer algebra tools requires making explicit the different roles of the letters to a further extent than is the case for paper and pencil work. This kind of explicitness that computer algebra demands is a burden but in the mean time it can stimulate the student to handle the operations more consciously.

Furthermore, from the perspective of Realistic Mathematics Education the integration of computer algebra is not a trivial matter. In Drijvers (2000) the issue is raised whether the development of informal strategies and the process of vertical mathematization, that are so important in this educational theory (e. g. see Gravemeijer, 1994), are stimulated in a computer algebra environment. As far as the informal strategies are concerned, it seems that the computer algebra environment does not support them. For vertical mathematization the CAS seems more appropriate.

Previous research and theoretical framework

Much research has been done into the concept of variable. Usiskin (1988) classified the different roles of variables as unknown, indefinite, generalized number, dynamical variable and parameter.
Not so many studies have been published on the learning of the parameter. Bloedey-Vinner (1994) stresses the hierarchy of substitution and the implicit quantifier structure that is often involved while using parameters. These 'hidden quantifiers' also are described by Furinghetti and Paola (1994), who state that parameters are conceptually more difficult than variables.

Several studies have been devoted to the use of computers for the learning of the concept of variable. Graham and Thomas (2000) successfully used the graphing calculator to stress the placeholder-role of the variable. Boers-Van Oosterum (1990) also claimed to improve the conception of the variable by using different software packages. Brown (1998) used a computer algebra environment for generalization of patterns, for solving equations step by step and for solving number problems. None of these studies used information and communications technology tools (ICT-tools) for the learning of the concept of the parameter, as is done in the project described here.

An important part of the theoretical framework of this study is the theory of the instrumentation of ICT-tools. Following Guin and Trouche (1999) and Lagrange (1999), we consider the development of instrumentation schemes as a crucial and non-trivial step in the appropriation of an ICT-tool. In the acquisition of such schemes, technical skills and mathematical conceptions are interwoven. Examples of this complex relationship can be found in Drijvers & Van Herwaarden (in press).

A second part of the theoretical framework concerns the dual character of mathematical concepts, that have both a procedural and a structural aspect. Sfard (1991) uses the word reification for the gradual development of a process becoming an object. In the function concept, for example, the process of calculating function values may develop into the image of a function as an object that is represented by a formula or a graph. Sfard and Linchevski (1994) elaborated this for the case of algebra. Close to the idea of reification is the encapsulation that is described by Dubinsky (1991). Dubinsky states that encapsulation of processes into objects is an important step in reflective abstraction. He suggests that performing processes using a computer may stimulate its encapsulation. As a third means of representing the bilateral nature of mathematical entities we mention the procept that has been developed by Gray and Tall (1994). 'Procept' is a contamination of process and concept. The authors stress the flexibility that learners of mathematics need in order to be able to deal with the ambiguity of mathematical notations. In 3+5, the + may be an invitation to perform the process of addition, whereas in a+b the + is only a symbol that defines the object 'the sum of a and b'.

It is our conviction that the theories of reification, encapsulation and procept are very relevant to the learning of algebra and to the instrumentation of computer algebra tools. For the students, the mathematical entities in such an environment may tend to have a structural character, whereas the processes are more distant to the objects than is the case with work using the traditional paper-and-pencil.
Research design and methodology

As a research paradigm, the developmental research method was used (see Gravemeijer, 1994). According to this methodology, the researcher tries to develop (local) instruction theories by means of constructing and developing thought experiments and educational experiments in the classroom situation. This involves a cumulative process of consideration and testing.

The research method was mainly qualitative. The most important data consisted of audio recordings and field notes of classroom observations, audio recordings of mini-interviews with students, and written work of the students. The data were analysed by coding the classroom incidents and solution methods according to previously defined categories. While doing so the most dominant categories came up clearly.

Development of the didactical scenario

A conceptual analysis of the phenomenon parameter led to the identification of three essential steps in the learning trajectory: the parameter as a placeholder, as a changing quantity and as a generalizer. The table below summarizes these steps. Also, it indicates by means of what kind of activities the students are supposed to pass to the next phase and how computer algebra supports these activities.

<table>
<thead>
<tr>
<th>parameter role</th>
<th>$a$ in $y = ax+b$</th>
<th>graphic model</th>
<th>student activity</th>
<th>CAS function</th>
</tr>
</thead>
<tbody>
<tr>
<td>placeholder</td>
<td>$a$ contains specific values, one by one</td>
<td>one graph, that can be replaced by another</td>
<td>systematic variation of parameter values</td>
<td>solve equations</td>
</tr>
<tr>
<td>changing quantity, ‘sliding’ parameter</td>
<td>$a$ walks through a set dynamically</td>
<td>‘comic’ of the dynamic graph</td>
<td>substitute</td>
<td>animate graphs</td>
</tr>
<tr>
<td>generalizer, ‘family’ parameter</td>
<td>$a$ represents a set, generalizes over situations</td>
<td>a sheaf of graphs</td>
<td>generalization of situations and solutions</td>
<td>graph sheafs solve parametric equations</td>
</tr>
</tbody>
</table>

Classroom experiment: aim and situation

The aims of the classroom experiment were to investigate if the students’ conception of parameter would develop according to the didactical scenario and if computer algebra serves as an aid for this. Also, we were interested in the process of instrumentation of the computer algebra tool with respect to the different roles of the letters involved.
The classroom experiment took place during a five week period in the spring of the year 2000. The subjects were 50 students of 14 – 15 years old, divided into two classes. The students were high achieving in general but not specifically in mathematics. As computer algebra tool the TI-89 symbolic calculator was used at school as well as at home. Each class had four mathematics lessons of 45 minutes each week. Because the students had no previous experience with technology such as graphing calculators, using this type of handheld technology was really new to them. Their knowledge of formal algebra was quite limited. For example, the general solution of a quadratic equation had not been taught so far, so the help of the symbolic calculator was needed in case such an equation was encountered.

Episodes of student behaviour

Classroom observations indicate that it was important that students are aware of the different roles of the letters, especially if there are parameters in the equations. We saw that some students found it natural to use parameters to generalize a relation or procedure, whereas others seemed to be confused by several letters in one expression, each having a different role. The differences between the students were considerably, as is shown in the following episodes, that concern the phase when students use the computer algebra environment to solve (systems of) parametric equations.

John and Rob work at the following assignment:

\[ \text{The two right-angle edges of a rectangular triangle together have a length of 31 units. The hypotenuse is 25 units long.} \]

\[ \text{a. How long is each of the right-angle edges?} \]

\[ \text{b. Solve this problem in case the total length of the two edges is 35 instead of 31.} \]

\[ \text{c. Solve the problem in general, that is without the given values of 31 and 25.} \]

At question c John and Rob wrote down in their notebooks:

\[ a^2 + o^2 = p^2 \]

\[ o + a = s \]

\[ o = s - a \]

\[ a = s - o \]
Then they entered into the TI-89:
\[
solve(o^2 + a^2 = p^2 \mid o = s - a, o).
\]
The wrong letter at the end. The response of the machine was:
\[
0 = -s^2 + 2.a.s - 2.a^2 + p^2
\]
The boys corrected this by solving this a second time, now with respect to \(a\):
\[
solve(0 = -s^2 + 2.a.s - 2.a^2 + p^2, a)
\]
This time John explained the choice for the letter \(a\) at the end:
"You want to know the \(a\)."
This way they found the solution for \(a\) expressed in the parameters \(s\) and \(p\).

John and Rob introduced the parameters themselves and generalized the problem solving strategy of the concrete cases of questions \(a\) and \(b\) without difficulties. Their solution schema did not seem to be confused by the presence of the parameters. However, there were some instrumentation problems at the start that may be related to a limited consciousness of the roles of the different letters.

For others, however, the presence of parameters was an extra complication, as illustrates the following observation of Sandra. The assignment was this time to calculate the dimensions of a rectangle with given perimeter and area. Using the viewscreen Sandra tried to demonstrate to the class how the corresponding system of equations could be solved:
\[
b + h = s
\]
\[
b \cdot h = p.
\]
First Sandra entered a re-written version of the first equation in itself:
\[
solve(b + h = s \mid b = s - h, b)
\]
The machine replied: true.

Rob commented: "She did not use the \(p\), she did not use the second equation."

Sandra changed the command into:
\[
solve(b + h = 20 \mid b = s - h, h)
\]
Before the generalization the value of the parameter \(s\) had been 20, and apparently she felt the need to return to the concrete case. The result, \(s = 20\), is logical but Sandra does not notice that. Then she realises that Rob was right, but she entered \(b + h = p\) instead of \(b \cdot h = p\):
\[
solve(b + h = p \mid b = s - h, h)
\]
The machine replied \(s = p\), which is also reasonable. At the end Sandra entered
\[
solve(b + h = s \mid b = p/h, h)
\]
and that gave the right answer.
Sandra's behaviour gives the impression that the parameters were an extra, complicating factor in the problem solving process. In earlier situations she had shown that she was able to apply this solution scheme correctly in concrete cases without parameters. It is not clear whether she really perceived a formula such as \( b = s - h \) as an object that can be substituted.

**Conclusion**

The conclusion of the above exemplary episodes is that the didactical scenario to use parameters for generalization was confirmed by some of the students such as John and Rob. Computer algebra was helpful to clarify the problem solving strategy. For others, the use of parameters complicates the situation to a greater extent. In order to be able to solve parametric equations, it seems to be important that students are able to perceive formulas as objects. If a formula invites to a calculation process in the eyes of the student, s/he will find a general solution containing parameters hardly satisfying. Some students were able to distinguish the roles of the different letters, whereas others seemed to be confused by the amount of variables.

The conjecture that performing procedures in the computer algebra environment would enhance the understanding of the global mathematical conceptions behind the procedures was confirmed only to a limited extent. Some students did not overcome the difficulties with the instrumentation scheme for solving systems of parametric equations. The equilibrium between paper-and-pencil work and machine work during the instrumentation process may be quite delicate, and we probably did not pay enough attention to the 'traditional' approach. Meanwhile, the teachers reported that they could benefit from the students' machine experience while treating the solution of quadratic equations after the experiment.

As a consequence for teaching, we would conjecture that the development of both the technical and the conceptual side of the instrumentation schemes deserve explicit attention. This can be done by means of student interaction, classroom discussions and demonstrations, so that the instrumentation process gets a more social character.

TAKING THE “FORM” RATHER THAN THE “SUBSTANCE”: INITIAL MATHEMATICS TEACHER EDUCATION AND BEGINNING TEACHING

Paula Ensor
Department of Education
University of Cape Town

This research paper explores the relationship between initial mathematics teacher education and beginning teaching. It describes a longitudinal study which tracked a cohort of seven student teachers through a one-year, full-time, preservice university-based teacher education course and then as secondary mathematics teachers into their first year of teaching in the Western Cape region of South Africa. Qualitative data in the form of interviews, students’ reflective journals and other written materials as well as lecture and classroom observation data were collected over a two-year period. The study found that in constituting their teaching repertoires, beginning secondary mathematics teachers appeared to take the “form” rather than the “substance” of their mathematics method course. They used a number of discrete tasks introduced there, as well as a professional argot, a way of discussing the teaching and learning of mathematics. There appeared to be a disjuncture between the practices privileged on the preservice course, and those used by beginning teachers in mathematics classrooms. A socio-cultural explanation for this is offered which turns centrally on the extent to which student teachers are given access to the recognition and realization rules of “best” practice.

Introduction

It is widely recognized that teachers do not always implement in their classrooms, or at least do not seem to implement, the practices they acquire on teacher education courses. If they draw on these courses at all, they appear to take on the “form” of these rather than their “substance”. This disjuncture has been variously explained: Lortie (1975) attributes it to educational biography and the ‘apprenticeship of observation’; Zeichner and Tabachnik (1981) to school setting; Lacey (1977) to differential engagement by students with their teacher education courses, and Cooney (1985) and Thompson (1992) to a failure to change student teachers’ and teachers’ belief systems. Less commonly, the seeming disjuncture is related to the structuring of the teacher education courses, be they preservice or inservice (although see for example, Borko et al, 1992 and Eisenhart et al).

This issue is an important one, since the entire rationale for teacher education rests upon its ability to prepare students as classroom teachers. In the South African context most particularly, where the educational system is in so many respects dysfunctional, the manner in which teacher education might be used to change teachers’ classroom practice has particular saliency. The professional development of teachers, through both preservice and inservice teacher education programs, is

1 I am grateful to Karin Brodie and Lynn Slonimsky for the formulation of the problem in this way. See Brodie et al. (2000).
regarded as a central pivot for educational transformation.

Inservice and preservice providers attempt to make available to teachers a privileged repertoire, a particular encapsulation of “best practice”. How this is configured clearly varies according to the particular teacher education program on offer, but in all cases the question arises: how are the principles underpinning this privileged repertoire made available to students (or in the case of inservice education, qualified teachers), and to what extent do teachers draw upon it in developing their own teaching repertoires?

The study

These questions provided the focus of a two-year longitudinal study (see Ensor, 1999a, 1999b) that tracked a cohort of seven students through the mathematics method component of a preservice Higher Diploma in Education (HDE) program and then as beginning secondary mathematics teachers into schools. The aim of the study was to provide a theoretical account of the recontextualizing of pedagogic practices by beginning teachers from this mathematics method course. Recontextualizing is a notion drawn from Bernstein (1977, 1990, 1996) and Dowling (1996, 1998), and points to the transformation of discourses as they are disembedded from one social context and inserted into others.

The study was stimulated by a broad theoretical interest in the articulation between sites of practice (such as signaled in the work, for example, of Rogoff & Lave, 1984; Carraher et al, 1985; Lave, 1988; Noss & Hoyles, 1996; Walkerdine, 1988, and others). It was concerned with how privileged forms of knowledge and practice about teaching were made available to student teachers and the extent to which these were used by beginning teachers in classrooms. Drawing on the work of Basil Bernstein (1990, 1996) and Paul Dowling (1998), a model was developed to provide an analysis, from a socio-cultural perspective, of a mathematics preservice teacher education course, of secondary mathematics classroom teaching and the recontextualizing of practices between them.

A variety of data was collected for the purposes of the study. In the first year, I took field notes of sessions of the mathematics method course and interviewed the two teacher educators responsible for it. I also collected a range of materials written by student teachers, such as reflective journals, examinations, and a curriculum project, and I conducted interviews with students. In the second year of the study, I interviewed each of the group of seven teachers four times over the year, and in conjunction with the third set of interviews, video recorded a number of lessons with each teacher on a specific day. I also interviewed the head of the mathematics department in each school, or, where there was no head, a senior mathematics teacher.

From teacher education to classroom teaching

On the mathematics method course, students were exposed inter alia to a range of exemplary mathematics tasks, research in mathematics education as well as
an approach to mathematics teaching that favored visualization and intuition as a gateway into formal, conceptual mathematics. “Relational” understanding was privileged over “instrumental” understanding. Students were given access to a range of resources: teaching resources such as geoboards and geostrips; the use of history in the teaching of mathematics; ideas for organizing classrooms, as well as exposure to issues such as racism and sexism. This privileged approach to teaching was made available through a range of exemplary mathematical tasks, and through explicit discussion. All of the teaching took place in the university context, however, and student teachers did not watch their teacher educators teach in classrooms, nor, whilst on teaching practice, did they gain the opportunity to put their own practices up for evaluation by mathematics specialists. In terms of the way in which the teacher education course as a whole was structured, students were supervised on teaching practice by lecturers who were not necessarily mathematics education specialists.

Over the period of the method course, students were given access to a professional argot, a way of talking about mathematics teaching which privileged, for example, “visualization”, “verbalization”, “relational over instructional understanding” and learners “discovering things for themselves”. A professional argot comprises terms and modes of argument used by members of a profession when either engaged in, or discussing it. Those aspects of the argot that are foregrounded or backgrounded at any point in time, and the level of specificity of the language used, depend on the evoking context. Different features are likely to be foregrounded when discussing with a colleague, for example, than with a layperson. A professional teaching argot provides a student teacher with access to a vocabulary and modes of argument to describe “best practice”. Of significance in the particular preservice course of my study was that this argot was elaborated independently of reference to actual classrooms, and thus embodied potential ambiguity about what practices would, for example, constitute “relational” and “instrumental” understanding.

Use of such an argot can be illustrated by the following comments by a student teacher, Thabo Monyoko. In his teaching practice journal and in an interview at the end of the HDE year, Thabo spoke positively about the mathematics method course, which he described as having effected a "complete revolution" in his thinking about teaching. He said he had been exposed to a new approach in terms of which “pupils come to discover some of the things on their own [...] They actually see how some of the things they do in mathematics is practical and some of the things they discover on their own.” He no longer "monopolized classroom activities", "standing in front like a priest", simply giving the formula "raw from the book" so that "people have got to ram it into their heads [...] In the past I would simply give the formula from the book and give them an exercise and they apply the formula, that's all”. On his second teaching practice he said he tried “to implement some of, you know, the hands-on approaches [...] I remember I implemented some of these self-discovery approaches by pupils, I mean they were very fantastic, they
were very interesting to the pupils and I think my lessons went pretty well, you know.”

These ideas were re-iterated by Thabo when I interviewed him as a beginning teacher the following year. He indicated that the mathematics method course had “turned me around” in that he was now more “responsive to students' needs” and interacted with them more instead of “teaching from the front”. For him, this meant walking around the class and “finding out what pupils were having difficulties with.” This he related directly to lessons which I observed him teach. The following is an extract from the beginning of such a lesson on sequences with Grade 12 students.

T: Let’s say that the sixth term of a geometric sequence is 3125 and the fourth term is 125. Now find the eighth term. [as he speaks, he reads from a textbook and writes on the board.]
   6th = 3125
   4th = 125  Find 8th
[He repeats again, given that the 6th term is 3125 and the 4th term is 125, find the 8th term]
Now because you don’t know the value of a, now remember in a geometric sequence the general term is
   \[ T_k = ar^{k-1} \]  [writes this on the board and speaks as he writes]
Now in order to find any term of a geometric sequence you must first find the value of a and the value of r. When you have a and r you can then find out the term. Now given that the sixth term is 3125 we can write
   \[ T_6 = ar^5 = 3125 \]
Now let’s call this our equation 1 [he writes 1 and circles it after the equation given above]
Now the fourth term is 125. Therefore
   \[ T_4 = ar^3 \] which is equal to [he turns his head to the class and cocks his head in expectation of a response. Someone says 125] 125. OK we’ll call this equation 2
(Thabo: extract from transcript of recorded lesson 2)

Thabo continued in this relatively unbroken expository style to solve two simultaneous equations on the board. At one point he turned to ask a student to check a calculation. When he completed the solution to the problem, he turned to the class, and for the first time and ten minutes into the lesson, he asked students by name if they had any problems: “Mr. Nzo, Nyamende, Zola?” He then proceeded to solve another problem on the board. Again, students were required to listen and take notes. Occasionally he posed a question, normally to ask students to calculate for him. After his explanation, he chose a question from the textbook for students to try on their own and walked around the class, discussing with the students in Xhosa and English.

Two interesting issues emerge from this brief discussion of Thabo’s practice.
Firstly, there appears to be a variation between Thabo’s preferred teaching style and that privileged on the method course, as well as a variation between what he said about his practice and how he actually worked in the classroom. In discussing the lesson afterwards, Thabo pointed to his use of questions, and his circulation around the class towards the end of the lesson, as evidence of the practices he had acquired from the mathematics method course. For him, there was no disjuncture between this course and his own practice, and between what he said about his practice and the way in which he actually taught. Yet, what Thabo said, both as a student and as a teacher, appears to be at variance in both these ways, a variation which was evident across the interviews and classroom practices of all seven beginning teachers. All seven teachers used discrete tasks (exemplary mathematical tasks and pedagogic resources made available to them on the course) and a professional argot of varying range. Teachers tended to deploy this argot, descriptions such as “verbalization”, “visualization” and “self discovery”, in ways consistent with their own practice. Thabo, for example, drew on the professional argot (“not teaching from the front”, and facilitating “student interaction”) to describe his teaching style, which was in many ways different to the approach developed on the course. So from the viewpoint of the teacher education course, it would seem that Thabo was saying one thing and doing another, taking its “form” rather than its “substance”. Yet from Thabo’s vantage point, this was not necessarily the case. He had acquired a professional argot and turned it to his own purposes. The ambiguity associated with the transmission of the privileged repertoire made this possible, an issue which I will return to below.

All seven beginning teachers recontextualized a small number of discrete tasks and a professional argot from their HDE method course. However, in interviews with them and in observation of their lessons, I found that they were not able to demonstrate access to the principles of selection, production or evaluation which underpinned this course. For example, they said they could not produce tasks like those introduced on the course, tasks which encapsulated its particular, privileged view of mathematics teaching, and they found it difficult to evaluate their practice in the ways that the teacher educators might do. Putting this differently, I would suggest that these teachers had gained partial access to recognition rules (they could describe aspects of “best practice” via the professional argot, in the ways the teacher educators did) but not realization rules (they were unable to produce tasks themselves which were consistent with the principles underpinning the method course).

Recognition and realization rules

Bernstein (1990) distinguishes between recognition and realization rules in the following way:

Recognition rules create the means of distinguishing between and so recognizing the speciality that constitutes a context, and realization rules regulate the creation and production of specialized relationships internal to that context. (Bernstein (1990), p. 15

PME25 2001
Bernstein elaborates these rules as part of his code theory. The present analysis is differently motivated methodologically but the distinction Bernstein makes can be related to the present project. Here we are interested in the extent to which student teachers are given access to both recognition and realization rules, for how “best practice” is to be recognized and how it is to be realized in practice. In the sense in which I am using these terms here, access to recognition and realization rules enables appropriate use of a professional argot (that is, its use as the teacher educators might use it) as well as its realization in practice. Access to recognition rules alone provides students with the ability to differentiate "best" from "poor" practice and to describe “best practice” discursively.

As illustrated above, Thabo demonstrated only partial access to recognition rules in that he used the professional argot largely inconsistently with the forms of “best practice” privileged on the mathematics method course. He was also was unable to demonstrate access to realization rules. I have suggested that these issues of access are related to the structuring of teacher education as a form of knowledge.

**Teacher education: knowledge forms and pedagogic modes**

Teacher education can be regarded as a hybrid of explicit, discursive practices (exhibiting what Dowling, 1998, terms *high discursive saturation*) and implicit, tacit practices (exhibiting low discursive saturation). Highly discursive practices are relatively context independent and can be realized to a substantial degree in language, while tacit practices are more context-dependent, and less easily grasped linguistically. Mathematics teacher education can be thought of as making available to student teachers a form of “best classroom practice” which comprises both explicit and tacit elements. The principles of selection, production and evaluation which underpin “best practice” can therefore be made available explicitly, through language, but not exclusively so. To become a teacher, one needs to watch teachers teach, teach oneself and open one’s efforts up for evaluation. Just as the crucial aspect for the transmission of discursive practices is that the generative principles of the privileged repertoire are made explicit in language, the crucial aspect for the transmission of tacit practices is that they are made available and acquired in the site of practice, the school classroom, through demonstration and correction. While it is productive to speak to student teachers or teachers about “best practice”, we also need to show them what this means, in actual classrooms, and allow them to put their own practice up for evaluation. This provides the basis for acquiring recognition and realization rules.

In the case of my study, students were exposed to “best practice”, described

---

2 Cases have been used in interesting ways in teacher education (see for example Merseth, 1996). I would suggest that while the discussion of cases outside of classrooms can effectively provide access to recognition rules, access to realization rules requires this engagement (see Pi-Jen Lin, 2000).
in part above, exclusively in a university setting. As I have said, because of the way
the HDE as a whole was structured, students did not observe mathematics teacher
educators teach in classrooms, nor teach in classrooms themselves and have their
performance evaluated by mathematics teacher educators. So while students were
able to gain some access to discursive aspects in the university setting, the more
tacit, implicit aspects, those which required elaboration and exemplification in
classrooms, were not made available. The professional argot was thus invested with
considerable ambiguity, and teachers were able to use it to describe practices that
were in many ways quite different to those privileged on the preservice method
course.

Conclusion

In this paper I have briefly described a longitudinal study which explored the
relationship between initial teacher education and classroom teaching. All seven
beginning teachers in the study took from the course a professional argot and a
range of discrete tasks (or, as some would suggest, its “form”) rather than working
independently with its underlying principles (its “substance”). This variation is
commonly explained in research literature on the basis of educational biography and
school setting. I have suggested elsewhere (see Ensor, 1999a) that school settings
produced constraints on the teachers of my study in terms of how they developed
their teaching repertoires, how they taught, and the extent to which they drew on
their preservice course in doing this. School settings, however, did not seem to
constrain teachers in a simple or obvious way, and did not appear to be decisive in
shaping the recontextualizing of pedagogic practices for the teachers of my sample.
A further factor which antecedent literature suggested might be important in shaping
the development of teaching repertoires, that of educational biography, was also not
decisive. What seemed overwhelmingly to affect recontextualizing was access to
recognition and realization rules. Access to recognition and realization rules
expands the range of tasks and approaches that teachers can draw on and provides
the possibility for the production of new tasks and pedagogic choices. In the case of
my study, lack of access restricted the recontextualizing potential to
tasks actually
encountered by students on the initial teacher education course and a professional
argot which teachers deployed selectively, and not always appropriately, to describe
their own practice.

This paper has been concerned with why teachers appear to practise
differently in their classrooms from the ways privileged on the preservice and
inservice courses they attend, and from the ways in which they speak about them. I
have attempted to offer a possible reason for this in the particular structuring of
teacher education discourse and its modes of pedagogy. Insofar as teacher education
occurs exclusively in a site removed from that of classroom practice, it is difficult to
make available fully the principles, the recognition and realization rules, that
generate any particular view of “best practice”. Instead, the latter will stand as a
collection of resources for potential, selective recruitment by teachers in forming
their individual teaching repertoires. For this reason they may appear to appropriate the “form” rather than the “substance” of best practice.

Abstract

Most Intelligent Tutoring Systems (ITS) have remained research tools and have not succeeded in bridging the gap from the laboratory to the school. The Guided Autonomous Learning System (GALS) is a new ITS model that is grounded in a substantiated model of learning, that would provide diagnosis and adapted remediation of errors, while at the same time paying attention to environmental factors and User-Machine Interface. GALS has been applied to a primary school mathematics program that is currently in use in Israeli classrooms. The paper presents the principles underlying the development of the GALS model, and describes the results of its experimental implementation in Grade 1 classes.

Introduction

When the concept of Intelligent Tutoring Systems (ITS) was first proposed, great hopes were raised that efficient models would be developed and implemented in schools (Murray, 1999). In fact, however, only a few such systems have transcended the confines of research models and have actually been implemented in classroom settings (Urban-Lurain, 1995). According to Rosenberg, two main reasons explain the lack of use of ITS in actual education:

1) “The systems are not grounded in a substantiated model of learning”.
2) “Testing is incomplete, inconclusive, and in some cases totally lacking” (Rosenberg, 1987).

Although it is clear that a good ITS must be able to handle student errors, Rosenberg points to the models by Burton and Anderson (Burton, 1982 and Anderson, et. al 1985) and asserts that “an exhaustive enumeration of error types is not a model” (Rosenberg, 1987, p. 8). He also argues that “lists of error types are only part of the raw data for a model of tutoring. Unanalysed listings do not illuminate the tutoring process.”

The following paper presents a model of a new ITS, that is indeed grounded in a model of learning, and includes diagnosis and remediation tools. This didactically-based ITS has been implemented in the study of mathematics in primary schools in Israel, and the results of its classroom use will be described. At the time of this writing, the GALS ITS is being used by more than 2,000 Grade 1 students.
The Guided Autonomous Learning System (GALS) ITS Model

As early as 1973, Brown noted the positive synergism that could result from combining the power of the new computers and advances in computer languages with research in didactics (Brown, 1973). For this reason, the new GALS ITS uses object-oriented programming and multimedia resources and we incorporated findings from didactic research in its design.

Anderson asserts that “cognitivism does not imply outright rejection of decomposition and decontextualization” (Anderson, 2000). The GALS model applies two basic principles stressed by Anderson:

1. “Assessing learning and improving learning methods requires careful task analysis at the level of component skills, intimately combined with study of the interaction of these skills in the context of broader tasks and environments” (p.3).
2. “Assessing learning and improving learning methods requires research and instruction in contexts that are consistent with the scopes of the skills currently under investigation.” (p. 4).

The GALS mathematics curriculum for first grade is comprised of more than 200 activities, each of which deals with one central concept. These activities are arranged in ascending order of difficulty, from the most simple to the most complex. The GALS model was first applied to mathematics rather than to other disciplines because the structure of mathematics enables the development of a logical program structure (Suppes, 1967).

Open models, such as simulations, play a very important role in the learning process; however, it is very difficult to deal with diagnosis and remediation in an open environment. For this reason, the GALS model, in which every activity has a well-defined goal, includes the following types of activities:

1) “Open-ended” activities, i.e. activities that can be approached in many ways and have more than one correct answer;
2) “Semi-open” activities, i.e. activities that have a goal, but which allow students to work in the way that they want;
3) “Closed” activities, i.e. activities that have a goal and only one way to reach it.

The inclusion of open-ended, semi-open, and closed activities in the GALS model enabled the integration of powerful diagnosis and remediation tools.

Each activity in the GALS model begins with an explanation that teaches the students a basic concept for the first time or reminds them of a concept that they have learned previously. The computer then demonstrates how the interface for the specific activity works (e.g. “just click,” “draw,” “select,” etc.). Following the demonstration, the student is asked to solve the identical exercise that the computer solved. Contrary to what one might expect, we did not find that students in such situations simply imitate without understanding; rather, it was found students who were not truly ripe for an exercise were not necessarily able to repeat the demo. An explanation for this can be found in the assertion in Vergnaud’s book on Vygotsky: “We can only imitate what lays in the zone of our own intellectual capacities” (Vergnaud, 2000, p. 28).
After the student solves the first exercise, s/he is presented with 2-7 similar exercises. These exercises are generated by the computer pseudo-randomly, such that two different students working on the same activity simultaneously receive different exercises, and students who do the same activity twice encounter different exercises. If the student solves an exercise correctly, s/he receives a funny animation, gets a green light, is awarded points, and is automatically presented with the next exercise.

Behaviorist models, which consider students to be a “black box,” resulted in major failures (Hativa, 1988). For this reason, any new ITS models should integrate an analysis of frequent errors and misconceptions, and should be able to deal with the reasons that underlie those mistakes. In addition, new ITS models should provide assistance and remediation built on mental models.

The strength of the GALS model is revealed when a student makes a mistake. For each concept presented in the program, the developers reviewed common mistakes and determined prevalent misconceptions. They then built state-machines that diagnose each foreseeable mistake. Findings of research regarding errors in specific domains were incorporated when available (e.g. Brown, 1978; Van Lehn 1982; Gray, 1994), and when there was no existing body of findings, research was conducted in order to map common errors.

As mentioned previously, it is not sufficient to know what the frequent errors are; rather, it is necessary to have a plan of action for instances in which errors of this nature are encountered. For example, the mistake most commonly found in response to the exercise “3 + __ = 8” is the answer “11”, i.e. the student adds 3 + 8 instead of determining the missing number (Conne, 1988). What should be done when a student makes such a mistake?

Cox has noted the need for an appropriate teaching method for providing remediation for specific errors: “Research on what teaching methods are appropriate for remediating specific errors are almost inexistent” (Cox, 1975).

Two basic approaches to correcting specific errors can be described:

a. The Piagetian “accommodation-assimilation” model: In simple words, if a learner makes a mistake in a given problem, he must abandon the algorithm applied and construct a new one that better fits the situation. This process is called “assimilation.” If the new algorithm works, the learner records the match between the algorithm and the situation, and correctly applies the algorithm upon encountering similar situations in the future. This is known as “assimilation” (Siegler, 1991). If we apply this model to our case, the appropriate remediation would be to inform the student that he made a mistake (e.g. by saying “you made a mistake,” “you’re almost there,” or “try again”) and to then allow him to build a new algorithm and to assimilate it.

b. The “private tutor” model: According to Anderson, a private tutor who is faced with a student who makes a basic mistake will commonly respond by simply teaching the concept again.

The basic problem with incorporating the Piagetian model is that many students are not bothered by the fact that their algorithm does not work when applied
to a specific problem; moreover, even if they are bothered, they often are not capable of constructing a new algorithm independently. The “private tutor” model of remediation is also problematic, in that students do not build their knowledge base by themselves if they are simply taught concepts again. Consequently, the GALS model developed an alternative method of responding to errors, which falls between the two models described.

Using Vygostky’s principle of a “zone of proximal development” (Vygotsky, 1986), the student’s mistake can bee seen as an indication that s/he is having difficulty “climbing the step” that leads up to the new concept. In such situations, students should be given a “stool” that is appropriate to their specific problem, so that they can “climb the step” by themselves. In our design of the GALS model, these “stools” took the form of “hints” that were carefully constructed based upon an analysis of the causes of common mistakes and misconceptions, and that give a basic adapted remediation.

Thus, for example, in our case of the mistaken response to the equation $3 + \_ = 8$, most students who had difficulty did not understand the order of the equation. They saw the 3, the plus sign, the 8, and the equal sign, and they simply solved the equation $3 + 8 =$, perhaps wondering if the teacher who wrote the exercise was feeling quite right. In response to such a mistake, one simple but efficient hint could be: “3 plus 11 does not equal 8” (which points out that student did not arrive at the correct answer). Similarly, the hint could be phrased “3 plus what equals 8?” (which explains the order of the equation). After receiving the hint, the student could then be given a second chance to solve the exercise.

If the student fails again after receiving a hint, GALS implements a method close to the “private tutor” model and presents the student with the solution, but only after explaining to the student what is wrong with the answer. (It is important to note in this context that since the exercises are generated in real-time, the hints and corrections are also generated in real-time by powerful engines.)

This method of remediation proved to be very efficient. For most students, the hint (and if necessary the full explanation) was sufficient to enable them to build a correct algorithm. However, occasionally it was found that students were unable to build a correct algorithm despite the fact that they received help and were shown how to solve this type of problem. As described below, the GALS model’s “Learning Manager” deals with such cases.
The Learning Manager

Lepper and Gurtner’s presentation of the advantages of computers as personal tutors included the fact that computer programs can be individualized for learners with different skills and capabilities (Lepper and Gurtner, 1989). In the GALS model, at the beginning of the school year, each student begins the program with the same first activity (albeit with different generated exercises). If she succeeds in the activity, she gets the next one, and so on, following the order of the decomposition of the program in basic units, which each deal with one specific concept.

One might think that the students would all proceed through the program in a common, linear path; in fact, however, no two children ever followed the same course through the program. This is because if a student encountered difficulties in an activity, the “learning manager” would send him to a revision activity that would have him complete all the prerequisites for the activity in which he failed. This revision activity could either be an exercise that the student had completed previously or a special remedial activity that would only be encountered by students experiencing difficulty. Conversely, students whose performance was found to be very good are sent by the “learning manager” to special activities reserved for students with high levels of achievement.

Although in most cases, the learning manager and the expert systems for each activity enable students to bridge the knowledge gap and move ahead, occasionally a given student still does not master a specific concept. In such cases, the teacher receives a special report that lists the students who experienced pronounced difficulty, as well as the specific difficulties of each student. This enables the teacher to provide appropriate remediation that is focused on the specific problems of specific students, and even to directly access the computer activity that revealed the student’s difficulty.

User-Machine Interface

According to Lepper and Gurtner’s outline of the advantages of computers as personal tutors, the computer always remains patient, nonjudgmental, and supportive. Moreover, because the computer is always fair and impartial, it may minimize the pernicious effects of teacher prejudices or favoritism (Lepper and Gurtner, 1989). For this reason, effort was made to build a user-friendly interface, to create a program that is both patient and funny, to determine objective criteria of success, and to be sure that the interface includes a dynamic adaptation to each learner.

The Experiment and Implementation in Schools

In 1998, the Israeli Ministry of Education appointed a commission to supervise an experiment that has been conducted by an independent professional team. During the first year of this experiment, the GALS-based program was utilized in Grade 1. In each of the following years, participating students moved on to the next grade of the program, while new students began the program at each grade. At the present time, more than 800 students are participating in the experiment. In addition, at the start of
In the 2000-2001 school year, the program became commercially available to Israeli schools, resulting in its current use by over 2,000 first grade students.

Beyond the computer program with hundreds of multi-media challenges, the computerized GALS-based math program in use in Israeli schools today is accompanied by a set of tools that includes student workbooks, ready-to-use exams, enrichment worksheets, manipulatives, and a teacher guide with suggestions for hundreds of discovery activities that can be done by groups or individuals. Students using the program spend an average of one class hour a week on the computer. The learning manager tracks the progress of each student, and teachers receive reports about the achievement of the class as a whole as well as the about the performance of individual students.

**Results**

The main results found by the independent professional team have been the following:

1. A comparative summative test of achievement of first grade students showed significantly better achievement (p<0.001) in the research group (10 classes, 217 students) than in the control group (10 classes, 211 students).

2. The integration of computer technology in the learning process was proven to contribute greatly to student achievement.

3. Most students mentioned the integration of the computer as the main factor of satisfaction of the program.

4. Both teachers and students reported a high level of satisfaction with all the parts of the program.

5. In the GALS program, students receive explanations each time they do not succeed in an activity. In this manner, beyond its role as a mechanism for practice and as a diagnostic tool, the program serves primarily as a teaching tool that enables the students to correct their mistakes and to understand the reason of their failure.

6. In many cases, it was found that the computerized activities presented students with concepts that had not yet been covered in class; nonetheless, the explanations provided by the program enabled the students to succeed in these activities. In addition, it was found that students who were exposed to concepts for the first time on the computer succeeded in the parallel textbook activities without needing additional explanations.

7. Students who encountered problems in a specific activity usually received efficient help and corrections, and were able to succeed and to move on to the next activity.
8. Most students succeeded in all the activities either after their first attempt or upon returning to the activities after being given additional remediation activities.

9. It was found that almost no random answers were given by the students.

10. Teachers reported that the software provided weak students with a learning experience that allowed them to remain “tuned in” during the lessons. This was not found to be the case with such students in previous years (Milgrom, 1999, Milgrom, 2000).

It should be noted that following the initial experiment, the Israeli Ministry of Education recommended pursuing a three-year trial and committed itself to continuing support for the program’s development.

Conclusions
These results seem to indicate that an Intelligent Tutoring System grounded in a substantiated model of learning can efficiently be used in classrooms settings.

More data about the effectiveness of the GALS model are expected to be available at the summative evaluation stage of the ongoing experiment, and could be validated in the course of a new experiment that has begun this year with first grade classes in France.

The Guided Autonomous System (GAL) model could be applied to the study of mathematics in higher Grades, as well as to other subject matters.

This paper is devoted to the problem of the interpretation of mathematical texts. Some ideas on mathematical language are shortly discussed with the help of some constructs from functional linguistics. Some evidence regarding the interpretation processes of a symbolic text by groups of 10-graders, including both written answers and the transcriptions of spoken interactions is presented and discussed. The outcomes of this study show that students often try to interpret mathematical statements according to everyday-life schemes. This suggests that in school practice mathematical expressions should be dealt with as texts (rather than as abbreviations or local conventions) and that metalinguistic awareness should become one of the goals of both linguistic and mathematical education.

Recently various theoretical frameworks have been diffused that enhance the role of languages in the learning of mathematics. This holds specially for the neo-Vygotskian standpoint, which gives great value to communication as a way to promote learning. More recently, in investigations more focused on cognitive aspects, Sfard (2000a, 2000b) interprets thinking as communication and assigns to languages a more complex role than the traditional one: they are not regarded just as carriers of (pre-existing) meanings, but as builders of the meanings. In a context where communication becomes central, it cannot be regarded but as "an activity in which one is trying to make his or her interlocutor act or feel in a certain way", i.e. an activity pertaining to the realm of pragmatics too. A thorough investigation of the languages of mathematics from the standpoint of pragmatics is far from being developed. Some example of application of pragmatic constructs to the learning of mathematics, such as Grice’s Cooperation Principle, may be found in Ferrari (2000). Morgan (1996, 1998) and Burton & Morgan (2000) have carried out investigations on mathematical language from the viewpoint of Halliday’s functional linguistics. They focus on some interpersonal aspects of mathematical language (such as the use of impersonal forms in academic mathematics textbooks) but take into account some aspect which are interesting from a cognitive

---

1 Through the paper the word ‘text’ is used according to linguistics to mean any spoken or written instantiation of language, independently from its length or complexity.

2 Grice (1975)

3 Halliday (1974, 1985)
viewpoint as well, such as cohesion\(^4\). In particular Morgan (1998) provides a general description of mathematical language as a set of registers as they are used in mathematical practice (rather than as they are usually accepted by mathematicians) which seems adequate to the needs of research and practice. The use of expressions like ‘mathematical language’ through this paper assumes Morgan’s definitions and discussions. The new functions of mathematical language in education require researchers and practitioners to consider it as a complex system, taking into account all its components (verbal, symbolic, visual, ...) that very often are combined. Ordinary languages and mathematical one are different as regards not only the symbolic or the visual component, but the verbal one too. In the new perspective the verbal component cannot but play a crucial role. Still, the symbolic component has played a major role in the development of mathematical thought and may play an important role in mathematics education. A thorough discussion of the functions of the symbolic component is far beyond the aims of this report. Symbolic notation systems are not important just because they are possibly more precise or less ambiguous than ordinary languages, but because of the computational opportunities they provide. Moreover, they allow people to get rid of some of the meanings embodied in everyday-life words, when it is necessary to build new meanings.

An important feature of educational pratice in mathematics is the need of using the same linguistic forms with different functions: to build and organize mathematical knowledge and to communicate with other people, their experiences and cultures. This plurality of functions may generate conflicts. For example, in contemporary mathematics, it is perfectly acceptable to name ‘rectangle’ a square shape, whereas this use is inadequate in some contexts as far as it violates pragmatic conventions, such as Grice’s Cooperation Principle. In a similar way, in some cases, logical connectives (and, or, if...then, not, ...), no matter whether in verbal or symbolic form, are to be used according to their truth-functional definition (for example, when defining set-theoretical operations), whereas in communication practices within the class they are required to play functions that go far beyond truth-functionality, such as the organization of the texts and of the links between the sentences that occur. If the understanding of texts in mathematics becomes a goal for education, then students have to deal with texts with different format, organization and functions almost at the same time. Different kinds of text may propose different interpretative problems. For example, some of the questions raised by Sfard (2000b) as concerns discursive focus\(^5\) are appropriate. A good share of

\(^4\) According to Halliday (1985, p.309) ‘cohesion’ refers to non-structural resources designed to establish relations within the text that are not only semantic but also functional.

\(^5\) In linguistics various constructs (such as theme/rheme, topic/comment, given/new, ...) have been proposed to deal with these issues. For detailed discussions see for example Halliday (1985) or Leckie-Tarry (1995).
the misinterpretations of texts by college students, for example, are related to failure in
the grasping of the focus of the text as a whole rather than in the interpretation of single
words or expressions. This may depend from the fact that often in mathematical texts
focus is not marked in the same ways as other texts. A closely linked question is
cohesion, i.e. the functional links among the various components of a text. Cohesion in
mathematical language (in all its components) is usually less explicitly marked than in
ordinary language, which may be an obstacle to students’ interpretations.

This study is devoted to the ways some groups of 10-graders interpret a text made up of
three symbolic expressions. We are interested in the ways students put together the
occurring expressions and the interpretation schemes they adopt when the expected
interpretation is not adequate from the standpoint of communication.

INTERPRETATION OF A SYMBOLIC TEXT
The following problem has been given, in December, 2000, to four classes of 10
g graders.

PROBLEM\textsuperscript{6}
The positive integers \( x, y \) are given. We know that all of the three following properties
hold at the same time

\begin{align*}
(a) \quad x^2 &< y^2 \\
(b) \quad 3x &> y \\
(c) \quad x^3 &> 10^6
\end{align*}

Based on the given data, for each of the following statements find whether it is true or
false:

\begin{align*}
(i) \quad x &\leq y \\
(ii) \quad 2 &< y
\end{align*}

Explain your answers.

A PRIORI ANALYSIS
This problem includes various critical points. First of all, there is the interpretation of
\( \leq \) in a true statement which violates pragmatic principles. A potential obstacle is the
interpretation of inclusive ‘or’ in a statement which is of the form ‘A or B’ with A
clearly true and B clearly false, which violates elementary pragmatic principles such as
Grice’s Maxim of Quantity, for ‘A’ alone would be less expensive and more
effective from the viewpoint of communication. Also the coordination of (a) and (c) may result
troublesome for a number of students. At this regard it must be remarked that cohesion

\textsuperscript{6} The original texts of the problem, of students’ answers and of the transcriptions of their spoken
interactions are in a language other than English. Some of their linguistic features are lost in the
translation process. For example, we are afraid that the English translations of the texts produced in the
interactions are not in the same register as the original ones. Nevertheless, in this paper we investigate
aspects which are not too much affected by the translation. Anyway, the original versions of the
materials are at disposal of anyone interested.
among (a), (b) and (c) is explicitly pointed out (at the meta-textual level) in the preceding verbal text ('all of the following ...', 'at the same time', 'based on the given information'), but this may be not enough, since neither specific algorithms nor standard linguistic markers are available. The problem has been designed in order to prevent students from applying some standard algorithm with little control, forcing them to use methods based on the interpretation of the given statements.

METHODOLOGY
The problem has been given to 4 classes of 10-graders (76 students altogether). Students have worked about 30' individually (producing written answers) and other 30' in small groups (2-3 students of different skill levels). Copies of their written individual answers were available to students during the interaction; the work of all the groups of one class has been recorded. We present some quantitative data on the whole sample and investigate the behavior of one group of 2 students more closely. Of course, the data of the first kind are gathered from texts actually written out by the students whereas the others are transcriptions of spoken interactions.

INDIVIDUAL ANSWERS
Question (i)
57 students claim that (i) is false, 16 that it is true and 3 give no answer. Negative answers mostly refer to the fact that "it cannot happen that x=y". Some other students are puzzled by the occurrence of '≤' in (i), whereas in the data occur '<' or '>' only.

Question (ii)
44 students claim that (ii) is true, 11 do not answer, 8 claim that it is false and 13 claim they have not data enough to give a definite answer. Altogether 21 students seemingly do not recognize the links between (a) and (c). Moreover the number of non-answers is larger than in question (i). Most of the answers to (ii) have been given with no explanations. Among the explanations given we mention: "I cannot know if 2<y, it depends on the values of x, y" or "I have no data on y" or "2<y is false because if x=1, then y could be 2".

Let us see some more examples.
Valentina answers to (i): "False because x is never equal to y", whereas to (ii) answers: "x>100 (c), x<2y (a) ⇒ y>2, since x, y are positive"

Ivano: "(i) is false because √x^2 < y^2 = x < y , (ii) is false too because y could be 2; if (ii) were with '=' it would be true"

Andrea: "(i) is false, because in (a) there is < whereas in (i) there is =. I do not know whether (ii) is true or false because I have data on x and not on y"
Sergio: "(i) is false. \( y = \sqrt{x^2 + k} = x + \sqrt{k} \) but this do not imply \( 2 < y \)"

Deborah: "(i) cannot be, because in the hypothesis there is \( x^2 < y^2 \); if it were \( x^2 \leq y^2 \) it would be true. (ii) is true"

Enrica: "(i) is false because \( y \) cannot be equal to \( x \) because if I square both they would be still equal; (ii) is true because else \( x \) would be less or equal to 1 and the third piece of information would be false"

It is noteworthy that among the 'improper' answers to (i) a good share are explained quite clearly (showing some command of mathematical notations), whereas it is difficult to find well explained answers to (ii). Moreover, no student refers to (b) in his or her answer to (i) and (ii).

INTERACTIONS

Let us examine the transcriptions of the interactions of the group made up by Valentina (a girl with excellent grades in all subject matters including mathematics) and another girl named Ines (rated at average level).

Valentina: "The first is false because \( x \) cannot be equal to \( y \"

Ines: "If the square is less, the number too is less"

V: "Hmm, here there is 'less or equal'

I: "It is the same!"

V: "It is not equal!"

I: "But it works all the same!"

V: "Why am I to write 'equal' if it is less?"

I: [a bit vexed] "Oh, it is like the elevator: there is 'Maximum weight three hundred kg' but you take it even when you are alone. [laughing] You do not weigh three hundred kg!" [Valentina is small and slim]

V: "Of course not. Maybe you are right. The second is true."

I: "We have no information on \( y \"

V: "The cube of \( x \) is ten to the sixth. So \( x \) is equal to one hundred. If \( x \) is at least one hundred, \( y \) must be one hundred one, at least."

I: "\( y \) could be one and the statement would be false"

V: "If \( y \) were one, \( x \) would be zero, the cube of zero is zero"

I: "It could be: [points at the occurrences of \( x \) and \( y \) in (a), (b) (c)] \( x \) is zero, \( y \) is one, \( x \) is one hundred one"
V: “x is always the same. Okay, we know that y is more than x, and x is more than one hundred one, then y is more than one hundred one”

DISCUSSION
A palpable outcome is students’ uneasiness in recognizing that $x \leq y$. Most of them adopt the argument that $x$ cannot be equal to $y$, so pointing at the communicative inadequacy of the formula rather than at its claimed falsity. Valentina’s answer is quite clear also because she shows a good command of mathematical notations and steadily applies even ‘ab absurdo’ arguments. It seem reasonable to conjecture that these students (rightly) feel the inadequacy of the statement $x \leq y$ which violates not only everyday-life pragmatic rules but even implicit rules of school practice: usually to answer a question it is not accepted just a true statement, but the statement which is the most adequate to the question and the related context is required. Other answers point out a further aspect: the difference between the relation ‘$<$’ occurring in (a) and ‘$\leq$’ occurring in (i). In this case it is questioned the adequacy not just of (i) but rather of the whole text.

As concerns (ii), the answers of students who fail in linking the question to both (a) and (c) can be classified into two groups. Who answers ‘false’ most likely focuses on (a) only and remarks that $y$ could be 2. (b) is neglected by almost all students, maybe because in it occurs ‘$>$’ in place of ‘$<$’ or ‘$\leq$’. Most likely (c) is not taken into account by some students as it does not involve $y$ explicitly. These answers seem depend on the lack of linguistic markers of cohesion between (a), (b), (c). The lack of cohesion induces some students to assign to each statement its own topic. The topic of (c) alone cannot be other than $x$, which is the only variable occurring. Some students try to apply algorithms to put data together.

The different features of mathematical language (in all its components) from the functional (not only grammatical or lexical) viewpoint may explain a number of students’ difficulties. Most of the students refuse $x \leq y$ as inadequate compared to the data available. Even the troubles with question (ii) may be explained in a similar way. Ordinary language provides a number of ways to mark the links between the statements in a text (intonation in spoken texts, vocabulary, pronouns, connectives, ... in all the texts) whereas mathematical one (in its symbolic and often verbal component) cohesion is usually marked in other ways, such as the spatial disposition of the formulas or the availability of specific algorithms or the repetition of some symbol or letter. This happens for example in the solution of linear systems: standard methods automatically take into account all the equations involved, that are identified mainly by their spatial disposition and by the occurrence of brackets or braces.

The spoken interaction between Valentina and Ines points out some interesting processes. Valentina, who usually takes good grades in mathematics, gets stuck because
of the occurrence of ‘≤’. Maybe Ines, who generally takes lower grades in mathematics than Valentina, is not completely aware of the question raised by her friend, but her indifference for the distinction between ‘<’ and ‘≤’ and her efforts to represent the data verbally play a positive role. Ines’ attitude is clearly agonistic, as she seems to be moved mainly by the wish of prevailing against Valentina. As regards question (ii) Valentina, in order to explain her answer, provides a sequence of examples that use statements that are not consequences of the data (“the cube of x is ten to the sixth”, “so x is equal to one hundred”) afterwards rectified by others (“if x is at least one hundred”). Ines clearly does not grasp cohesion among the data and interprets the two occurrences of x as different numbers. Both the parts of the interaction enhance some features of verbal language. Ines and Valentina are both inaccurate in their interpretations. Ines tries to use ‘less’ to interpret both ‘<’ and ‘≤’, which is inaccurate, but succeeds in drawing Valentina’s attention on some aspects of the meanings involved that are relevant to the answer. Moreover she uses an example (the elevator) which is not closely related to the problem, but where the pragmatic function of the warning ‘Maximum weight three hundred kg’ is made straightforward by the situation and one’s everyday experience. In other words, the example of the elevator is pragmatically rather than semantically related to the problem situation. Also Valentina, as remarked above, is inaccurate in her examples. Her efforts to give x and y values compatible with the data seem useful steps toward the solution. In both cases, verbal language (in a spoken register) allows her to make inaccurate statements and rectify them afterwards without too much danger. If Valentina had written down her examples in symbolic form (“x^3=10^6”, “x=100”) and had applied to them standard algebraic transformations, she could have lost the control of the function of her productions. In other words verbal language (in both spoken and written registers) not only provides much more opportunities to mark some of the functional features of the texts (topic, cohesion, ...) but is also more flexible than symbolic one, as it allows people to produce inaccurate statements and to rectify them afterwards, or to mark them as conjectures, or examples, or other. Very often I find college students who write down formulas that are not consequences of the assumptions but only examples. Unfortunately, they often forget the functions of their writings, and apply to them algebraic transformations, and derive false conclusions. Their behaviors, that are sometimes labelled as ‘incorrect applications of rules’ could more effectively be regarded as examples of failure in the control of the functions of the texts produced.

TEACHING IMPLICATIONS
A possible interpretation of this data is: experiments of this sort have no relevant teaching implications as the problems assigned are tricky and unfair. This opinion is compatible with traditional teaching practices that mainly enhance the learning of standard procedures in standard formats. If we give a central role to communication the role of languages becomes more relevant. In particular it seem reasonable that students
should interpret simple texts in mathematical language including those containing symbols, even if they are not in standard format (as happens in everyday-life communication). The outcomes of this experiment point out the need that students command the transitions between different languages or registers, with the related functional properties and conventions. This suggest that mathematical expressions should be studied as texts rather than just as local conventions or abbreviations. This implies a better coordination between the teaching of languages and the teaching of mathematics and a stronger focus on aspects like metalinguistic awareness, i.e. awareness of form and functions of a text, in addition to its meaning, as suggested by MacGregor & Price (1999). Of course, further research is needed to refine these ideas and to design the teaching methods more suitable to attain the goals suggested above, but we believe that anyway mathematical language should be considered in the context of actual interactions (rather than as a separate code) with all its components.

ALGEBRAIC SYNTAX AND WORD PROBLEMS SOLUTION:
FIRST STEPS

Eugenio Filloy and Teresa Rojano
Department of Matematica Educativa
Center of Research and Advanced Studies, Mexico

In Filloy and Rojano (1989) we introduced the use of concrete models for the
teaching of solving linear equations and studied the abstraction processes that take
place when such models are put in work by pupils of 12-13 years of age. In this
paper we discuss how concrete modeling in algebra influences the way children in
the arithmetic/algebra transition can learn to solve word problems. We discuss the
stage in which the algebraic syntax developed to solve equations has just been
acquired and then used to translate the word problems into the algebraic code.

Previous research has been undertaken to probe cognitive processes that take place
in solving word problems in the transition from arithmetic to algebraic thinking.
Bednarz and Janvier (1996) have substantially contributed to this aspect of
research in problem solving in algebra. Puig and Cerdan (1990) have formulated
criteria to determine when a word problem can be considered as algebraic. From a
different perspective, A. Bell (1996) has approached this matter by showing
through examples how generic problems can provide algebraic experiences that
develop manipulative algebraic abilities. Sutherland and Rojano (1993) have
studied how a technological environment can help students to represent and solve
word problems without having to take on board with the algebra symbolic code,
from the very beginning. The present paper addresses the theme of extending the
use of basic algebraic syntax to the context of the solution of arithmetic/algebraic
word problems. Pupils of 12-13 years of age were interviewed just after they had
learned how to solve linear equations with one unknown appearing on both sides.
In a first stage of the interview, a teaching approach using "concrete models" for
solving equations was used (items in sequence I) and in a second stage, children
were given two sequences of word problems. Sequence A included problems
of the type: “find a number that...”; and Sequence P, included problems posed in a
variety of contexts and in which a progressive symbolization process is required to
make up the equation that solves the problem. The purpose of facing children with
problems of sequence P was to study their potential in transferring basic algebraic
syntax, recently learned, to other contexts, different from those used for the
teaching of solving equations. Items of sequences I, A and P of the interview
constitute a teaching strategy that aims to provide with senses the learning of
algebraic syntax (Filloy, 1991). With this strategy, it is possible to complete the
teaching cycle:
I.-Meaningful introduction to algebraic syntax (through "concrete models" for solving linear equations);

II.-Immediate use of the elements of manipulative algebra, just acquired, in the resolution of word problems (progress towards a semantic use of algebraic syntax);

III.-Meaningful progress towards a more complex level of algebraic syntax.

In this paper we report results from a case study with 12-13 year olds, who were introduced to the algebraic realm, using the teaching cycle described above. Among the twelve participants in the study, Mariana, a girl with a history of being successful in mathematics, got to complete the teaching cycle during a 1:45 hr session of clinical interview. In the following sections, we discuss some relevant issues from Mariana’s interview, with regards the extension of syntactic skills through problem solving activity.

Theoretical and Methodological Framework

In Filloy (1990) we introduced the methodological framework of local theoretical models in which the object of study is brought into focus through four interrelated components:

1. Teaching models together with 2. models of cognitive processes, both related to 3. models of formal competence that simulate competent performance of the ideal user of a Mathematical Sign System (MSS) and 4. communication models to describe rules of communicative competence, production of texts, texts decoding, and contextual clarification.

The following scheme describes the rationale of the case study:

Implementing a controlled teaching system → Local Theoretical Model

Choosing population to study within the controlled teaching system

Applying a diagnostic evaluation to the chosen population, to measure its effectiveness in the use of more concrete MSS strata within the new, more abstract MSS.

Classifying the population in strata or profiles according to their performance in the diagnostic evaluation → Choosing a subgroup of the population, in which different classes or profiles are present, for observation in clinical interviews.

Analysis and interpretation of interviews → Written report of observations, in terms of the theoretical objectives of the study

Cognition: Compiling a catalogue of observations related to the model of cognitive processes

Teaching: Compiling a catalogue of observations related to the teaching model utilized

Communication: Compiling a catalogue of observations related to the communication model.

The problem in the perspective of a new Local Theoretical Model and its design.
Results from the diagnostic test located Mariana in the category of students with high proficiency in a) solving "arithmetic" linear equations; b) solving arithmetic word problems; and c) numeric skills. Before the interview, Mariana had not had been taught any algebra.

THE INTERVIEW ITEMS (Sequences I, A and P).
We will write I Mr.n for the nth item of Sequence I Series in Mariana’s interview.

Sequence I

| I Mr.1 | I Mr.2 | I Mr.3 | I Mr.4 | I Mr.5 | I Mr.6 | I Mr.7 | I Mr.8 | I Mr.9 | I Mr.10 | I Mr.11 | I Mr.12 | I Mr.13 | I Mr.14 | I Mr.15 | I Mr.16 | I Mr.17 | I Mr.18 | I Mr.19 | I Mr.20 | I Mr.21 | I Mr.22 | I Mr.23 | I Mr.24 |
|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|
| x + 2 = 2x | x + 5 = 2x | 2x + 4 = 4x | 2x + 3 = 5x | 6x + 15 = 9x | 4x + 12 = x | 4x + 12 = 6x | 5x + 8 = 3x | 5x + 8 = 8x | 7x + 468 = 19x | 113x + 332 = 321x | 7x + 23x + 6 | 13x + 20 = x + 164 | 8x + 12 = 4x + 52 | 28x + 348 = 52x + 12 | 5x – 3 = 2x + 6 | 15x + 1590 = 71x – 202 | 11x + 687 = 45x – 27 | 10x – 18 = 4x | 8x – 7 = 4x + 13 | 7x – 1114 = 3x + 1001 | 7x – 1114 = 3x – 1001 | 7x + 1114 = 3x – 1001 | 113x – 70 = 22x + 1022 |

Sequence A (a sample of items)

| A Mr.1 | If you add five to a number, then subtract thirteen and the result is forty-five, what is the number? |
| A Mr.3 | If you add two to a number and the result is double that number, what is the number? |
| A Mr.5 | If to forty-eight you add three times a number and the result is nineteen times that number, what is the number? |
| A Mr.6 | Five times a number plus three is equal to double that number plus twelve. What is the number? |

Sequence P (a sample of items)

| P Mr.1 | There are chickens and rabbits in a yard. There are sixteen heads and fifty-two feet. How many chickens and rabbits are here in the yard? |
| P Mr.2 | There are chickens and rabbits in a yard. There are sixteen heads and fifty-two feet. How many chickens and rabbits are there in the yard? |
| P Mr.4 | Mariana is thirteen; Eugenio is forty. When will Eugenio be twice Mariana’s age? |
| P Mr.5 | Mariana is thirteen; Roberto is twenty-eight. When will Roberto be twice Mariana’s age? |
The Interview-Some issues.

MARIANA'S PERFORMANCE BEFORE THE INSTRUCTION PHASE

Mr. approaches the first items of sequence I with the trial and error method. She previously reads the equation: "I need to find a number that multiplied by 2, plus 4, equals ...". Like all the children in the same category as Mariana, she, very quickly, stops trying to use this method. Thus, in item I Mr. 4 \( 2x + 3 = 5x \), which could be easily solved by trial and error, she demands being taught a (school) method. At this stage the instruction phase begins on how to operate with unknown quantities by using a "concrete" (geometric) model (see Filloy/Rojano, 1989, and Filloy/Sutherland, 1996, for a detailed description of this model).

MARIANA'S PERFORMANCE AFTER THE INSTRUCTION PHASE

Mariana's work with the concrete model to operate with unknown quantities is characterized by an immediate abstraction of the actions performed in the model to the level of algebraic syntax. This could be clearly observed in item I Mr.6. A factor that may have influenced this abstraction process is the parallel register that Mariana carried out using the algebraic code, while she was dealing with areas comparison in the model. In this way, the abstraction process towards the algebraic language was reduced to an immediate translation of her actions in the model to this language. This immediate abstraction of the model's actions to algebraic language is not uniform throughout Mr.'s performance. The presence of more complex modes of equation, or equations with a non-trivial numerical structure \( (C < A, \text{ in } Ax + B = Cx) \), hindered the way operations were abstracted. Items I Mr. 8 and I Mr. 12 showed this phenomenon: If certain syntactic elements are locally generated (let's say, using a certain mode of equation) they are not transferred automatically to new modes. It is necessary to return to work with the semantics of the model to reconstruct the actions carried out and recover them at the level of algebraic syntax.

PROGRESS TOWARDS SEMANTICS (Solving word problems and the role of algebraic syntax)

Finally, in sequence P, Mariana was asked to solve the word problems that were presented in pairs. The second problem, of each pair, is obtained by changing only the data of the first one. The pairs in the sequence P are P Mr. 1 and P Mr. 2; P Mr. 4 and P Mr. 5. The interviewer intervened to help Mariana to build up the equation in the first of each pair, while in the second, Mariana showed to be able to produce the equation and to solve it, using the recently-acquired syntactic skills to solve equations with more than one occurrence of the unknown.
PMr1 and PMr2 (fragments of Mariana’s interview)

There are chickens and rabbits in a yard. There are sixteen heads and fifty-two feet. How many chickens and rabbits are here in the yard?

The interviewer (I) suggests Mariana (M) to use letters to represent the number of rabbits and chickens. She writes down $x$ for the number of rabbits and $16-x$ for the number of chickens.

I: How many rabbit’s feet I can see?
M: eight
I: If there is one rabbit, how many feet?
M: four
I: If there are 2 rabbits?
M: eight
I: If I see this number of rabbits ($x$) how many feet?
M: I don’t know

-----------
I: How could you name the number of feet, using this …? (he points out the ‘$x$’)
M: Interrupting the interviewer writes down: $4x$
I: How could you find out the number of chickens’ feet? Do you have a name for the number of chickens?
M: The name of the chickens’ number times two
I: And, how is it? Two times…
M: writes down: $2\cdot (16-x)$
I: If $4x$ is the number of rabbits’ feet and $2\cdot (16-x)$ is the number of chickens’ feet, How can I obtain the 52 which is the total number of feet?
M: Adding, $4x$ to $2\cdot (16-x)$
I: Write it down
M: writes: $4x + 2\cdot (16-x) = 52$
I: This is an equation.
At this point, Mariana had not had instruction to remove the brackets in the left hand side expression. So, the interviewer intervenes with a piece of instruction to teach Mariana the distributive law in expressions that include ‘x’. He uses a geometric representation, which in general terms corresponds to the following figure:

![Geometric Representation](image)

The interviewer asks Mariana to generalize the law to expressions such as 3\(x\) (16-x); 4\(x\) (16-x); etc. Finally, she writes down the equation: 4\(x\) + 32 - 2\(x\) = 52

I: Can you solve it?

M: writes down the simplified equation: 2\(x\) + 32 = 52

At this point, she used the syntactic elements she learned in the sequence I of the interview.

Mariana inverts the operations present in this equation and finds the number of rabbits.

M: Ten, is the number of rabbits

I: And, how many chickens?

M: points out the expression 16-x, and says “six”.

When the item PMr.2 is presented to Mariana, she quickly recognizes that it is the same problem, but with different data and proceeds to solve it without any difficulty.

This strategy of using pairs of similar problems, is used in one part of sequence P. It could be observed that, once the greatest difficulty was overcome, that is the translation of the problem into an equation, the problem became a routine one for Mariana. This was because the syntactic elements that she had recently learned were applied immediately. This type of transfer allows the recently-acquired operational capacity to be considered as a potential tool to solve a larger family of problems, that is, a family that includes statements that lead to linear equations, which are here called ‘non-arithmetic’ (with more than one occurrence of the unknown).
FINAL REMARKS
The teaching strategy used to help Mariana to identify problems belonging to the same family consists in giving to the new type of expression, such as $A' \ (B+x)$ a treatment which is analogous to that given to the expressions of the type $Ax + B = Cx$. That is, translating these sorts of expressions into more 'concrete' terms in a context of areas and recovering the actions in the algebraic code. This strategy showed to be helpful to Mariana to extend the use of her syntactic skills to word problems, posed in a variety of contexts. In fact, Mariana's performance in the last items of sequence $P$, where she put into work new elements of algebraic syntax, provides evidence of a real progress towards the use of manipulative algebra in contexts different from those used in the teaching of such syntactic elements. Mariana's case illustrates how this type of return to the evolution of syntax can provide the elements of the manipulative algebra with meanings that enable them to be applied to the solution of entire families of word problems.

GEOMETRY AT WORK
(or Pytagoras will never fail you!)

Gema Fioriti and Núria Gorgorió
(Universidad Nacional General San Martín de Buenos Aires, Argentina; Universitat Autònoma de Barcelona, Spain)

Abstract: This research report presents an empirical study of the geometrical knowledge 'hidden' in the working practices of Argentinian bricklayers. The aim of the research was to find clues to improve the mathematics education of adults within the vocational and professional training system. The results of the study concerning the construction of right angles are partially presented to illustrate some of the differences between the geometric knowledge situated in the school context and in the work place context. The paper finishes by raising some questions about the need and the possibility of trying to establish links between the different contexts for everyday mathematical practices and the school practices.

Some of the reasons for the study
In the Argentinian province of Rio Negro, where the study was developed, the illiterate population reaches 34.04% (illiterate and functionally illiterate). Certainly, there are economic and social reasons that explain why a significant number of young people drop out school before reaching the end of compulsory school age. These reasons are reinforced by the academic failure of some students. Mathematics, as a school subject, has a big share of the responsibility for this failure, since it still operates as a selection instrument. This selection, moreover, takes place within a system where the meaning of the mathematical knowledge decreases for the student as she/he progresses.

On the other hand, only 3.1% of the illiterate adult population attend vocational schools, adult schools or literacy and numeracy programs. Moreover, the programs offered have little connection with the real needs of their potential students, or with their possibilities to gain knowledge, or with their abilities, or with procedures that would facilitate their effectiveness in the work place and their participation in the social life as citizens.

Within this context, the main goal of this study was to analyze the characteristics of the mathematical knowledge as used and valued by those
that could benefit from attending vocational and adult programs\(^1\) compared to the mathematical knowledge as it is promoted for them. In particular, we studied the practical problems that building workers face, as members of a community of practice, in their workplaces to identify the geometrical knowledge, either hidden or explicit, that they use to solve them. We also analyzed how the workers relate to the knowledge learnt in school and to the knowledge in-practice, and how they understand and value them as knowledge. We chose to work with the community of bricklayers and building workers because of our interest in the teaching and learning of geometry and of spatial abilities and concepts.

**Framework and research questions.**

Our study is framed within the everyday mathematics cognition trend that sees everyday mathematics as a body of mathematical knowledge and practices accumulated through the development of everyday activities (Nunes, Schliemann and Carraher, 1993). Gerdes (1988, p.140) referring to the traditional forms and shapes given to objects affirms that this 'It constitutes not only biological and physical knowledge about the materials that are used, but also mathematical knowledge, knowledge about the properties and relations of circles, angles, rectangles, squares....'. Our starting point is that the traditional procedures used by building workers also reflect a lot of 'hidden' or 'frozen' mathematics (Gerdes, op.cit.).

The authors of this paper would not make a strong argument in favour of the 'utilitarian mathematics culture' but are convinced that knowing more about this hidden mathematics in the adult context could contribute to the development of a realistic curriculum and would help to give meaning to mathematical tasks, to motivate adult students, and to them valuing their own situated knowledge. Nunes and Bryant (1996, p.108) referring to the mathematical knowledge that can be found embedded in many everyday activities, state that 'These points are not mere curiosities about mathematics: they have an impact on children’s future chances because they can actually affect how well they do in school'.

Our purpose is not to discuss whether or not the geometrical knowledge used at the work place to solve practical problems should be considered 'true' geometrical knowledge, but to find clues that contribute to create learning situations that establish links between the knowledge at work and the school knowledge.

With this purpose the research aimed at identifying and analyzing:

---

\(^1\) Due to length reasons, we do not report here the analysis of the formal educational system that refers to vocational, professional or adult schools.
a) work tasks, as developed in practice, that involved the use of geometrical knowledge and the planning and the verification of those tasks by the workers,

b) the use of work tools that materialize mathematical knowledge, and
c) the acknowledgment and valuing by the workers of their using of mathematical knowledge and its usefulness.

The problem that motivated our analysis was essentially to establish some of the differential traits between the two forms of geometrical knowledge, that embedded in work and that promoted at school.

Nunes (1992) points out that there are two distinct approaches to the study of cultural influences on mathematical knowledge, one based on the content of the knowledge and another based on the use of the knowledge. We wanted to know if the knowledge, in the sense of content of knowledge, present in both contexts of practice was the same and to identify and describe work tasks in which geometrical knowledge was embedded. However, our main focus of interest was on how this knowledge was used, what was its function in the thinking processes, in the way of approaching and solving the problems, not only from the point of view of mathematics, but also from the perspective of the relationship that the person establishes with the knowledge.

Research procedures

When deciding how to approach the world of the building workers it was clear to us that our research methods would depend not only on the research aims but also on the research context. We really felt outsiders in that particular world: our knowledge of the work tasks was sparse or zero, our gender made us 'uncommon' among them, our social norms came from the academic world, our register of language was completely different from theirs... and we had 'plenty of time to waste, while they were there to work' (as Juan confessed when we reached a friendly relationship).

To overcome this obstacle the talking of the first author with the engineers, architects and responsible persons in the building company was a great help to us. Through those conversations, we were not only granted permission to develop the study, but more importantly, we were 'introduced' to the field. The languages and the contexts being closer, the building company's personnel understood the aims of the research, and they provided us with descriptions of the roles and the tasks performed at the work place, and they also helped with the selection of workers to be interviewed.

Observing the actual working practices, and reading some previous interviews, were useful to identify certain activities where geometrical knowledge was potentially in use or embedded. However, observation was not the main procedure used. We could have gained information about how
knowledge is transmitted from experts to learners in the community of practice, but we discarded this method: it was too expensive on time, too dependent on our interpretation, and it would give us little information on how decisions were taken.

Interviewing the workers was the research method chosen. The first author interviewed 12 workers selected according different criteria: the tasks developed and level of responsibility in the work place, their experience and their abilities as workers, and their previous school experience. The suggestions from the company people were very useful, since they helped to ensure that we would interview those bricklayers who would be ready to help and open enough to make the interviewing smooth.

Only bricklayers, building carpenters and foremen were interviewed but not building labourers, since they, being unskilled workers, rarely took decisions on their own regarding the planning or supervising of the work. All of them had more than four years practice, and regarding their level of formal education there was a range varying from illiterate workers to some who had passed succesfully through part of secondary school education.

The content of the interview was directly related to their actual work or required to evoke it. This means, for instance, there was no question asking how do you draw a right angle?, but how do you proceed to make the frame of a door?. The questions asked the reasons for a technique observed or the explanation of a particular procedure. Some examples of the topics that guided the interviews are:

a) how to ensure the perpendicularity of the walls and the floor, how to ensure that the floor is flat and horizontal, how to know where the walls have to be built, how to build a doorframe, a windowframe, an arch...

b) how to use some of the working tools like the carpenter’s square or the angle iron, the plumb-line, the spirit level ...

c) how conscious they were of having learnt at school (if they attended) any knowledge that was useful to their job, of using any mathematical or geometrical knowledge and how they valued that knowledge ...

The interviews took place in the work place, some of them in the open air, some of them in the storeroom. The interviews were tape-recorded. The difficulties of convincing them to allow us to use the tape-recorder discouraged the use of a video camera, despite the fact that the gestural language was of great importance in our study. During the interviews, drawing tools like those normally used in the work place were at hand and spontaneously used. The interviewer took notes of the gestural language and drawn schemes to help with the later transcription. Keeping a record of the gestural language was of great importance, because many times it was the clue to understand the non-formal language. Data was interpreted through succesive and recursive analysis.
Some findings

Following we present some of the findings to illustrate the tasks identified as involving geometrical knowledge and to describe how this knowledge is used. The findings correspond to the procedures used in the construction of right angles and its verification. Six of the workers interviewed referred to and explained the construction of right angles in different tasks. The procedures reported were repeated in different interviews and involved:

1. The Pythagorean relationship

One procedure uses a particular Pythagorean triplet to construct and control the right angle when building window or door frames. Once having fixed the two sides for the right angle - 0.60m and 0.80m - then the length of the hypotenuse being 1m will ensure that the constructed angle is a right one.

Juan: I tell you a trick that will never fail you. You make it here 80 and there 60 and then you open or close the frame until you get one meter, then the sides are squared.

Some of the workers show a functional use of this knowledge that goes beyond just a routine use

Carlos: You measure 80 and then 60 and you have to have one meter, and you have there the squared corner and then you increase when the length of your square increases.

Interviewer: And how do you increase?

Carlos: Instead of 60, 120 and you increase that way, and the same there, 80, 160 and to obtain the square, you have one meter, two meters...

We want to note that while in school the ‘direction of the implication’ of the Pythagorean relationship used is the ‘if’ (if you get a right angle, then the relationship verify itself), the workers use the other direction of the implication, the ‘only if’, to construct and to control the right angles:

José: for instance, to square, we make on one side 60, on the other side we make 80, and we see, if we get one meter, then it is because it is squared ... but if we get a little more, this is out of square, it is out of shape.

2. Properties of the diagonals of a rectangle

Another geometrical fact hidden in one of the procedures used to construct and control right angles concerns the properties of the diagonals of a rectangle or of those of a square. The first one is very similar to that found among Mozambican peasants by Gerdes (1988).

Santiago gave the following explanation, accompanied by a drawing, of how he proceeded when he needed to draw a right angle while ‘copying’ the basic plan of the house onto the actual ground.
Santiago: (he wants a perpendicular to AO at O)...like being squared here\(^2\) (pointing at O), the axis (the vertex O), ... we start here (O) to all the sides, this is the main axis (pointing at the segment AO), we tighten the thread from here (from A to B by O), and another from here (OC, a thread not yet fixed to the ground), and then we have 5 meters (as required by the plan) here (OA), 5 here (OB), and 5 here (OC), then to have this squared (right angle at O) you need (to get) the same (length) from here to here (AC) and from here to here (BC).

Again the direction of the implication used by Santiago (‘only if’) is the contrary to the one more commonly used at school (‘if’).

3. Concretizing the idea of perpendicularity

Another procedure used to construct right angles when building door or window frames is based on the idea of perpendicularity concretized in the intersection of vertical and horizontal lines, concepts that correspond to the physical world and that are materialized in the working tools: the spirit level and the plumb-line.

Daniel: You hang the plumb-line at the two corners, then the frame is 'plumbed', and then you have to get it at 'level', at the corners, with the spirit level.

4. Using a working tool that concretizes the geometrical concept

Finally, another procedure used was based on the use of the iron angle, a metal square, which materializes the geometrical concept of right angle.

Daniel: This is an iron angle, you put it at the corner of the door frame, and you square it, if your square is false, then you get it more open, and then with the iron angle you should adjust the frame, the frame is not yet fixed.

Some results and further questions

The range and richness of content of knowledge we could identify throughout the different interviews is impressive, to the point that we found a procedure to construct angles of any measure smaller than 90° based on the concept of tangent. The content is related to the ideas of parallelism, angle, plane, straight line, proportionality, circle, triangle, square and rectangle. We also observed abilities related to measurement, visualization, interpretation of plans, and locating. Concerning how this knowledge is used there are some constant features that repeatedly appeared. We summarize them below staying with the example of right angles.

\(^2\) The letters in the drawing are ours to help the reader following the explanation.
In the interviews, most of the workers referred to the use of more than one procedure and related its use to the requirement of the task or the particular situation. We may talk about two different kind of procedures: those based on geometrical facts, and those based on the use of physical tools that materialize geometrical concepts. For instance, only one of the workers referred to using the iron angle to construct right angles; the other two that referred to the instrument explained how to use it to verify the squareness.

One of the workers, Eduardo, referred to using three different procedures (1, 2 and 4) and made explicit the fact that he is able to adapt the procedure to the particular requirement of the task. Eduardo is the one who has both a bigger responsibility in the work place and a ‘better’ academic history. The richness of the procedures used could depend on both the task to be solved and the worker’s knowledge of relevant geometric facts, with this knowledge having been acquired ‘in situ’ or at school.

Referring to different uses of the knowledge we want to note that the different use of ‘implications’ we have illustrated in the previous section appears repeatedly and relates our findings to the idea of inversion in the works of Lave (1988), Carraher (1986) and Schliemann and Carraher (1990).

The interviews also showed us that the relationship established with the knowledge in use was different from that promoted in school. In particular, the workers made explicit that they could use more than one method in every situation, one to control the construction and the other to verify it. For instance, two of the workers use the Pytagorean relationship and the properties of the rectangle to control the construction process, and to verify the result one of them used the iron angle. It is important to note that this idea of further verification is one of the characteristics that makes a distinction with what is taught at school and is linked to the fact that in work places the idea of ‘error’ is linked to ‘loss of effectiveness’.

We observed a wide range of possible procedures to solve particular tasks, and that the ‘frozen’ knowledge can be made operative, adapting it to the requirements of the context, for instance adapting the procedure to the size of the object by using proportionality facts. Also different personal experiences may engender different degrees of flexibility for the procedures used by the participants.

Some of the procedures used can be thought as being general, as being applicable to several circumstances, some of them being based on geometrical properties or facts, flexible in their application, and some of them being concretized in tools. Among the first we could include the use of the Pytagorean triplets, and among the second the use of the iron angle. Some of the procedures are specific, being like algorithms, as set of rules for getting a specific output from a specific input, like the use of the plumbline and the spirit level to make a door frame. When geometrical
knowledge is flexibly used we can think of the procedure as being a problem solving strategy, not a simple routine technique.

As a conclusion, we want to share with the reader further issues that we have raised ourselves. If one wants to obtain new insights for the teaching of mathematics, more detailed descriptions are needed about the informal and formal procedures for solving geometrical problems and, in particular, how the particular situation presents conditions that elicit different types of strategies. However, at which point can the informal content of the lessons become an effective foundation for more formal mathematical reasoning, and what are the limits of engaging students in contextualized reasoning and learning?

The situation in which the problems are embedded may have a strong impact on how they are solved, the impact seeming to result from the meaning that problems have for the ones engaged in problem solving. School mathematics promote classroom exercises that elicit algorithmic solutions, making the students lose track of the meaning of the problem within the situation and within the structure of the knowledge.

The divorce between understanding and the use of algorithms is a by-product of an educational system that leads children to focus not on meaning but on routines. The algorithmic approach promoted in our classes makes students use knowledge as a tool, not as an object in itself to be thought of. Therefore we have two more questions: Can everyday mathematics help with the transition from tools of knowledge to objects of knowledge? Can actual mathematics teaching benefit from teachers and text-book writers, among others, being acquainted with non-formal mathematical knowledge and everyday procedures?

Historically mathematics was considered a pursuit more suited to males than females. Using a new instrument, contemporary high school students' beliefs about the gender stereotyping of mathematics have been measured and an apparent change in beliefs reported. The same instrument was administered to preservice teachers in Australia and the USA. These countries share common social and cultural characteristics and both were active in addressing identified female disadvantage in mathematics education outcomes. The preservice teachers were asked to respond to the survey items as they believed high school students would answer. The Australian and US preservice teachers' responses were compared. The results are reported and discussed in this paper.

Introduction

Over the past 25 years or so, researchers, practitioners, and policy makers have been active in attempting to redress gender differences favouring males in mathematics learning outcomes (for extensive reviews, see Leder, Forgasz, & Solar, 1996; Forgasz, Leder, & Vale, 2000). Areas in which females had been identified as disadvantaged included: enrolments in the most advanced mathematics subjects and in courses requiring these subjects as pre-requisites, and the attainment of well-above average scores. In the past, mathematics was strongly believed to be a male domain. This view was not only held by students and their parents but also by teachers (e.g., Leder, 1986). Researchers postulated that this belief contributed to females' decisions not to pursue studies in non-compulsory and/or challenging mathematics courses to the same extent as males.

More recently considerable attention has been placed on boys' educational issues. Views of boys' disadvantage, even in the traditionally male preserves of mathematics and science, are receiving increasing media publicity and coverage (e.g., Colebatch, 2000; Gough, 2000). The impact of gender on performance and participation in mathematics continues to be of concern to the community.

Background to the study

Mathematics as a male domain. It is widely accepted that “affective issues play a central role in mathematics learning and instruction” (McLeod, 1992, p.575). The Fennema-Sherman [F-S] Mathematics Attitudes Scales [MAS] are frequently used to measure students’ attitudes towards mathematics (Walberg & Haertel, 1992). The MAS consist of “nine, domain specific, Likert-type scales measuring important attitudes related to mathematics learning” (Fennema & Sherman, 1976, p.1). The Likert format makes the scales easy to administer and score. One of the subscales of the MAS is the Mathematics as a male domain [MD] scale. Based on the assumption
that “the less a female stereotyped mathematics as a male domain, the more apt she would be to study and learn mathematics” (Fennema & Sherman, 1976, p.7), the MD was designed so that high scores reflected less stereotyped beliefs and low scores more strongly held views stereotyping mathematics as a male domain. Consistent with the prevailing Western societal views of the 1970s when the MD scale was developed, it is not surprising that no allowance was made for beliefs that mathematics might be considered a female domain. Forgasz, Leder and Gardner (1999) provided research evidence to demonstrate that this view was no longer tenable and argued that many of the items on the MD scale were anachronistic and others no longer valid. The scale was, they claimed, much in need of revision.

**Two new instruments.** Two new instruments – *Mathematics as a gendered domain* and *Who and mathematics* - have been developed and trialed. The aim of both versions is to measure the extent to which mathematics is stereotyped as a gendered domain; that is, the extent to which it is believed that mathematics may be more suited to males, to females, or be regarded as a gender-neutral domain. Details of the process for the development of the items on the scales, and the establishment of the validity and reliability of the items are described elsewhere (see Forgasz & Leder, 2000; Leder & Forgasz, 2000).

The results of the administration of the two new instruments to 861 Australian grade 7-10 students during 1999 have been reported (Forgasz, 2000; Forgasz & Leder, 2000; Leder & Forgasz, 2000). The findings appeared to challenge notions of mathematics as a masculine endeavour.

In this paper, data from only one of the two instruments – the *Who and mathematics* scale – are presented. Specifically, two groups of preservice teachers – one in Australia and one in the USA – were asked to complete the instrument as they expected students to do. Comparisons could thus be made between the two preservice teacher groups, and those of Australian students.

**The Who and mathematics scale**

An innovative response format was adopted for the Who and mathematics version of the instrument. Thirty statements were presented and for each statement, respondents had to select one of the following responses:

- BD – boys definitely more likely than girls
- BP – boys probably more likely than girls
- ND – no difference between boys and girls
- GP – girls probably more likely than boys
- GD – girls definitely more likely than boys

**Scoring.** In order to interpret responses to items on the *Who and mathematics* instrument, the categories are scored as follows: BD = 1, BP = 2, ND = 3, GP = 4 and GD = 5. Responses are entered into a database and analysed using SPSS_WIN. Mean scores are calculated for each item. One-sample t-tests are conducted on the item
means to test for statistically significant differences (at the p<.01 level) from the middle score (ND) value of 3.

**Interpretation of results.** For items with means not significantly different from 3, respondents, on average, believe that there is no difference between girls and boys with respect to the wording associated with the item.

For items with mean scores statistically significantly different from 3:
- mean scores <3 mean that, on average, respondents believe that boys are more likely than girls to match the wording of items, and
- mean scores >3 mean that, on average, respondents believe that girls are more likely than boys to do so.

**The items, predicted responses.** The 30 items, in the order they appear on the *Who and mathematics* instrument are shown in Table 1. The predicted gendered response directions for the items, based on previous research findings on perceptions of mathematics as a *male domain*, are also shown.

**Previous findings from the new ‘Who and mathematics’ instrument.** The previously reported response directions of the Australian grade 7-10 students (see Forgasz, 2000; Leder & Forgasz, 2000), based on mean scores for each item on the *Who and mathematics* scale, have also been included in Table 1. The data reveal that for only eight out of the 30 items students’ responses were in the directions predicted by previous research in the field (Items: 2, 3, 10, 16, 21, 24, 28, 30).

**The study**

**Aim.** In 2000, the *Who and mathematics* instrument was administered to preservice teachers in Australia and the USA. The aim was to explore whether Australian and US preservice teachers held common or different views of contemporary high school students’ beliefs about the gendering of mathematics. It should be noted that data from US high school students have also been gathered. As yet, comparisons between the US students’ and US preservice teachers’ views have not been reported.

**Sample and methods**

The sample sizes were: 394 Australian and 96 US preservice teachers. The 30 items of the *Who and mathematics* instrument (Table 1) were administered to the Australian and US pre-service teachers. Because of the wording of items, the instructions to the preservice teachers were slightly different from those given to the high school students. Students were asked for their reactions to each statement. The preservice teachers were asked to answer as they believed high school students would respond. Thus comparisons between the findings of high school students and preservice teachers reflect consistencies and differences in students’ beliefs and preservice teachers’ beliefs about student beliefs.

The data gathered from the preservice teachers from both countries were entered into a database and analysed statistically using SPSS\textsubscript{WIN}.
Analyses, results and discussion

Independent groups t-tests, by country, were conducted for each of the 30 items. Mean scores for all items and the p-levels for items with statistically significant different means are shown in Table 2.

Table 1. *Who and mathematics:* The 30 items, predicted directions of item responses (Pred), and response directions of 861 Australian grade 7-10 students (Aus students).

For each country, a one-sample t-test was conducted on the mean score for each of the 30 items to test for a statistically significant difference from 3 – the middle of the range of potential mean scores. Mean scores not significantly different from 3 (at the p < .01 level) are shown in italics in the Table 2.

The mean scores for the Australian and US preservice teachers are also represented graphically in Figure 1. The line down the middle of the graph is at the value 3 – the mid-point of the range of possible mean scores. Bars to the left of the centre line represent mean scores <3; bars to the right, mean scores were >3.

As is evident from Figure 1 (and Table 2), for all items except Item 4, the direction of the beliefs of the pre-service teachers from the two countries were the same. The means for Item 4 indicate that the Australians believed that high school students would respond that there would be no difference between girls' and boys' likelihood to "give up when they find a mathematics problem is too difficult"; the Americans, however, indicated that they believed high school students would consider girls were more likely than boys to do so (mean score >3).

When the directions of the preservice teachers' responses are compared to the predictions from the research (see Table 1), it is clear that the pre-service teachers in both countries believe that high school students hold views consistent with previous research findings. In other words, the preservice teachers believe that high school students still have traditionally stereotyped views of mathematics as a male domain.

Table 2 reveals that there were 17 items (1, 3-6, 11-13, 17, 18, 20, 22, 23, and 26-29) for which there were statistically significant differences in mean scores by country.
Who & Mathematics: Preservice teachers  
Australia & USA  
Means<3: "Boys more likely than girls"; Means>3: "Girls more likely than boys"

Figure 1. Mean scores: Australian and US Pre-service teachers
From the Australian data, it is clear that the preservice teachers’ views (Table 2 and Figure 1) did not match with the students’ views (Table 1). The gendered directions of their responses differed on many of the items. It is tempting to speculate that the same will be found when the US student and preservice teacher data are compared.

Final words

The responses of the pre-service teachers to the Who and mathematics instrument were consistent with the predicted gendered directions of responses based on previous research in the field. The preservice teachers in both countries held similar gender-stereotyped expectations that high school students’ beliefs would continue to reflect views that mathematics was a male domain.

In reality, it is highly likely that the pre-service teachers’ views of high school students’ beliefs actually reflected their own personal experiences and beliefs. The Australian preservice teachers would have been in grade 7 at least six years earlier; others, earlier still. When the Australian high school students’ views are considered, it seems that the preservice teachers (about 10 years older than the participating grade 7 students), are ‘out of touch’ with contemporary high school students’ views on the gender-stereotyping of mathematics. It is interesting to speculate what will happen when the preservice teachers enter the profession to find that many of their expectations differ from those of their students.

The data gathered from the Who and mathematics instrument appear to raise more questions than answers. Alternative data gathering methods would be needed to try to understand what has brought about the apparent change in student views of the gender stereotyping of mathematics and why preservice teachers’ understandings of the high school students’ views differ so much from the teenagers’ beliefs.

Interestingly, in both countries the majority of respondents was female – Australia: 83% and USA: 89% - a telling reflection of the gender profile of the future teaching profession in both countries. To undertake a valid gender analysis of the data (particularly from the USA) and make comparisons, larger samples would have been required to compensate for the gender imbalance in participant numbers.

In the study reported here, other socio-cultural factors were omitted – for example, developed/developing nation status, ethnicity/race, culture/religion, and socio-economic background/class. Researchers using the Who and mathematics instrument and including these factors may uncover differences in views that would assist in more effectively identifying gender-based inequities demanding action. It remains important, however, to continue monitoring broadly-based gender issues in mathematics.

STUDENTS' CHOICE OF TOOLS IN SOLVING EQUATIONS IN A TECHNOLOGICAL LEARNING ENVIRONMENT

Alex Friedlander        Hana Stein
Department of Science Teaching, Weizmann Institute of Science, Israel

This paper presents several findings on 13-14 year old students' ability to choose, employ and integrate various tools in their solution of four equations. We analyzed the ability and preferences of six pairs of students to use paper and pencil and four computer tools in their solutions. The interviewed students were able to produce various solution methods, make transitions between them, and find a complete solution of each equation. With regard to their choice of a preferred tool, the students displayed in their actual work a preference for manual, algebraic algorithms. In their comments, however, they frequently expressed a preference for a technological tool, and could provide an explanation for their opinion.

Introduction

Many researchers in mathematics education recommend the use of computerized tools in algebra (Dörfler, 1993; Balacheff & Kaput, 1996; Yerushalmy & Schwartz, 1993). These claims are backed by research on students' work on algebraic tasks with specific computerized tools – such as spreadsheets, graph plotters and algebraic symbol manipulators. On the other side, research on students’ ability to choose, employ and integrate various tools in the solution of an algebraic task is scant. Our limited knowledge on this issue is also related to the fact that regular classroom tasks in algebra frequently recommend explicitly the representations and tools that should be employed.

The goal of this paper is to present several findings on (a) students’ solutions of algebraic equations, in an environment that provides a variety of tools, (b) students’ ability to choose, employ and integrate various representations and tools in their solution process, and (c) students' view of their solution tools.

The study was conducted within the learning environment of the CompuMath project (Hershkowitz et al., in press). The project developed a junior high school mathematics curriculum, integrating an interactive computerized learning environment. The CompuMath students work one to two (out of five) weekly lessons, in a computer lab. The topics of the algebra course include algebraic generalizations in the first year (with spreadsheets as a technological tool), solutions of equations in the second, and functions in the third year (with a graph plotter and a symbol manipulator as technological tools). Learning is based on a cyclic sequence of investigating open problem situations in small heterogeneous groups, followed by consolidations of mathematical concepts and processes and reflective actions. The
curriculum supports a broad understanding of the equation concept, both as an algebraic or numerical equality, and as a particular point in a continuous variation.

**Procedure**

Six pairs of 13-14 year-old higher, and average ability students were interviewed. The students belonged to a selective, but not mathematically oriented urban school. They were in the first month of their last year of a three-year algebra course. The findings reported here are based on written protocols taken during the interviews and on students' written work from these interviews. Each interview lasted about 90 minutes.

The students were presented a sequence of two single equations and two systems of equations (one linear and one quadratic in each case). The equations are presented in the leftmost column of Table 1. Before presenting the first equation, the interviewer explained to the students, that they will receive a sequence of four algebraic equations and will be required to solve them in *as many different ways* as they can. The students were also shown four possible tools, to accomplish the task: paper and pencil, and three computerized tools -- graph plotter, algebraic symbol manipulator and spreadsheet. During their work, the students received no instructions or hints with regard to their choice of tools or solution methods. At the conclusion of each of the four tasks, each student was asked separately (but in the presence of his/her peer) about his preferences towards the employed tools.

**Solution methods**

During the interview, the students used a variety of solution methods (an average of 3.8 methods per pair, per equation) and employed all four available tools. All pairs found the solution of each equation, even when they were unable to provide a paper and pencil solution. Table 1 presents the students' solutions of the four equations. Due to limitation of space, some secondary variations in solution processes were not included.

Remarks: (a) During their course work, the students did not encounter the algebraic algorithm for solving quadratic equations or systems. (b) During their course work, spreadsheets were used to describe and investigate variations, but were not employed as a tool for solving algebraically presented equations. (c) A spreadsheet solution of equations with two variables is very complex and inconvenient. (d) The students had no previous experience with parallel work on several computer tools and with the need to choose a tool according to their considerations.

The first remark explains the students' relatively low level of success in the use of paper and pencil to solve quadratic equations, whereas (b) and (c) may explain the relatively low frequency of their use of spreadsheets, as compared to other tools. Another fact that should be mentioned is that (d) did not seem to have a limiting

on students' facility in their transition from one tool to another and on their ability to make connections between their work on different tools. Thus, for example there were at least ten cases of going back from a technological tool to previously performed paper work, in order to find out "what went wrong". Instances of students making connections between outcomes obtained on different technological tools were also observed. For example, pairs E and F reported that they used the results obtained on the algebraic manipulator, in order to verify their previous work on the graph plotter.

**Choice of solution tools.**

We will report here several findings on students' preference for solution tools. The analysis was based on several sources: (a) observations of their actual work, (b) students' comments made after the solution of each equation and (c) spontaneous comments made by students during their work.

All six pairs started each task with paper and pencil. The fact that the solution algorithm for solving a quadratic equation was unknown did not deter them from employing an algebraic approach as a first attempt. For example, pair A attempted to solve Equation 2 as follows:

A1: *Let's do -6* [Writes \(x^2 - 5x = -6\)] *Can we divide by x?*

A2: *May be [square] root of x?*

A1: *Let's do +5x and then the root* [Writes \(x^2 = 5x - 6 / \sqrt{x}\)]

A2: *We were not taught to take this apart [separate x].* [Writes \(x = -6 + \sqrt{5x}\)]

A1: *We'll put it together, take it apart, put it together, take it apart, until we get [the solution].*

Table 2 presents the interviewed students' preference of tools, as expressed explicitly at the end of solving each of the four equations.

**Table 2. Students' preference of tools for each of the four equations (N = 12).**

</tbody>
</table>

Although in their actual work, all six pairs chose to start each of the four solutions on paper, the students were less committed to this tool in their comments made at the end of each task. Table 2 indicates that in the case of the linear equation, most
students preferred a solution on paper. In the other three tasks, however, most students chose one of the two computerized tools as their first preference.

The preference for paper and pencil was backed up by several reasons. We cite selectively because of space limitations.

- Level of involvement in the solution process.

  My knowledge is better on paper. You don’t make efforts on the computer. That’s good for the lazy ones. I like to use the paper, but sometimes it gets complicated ... I like challenges.  
  \textit{(E2, Eq. 1)}

  If I use Derive, it does not mean that I did it. The computer did it. 
  \textit{(F2, Eq. 2)}

- Availability.

  Chances are that I may be without a computer – on the matriculation exam there are no computers. 
  \textit{(B1, Eq. 1)}

- Need for understanding and for transparency.

  Derive did not show anything ...just gave the answer and did not show anything. 
  \textit{(B2, Eq. 2)}

  The paper seems to me safer, although Derive solves everything. [Working with Derive] on complicated equations, it may get complicated and you don’t understand what did you get ... Derive is more convenient, but if [the equation] is complicated, I don’t understand how did I get the x. 
  \textit{(D2, Eq. 1)}

- Teacher/Interviewer expectations.

  Derive is the best and is quick, but in exercises the teacher wants us to show the way. 
  \textit{(B2, Eq. 4)}

  The computer is better, easier, but this is not a way. On a test they won’t let us use it. If we were allowed, of course. 
  \textit{(F2, Eq. 3)}

- Personal attitude.

  I don’t want to deal with graphs. 
  \textit{(C1,C2 Eq. 2)}

  I like the paper. It’s comfortable. 
  \textit{(E1, Eq. 1)}

Most students could recognize, at least at a declarative level, the advantages of computer tools. In view of the objective difficulties raised by solving an equation in a spreadsheet (Excel) environment, we will relate here to students’ attitude towards the graph plotter (Mathemati-X) and the symbol manipulator (Derive). Students
mentioned (mainly when their knowledge did not allow them to solve the given equation manually) the computer's ability to solve any equation.

*The computer can find every possible result and I can't*  
(C1, Eq. 4)

Students mentioned as the main advantage of the graph plotter its transparency, whereas the symbol manipulator's main strength, according to them, lies in its speed and operational easiness.

*The solution [on paper] is a little difficult. I prefer the graph. It gives the intersection point. By substituting numbers [i.e., trial and error] we could have thought that there is only one solution \( x = 2 \). We could have stopped at 2. Here [on Mathemati-X] we see the graph going up and down and we can find both solutions.*  
(A1, Eq. 2)

A preference for the graph plotter was frequently attributed to the fact, that the manipulator did not satisfy the need to understand the solution process.

*Between Derive and Mathemati-X, I prefer Mathemati-X, because it's more concrete. When we see the graph, we understand, we see it concretely, clearly.*  
(D1,D2, Eq. 2)

*Derive was the best and the quickest.*  
(B2, Eq. 4)

In some cases, the legitimacy of a symbol manipulator as a solution tool was questioned altogether.

*Derive is not really a way [for solving equations].*  
(F1, Eq. 1)

*[Derive] is easier – but it is not a way.*  
(F1, Eq. 3)

**Conclusion**

The findings clearly indicate that the interviewed students were able to employ a variety of solution methods. They made connections between various meanings of the equation concept and of the solution process employed with each tool.

Some researches showed that even when students were able to solve standard problems in both symbolic and graphical representations, their actual understanding of connections between representations was often superficial and vague (Yerushalmy & Schwartz, 1993; Knuth, 2000). This difficulty was not observed in our case. The interviewed students were able to present the concept of equation in various representations, move between tools and between representations and connect the outcomes. They were able to produce various solution methods, make transitions between them, and find a complete solution, even when a standard algebraic, paper and pencil method could not be produced.
With regard to their preferences of the four available solution tools (paper and pencil, graph plotter, algebraic symbol manipulator and spreadsheet), the picture is less clear. For affective, cognitive and external reasons, students displayed in their actual work a preference for manual, algebraic algorithms. In their comments, however, they expressed a less univocal stand. They frequently chose a technological tool as their first preference, and explained the reason for their expressed preference. The main criteria that influenced the students’ choice of tools were a potential to display the solution process, a potential to allow a higher extent of student involvement in the solution process and compliance with accepted norms of work.

CONSTRUCT VALIDITY OF A DEVELOPMENTAL ASSESSMENT ON PROBABILITIES: A RASCH MEASUREMENT MODEL ANALYSIS

ATHANASIOS GAGATSIS, LEONIDAS KYRIAKIDES & ARETI PANAOURA
DEPARTMENT OF EDUCATION, UNIVERSITY OF CYPRUS

ABSTRACT
The aim of the study reported in this paper was to obtain construct related evidence of a test on pupils' understanding on probabilities. The theoretical background underlying the design of the test is presented. The test was administered to year 4, year 5 and year 6 Cypriot pupils (n=623). The Extended Logistic Model of Rasch was used and the data were analysed by using the computer programme QUEST. A scale was created for the test and analysed for reliability, fit to the model, meaning and validity. It was also analysed separately for each of five groups (boys, girls, year 4, year 5 and year 6 pupils) to test the invariance of the scale. Analysis of the data revealed that the instrument has satisfactory psychometric properties. Five levels of probabilistic thinking were also identified. Despite the fact that there is a linear sequential hierarchy among the five levels, a big difference between the second and the third level was found. The findings are discussed with reference to intended uses of the assessment. Suggestions for further research are also drawn.

I) INTRODUCTION
In recently published literature on mathematics education there is a movement to introduce elements of probability into the elementary school curriculum. Thus, nowadays probability is one of the major areas of mathematics in primary curricula (NCTM, 2000; DfEE, 1999; Ministry of Education, 1994). The main purposes of the studies which have been developed by educational psychologists and mathematics educators about probability were the investigation of the conceptions of pupils about probability and the understanding of the concept of probability (Jones et al, 1999; Konold et al, 1993), the investigation of the misconceptions of children (Garfield & Ahlegren, 1998; O'Connell, 1999; Ayres & Way, 2000) and the proposition of valid framework which would enable young children's probabilistic thinking to be described and predicted across levels (Jones et al, 1997; Amir & Williams, 1999). It has been shown that early primary pupils are able to develop conception about probability prior to classroom instruction and the experiences of the six years old pupils are useful for the teaching of probability (Ayres & Way, 1999; Ojeda, 1999). Children bring informal knowledge acquired in daily life from their culture which might interfere with their learning of probability. Ayres and Way (1999) reveal that children without any formal probability schooling can make decision based on likelihood. However, Amir and William (1994) argue that it is possible for pupils of
twelve years old to encounter difficulties in predicting the probability of tossing a coin, believing that it depends on how you toss it.

Although there has been considerable research into students’ probabilistic thinking, there has been almost no research on the development and evaluation of instructional programmes in probability. Instructional programmes are expected to be flexible and guided by formative assessment of pupils’ understanding of the subject, according to the cognitive stages of children. Jones et al. (1999) supported that pupils’ thinking about probability could be divided into four stages. At the first stage pupils predict the probability of an outcome on the basis of subjective judgement. At the second stage they predict the probability of an outcome after a combination of quantitative judgements and subjective judgements. At the third stage they compare the probabilities of different types of outcomes on the basis of consistent quantitative judgements and they distinguish “fair” and “unfair” probability generators on the basis of valid numerical reasoning. At the fourth stage they solve different types of problems on probabilities. This kind of theories empowers the construction of appropriate instructional programmes with purposes and school activities which are connected with students’ thinking about probability. In the absence of a framework for systematically describing and predicting young children’s thinking on probability the instruction of probability in primary education is possible to be inappropriate. According to Shaughnessy (1992) there is a need to develop appropriate tasks to assess students’ conceptions of probability, their understanding of probability and their ability to solve problems on probabilities.

In this context, the main purpose of the study was the development of an assessment tool for measuring primary pupils’ ability on the understanding of probability and the examination of the construct validity of the test. A test’s construct validity is defined by the degree to which a set of items measures the theoretical construct it was designed to measure (Allen & Yen, 1979). Construct validity is an ongoing process whereby a test is evaluated in the light of a specific construct. It is therefore important to collect data to verify that the measured attribute behaves in concordance with the underlying theory (Cronbach, 1990). Eventually, the purpose of the study was not only to construct a valid tool of assessment on probabilities for pupils of primary school but also to identify levels of probabilistic thinking which could be helpful for diagnostic teaching of probabilities at primary education.

II) THE DEVELOPMENT OF THE TEST: SPECIFICATION OF THE CONSTRUCT DOMAIN

The construction of the test was guided by existing research and theory in the following two areas: a) current philosophy on Mathematics Education and b) research and theory on developmental assessment. Moreover, a key requirement in designing the test was its alignment with the mathematics curriculum that was operative in the area where the study is conducted. It was therefore taken into
account that probabilities consisted a major part of the Cyprus primary mathematics curriculum. A content analysis of the national textbooks in Mathematics was conducted which helped us to identify seven main aims of teaching probabilities at primary schools and the emphasis which is given to each of them. Moreover, a documentary analysis of the National Standards of the USA (NCTM, 2000) and of the English National Curriculum (DfEE, 1999) was conducted. It was found that these seven aims are also implied in the national standards of USA (NCTM, 2000) and the English national curriculum (DfEE, 1999). Thus, the test tasks were constructed according to these seven aims (see Table 1). As far as the influence of research and theory on developmental assessment, the applications of developmental assessments for measuring proficiency in cognitive abilities and content areas (Brown et al, 1992) were taken into account. Two essential concepts derived from these works were as follows: a) the developmental ordering of tasks on a continuum of difficulty and b) the provision of controlled, interactive support to examinees during the testing process. It was therefore decided to include in the test assessment tasks related with each aim on pupils’ skills in probabilities which will cover a range of item difficulties. Moreover, in the instructions given to teachers who were asked to administer the test information were provided on the kind of support that pupils could have.

III) METHODS

Once the final version of the test was developed, a table which indicated the relations between the tasks of the test and the aims of the teaching of probabilities was created (Table 1). The specifications and the tasks were content validated by two experienced primary teachers, the authors of the national textbooks, two postgraduate students of Mathematics Education, and two members of the Educational staff of the
Department of Education at the University of Cyprus. The “judges” of the content and the face validity of the test were asked to mark-up and to make comments on the items. In the light of their comments minor amendments were made. The final version of the written test was administered to 623 Cypriot primary pupils of year 4 (220), year 5 (218) and year 6 (185). Additionally, 318 of the subjects were girls and 305 were boys.

The Extended Logistic Model of Rasch (Rasch, 1980) was used and the data were analysed by using the computer programme Quest (Adams & Khoo, 1996) to create a scale satisfying the seven measurement criteria set out by Wright and Masters (1981) which have to be met in order to claim that the items form a valid and reliable scale. The scale is based on the log odds (called logits) of pupils' abilities to answer correctly the 19 items of the Probability Test (PT). The items are ordered along the scale at interval measurement level from easiest to hardest. The Rasch measure produces scale-free measures of pupils’ abilities and sample free-item difficulties (Wright & Masters, 1981). This implies that the differences between pairs of measures of pupils’ abilities and item difficulties are expected to be sample independent.

IV) FINDINGS

The data were analysed initially with the whole sample (n=623) and all the 19 items together. There were two items (16 and 17) which did not fit the model. Thus, the analysis was repeated with the whole sample and the 17 remaining items. Then, the analysis was repeated with each of the five groups of the sample. This was done to investigate whether the test is used consistently by boys, girls, year 4, year 5 and year 6 pupils and is part of the measurement criteria set out by Wright and Masters (1981).

</tbody>
</table>
Separability (reliability) represents the proportion of observed variance considered to be true. A value of 1 represents high separability and a value of 0 represents low separability.

Table 2 provides a summary of the scale statistics for the whole sample and the five groups. The following observations arise from this table. First, we can observe that for the whole sample and for each group the indices of cases and item separation are higher than 0.85 indicating that the separability of the scale is satisfactory. Second, the infit mean squares and the outfit mean squares are approximately 1 (0.99 up to 1.03) and the values of the infit t-scores and the outfit t-scores are approximately zero (-0.07 up to 0.11). And since the mean squares are within 30% of the expected values, calculated according to the model, it can be claimed that there is a good fit to the model. It is also important to note that all the items have difficulties which could be considered invariant across the 5 groups, within the measurement error (0.15). Thus, an important aspect of creating a scale (sample-free item difficulties) has been achieved. Third, the mean scores of pupils' performance indicate that an increase of performance by age can be identified. However, even the mean of year 6 pupils is relatively low (-0.22) and thereby the mean of the whole sample is very low (-1.18). Fourth, the standard deviations of the abilities of each year group but year 4 are relatively high. This implies that there is a big variation among the responses of year 5 and year 6 pupils whereas the performance of year 4 pupils was generally very low.

Figure 1 illustrates the scale for the remaining 17 items of the test with item difficulties and the whole group of pupils' measures calibrated on the same scale. The following observations arise from Figure 1. First, the items are well targeted against pupils' abilities in probabilities. More specifically, pupils scores range from -4.18 to 3.04 logits and the item difficulties range from -3.34 to 2.68. It can be, however, claimed that the targeting of the items at pupils' abilities in probabilities could be improved by adding some very easy items (Thresholds = -4.00). Second, the most important weakness of the test is the absence of moderately easy items to moderately hard (i.e. from -0.76 to 0.91 logits). Thus, although the psychometric properties of the test seem to be satisfactory, the Probability Test could be improved by adding items which are neither easy nor hard. Third, five levels of probabilistic thinking can be identified. These levels are very similar to the levels mentioned at the specification table of the test. More specifically, pupils who are at the first level (i.e. below -2.00 logits) are able to describe events as impossible, likely or certain. They are also able to find which of two events is more likely to happen and their decision is based on the fact that they have realised that the probability of an event A depends on the number of outcomes of type A. However, pupils who are at the second level (-2.00 up to -0.75) are able to use the formula of Laplace for computing a probability and to compare events according to their degree of likelihood. After the second level, there is a relatively big area where none item is included. This could be attributed to weaknesses of the test either in including neither easy nor difficult tasks or in the fact that another level of probabilistic thinking should be included in the design of the specification table. However, this finding may reveal a gap between the
second and third level and that pupils have to make an important progress in order to move from the second to the third stage. At the third level (0,90 up to 1,30), pupils are able to compute probabilities for simple compound events (e.g. throwing two dice), using such methods as organised lists or tree-diagrams. They are also able to predict the changes of the probability of an outcome of type A when the conditions of the relevant experiment are changed. Pupils who are at the fourth level (1,30 up to 2,00) they can not only find the probability of an outcome of a specific type but are also able to use Laplace formula in order to compute the total number of possible outcomes or the number of outcomes of a specific type. Finally, pupils at the fifth level (above 2,00) are able to examine the rules of a game and find out whether the game is fair.

V) DISCUSSION

The Extended Logistic Model of Rasch was useful in creating a good interval level measure of the Probability Test identifying primary pupils' abilities in probabilities and for investigating its validity and reliability. The Rasch model was also helpful in analysing the conceptual design of the test. The findings of this study reveal that the Rasch analysis supports the conceptual design of the instrument. The underlying trait, that is primary pupils' abilities in probabilities, seems to be an overarching concept comprised of five different levels of probabilistic thinking. Thus, the Probability Test and its Rasch scale may help teachers decide how to identify and meet pupils' learning needs in relation to the five levels of probabilistic thinking and how to use their teaching time and their resources. An important implication of the identification of learning needs is that decisions about the next learning steps follow from it and pupils could be helped to improve their abilities and move from a lower level of thinking to a higher level. However, teachers should be aware of the fact that although the five levels follow a linear sequential hierarchy, there are pupils who are at the same level but their abilities may differ. Moreover, there is no clear distinction between the levels but between the second and the third level. It is important to note that acceptable fit was also obtained using structural equation modeling procedures for the theoretical five-factor first-order structure. A two second-order factors structure was also supported revealing that factors 1 to 2 (i.e. levels 1 and 2) were explained better by a second-order factor variable which was substantively different from that which was explaining factors 3 to 5. However, further research regarding the levels of probabilistic thinking is needed in order to examine whether a new level covering aims of teaching probability which are not mentioned in the Cyprus curriculum should be included in order to cover the area between the second and the third level of probabilistic thinking. Finally, the analysis leads to suggestions for improving the targeting of items against pupils' measures through the addition of one very easy item and some neither easy nor very difficult items (-0.5 up to 1.0 logits). Thus, further validation studies of a new version of the Probability Test may be needed in order to obtain a better targeting against primary pupils' abilities in probabilities.

DIFFICULTIES WITH NEGATIVE SOLUTIONS IN KINEMATICS PROBLEMS

GALLARDO, A. & ENCALADA, N.
DEPARTAMENTO DE MATEMATICA EDUCATIVA

ABSTRACT: The article reports a Case Study (Heidi) described in a wider research work on Problem Solving in Kinematics, involving 28 high school students. The study provides evidence that Heidi's proficient academic performance leads her to the correct answers and verbal description of the physical phenomena involved. However, when explaining the answer in algebraic language, Heidi cannot interpret it because of her lack of acquaintance with negative numbers as final results, although she has dealt with them as part of the intermediate procedures.

RESUMEN: Este articulo reporta un Estudio de Caso (Heidi) descrito en una investigacion mas amplia sobre Resolucion de Problemas de Cinematica, realizado con 28 estudiantes a Nivel Secundaria. Los resultados de este Estudio muestran que el alto desempeno academico de Heidi le permite llegar a las respuestas y dar descripciones verbales de los fenomenos fisicos involucrados en los problemas. Sin embargo, al expresar las respuestas en lenguaje algebraico, no logra interpretarlas debido a que Heidi desconoce a los negativos como resultados finales a pesar de trabajar con ellos en procesos intermedios de resolucion.

INTRODUCTION

A research project was recently carried out whose central problem was the study of negative numbers in their interaction with the languages and methods used to solve equations and problems (Gallardo, 1994). The general methodology of the project dealt with the interaction of these categories on two levels, the historical and the didactic. The historical-critical analysis carried out in this work allows us to conclude that the presence of subtractive terms and the laws of the signs appear in remote times, as do the elements necessary for the operativity of signed numbers. It can be said that a crucial step in the recognition of these numbers is the acceptance of negative solutions. The empirical analysis is based in the preceding historical study of negative numbers in the resolution of algebraic equations. In this research, we identified different stages of conceptualization of negative numbers which appear both in the historical and didactical spheres.

THE STUDY

Once research on negative numbers in the arithmetical-algebraic domain has been concluded, a second stage is initiated where the incidence of these numbers in high school physics is analyzed. The methodology used in this particular stage is the same methodology applied in the project as a whole, that is, using the historical-critical method in order to search for elements of analysis that may explain students' difficulties in interpreting negative magnitudes in elementary kinematics problems. Galileo and Newton's physics were revisited. In Galileo's text, motion laws are described and interpreted through dialogues that lead to the birth of the New Science
(Crew, 1914). Newton sets up kinematics' axioms which, as their name indicates, are expressed mathematically (Whiteside, 1972). In relation to our purpose, we must mention that neither Galileo nor Newton present any occurrence of negative numbers as solutions.

This article reports a first experience in the teaching of kinematics. The traditional teaching-learning process involving the motion laws is analyzed. The problems dealt with herein are those applied in the high school context and were picked out of the Lima, Perú High School Physics Program (Encalada, 1999). Three out of 20 considered “Typical Problems” (Laglois et al, 1995) were selected. An exploratory questionnaire including these three problems was developed and applied to 28 students from four different groups of a same teacher. The researcher picked out the brighter students for the clinical videotaped interview purpose. Such selection was based on the fact that a good performance in physics and mathematics is necessary condition to do well at solving physics problems (Lang Da Silveira et al, 1992).

The case of one of the students, Heidi, is featured in the paper. A Formula Table containing conventions regarding the plus and minus signs is handed out to the students together with the problems (Fig. 1).

</tbody>
</table>

Fig. 1: FORMULA TABLE handed out to the students.

As shown hereafter, the use of the Formula Table leads to positive solutions on both problems. In fact, the general formulas of the Uniformly Accelerated line Motion are the following: \( V_f = V_0 + at \); \( V_f^2 = V_0^2 + 2ae \) where letters may have any value, including negative solutions.

**SOLUTION PROCEDURES OF TWO KINEMATICS PROBLEMS.**

**PROBLEM ENUNCIATION I:** The brakes of a car travelling at 200m/s are applied and the car comes to a complete stop after 80 meters. Estimate the car’s acceleration and the time it takes to stop.

---

1 It is important to mention that historical analysis of this second stage of the project is still under way.
2 All of the letters take on positive values or zero only.
3 Two problems with negative solutions were selected. The third one has a positive solution and is not presented in this article.
**Analysis of the first question: Estimate the acceleration**

- The student writes problem’s data and unknown.

  \[ V = 200 \text{ m/s}; \ V_f = 0; \ e = 80 \text{ m}; \ a = ?; \ t = ? \]

- She explains that “V=200m/s is start off velocity” [Note that initial velocity is designated by \( V \) and not by \( V_0 \)]

- She recognizes that final velocity is zero when she asserts that “velocity decreases and the car comes to a stop”.

- She checks her Formula Table (See Fig.1) and writes: \( V_f^2 = V_0 - 2ae \). (Mistaken because initial velocity is not squared).

- She inserts her data and obtains: \((0)^2 = 200 - 2a(80)\). She continues the algebraic procedure and states the following: “This two \( 0 = (200) - 2a(80) \), comes here \( 0 = (200)^2 - 2a(80) \).” The error in formula \( V_f^2 = V_0 - 2ae \), is compensated when placing the exponent 2 on the numerical term that corresponds to \( V_0 \). She adds: “zero \( 0 = (200)^2 - 2a(80) \), you don’t put anything else. \( = 40000 - 160a \), because it’s zero”. For a moment, the first member of the expression disappears. This indicates that she does not have full understanding of the equation concept. The process continues correctly: \( 160a = 40000; \ a = 40000/160; \ a = 250 \text{m/s} \) (Incorrect unit). Deficiencies in the acceleration concept can be perceived in the following dialogue:

  Interviewer asks: “what does acceleration mean?”

  Heidi answers: “Acceleration appears to be the relationship between the distance and... and the distance. Well, that is to say, the distance it covers during the time it’s moving\(^4\). That is veloc...acceleration. Distance over square time”. She adds exponent 2 to her previous answer: \( a = \frac{250m}{s^2} \)

  When obtaining a positive solution, she does not retrieve the interpretation she herself verbalized before she looked at her Formula Table when she stated: “velocity is decreasing and the car stops”.

  If the student had used the general formula: \( V_f^2 = V_1^2 + 2ae \), she would have arrived at a negative solution \( a = \frac{250m}{s^2} \).

  The minus sign could have helped her provide a physical interpretation of the problem instead of repeating mechanically that acceleration is “the distance divided by the square time”, as occurred when she used the “positive expression” that appeared on the Formula Table. The previous fact identifies a difficulty in the teaching of kinematics at high school level.

---

\(^4\) She’s not clear about the acceleration. She mistakes it for velocity. The correct relationship established by the acceleration is between velocity and time.
Analysis of the second question: Estimate the time it takes to stop.

- Once the acceleration is known, the student realizes she must find out the time. She then writes: \( V_f = V_0 - at \). She explains this by indicating “because I have all those data and only the time is missing”.

She inserts her data on the previous formula, obtaining: \( 0 = 200 - 250t \). She then writes: \( 200 - 250t \) and states “Here \( 0 - 250t \) is zero, so you don’t put it”. Again, the equation disappears in front of zero. She now adds the zero and the equal sign in order to do an operation. She obtains \( 0 + 250t = 200; 250t = 200; t = 0.8 \) s (correct answer).

- The researcher poses her an additional question to analyze the velocity magnitude.

ADDITIONAL QUESTION TO PROBLEM 1: A car starts from rest. Its velocity is \( 80 \) m/s after running \( 100 \) meters. Estimate the acceleration.

- She asserts that “the car is at absolute rest so it doesn’t move and the velocity is zero”. She writes the problem’s data and unknown:
  
  \[
  V_0 = 0; \quad e = 100; \quad V = 80 \text{ m/s}; \quad a = ?; \quad V_f = 0 \quad \text{(error)}.
  \]

Because of the error on \( V_f \) [final velocity] and because Heidi writes down three velocities, the researcher asks her “what does \( V = 80 \text{ m/s} \) mean?” She replies: “It starts from rest, so \( V_0 = 0 \) and \( V = 80 \text{ m/s} \) is the velocity it goes at; it is just the velocity. It cannot be the final velocity because…” (silence).

She is mistaking uniform straight line motion, where velocity \( V \) is constant, with uniformly accelerated motion where the velocity changes at each time unit at the so-called acceleration rate. The researcher uses a scheme to elucidate the difficulty to the student.

\[
\begin{array}{cccc}
    & V_0 & 80 \text{ m/s} & \\
0 & 0 & e = 100 \text{m} & \\
\end{array}
\]

She adds the velocity’s notation \( V_f \)

The diagram now appears like:

\[
\begin{array}{cccc}
    & V_0 & V_f = 80 \text{ m/s} & \\
0 & 0 & e = 100 \text{m} & \\
\end{array}
\]

This way, the student recognizes that \( V \) is the final velocity \( V_f \).

- Heidi indicates she will use the formula: \( V_f^2 = V_0^2 - 2ae \), but with the positive sign, namely, \( V_f^2 = V_0^2 + 2ae \), “because the mobile is moving”.

- She inserts her data \( (80)^2 = (0)^2 + 2a(100) \). She goes on with the procedure:

  \[
  6400 = 0 + 200a; \quad 6400 = 200a; \quad a = 6400/200 \quad a = 32 \text{ m/s}^2 \quad \text{(Correct result. She spontaneously adds the measurement unit).}
  \]
SOLUTION PROCEDURE FOR PROBLEM 2

PROBLEM 2 ENUNCIATION: A balloon⁵ rises at a constant velocity of 5m/s. When it is 30 m. away from the ground, a stone is let down from it. At what velocity and after how long will the stone reach the ground?

- The student begins with the second question (time). She indicates: “This is the height reached by the stone” and writes h = 30 m (She does not consider the balloon). She writes the problem’s unknowns V = ?, t = ?; she mentions that “when a body is at height, there is gravity”. She writes g = 9.8 (She omits the measurement unit). Note that she recognizes an implicit datum. Gravity does not appear in the problem’s enunciation.

- Heidi now goes to the Formula Table and writes h = at²/2 (She does not consider gravity as g in this expression). The researcher asks her about this: “This formula h = at²/2 Why?”. The student answer:

“They ask for the velocity, they ask for the time, but I have none. There are two unknowns here (h = at²/2) and I must find one”.

She then points out at the data on the paper (V = ?, t = ?, g = 9.8) and recovers the gravity’s acceleration. She substitutes acceleration (a) for (g) on the formula, obtaining h = gt²/2

She inserts the height as well (h=30m) and carries out the inverse operations correctly: 30 = 9.8(t)²; 60 = 9.8t²; t² = 60 / 9.8; t = 2.47 (She omits the measurement unit)⁶

- She now goes to the first question of the enunciation: what is the stone’s velocity when reaching the ground? She writes: Vf² = V₀² + 2gh, and explains “This is (Vf) what they are asking me for”. She places the value of V₀ on the expression and obtains Vf² = (0)² + 2(9.8)(2.47). She mistakenly justifies initial velocity zero stating that: “it starts from rest and then it goes up”. She also makes an error when substituting time for height (she writes 2.47 where it should be 30).

Observe a contradictory situation on the following dialogue:

E: “What is the stone’s velocity when you let go of it?”
H: “Well, the same. If you go up at that velocity and come down at the same velocity, it is going to be the same. When going up, the balloon and the stone go at the same velocity V₀ = 5m/s, but when reaching a 30 m. height, the stone gets there at Vf = 0 because it is going to come back down”.

⁵ Hidrostatic balloon containing the stone.
⁶ Only the positive square root is considered in teaching. So time is always not-negative. This solution is incorrect because the stone’s initial velocity is different from zero, namely V₀ = 5m/s.
Note that taking the balloon into consideration helps her conceive $V_o \neq 0$. When she omits the balloon and only takes the stone into consideration, she obtains $V_o = 0$. After she provides the answer $V_o = 5$ m/s, the researcher has her check her previous formula to compare both results.

E: “If $V_o = 5$ m/s, so why did you put zero in here $V_f^2 = (0)^2 + 2(9.8)(2.47)$?”

The student remains silent. She now goes on to the first question of the problem. She does not notice that she made a mistake when placing time instead of height and goes on with the procedure: $V_f^2 = 0 + 48.4; V_f = 6.95$ (Omits the measurement unit). Her final result is wrong, it should be 25 m/s (stone’s final velocity when reaching the ground).

- The researcher poses one more question to elucidate student’s confusion in relation to the initial velocity.

**ADDITIONAL QUESTION TO PROBLEM 2.**

* A stone falls from a 100 m. height. Estimate the time it takes for it to reach the ground and the velocity when reaching it.

- Heidi writes the problem’s data and unknown: $h = 100$ m; $t = ?$; $V = ?$; $g = 9.8$ (Omits the measurement unit).

- She then writes the following formula: $h = gt^2/2$

- She goes on with the correct insertion of her data and the inverse operations:

  $100 = 9.8t^2/2; 200 = 9.8t^2; t^2 = 200/9.8; t = 4.5$ (Omits the measurement unit)

- She writes $V_f^2 = V_o^2 + 2gh$. She asserts that “velocity is zero because I consider the stone only when it is let down” (she refers to the initial velocity). She inserts her data and obtains: $V_f^2 = (0)^2 + 2(9.8)(100); V_f^2 = 1950$

  $V_f = 44.2$ (Omits the measurement unit). This solution is correct.

- When the researcher asks her to compare problem 2 with the additional question, Heidi asserts “they are the same because you use the same formulas to solve them; but they follow a different procedure, because the balloon and the velocity 5 m/s, which I never used, have a part in problem 2. On the other case (she refers to the additional question to problem 2), the velocity is null and the balloon does not appear”. It is plain to see student’s misconception that at free fall initial velocity is always zero. She forgets that an object may be hurled with an initial velocity different from zero.

**STUDY CONCLUSIONS.**

The article shows the difficulties that a highly qualified student faced in order to interpret the solution of kinematics problems. Such difficulties derived from the previous teaching on the subject. Such teaching encourages the use of the Algebraic Formula Table leading always to positive solutions. It is worth noting that the
convention of the plus and minus signs in formulas implicitly contains a Cartesian reference system that is not mentioned to the students.

Teachers resort to the use of signs instead of referring to signed magnitudes which, at a higher level, would be considered as vectorial magnitudes. Also, given the fact that difficulties to these problems lie in the relativity of time and space where physical phenomena take place, defining the participating objects and their motion reference point or the time interval where they take place is necessary. Again, elucidating the reference system in use is very important.

Another problem in teaching is the omission of the dimensional analysis. The measurement units associated to magnitudes should be kept in mind all throughout the solving procedure. This consideration would help verifying if the answer is correct and might bring to light possible errors on the designated formulas and on the operations carried out with the corresponding magnitudes. The most generalized tendency among students is to fit in the measurement units once the final result has been obtained.

As far as the student's performance is concerned, our conclusions are the following: She shows better understanding of the physical phenomena after reading the problem and before consulting the Formula Table. She is not able to put in algebraic language what she expresses in natural language, since the former is mediated by a convention of signs that appears unintelligible to her, and which cover up the coordinates system in use. So in problem 2, she mistakes the velocity rate as null because she was not aware of the reference system; had she been aware, she would have placed the origin at 30 m. from the ground, and would have considered the balloon containing the stone, and would have noted that both move at initial velocity of 5m/s (See Appendix).

It is worth mentioning that during the Problem 1 solution procedure and Problem 1 Additional Question, arises what we have called an error compensation, that is, Heidi mistakenly omits exponent two in the algebraic expression but then puts it back in when carrying out an erroneous transposition of the members of the equation. So the second error makes up for the first error. On the other hand, we know the student has not consolidated the equation concept because she does not write the complete equation, and integrates it only when carrying out the operations. As far as the physical context is concerned, Heidi seems confused at the types of motion she has been exposed to, since she is not aware of the different velocities involved in each of them. This, in turn, manifests her not having full understanding of the acceleration concept.

**APPENDIX: CORRECT ANSWER TO PROBLEM 2**

**ENUNCIATION OF PROBLEM 2:** A balloon rises at constant velocity 5m/s. When it is 30 m. away from the ground, a stone is let down from it. At what velocity and after how long will the stone reach the ground?
DATA: \( g = -9.81 \text{ m/s}^2 \equiv -10 \); \( V_o = 5 \text{ m/s} \); \( h = -30 \text{ m} \); \( t = ? \); \( V_f = ? \)

Note that the problem involves the use of vectorial magnitudes, since it introduces a coordinates system. The origin is considered at 30 m above the ground, that is, at the point where the stone is let down.

SOLUTION:

- **Time it takes the stone to reach the ground (Second question).**
  
  \[
  h = V_o t + \frac{gt^2}{2} \]
  
  Replacing the data we have: 
  
  \[
  -30 = 5t - \frac{10t^2}{2}
  \]

  Solving the quadratic equation we arrive at answers: 
  
  \[
  t = 3 \quad \text{and} \quad t = -2
  \]

  Result \( t = -2 \) is discarded because that would mean the stone should have been let down two seconds before. If it were so, it would have not spanned the mentioned distance but more meters. So, the time it takes the balloon to reach the ground is 3 seconds.

- **Velocity at which stone reaches the ground (First question).**
  
  \[
  V_f = V_o + gt
  \]

  Inserting the data, we have: 
  
  \[
  V_f = 5 + (-10)(3) = -25
  \]

  Thus, the stone will reach the ground at a velocity of 25 m/s.

REFERENCES

ABSTRACT: This paper presents a study concerning novices’ cognitive apprenticeship in the field of inequalities. A specific educational context was designed with the purpose of revealing and enhancing the students’ potential in dealing with inequalities according to a functional approach. A preliminary analysis of students’ solutions is provided.

1. Introduction

In many mathematics domains, mathematics education research must face widespread, strong difficulties in teaching and learning specific subjects. Difficulties met by teachers and students frequently bring to postpone those subjects and/or reduce their teaching to procedural aspects. In some cases epistemological, didactical and cognitive analyses can help planning teaching experiments which allow researchers to better understand the reasons for these difficulties and, possibly, reveal students’ potential in dealing with those subjects. Innovative educational choices are an expected reasonable outcome (cf. Arzarello and Bartolini, 1998). In particular, didactical analyses may point out conditions under which difficulties take place and peculiar didactical choices related to them; while epistemological analyses may enlighten the nature of involved mathematical concepts. Cognitive analyses seem to be necessary in order to detect crucial mental processes underlying specific mathematical performances, with the aim of enhancing them through classroom work.

In this report we present the guidelines and some preliminary results of a research program conceived according to the above perspective and concerning the approach to inequalities in 8th-grade. Our working hypothesis is that a functional approach to inequalities (i.e., an approach based on the comparison of functions), when suitably managed by the teacher, can reveal (from the research point of view) and allow to exploit (from the curriculum design point of view) a students’ potential which goes far beyond the mathematics content involved (inequalities). Our preliminary results support this hypothesis and enlighten some conditions concerning the educational setting which students’ success seem to depend on.

2. Inequalities: a challenge for teaching and research

In most countries, inequalities are taught in secondary school as a subordinate subject (in relationship with equations), dealt with in a purely algorithmic manner that avoids, in particular, the difficulties inherent in the concept of function. For instance, in Italy and some other countries students are taught to deal with second order inequalities depending on a parameter (e.g., $x^2+Kx+1>0$) in a very rigid, prescriptive way: they must solve the equation $x^2+Kx+1=0$ (distinguishing between the three cases: no real solution, two coincident real solutions, two distinct real solutions); then they must build up a schema where "concordances" and "variations"
of signs, in relationship with the values of the parameter K, provide the student with the solutions for the given inequality. We observe that this approach implies a "trivialisation" of the subject, resulting in a sequence of routine procedures, which are not easy to understand, interpret and control.

As a consequence of this approach, students are unable to manage inequalities which do not fit the learned schemas. For instance, according to different independent studies (cf Boero, 2000; Malara, 2000), at the entrance of the university mathematics courses in Italy most students fail in solving easy inequalities like \( x^2 - 1/x > 0 \). In this task, proposed to a sample of 58 students entering the Faculties of Science of Genoa and Pisa Universities, less than 60% engaged in solving the inequality (the others answered "I am not able", "I did not study it"); most of them performed the following transformations: from \( x^2 - 1/x > 0 \) to \( x^2 > 1/x \) to \( x^3 > 1 \). Few students took care of the case \( x = 0 \); less than 10% of the whole sample made a distinction between the case \( x > 0 \) and the case \( x < 0 \). In general, graphic heuristics were not exploited and algebraic transformations were performed without taking care of the constraints deriving from the fact that the \( > \) sign does not behave like the = sign (see Tsamir et al., 1998, for a deep analysis of such behaviour). Similar phenomena were described in some studies concerning the French situation (see Assude, 2000; Sackur and Maurel, 2000).

This brief presentation brings to the following conclusion: the prevailing manner of teaching inequalities in school neither is efficient (as concerns the results, in terms of capacity of dealing with a large set of rather simple inequalities) nor results in acquisition and/or reflection about the mathematics concepts involved. We may ask ourselves what are the reasons of this situation.

One reason could be the fact that equations (and inequalities) are considered (in most of European countries, including Italy) as a typical content of school Algebra; this subject matter is distinguished from Analytic Geometry and does not include functions. This might explain why inequalities (and equations) are not dealt with in those countries from a functional point of view. But even in countries where functions (and Analytic Geometry) belong to school Algebra (cfr. NCTM Standards, 1989) the procedural, algebraic approach prevails in many curricula and even in innovative proposals (cf Mc Laurin, 1985; Dobbs and Petersen, 1991).

Another possible hypothesis is that inequalities are a very complex and demanding subject; dealing with few and well codified cases in an algorithmic way appears as a consequence of these intrinsic difficulties. In order to support this interpretation we may observe that (from an epistemological point of view) the functional aspect plays a crucial role, both for equations and inequalities. Indeed, let us analyse mathematicians' work when they solve equations with approximation methods, deal with the concept of limit or treat applied mathematical problems involving asymptotic stability: the functional aspect of inequalities plays a crucial role. This fact is often neglected in traditional teaching: as suggested at the beginning of this Section, we may recognize that the traditional teaching of inequalities avoids the "function" concept and reduces the difficulties inherent in the "variable" concept and the complexity of the solution process by treating inequalities as a "special" case of equations.

Under the same perspective we can make the hypothesis that an alternative approach to inequalities based on the concept of function could provide an
opportunity to promote the learning process of the difficult concepts involved and the development of the inherent skills. It could also ensure an high level of control of the solution processes of equations and inequalities (Sackur and Maurel, 2000).

Finally, we must remark that in spite of the importance of inequalities in mathematics and of the difficulties met by teachers and students in dealing with them, few studies in mathematics education concern the school approach to inequalities (see References). It is like if the subalternity of inequalities to equations in the teaching of mathematics, was reflected in a scarce relevance for inequalities in mathematics education research; in particular, as concerns the functional approach to inequalities.

3. Method
Keeping the previous analysis into account we have planned a teaching experiment in two VIII-grade classes with two rather limited aims: investigating the feasibility of an early functional approach to inequalities; and revealing students' potential and difficulties in dealing with this subject as a special case of comparison of functions. We choose to guide VIII-grade students in a cooperative, gradual enrichment of tools and skills inherent in the functional treatment of inequalities. Then we have analysed how (in relatively complex tasks) they were able to use their knowledge and increase their experience in an autonomous way.

3.1. The educational context
36 VIII-grade students (divided into two classes) were involved; as usual in Italy, they had started to work with the same mathematics and science teacher in grade VI. The didactic contract established in grades VI, VII and at the beginning of grade VIII was coherent with the methodological choice of a cooperative, participated, guided enrichment of tools and skills in the planned activity. A rather common routine of classroom work consisted in individual production of written solutions for a given task (if necessary, supported by the teacher with 1-1 interventions), then the teacher guided classroom comparison and discussion of students' products; possibly, the adoption of other students' solutions in similar tasks followed. Another aspect of the didactic contract included the exhaustive written wording of doubts, discoveries, heuristics, etc.

3.2. Specific content and educational choices
As concerns the content, the concepts of function and variable have been approached through activities involving tables, graphs and formulas. At the beginning the geometrical context (area, perimeter, etc.) was prevailing, then it has been progressively left aside. At the beginning the function was presented as a machine transforming x-values into y-values (machine view in Slavit, 1997), then classroom activities focused on the variation of y as depending on the variation of x (covariance view). By this way a dynamic idea of function gradually prevailed on the static consideration of a set of corresponding pairs (correspondence view). As a consequence, a peculiar aspect of the concept of variable was put into evidence (a variable as a "running variable", i.e. a movement on a set of numbers represented...
on a straight line) (cf Ursini, 1997). Finally, the approach to inequalities was realised by comparing functions.

The didactical contract demanded to compare functions as global, dynamic entities. Students knew that they had to compare functions by making hypotheses based on the analysis of their formulas. The point-by-point construction of graphs was discouraged. As a consequence, the ordinary table of x, y values was sometimes exploited as a tool to analyse how y changed when x changed (column-vertical analysis) and not as a tool to read the line-horizontal point-by-point correspondence between x-values and y-values. Finally, we can remark that the algebraic and the graphical settings were strictly related (formulas were read in terms of shapes in the (x,y) plane, while graphs evoked formulas).

As concerns the educational choices related to classroom management of the functional approach to inequalities, the following points were considered crucial:

- classroom discussions about "what do we loose and what do we earn" when a function is represented through formulas or graphs or tables or common language;
- different ways of describing given functions have been encouraged. For instance the discovery that the formula y=2x^2 corresponds (within the table of the x and y values, read vertically according columns) to an "irregular" increase of y which is different from the "regular increase" in the case of y=2x, and that the irregular increase results in a curved line when the graph is drawn (later on the teacher will call it "parabola") allows to link different ways of representing functions (see Duval, 1984: coordination of different linguistic registers). They will become personal tools exploited and transformed (see Ex.1 in the next Section) to compare functions. Even the metaphors used by students to describe the role of different pieces of the same formula have been encouraged and discussed.

3.3. Individual task

We will consider the following task:

"Compare the following formulas from the algebraic and graphic points of view. Make hypotheses about their graphs and motivate them carefully, finally draw a sketch of their graphs. A) first function. B) second function"

Slightly different functions A and B were chosen according to the students' levels. In particular in this paper we will analyse the solutions of three students engaged in solving the problem with the following functions (of mean level of difficulty):

A) y=x^2-4x+4; B) y=-x^2+4

In every case the above task was significantly more difficult and complex than the previous ones: they concerned the comparison of functions like y=x^2, y=-x^2+4

We expected that (according to the didactical contract and previous experiences) most students could explore both functions in a dynamic way, trying to answer the following questions:

- What does happen with y when x>0 or x<0? Does it increase? Does it decrease?
- Are there meeting points between the two graphs? Where? When?
- Does the first graph overcome the second one? Where?

All individual solutions were collected (some protocols contain questions and comments written by the teacher during the 1-1 interactions). We collected also some recorded interviews performed after the end of the activity and concerning the strategies produced by students and their general ideas about inequalities.
4. Preliminary results

4.1. Some quantitative data

- 5 students out of 36 did not succeed in tackling the problem (they did not understand it, or were stuck)
- 7 students (out of 31 who were able to tackle the problem) arrived to incorrect conclusions (sometimes due to trivial mistakes in calculations).
- 3 students (out of 31) build up graphs point by point (against the didactical contract), while the others compare functions in a dynamic and global way with different strategies.

4.2. Some qualitative data.

From a qualitative point of view collected data are interesting for the following reasons:

a) 28 students (out of 31) show good skills in coordinating different linguistic registers (formula, graph, verbal language, etc.)

b) a plurality of strategies of comparison between the two functions, frequently consisting in a personal blend of strategies and moves compared and discussed in previous classroom activities. In particular we can find:

b1. Strategies based on the relationships between formula and shape of the graph (6 out of 28 who keep the didactical contract).

Formulas, or some of its parts, are associated with a peculiar shape of graph (Ex. 1, Davide).

In the case of Davide, $x^2$ evokes the shape "parabola" and the other elements of the given formula are interpreted in terms of transformations of the prototypical graph: for instance the presence of a negative sign before $x^2$ suggests the "reversed U shape" (for a similar behaviour cf an example provided by R. Hershcowitz: the student detects the graph of $y=-x^3$ by referring it to the well known graph of $y=x^3$). The dynamical aspect of the solution consists in the interpretation of the different parts of the given formula as transformations of the prototypical formula.

Davide seems to ask himself questions like "What does it mean $+4$ in the graph? And what about the sign - on the left of $x^2$? What does it mean $-4x$ in the graph?". The most interesting fact is that the graph seems to be "an object", a shape which can be moved as a whole.

We can ask ourselves how the relationship between the shape "parabola" and the formula " $y=x^2$ " was established by Davide. Considering the background of his class and his personal history we may make the hypothesis that such relationship was probably acquired through the activities of drawing graphs and that the dynamical dependence of $y$-values on $x$-values that was observed and discussed in the classroom (with the help of the table) could have "condensed" in a shape. This hypothesis implies that for Davide the shapes of the graphs are not mere shapes,
because they bear the peculiar modality of increase of y when x increases. A careful analysis of his protocol seems to confirm our hypothesis.

Ex.1, Davide: compare the two functions \( y = x^2 - 4x + 4 \) and \( y = -x^2 + 4 \)

In the graph \( x^2 \) and \(-x^2\) are two parabolas: the former is over 0 and looks like U, the latter looks like a reversed U. In both functions there is +4, thus we can say that both parabolas stand over the x-axis of +4.

(Fig. 1: he sketches the graphs of \( y = x^2 + 4 \) and \( y = -x^2 + 4 \))

In function \( A \) there is an operation \((-4x)\) which moves and transforms this parabola.

\( A \) when \( x=2, y=0 \), thus we can say that, when \( y=0 \), the parabola stands in \( x=2 \).

(Fig. 2: a parabola with the vertex in the point \((2, 0)\))

This parabola does not go under zero when x is negative.

This parabola starts slowly, because \(-4x\) decreases its speed, but successively goes up quickly.

(Fig. 3: superposition of parabolas \( A \) and \( B \)) [...].

b2. Strategies based on the relationship between formula and increase or decrease of y when x increases (14 out of 28).

In this case students analyse the behaviour of the formula according to \( x>0 \) or \( x<0 \) (Ex. 2, Lorenzo). We can imagine that Lorenzo asks himself questions that are very different from those considered by Davide: "What does it happen if \( x<0? \) And if \( x>0? \) Does it increase? Does it decrease?"). In this case the only dynamical aspect concerns the analysis of how y changes in relationship with x. Also in this case the approach is global: it is the whole function that decreases or increases when x changes. For Lorenzo the graph represents a synthesis and the visual validation of his previous analysis.

Ex.2, Lorenzo: compare the two functions \( y = x^2 - 4x + 4 \) and \( y = -x^2 + 4 \)

- In both formulas you have always found a +4. In the former \( x^2 \) you always have a positive result, while in the latter you never find it, because there is a minus before.
- If \( x<0 \): The former increases more because there is \( x^2 \), always positive, and the sign changes also in \(-4x\), which turns out \(+4x\).

On the contrary, the latter decreases only because I take out an \( x^2 \) and at a certain point the +4 cannot keep the \(-x^2\) above the zero. There is no meeting point.
- If \( x>0 \): The former decreases for a certain period (from 0 to +2) because the +4 and the \( x^2 \) don't keep the \(-4x\), while after that [the function] increases.

The latter for a certain period stays above zero (from 0 to +2) because the +4 supports the \(-x^2\) while after that it decrease below zero.

Meeting points \( x=0, y=4 \) and \( x=2, y=0 \)
b3. Strategies based on the search for "remarkable points" (8 out of 28). (Ex.3, Laura)

These students through the discovery of remarkable points \((x=0 \ y=..., \ y=0 \ x=...)\) perform an analytic-inductive analysis of the functions under comparison and get an idea of the shape of the graph. In particular Laura finds some points of the first function, then declares: "It does not touch the origin and \(y\) is never negative!!". This behaviour can be considered (in the case of the two functions) as intermediate between the preceding two. Indeed neither the use of the graph is prevailing (like with Davide), nor the analysis of how \(y\) changes in relationship with \(x\) (like with Lorenzo), but these two aspects are intermingled.

Ex.3, Laura: compare the two functions \(y= x^2 - 4x+4\) and \(y= -x^2 +4\)

Both formulas have +4 in the end, and thus we can neglect them (translate of +4 with respect to the \(y\) axis). They both are parabolas. The first one (A) is the greatest.

Now I proceed by means of "oriented" computation.

\[
\begin{align*}
\text{A) } x=0 & \quad y=0; & \quad x=-4 & \quad y=16; & \quad x=+4 & \quad y=0; & \quad x=2 & \quad y=-4 \\
\text{between } +4 \text{ and } 0 \text{ the result is } <0!! & \quad \text{Now I add } +4!! \\
\text{It does not touch the origin and } y \text{ is never negative!!}
\end{align*}
\]

B) \(x<0\) \(y\) negative, except for \(x= -2\), where \(y=0\)

\[
\begin{align*}
x<0 & \quad y=\text{negative, except for } x= -2, \text{ where } y=0 \\
x<0 & \quad y=\text{negative, except for } x=+2, \text{ where } y=0 \\
\text{It does not touch the origin and it is positive (only) between } x= -2 \text{ and } x=+2.!
\end{align*}
\]

Curiosity: what is \(y\) like, when \(x\) is greater than \(-2\) and smaller than \(+2\)?

\[
\begin{align*}
x=-1 & \quad y=+3 \\
x=+1 & \quad y=+3
\end{align*}
\]

The matching point of the two graphs is +4 in the \(y\) axis and the second point is in \(x=+2\) \(y=0\)

(drawing: superposition of the parabolas A and B)

As I observed above, A is the greatest, but there is a little overcoming of B between \(x=0\) and \(x=+2\)

c) Plurality of meanings of pieces of formulas

In the task of comparing the two functions \(y= x^2 - 4x+4\) and \(y= -x^2 +4\) a crucial difficulty concerns the role of "-4\(x\)" in the first function. We can observe how, according to the peculiar strategy of each student, "-4\(x\)" takes different meanings.

For instance, in the case of Davide (Ex.1, underlined parts): "-4\(x\)" is responsible for "moving and transforming the parabola"; later on "-4\(x\)" takes another meaning: it "diminishes the speed of increase". For Lorenzo (Ex. 2, underlined part) "-4\(x\)" is "responsible for the decrease of the function between 0 and 2", in relationship with the other parts of the formula. Other students declare that "if -4\(x\) did not exist the two parabolas would be equal: the former oriented upwards and the second oriented downwards". This diversity of meanings attributed to the same piece of the formula enriches the interpretation and representation of the whole formula. The same phenomenon occurs for other pieces of the same formula: for instance "+4": for some students "+4" means that "the parabola does not pass through the origin" of cartesian axes, for other students it means that "it moves the parabola upwards."
Conclusion

As a consequence of epistemological analyses (which reveal the importance of the functional aspects of inequalities in mathematicians' work), and didactical analyses (which show how the current approach to inequalities based on purely algebraic procedures produces very limited learning results), and keeping into account cognitive studies about functions, a teaching experiment aimed at exploring the feasibility of an early functional approach to inequalities with VIII-grade students was planned and analysed. Collected data seem to support our didactical and educational choices; in particular, inequalities appear an interesting issue to study the students' construction of different aspects of the concepts of function and variable, and a promising learning context for these concepts. This means that the functional approach to inequalities, originally intended to better understand and possibly solve some teaching and learning problems concerning inequalities, offers a possibility for studying and improving teaching and learning of functions.

A relevant aspect of our study concerns the educational choices related to the aim of a cooperative enrichment of tools and ways of reasoning useful to deal with inequalities. Here we may say that the approach to inequalities based on a global, dynamic approach to functions seem to fit very well with this aim: graphic representations, gestures, metaphors concerning functions were very easy to share in the classroom (once the teacher decided to encourage their use by students).

MATHEMATICS TEACHER BELIEF SYSTEMS: EXPLORING THE SOCIAL FOUNDATIONS

Peter Gates
University of Nottingham, UK

Abstract

There is a considerable literature on teachers' beliefs and conceptions and their effect on the teaching of mathematics, but much of this literature either is located within a psychological paradigm, or where a more eclectic perspective is adopted, fails to locate the sources of beliefs in the social world. In this paper I look at some of the present models and approaches to teacher belief systems and argue that these can only give us an incomplete picture leaving as they do, the source of belief systems in the social world unexamined or unproblematised. I offer some sociological concepts that can help us understand better how belief systems are constructed upon teachers' ideological foundations.

The social role of mathematics education

Naturally there is diversity and variety in all mathematics teaching – a diversity that finds its rationale in mathematics teachers’ belief systems. While what teachers do is based upon what they believe – what they do has both unintended as well as intentional consequences. It can hardly be contested that we live in an uneven and unjust society where access to education and to justice depend on the capital one can appropriate and accumulate. There is so much evidence in the literature to support this contention that it is hardly now contentious. Injustice is a process that goes on all around us, even when - and arguably especially when - we do not look for it or recognise it. Mathematics plays a significant role in organising the segregation of our society, as Sue Willis cogently argues:

Mathematics is not used as a selection device simply because it is useful, but rather the reverse.

(Willis 1989, p 35)

In other words, mathematics education plays its part in keeping the powerless in their place and the strong in positions of power. It doesn’t only do this through the cultural capital a qualification in mathematics endows on an individual. It does this through the authoritarian and divisive character of mathematics teaching. Mathematics thus performs a social function, and by engaging in mathematics teaching, teachers are consequently involved in a social function. Hence in order to understand better the nature and functioning of mathematics teaching we need to look for foundations, predilections and structuring frameworks that would support a social model for understanding the discipline. Such an approach requires us to locate ourselves within
a dynamic and dialectical analysis of the relationships between human agency – the will of the individual – and social structure – the wider enabling and constraining forces operating on us. Indeed, it requires us to look for social forces not only as acting on us, but also as acting in us. Karl Mannheim takes this argument a little further.

Strictly speaking it is incorrect to say that the single individual thinks. Rather it is more correct to insist that he participates in thinking further what other men have thought before him. He finds himself in an inhabited situation with patterns of thought which are appropriate to this situation.

(Mannheim 1936 (2nd Edition 1952), p 3)

There is much evidence to suggest that school mathematics has a firmly established cultural tradition. This “school mathematics tradition” (Cobb, Wood, Yackel, et al. 1992) can be classified as teacher centred, where classroom routines incorporate the introduction of a new technique, presentation of examples and setting of exercises. In this routine, the teacher does most of the talking, directing and instructing pupils. Mathematics is presented as little more than replication of procedures demonstrated by the teacher (Brown, Cooney and Jones 1990) with a focus on memorisation and drill making the subject dull and uninteresting (Ball 1990, p 12). This characterisation of mathematics teaching is not only widespread (Romberg and Carpenter 1986), but is also historically persistent as a dominant model over the past 100 years (Cuban 1984). In addition, this pattern has been described as “the most consistent and persistent phenomena known in the social and behavioural sciences” (Sirotnik 1983, pps 16 – 17). There is considerable evidence that curriculum innovations become largely incorporated into teachers’ existing teaching approaches and styles. Furthermore there is evidence that teachers portray their own teaching as more open than it might be described objectively (Edwards and Mercer 1987). This is a serious situation, which requires us to look for creative explanatory models of human behaviour.

Jeff Gregg has reported a study into the reasons for the persistence of the school mathematics tradition (Gregg 1995a, b). Synthesising research over the past 20 years, he suggests, “there are certain beliefs about mathematics and its teaching as well as certain classroom practices that are taken-as-shared by many in our society” (Gregg 1995b, p 443). He claims the hegemonic nature of these beliefs may be responsible for the widespread failure of the history of reform in mathematics education. Jeff Gregg describes a process whereby not only are teachers socialised into a culture of teaching, but “teachers, students and administrators actively participate in the production and reproduction of these processes” (Gregg 1995b, p 461). He suggests that by separating teaching from learning, and adopting a view of ability as capacity, teachers are able to act without questioning the taken-as-shared beliefs and practices of the dominant school mathematics tradition (Gregg 1995b, p 462). Whilst Jeff Gregg’s study and analysis is a useful insight into the acculturation of mathematics
teachers, what he lacks is an explanatory framework for understanding the nature and roots of the phenomenon he describes. To provide this, we need to look more deeply into the organisation and source of teacher belief structures.

Mathematics teacher belief structures – some theoretical limitations

Studies of teacher beliefs often focus attention on beliefs as if they existed in a social and political vacuum drawing fundamentally upon a psychological paradigm, which seems unable to account adequately for the difficulties of teacher change. However, as the Centre for Contemporary Cultural Studies has suggested, beliefs do not exist in a social vacuum:

If we are interested in the ways in which consciousness is formed, we cannot stop at the level of lived beliefs. Beliefs, conceptions and feelings are not only carried in the minds of human subjects; they are also written down, communicated, 'put into circulation', inscribed in physical objects, reproduced in institutions and rituals and embodied in all kinds of codes.

((CCCS) 1981, p 27 - 28)

Hence, beliefs have a wider and deeper dimension, rooted in cultural norms and forms that are themselves rooted in social structure. These have a huge influence over consciousness and ideology, setting many agendas and putting boundaries around what is considered as possible, describable or even legitimate.

Studies of teachers' belief and knowledge structures have increased considerably during the 80s and 90s. Kenneth Zeichner, Robert Tabachnick and Kathleen Densmore (Zeichner, Tabachnick and Densmore 1987) suggest that we need to consider adopting approaches to teacher development that recognise the complexity of the nature of knowledge (Zeichner, Tabachnick and Densmore 1987, p 24). They identify a lack of consensus in the literature on teacher socialisation and challenge the view that student teachers change and modify their views on teaching through experience and teacher education. Rather what happens is an elaboration of previously existing perspectives and a selective focus on experiences that validated their own perspectives. Again providing evidence for the inherent stability of belief systems.

Thomas Cooney and his associates have worked for some time on the knowledge and beliefs of preservice secondary mathematics teachers. They recognise that beliefs about mathematics and how to teach it are influenced by experiences with schooling long before prospective teachers enter professional training and that these beliefs seldom change (Brown, Cooney and Jones 1990). Such a worrying state of affairs requires us to try to understand therefore not just what it is that teachers believe, but how these beliefs are structured and organised (Cooney, Shealy and Arvold 1998).

Alba Thompson worked for a number of years on mathematics teacher beliefs. She claimed that teachers' patterns of behaviour characteristics are a result of consciously
held beliefs acting as a ‘driving force’. In addition, practice can be the result of unconscious beliefs and intuitions (Thompson 1984). What is unclear is the nature of these ‘driving forces’, where they emanate and how they become operationalised. Alba Thompson suggested that more research was needed on the stability of teacher beliefs.

This phenomenon of teachers modifying new ideas and practices by adapting them to fit existing practices is now well understood (Thompson 1992, p 140). Underlying this problem is the issue of stability of the structures of commitment that we hold as individuals acting within a social world. This is an example of the difficulty in changing deeply help ideological dispositions and underpinnings. We may change words, we may change the context to (pseudo) real life situations, and we can even change the architecture of the school buildings, but little changes in the relations of power and domination in the mathematics classroom. “Unfortunately the literature on teacher change, though rich with tips, does not offer explanations for this phenomenon” (Thompson 1992, p 140).

Alba Thompson reviewed much of the research on mathematics teacher beliefs (Thompson 1992) yet it becomes clear in her review that much of the driving force in this research comes from the belief that it is the teacher’s view of mathematics that is responsible for classroom practice. Such a view is typically represented by two comments:

One’s conception of what mathematics is affects one’s conception of how it should be presented. One’s manner of presenting it is an indication of what one believes to be most essential in it. The issue then is not, what is the best way to teach it, but what is mathematics really about?

(Hersh 1986, p 13)

All mathematical pedagogy even if scarcely coherent rests on a philosophy of mathematics.

(Thom 1973, p 204)

These positions need to be questioned and deconstructed. Without further clarification, one reading is that one’s conception of mathematics is the deciding factor in structuring one’s teaching. Rene Thom seems to go further in using the word ‘rests’ – a spatial metaphor that has a sense of dependency embedded in it. He question this begs is – on what does ones philosophy of mathematics itself rest.

Teachers’ social perspectives – the missing dimension?

Much research undertaken on various aspects of teacher beliefs tends “inadequately to explore teachers’ social beliefs” (Liston and Zeichner 1991, p 61). Teachers’ social knowledge
tends to be inadequately addressed in most accounts of teacher knowledge, is rarely examined in teacher education curricula and is awkwardly handled in the prominent models for cultivating reflective thinking and action in teachers.

(Liston and Zeichner 1991, p 61)

As social beings, mathematics teachers do not come to the classroom devoid of social and political motives and intentions. Yet nor can we merely append ‘social knowledge’ to a growing list of categories of professional knowledge alongside ‘knowledge about children’, ‘pedagogical content knowledge’ etc. because of the fundamentally constitutive nature of social beliefs.

In developing a theoretical framework, we need to be able to conceptualise this dialectical relationship between the individual and the social. Pierre Bourdieu offers a way through this in his appreciation of the interplay between objective social structure and subjective personal dispositions, which forms the central methodological and conceptual organisation of his work and informs his empirical studies (Bourdieu 1972, 1990b). It is his assertion that objective structures are actualised and reproduced through subjective dispositions (Bourdieu 1972, p 3). This does not mean that subjective dispositions have a primacy over more objective social structures. Rather that the development of individual dispositions is influenced and constrained by objective structures, the nature of hierarchy, the form of hegemonic positions and so on, which in their turn reinforce the objective structures. What distinguishes Pierre Bourdieu’s approach is the way in which social structural properties and social and economic conditions are always embedded in everyday lives and events of individuals (Harker, Mahar and Wilkes 1990, p 8). Of course implicit in here is a readiness to accept that:

There exist in the social world itself, and not merely in symbolic systems, language, myth etc. objective structures which are independent of the consciousness and desires of agents and are capable of guiding or constraining their practices or their representations.

(Bourdieu 1990a, p 14)

Within this framework, there are two main conceptual tools that can be incorporated into research on teachers’ beliefs that will give us access to some previously un-illuminated routes to the roots of the systemic logic of teachers’ belief and values systems – the habitus and ideology.

Habitus

For Pierre Bourdieu, this symbiosis can be examined and understood through the elaboration of the habitus. I explore this in more detail, theoretically and empirically, elsewhere (Gates 2000), but briefly, the habitus is the cognitive embodiment of social structure. Our habitus forms the generative principles that organise our social practices leading to social action and provide us with systems of dispositions that
force us (or allow us) to act characteristically in different situations. The *habitus* thus resides within patterns of interactions and needs to be explored using techniques that dig deep enough into the logic underpinning the observable practices - a logic that is interwoven with the social origins of one’s predispositions.

The mathematics teacher’s *habitus* will be at the root of the ways in which teachers conceptualise themselves in relation to others; how they enact and embody dominant social ideas and well as how they transform and adapt them. The *habitus* is at the bottom of how we react, judge and evaluate.

Working with the *habitus* though is not enough. To help us understand the social foundations of mathematics teachers we have to look also at how the *habitus*es of groups of teachers gel into or organised forms of thinking and cooperation. Teachers become pulled together or ‘interpellated’ into social groupings and formations through the sedimentation of the individual *habitus* and predispositions into more socially organised ideological frameworks.

**Ideology**

Fundamentally, what distinguishes ideology from general sets of ideas is that ideology is about the relationship between ideas and society and the relationships between individuals. What typifies ideological ideas is their relation to the conflictual nature of economic and social relationships. Ideology thus relates to matters of power and social structure as well as relating ideas and activity to the wider socio-cultural context. Hence, looking for ideological underpinnings require us to look at language forms used, to explore the social imagery adopted, to elaborate on how individual teachers categorise and organise their ideas especially in relation to others. These in particular will need to connect with ideas on the nature and form of society and how it operates. In addition, these will need to be tied to issues of practicality, which embody relations of domination. Relating this discussion to teaching, ideological underpinnings appear as ideas and assumptions about human nature, about learning and educational difference, the role of education, the role of the teacher and ideas about priorities for teacher professional development. Ideology can thus be represented as relatively stable, deep structures of ideas. Our ideological makeup, establishes us as being the same as and different from the individuals and groups with whom we associate or work – but a positioning process founded not upon some philosophy of mathematics, but upon one’s social frameworks.

**Conclusions**

I am arguing here that while strictly psychological models of teacher beliefs can give us considerable insight into the structure of teachers’ knowledge, they have some limitations when we come to want to look at some of the wider and possible unintended consequences of the education system. This can be informed by adopting models of belief systems as well as research techniques that look at how an individual constructs a system of beliefs both structurally and temporally. As researchers it
requires us to go beyond the data of observable practices and into the realms of those patterns and generative principles of which the teachers themselves may not even be aware. Underlying such an approach is the ideological predisposition that sees thinking as a social act, and systems of beliefs as representing dominant and objective social structures as well as helping those structures to operate and reproduce.

PUPILS PERCEPTION OF THE LINKS BETWEEN DATA AND THEIR ARITHMETIC AVERAGE

Linda Gattuso
Université du Québec à Montréal

Claudine Mary
Université de Sherbrooke

The results presented in this paper are part of a larger study on the strategies used by pupils to solve arithmetic average problems. The arithmetic average being a widely used concept, it is important to study pupils' knowledge and their difficulties in order to improve their learning. Two questions arose from previous studies: 1) up to what point do pupils perceive the links between data and their average? and 2) does the introduction of a null datum (=0) complicate the situation? A first task asked for an estimation of the effect of the modification of a datum on the average and a second required finding the datum which would leave the average unchanged. The results tend to demonstrate that pupils have a fairly good perception of the effect of data modifications on the average with better results if the datum is zero.

Les résultats présentés sont extraits d'une étude sur les stratégies utilisées par les élèves pour résoudre des problèmes de moyenne. Vu l'utilisation répandue de ce concept, il est important de sonda les connaissances et les difficultés des élèves pour en améliorer l'apprentissage. Deux questions se sont posées à la suite d'études précédentes: Jusqu'à quel point les élèves perçoivent-ils les liens entre des données et leur moyenne? et La présence d'une donnée nulle (=0) rend-elle la situation plus difficile? Nous avons construit deux tâches dans lesquelles on demandait d'estimer l'effet du changement d'une donnée sur la moyenne et de donner la valeur qui laisserait la moyenne inchangée. Les élèves semblent avoir une assez bonne perception de l'effet de la modification d'une donnée et ceci encore mieux dans le cas d'une donnée nulle.

The arithmetic average is certainly a widely used concept and not only in the context of statistics. In fact, we can trace attempts to make many observations of the same phenomenon as far as the Babylonians (500-300 BC). It is not before the work of Tycho Brahe (16th century) that the use of the average becomes clearly distinct. However, as it is largely documented, today's students have trouble understanding this concept. In the past, many studies have stressed students' difficulties with problems involving averages, particularly when weighted averages are concerned (Pollatsek, Lima, Well, 1981; Gattuso, Mary, 1996). Clearly, this is not a simple computational algorithm, and it is not well understood.

Young children already have conceptions (or misconceptions) of representativeness, and a study from Mokros and Russell (1995) reveals that they perceive the average in five different ways: as a mode, an algorithm, a reasonable value, a midpoint or as a point of balance. However, Cai (1995), questioning sixth-grade pupils, found that although 90 % of them knew the computational algorithm for the average, less than half had reached a conceptual understanding of...
the concept. Other results show that 8th grade students are able to find a weighted average without previous specific instruction, and that instruction may even interfere, since older students have a poorer performance (Gattuso, Mary, 1998). This conclusion agrees with earlier findings of Pollatsek (1981), where only fourteen out of 37 college students answered correctly to a weighted average problem. Leon and Zawojewski (1990) also established that most students can understand the mean as a computational construct, but have more difficulty seeing it as a representative value. Young children seem to have a fairly good perception of the average, but this does not seem to develop into a deep understanding of the concept and difficulties show up if the problem asks for more than a simple computation, and there is no real improvement with age.

In addition, zero presents a particular problem, as in other mathematical situations, such as division by zero or 0 as an exponent. Looking into the properties of the average, a study revealed that college students with basic statistical education had a tendency to apply the four axioms which constitute an additive group to the computation of means (Mevarech,1983). Particularly, in the case where one datum is 0, some pupils consider it as the neuter element and assert it does not change the mean. Strauss and Bichler (1988) observed difficulties among 8 to 14 year-olds while looking at the development of children's concepts of the arithmetic average. Not only do children have problems understanding that the sum of the deviations to the mean is zero, but they also fail to understand that the average is representative of the values averaged and in to take into account a zero value in the computation of the average. Again, this fact seems to be independent of the age group.

RESEARCH ISSUES

In this paper we focus firstly on the understanding of the links between the data and the mean. More precisely, the issue of "representativeness" was translated in a simpler question: "Do pupils perceive that changing even one of the data affects the mean?" The second aim is to examine, in parallel, the difficulties encountered by the introduction of a datum equal to zero: "Are similar situations dealing with a datum equal to zero more difficult?"

To improve the understanding of such a concept, it is important to know how children cope with it in different situations, how much they know about it and what are the difficulties. The final aim is to investigate if pupils perceive the connections existing between the data and the average and to analyse their strategies and reasoning for eventual use in the construction of teaching interventions. Ultimately, we hope that the results of this study will help setting up future teaching experiments.

METHOD

Context of the study

Although simple arithmetic average problems are part of the elementary
mathematics curriculum, it is not before the 9th grade that Québec students encounter the concept of weighed average. The results presented in this paper are part of a larger study on the strategies used to solve problems of weighted averages by children through their high-school years. A total of 638 high school students from grades 8, 9 and 10 (ages 13 to 15) participated in the study. Each student answered 5, 6 or 7 questions depending on whether they were in 8th, 9th or 10th grade respectively. A total of 24 different tasks were designed, each of which was administered to part of each year group. This paper discusses the results of 6 of these tasks.

Description of the tasks

The tasks were meant to investigate the pupils' understanding of the link between the data and the average and to see if the same situation using a datum equal to zero would pose greater difficulties. The tasks were framed into three different situations consisting of modifying the data set by: 1) adding one datum, 2) replacing one datum by another and 3) removing one datum. In each situation, two options were considered, using a non null datum or a datum equal to zero (see appendix for examples). Two questions were asked: a) Does the average increase, remain unchanged or decrease? b) If you think the average is modified, what value would leave it unchanged? Even though the first question calls for a qualitative answer and the second one does not really require computations, the numbers were chosen so as to make the calculations easy if ever the pupil found the need to do some.

We posed two hypotheses. The first one was that the question that proposed the replacement of one datum by another would be the most difficult because it required more steps that the one presenting the addition or removal of a datum. Between the latter two, adding a data should be easier. Secondly, because previous studies had shown that students do not seem to take into account zeros, it was assumed that problems involving a zero would produce poorer results.

RESULTS

Performance

Looking at Table 1, we see that for cases involving a datum different from 0, the results seem to confirm the fact that it is more difficult for the students to estimate the modification of the average if there is replacement of data; in this case, one datum smaller than the previous average was replaced by one datum greater than the original average. For problems involving addition or removal of one datum, results are higher, showing very little difference between the two.

Cases involving a datum equal to zero produce a different outcome. Our hypothesis is not supported: the case involving the replacement of one datum is no longer the most difficult one. The case where one datum is removed has the lowest results. Furthermore it seems that problems involving a datum equal to 0 are easier.
than previous cases involving a data \( \neq 0 \). Here, a datum smaller than the original average was replaced was by a datum equal to zero (also smaller than the average).

Table 1: Question a) correct answers

<table>
<thead>
<tr>
<th>Data</th>
<th>Adding one datum</th>
<th>Replacing one datum</th>
<th>Removing one datum</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>( \neq 0 )</td>
<td>68/98</td>
<td>52/107</td>
<td>74/109</td>
<td>194/314</td>
</tr>
<tr>
<td></td>
<td>69,40%</td>
<td>49,50%</td>
<td>67,89%</td>
<td>61,78%</td>
</tr>
<tr>
<td>= 0</td>
<td>91/101</td>
<td>75/104</td>
<td>68/105</td>
<td>234/310</td>
</tr>
<tr>
<td></td>
<td>90,10%</td>
<td>72,12%</td>
<td>64,76%</td>
<td>75,48%</td>
</tr>
</tbody>
</table>

Looking at the results of the second question asking what should the modified datum be so the average would not change, the overall pattern is similar although the results are clearly lower. Again, the situations involving a zero seem to be easier except in the case of the removal of one datum. Let us emphasise the fact that no calculations were absolutely necessary for answering these questions. We also examined the results as a function of age group. Although there is no obvious pattern, we can say that the 8th grade students perform often better or at least as well as their older counterparts.

<td>76,24%</td>
<td>59,22%</td>
<td>37,14%</td>
<td>57,28%</td>
</tr>
</tbody>
</table>

Strategies for question a)

We analysed the strategies (or reasoning) used by the students to try to understand these results. In general, in cases where the modified datum is \( \neq 0 \) (Table 3), we can say that the strategy used most successfully and most often by the students is to compare the modified data to the original mean. The student asserts: "a value greater than the mean is taken out, so it will decrease...". However another reasoning also focusing on the data leads to wrong answers when a datum is replaced because it says, for example: "We take out something and put back in compensates..." without any regards to the values of the data and with no reference to the mean value. They add the effects of the modified data instead of subtracting them.

Problems in which there is a zero (Table 4) are easier because the reasoning, in the case of adding or removing a datum, involves only the number of data, the total remaining the same. In the case of the replacement of one datum by another, what makes it easier is the fact that students mostly reason on the difference in the total, which in this case is the modified value: a datum \( \neq 0 \) is replaced by a zero, so
the total decreases while the number of data remains unchanged. Here also, only one factor varies.

Table 3: Strategies: Data ≠0 Question a)

<table>
<thead>
<tr>
<th>Data ≠0 a)</th>
<th>Adding one datum ≠0</th>
<th>Replacing one datum by ≠0</th>
<th>Removing one datum ≠0</th>
</tr>
</thead>
<tbody>
<tr>
<td>Correct strategy mostly used</td>
<td>&quot;A datum smaller than the mean is added&quot; 45.92%</td>
<td>&quot;A datum smaller than the mean is removed and a datum greater than the mean is added&quot; 33.64%</td>
<td>&quot;A datum greater than the mean is removed&quot; 47.71%</td>
</tr>
<tr>
<td>Incorrect strategy mostly used</td>
<td>(Average + datum)/2 Wee (without weight) 16.33%</td>
<td>False Compensation of effects Fcom 17.76% Wee (as much as in Adding) 16.82%</td>
<td>Nothing particular</td>
</tr>
</tbody>
</table>

Another noticeable result is the fact that many errors are due to reasoning based on a misconception or, more accurately, a conception inadequately used. More than half of these answers are of the type: "0 is removed, it doesn't change anything...", treating 0 as the neuter element. Another erroneous reasoning is based on the conception that each datum is equal to the average. Even though it is mentioned in the problem that the datum removed is equal to zero, some pupils still think that each datum being equal to the average "Nothing changes, they all have the mean...".

Table 4: Strategies: Data =0 Question a)

<table>
<thead>
<tr>
<th>Data =0 a)</th>
<th>Adding one datum =0</th>
<th>Replacing one datum by 0</th>
<th>Removing one datum=0</th>
</tr>
</thead>
<tbody>
<tr>
<td>Correct strategy mostly used</td>
<td>&quot;There are more persons for the same total&quot; Eff 53.4%</td>
<td>&quot;The total decreases&quot; Tot 38.46%</td>
<td>&quot;There are less persons for the same total&quot; Eff 47.0%</td>
</tr>
<tr>
<td>Incorrect strategy mostly used</td>
<td>No explanation or answer Nex 12.50%</td>
<td>Misconception 24.8%</td>
<td></td>
</tr>
</tbody>
</table>

Strategies for question b)

The strategies change with the questions when students are asked to give the datum that would leave the mean unchanged (Table 5). In T/n - if you add a datum it has to be equal to the mean so the ratio (Total/nb of data does not change)-- and Mean, --take out a value equal to the mean-- we may say that the fact that "if all data should be equal, then each datum should be equal to the mean" is correctly used although it is not explicitly said. It is however difficult to distinguish between a
correct answer and one misusing a conception saying that all data are equal to the mean. A great number of "no answer" or "no explanation" is also noticeable in the case of the removed and replaced data \(0\) that did not appear so much in the other problems.

Table 5: Strategies: Data \(\neq 0\) Question b)

<table>
<thead>
<tr>
<th>Data (\neq 0) b)</th>
<th>Adding one datum (\neq 0)</th>
<th>Replacing one datum by (\neq 0)</th>
<th>Removing one datum (\neq 0)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Correct strategy mostly used</td>
<td>&quot;If there is a person more, we add the mean to the total then it's unchanged( T/n) 24,74%</td>
<td>&quot;The same as what is removed&quot;(\text{Com}) 38,68%</td>
<td>&quot;It should be the mean so it does not change&quot;(\text{Mean}) 30,28%</td>
</tr>
<tr>
<td>Incorrect strategy mostly used</td>
<td>Various calculations without weight( \text{Wwe}) 19,59%</td>
<td>Various calculations without weight( \text{Wwe}) 7,5%(\text{And Nex}) 27,36%</td>
<td>No explanation or answer(\text{Nex}) 35,78%</td>
</tr>
</tbody>
</table>

The case of the datum equal to zero gives rise to the usual misconceptions: "Adding (or removing) 0 does not change anything..." and when the datum is replaced: "it should be the average value so everyone has the same". Many students think that every datum is equal to the mean unless otherwise specified. It is in fact possible, and also it is often said "that the mean is the value each datum would have if every data should be equal" the second part of the sentence (if...) seems to have disappeared.

Table 6: Strategies: Data =0 Question b)

<table>
<thead>
<tr>
<th>Data = 0 b)</th>
<th>Adding one datum =0</th>
<th>Replacing one datum by 0</th>
<th>Removing one datum =0</th>
</tr>
</thead>
<tbody>
<tr>
<td>Correct strategy mostly used</td>
<td>&quot;It should be the mean so it does not change&quot;(\text{Mean}) 36,63%(\text{and T/n}) 21,78%</td>
<td>&quot;The same as what is removed&quot;(\text{Com}) 50,96%</td>
<td>&quot;It should be the mean because everyone has it&quot;(\text{Misconception}) 15,24%</td>
</tr>
<tr>
<td>Incorrect strategy mostly used</td>
<td>Misconception 14,5%</td>
<td>Misconception 11,54%</td>
<td>Misconception 9,52%</td>
</tr>
</tbody>
</table>

DISCUSSION

The results call for a different point of view on the situations involved. Our hypotheses were based on previous research and on the complexity of the mathematical operation involved, but children naturally use comparison confronting the modified data with the mean or looking at what is changed, the number of data
or the total. These comparisons seem easier if the datum is zero because only one factor varies.

If we look at each modification separately, we see that adding a datum affects the mean in the same direction. If the added datum is greater than the average, the average increases and so on. The opposite is true when removing a datum. The situation were a data is replaced is not as difficult as was thought a priori, since if you look at the modification of the total while the number of data remains the same, the changes also vary in the same direction. These facts should not be presented directly but children should experience these different situations and be encouraged to estimate the results. A datum equal to zero should be treated as another datum (often smaller that the average in simpler contexts).

However, many errors are due to an incorrect application of some conception of the mean, particularly, one giving equal value to each datum. Various analogies are used in teaching but they present some limits. One example, often used in teaching the mean, is "equalising a pile" or distributing a quantity equally. The fact that all the data are not equal at the beginning should be emphasised, and probably working inversely, asking to construct a list of data given a certain mean (with or without additional constraints, like no data equal to the mean) could help the pupil to see that the data are not necessarily all equal. Every time an analogy is used, we should insist on the limits of it's validity.

Certainly, these results are incomplete and are not meant to be generalised but a majority of students do perceive the link between data and their mean, and their 'natural' strategies should be looked into and analysed for further applications in constructing teaching situations. As a matter of fact, these types of situation are scarcely used in the classroom, students should be encouraged to rely more on estimation before indulging in automatic computation.

1 Unless otherwise specified, in this text the words "average" and "mean" are used synonymously and refer to the "arithmetic mean" or "arithmetic average".
2 This problem was not the last one in the questionnaire.

APPENDIX

Replacing one data = 0

A group of eight friends empty their pockets. They have an average of 11$ each. Peter decides to take back the 4$ he put in and goes to work. At the same time, Jean-Philippe joins the group but he does not have a penny. What happens with the average?

a. 1) It decreases    2) It does not change    3) It increases  
b. If you think that the average has changed, how much should Jean-Philippe have so that the average remains the same?

Removing one data ≠ 0

The average age of the first seven first persons attending Geneviève's party is 21 year old. When Jean-Philippe who, is 27 year old, leaves. What happens to the average age?

a. 1) It decreases    2) It does not change    3) It increases  
b. If you think that the average has changed, what age should Jean-Philippe have so that the average remains the same?
RESEARCH ON ATTITUDES IN MATHEMATICS EDUCATION:
A DISCURSIVE PERSPECTIVE

Uwe Gellert
Freie Universität Berlin (Germany)

Abstract: Attitude to mathematics is generally assumed to be a stable and reliable construct. Closer examination, however, reveals, that the specific interrelated conditions in which attitudes are both expressed and studied have a striking impact on the way people respond to research instruments. In this paper, an exemplary analysis of the discursive practices and the resources which are used in the organisation of an interview is carried out. This is leading to a discussion of the problems that emerge when the categories of observers are rashly superimposed on the utterances of the observed.

Introduction

In mathematics education as a theoretical field language plays a crucial role. It is not only the vehicle with which findings are reported and the recent questions of the field are discussed. It also is the most important resource for describing the practice of mathematics teaching and learning. Moreover, this practice mainly is accessible via the language that is used within it (e.g., Adler, 1995; Dowling, 1996; Krummheuer, 2000; Pimm, 1987; cf. Mason and Waywood, 1996). Apart from that, language even serves as the predominating means to examine mental orientations like attitudes where the mental is taken to subsume cognitive, affective and enactive aspects of the psyche. In this contribution, the role of language in the research on attitudes and similar concepts is discussed.

It appears to be well accepted that the mathematics teacher's expectations and attributions on students' learning as well as her beliefs, attitudes and orientations have a substantial influence on classroom practice (c.f., McLeod, 1992; Ruffell, Mason and Allen, 1998; Thompson, 1992). On the side of the students, their attitudes are considered to be very significant factors underlying their school achievement (c.f., Leder, 1992; Ponte et al., 1992). These judgements are based on the assumption that attitudes and the like are relatively stable and reliable constructs so that they can be used for describing a person's mind. According to Ajzen's (1988) definition, attitude is "a disposition to respond favourably or unfavourably to an object, person, institution or event" (p. 4). If, in contrast, an individual's attitude was something situational bound, the concept would lose some of its effects. On the other hand, if too stable, the concept would go down in value for descriptions of change processes in mathematics teacher education or student's learning.
After having undertook a set of empirical studies of attitude, Ruffell, Mason and Allen (1998) doubt the stability and reliability of what is considered an attitude. In their research, they experience attitudes as highly influenced by the social and emotional conditions in which they are both perceived and observed. In the end, they challenge the very construct of attitude as a fruitful taxonomy for research or for the practice of teaching. In essence, it can be considered as questionable whether people actually possess attitudes and the like, or whether these constructs are just categories of observers who wish to account, by language, for what they claim to see. This looks very much as if a discussion of this issue under a discursive perspective could be promising.

Theoretical position

According to Austin (1962) and Searle (1969), language is a human practice. People use it to get things done. The fundamental tenet of Austin's and Searle's speech act theory is that all utterances state things and do things. What constitutes a speech act can be analytically divided into three parts (c.f. Ricœur, 1978): The act of the speech itself (propositional act), that what we do in the speech (illocutional act), and that what we do by means of the speech (perlocutional act). The words 'shut the door' can be used as a request, or with the force of an order. Alongside the specific meaning of the words (their propositional character), the specific way in which the words are spoken make for the illocutional act of the speech. Finally, this very way in which the utterance 'shut the door' is spoken may have the stimulating effect of making the hearer anxious or annoyed (the perlocutional act). It may produce a certain reaction on the side of the hearer.

Austin and Searle offer a highly social perspective on language: Ways of talking are considered as social acts. They draw the attention to conventions in the achievement and performance of actions through talk. In their view, language use is embedded in a social environment that has a strong impact on the way in which a speech act is perceived. On the surface, this issue is intuitively taken into consideration when an interview about a person's attitudes to mathematics is organised. The interviewer may arrange the interview conformably to the social conventions for interview situations, she may care for an undisturbed room and a relaxed atmosphere where the interviewee feels safe and willing to express her opinion about mathematics.

Less obvious, and rarely considered in empirical studies on attitudes, is the fact that the interview talk itself is a social construction in which the speakers do things with words. The interviewer tries to stimulate the interviewee to put into words what she thinks or feels about mathematics. This is done in a more or less sophisticated way but it has to be methodically controlled. What the interviewer's questions and utterances intend to do is part of the interview strategy. On the other side, the interviewee is not just the victim of the interviewer's questions. With every of the interviewee's utterances something is stated or done. Or, as Ricœur (1978) put it, the
utterances in themselves state things and do things. Thus, by giving a specific response to the interviewer's stimuli the interviewee is constructing a particular version of what the interviewer later on will call an attitude: the interviewee's talk carries an action. The interviewee organises her utterances along social conventions of how language is used in interview situations but not without taking into account her own goals and aims within the interview.

Traditionally, the conventions of how language is used in the way social life is put together are studied within the field of conversation analysis (e.g., Sacks, 1992; Sacks, Schegloff and Jefferson, 1974). Conversation analysis, an approach based on the discipline of ethnomethodology (e.g., Garfinkel, 1967), reflects upon every utterance as locally meaningful and conditional for the course of the talk. By studying talk as an object in its own right, conversation analysts found out that the way talk is formally organised is not a creation of individual persons but shared across collectivities. For instance, turn taking within everyday conversation is predominantly organised by a structural feature known as adjacency pairing: a question requires an answer, a greeting a return greeting. Results like that allow access to the modes of operation of how words do what they do.

Taken together, these features suggest language should be of enormous interest in the study of attitudes. Such a discourse oriented and sociopsychological perspective has been elaborated under the label of 'discursive psychology' (e.g., Edwards, 1997; Potter and Wetherell, 1987; Smith, Harré and van Langenhove, 1995; van Dijk, 1997). In order to draw a clear dividing line between cognitive and discursive psychology, it can be stated that cognitive approaches generally try to configure unambiguous results by systematising the reactions of the participants in a specific setting. In contrast, discursive psychology reflects upon descriptions, explanations and justifications given in the course of a talk or a written report. The analytical task of a discursive psychology is to take apart, to split up such descriptions and justifications. It is studied in which ways consciousness is constituted through discourse (Lerman, 2000): when and how peoples express explanations, how they position them strategically compared with alternative justifications, and in which sequence descriptions, justifications and explanations are produced.

We reject a product-and-process psychology of mental development, where mind is viewed as an objective development outcome. In its place is a discursive-constructive notion of mind as a range of participants' categories and ways of talking, deployed in descriptions and accounts of human conduct. (Edwards, 1997, p. 48)

The discursive psychological perspective is sensitive to the relation between an object and its description. It challenges both the existence of attitudes in the mind of interviewees and the alleged objectivity of interviewers' classifications. To put it in slightly drastic terms: The attitude categories used by the observer to classify the interviewees' utterances may tell us more about the observer than about the interviewees. Discursive psychology, however, determines the discursive practices of
the people under study as well as the resources (e.g., systems of categories, narrative characters, interpretative repertoires) which are used in the organisation of the discourse. Discourse is considered as cognition-in-action.

Under the perspective of discursive psychology, some traditional sociopsychological concepts have been revisited (e.g., Edwards and Potter, 1992; Potter and Wetherell, 1987), but not within the field of mathematics education. In the following, an example from my own research is analysed in order to demonstrate how the discursive approach has an impact on the practice of research on attitudes in mathematics teaching and learning. It is not intended to give a comprehensive discourse analysis but to focus on some details that already show the significance of a discursive psychology for mathematics education research.

**Example from research**

The passage I want to discuss originates from an audio-taped interview with a student teacher. The interviewer is a peer and the interview is done at the interviewee's home. As a matter of course, the passage is derivative in at least three aspects: firstly, it is part of the transcript of the interview and as such already focussed on, secondly, the focus is on the words and not on their pronunciation, lastly, it is a translation from the German original. Points in brackets symbolise seconds of silence and do not represent parts that have been omitted, italics refer to paralingual recordings.

Interviewee: all right then with mathematics I firstly connect (...) with mathematics I firstly connect numbers (...) then any formulas and (...) yes mathematics is simply driving me to desperation

(laughs)

Straightaway, this counts as a negative statement to mathematics. In terms of attitudes, the interviewee explicated the construct mathematics and gave her opinion on it. Thus, the interviewee should be considered, or classified, as a person with a desperate attitude to mathematics, in particular to numbers and formulas. On a fictitious Likert-scale to an item 'I like mathematics' this could be translated into a marker at the total-disagreement end of the scale, both by the participant of the study and by the observer. But when we look at the course of the interview the situation gets more complex. After the laughter of the interviewee, the interviewer remained silent for a moment. According to conversation analysis, such ignorance of a turn giving marker may result in an explanation (or, sometimes, a repair) of what has been uttered previously. Apparently, the silence, here, invited the interviewee to extend her response:

Interviewee: all right then with mathematics I firstly connect (...) with mathematics I firstly connect numbers (...) then any formulas and (...) yes mathematics is simply driving me to desperation

(laughs) (...) well from first to fifth grade mathematics was really great fun that is it was not my favourite subject or so (...)
but I liked it like all other subjects and it was absolutely okay. then we had a new absolutely stupid incompetent teacher she was absolutely unqualified she has then no mathematics at all been able to teach us and from this moment onwards mathematics was nothing but driving me to desperation didn't like

Now, what previously has been said about the interviewee's attitude to mathematics should be withdrawn and modified. For grades 1 to 5 mathematics had not been driving her to desperation: Mathematics was really great fun. Therefore, we cannot certify her anymore a totally desperate attitude to mathematics. Moreover, the passage reveals that less the numbers and formulas account for the partly desperate attitude, but the absolutely stupid new teacher. Apparently, the personality of the teacher dominated the mathematical content as long as the generation of a positive or negative attitude to mathematics was concerned.

In the end of the passage, the interviewee uttered didn't like. On one hand, we can interpret this as a judgement about the teacher, but this is not so surprising when we take into account that the teacher was previously attributed to be absolutely stupid, incompetent and absolutely unqualified. Rather, the moderate expression would be astonishing. On the other hand, didn't like can be read as in relationship with mathematics. Thus, it could have served as a mitigation of the beforehand expressed desperate attitude to it. According to this interpretation, on the fictitious Likert-scale the interviewee would have made a second marker because she felt bound to develop her first opinion. As a matter of fact, this is more easily done within interview situations than on questionnaires. As a result, the context by which utterances are framed is influential in two ways: Firstly, the organisational and methodical setting in which the research is conducted influences the manner of the utterance. Secondly, the surrounding textual association of an utterance is leading to a more profound or, at least, modified understanding of it. This issue is well acknowledged in traditional cognitive psychological research when it operates with interviews or observation. In the case of data collection by means of questionnaires the textual context in which single items occur, that is their sequence, is often neglected and the responses to the items are treated as isolated judgements.

Further, in the first part of the passage the interviewee characterised mathematics as numbers and formulas and immediately concluded that mathematics was driving her to desperation. So, on a first view, the numbers and formulas take the responsibility for the negative attitude. But this is inconsistent with the fact that numbers in particular are of paramount importance in primary mathematics, and that was a time when mathematics was really great fun. The clue, here, are the first words in the passage: with mathematics I firstly connect. This introduction, especially the word 'firstly', points to the possibility that the following statement should rather be regarded as spontaneous and immediate than as a reflected definition. Consequently, in the second part of the passage where the interviewee starts to reflect on her school
experience, this first characterisation of mathematics is of less importance. Thus, the passage under study results to be stratified: After the short common sense introduction, an explanation on a higher level of reflection is given. What firstly appeared to be an inconsistency within the interviewee's attitude now proves to be an organisational aspect of the text.

Another striking aspect of the passage is the choice of words by which the interviewee tried to convincingly describe her attitude to mathematics. At several points, she used what Pomerantz (1986) has called an "extreme case formulation". If, for instance, somebody argues 'nobody in his right mind ever needs calculus in his life' this can express an argumentative support of his own lack of understanding of calculus. It is the purpose of extreme case formulations to verify a judgement at its extreme limits. In the first passage, mathematics was simply driving her to desperation, formulas were any formulas. Then, mathematics was really great fun, it was absolutely okay. The new teacher was absolutely stupid, absolutely unqualified and has not been able to teach mathematics at all. The interviewee's repeated use of 'absolutely' can be interpreted as putting all the blame on the teacher in order to release herself from any participation in the generation of the desperate attitude. The interviewee's extreme case formulations can indicate that she is used to explain her relation to mathematics as outwardly determined.

**Implication for future research**

These observations clarify two points: Firstly, some information on the parts of a discourse that surround an expression can be sufficient for challenging what beforehand has been putatively proved as a reasonable interpretation of the utterance. Secondly, it has been demonstrated that interviewees' responses, as any discourse, are organised according to certain aims. In the case that has been analysed, the interviewee's construction and formulation of the response make it easier for her to impute accountability for her desperate attitude to the teacher.

These points are of the greatest importance for the attribution of attitudes to individual persons, and their classification. The interpretation of a single isolated utterance can lead to oversimplified, distorted or wrong evidence - not to think of starting from a simple marker on a scale. Apparently, attitudes, if ever regarded as a meaningful construct, are far more complex than all what can be deduced from a one-dimensional judgement. The transcript analysed above offers some insight in what the interviewee considered spontaneously as mathematics and how she judged these issues. But it is highly problematic to take this specific judgement for the interviewee's attitude to mathematics.

This critique signifies that a simplistic separation of the construct 'attitude' from its position related to a single dimension of judgement is critical. Whenever attitudes to mathematics are imposed, this implies the existence of a homogeneous and consistent understanding of what mathematics is. But this is, obviously within the passage, a
fiction. Before giving a judgement, the interviewee explained what it is that she is going to judge. Again, this explanation is not a neutral description of mathematics. Instead, the concept 'mathematics' is actively reconstructed by the interviewee's utterance, it is defined in a specific situation. This argument also invalidates a simplistic separation between the object and its description.

If we want to find out how and what people think and feel about mathematics, we should resist the temptation to rashly superimpose our system of categories on people's talk or people's responses. A more sensible approach starts with the reconstruction of the systems of categories, the narrative characters and strategic devices of the people under study in order to understand the organisation of the discourse first. Such scrutiny may reveal that what people think and feel about mathematics is not stable and consistent but strongly situational and more or less determined by context. Admittedly, the discursive approach tears us away from, and beyond, attitudes.

DEEP STRUCTURES OF ALGEBRA WORD PROBLEMS: 
IS IT APPROACH (IN)DEPENDENT?
Shoshana Gilead and Michal Yerushalmy
Haifa University, Haifa, Israel

Research of word problems in arithmetic as well as in algebra has long stated that meaningful categorization that should lead to problem solving with understanding takes into account the deep structure of the problem. But is the “deep structure” approach independent? In this article we discuss the possible impacts of the domain of functions on the ability and the difficulty to solve motion problems in algebra. We studied students who participate in the VisualMath curriculum (a function approach to algebra in grades seven to nine). What might be a pedagogical obstacle was encountered in work of students learning by this functions-based approach. It suggests that construction of equations as a comparison of two functions is harder when the equation cannot explicitly describe the situation model unless another variable or a parameter is introduced. Thus, the emphasis on algebraic symbols being meaningful modeling language rather than solely the objects of manipulations may set a new cognitive sequence that removes previously known obstacles and introduces new ones. The finding that the categorization of word problems seems to be approach-dependent represents a more general view about emergent research of curricular change.

DEEP STRUCTURES OF WORD PROBLEMS

A word problem is examined at two levels of abstraction: the quantitative structure, which describes arithmetic operations and relations among symbolic or numerical entities, and the situational structure, which describes relations among physical properties of the entities within a story problem (Bednarz and Janvier, 1996; Hall et al., 1989; Shalin and Bee, 1987; Yerushalmy and al, 1999). Each one of these two structures determines the deep structure of a problem and therefore might be responsible for the problem’s difficulty. Several studies have shown that performance on solving word problems is a result of an interaction between an individual and a problem, so it needs to be understood in light of both the knowledge and skills the individual brings to the solution process and the nature of demands imposed by the problem (Sebrecht, 1996; Bednarz and Janvier, 1996; Nesher and Hershcovitz, 1994).

The traditional approach to algebra centered on symbolic manipulations, solving for unknowns and structures of algebraic expressions. This strand usually navigated the solving of algebra word problems to concentrate on the quantitative structure, by assigning symbols to unknown quantities and arranging them in an algebraic relation to answer the questions posed (Nathan and Koedinger, 2000). On the other hand, studies demonstrated that pre-algebra students often think of a problem purely in situational terms (Baranes, Perry and Stigler, 1989). Yet another finding is that
students representing story problems in formal problem model terms tend to disregard the meaning associated with the equation of the values and thus may provide solutions which are physically or situational implausible (Silver, 1988). Observations of highly competent solvers show their skills in using the situation model and the quantitative model within a problem (Hall et al., 1989) in an integrated fashion. The coordinated use of situation model with one's formal problem model appears to be fundamental to problem solving with understanding, in a variety of domains (Koedinger and Anderson, 1990).

**Figure 1a:** An example of a typical rate problem to which we refer in this paper

**Figure 1b:** Qualitative graph of the situational structure of problem 1

**Figure 1c:** Qualitative graph of the situational structure and the quantitative structure within the same model

The concept of function provides a set of terms for mathematical modeling that can turn routine symbolic work into model construction to describe the problem's situation in numerical, graphical, and symbolic terms (Heid, 1995; Yerushalmy, 1997; Nemirovsky 1996). More specifically, situations involving a single variable can be described in a two-dimensional Cartesian system by use of a triad of quantities, two quantities representing the independent and dependent variables respectively, and the third representing the rate of change of the second quantity as a function of the first. Constant-rate problems are frequently present in algebra texts. Such problems (as in figure 1a) are usually solved by means of DeRT tables as an organizing structure to the construction of an equation. When experiencing a new function-based algebra curriculum based on intensive use of functions' graphing tools (Yerushalmy and Gilead, 1999), we learned that functions can turn solving such common algebra rate problems into a meaningful activity that emphasizes both the modeling and manipulation skills. The situation can be modeled graphically by two
linear functions of time. Semi-quantitative sketches of functions (figure 1b) or graphs that accurately describe the given quantities form a visual presentation of the situational structure and may help students to express correctly in algebraic terms the quantitative relations. A set of given quantities, unknowns, and some constraints, formed by arithmetic operations between pairs of unknowns, form the quantitative structure of the problem. Thus the graph (as in figure 1c) models the situational structure of a problem and the quantitative structure (Chazan, 1993).

Studying our students' problem-solving attempts, we observed unexpected achievements and unexpected obstacles. Often we were surprised to see how successful was the solving of problems considered complex by the traditional approach, and at other times how very similar problems were far harder. A first attempt to investigate further what seemed to be a phenomenon was a systematic analysis of the domain of constant rate problems according to the range of possible interactions between quantitative structures and situational structures (Gilead, 1998; Yerushalmy et al., 1999; Yerushalmy and Gilead, 1999). We suspected that differences between constant rate problems would not be fully explained by differences in the quantitative structures or by the differences in situational structures, but by the interaction between the two. We also wondered whether this complexity is an epistemological or a didactic obstacle and whether it is an outcome of the function approach. An empirical study was designed to test our conjecture on the effect of the situational structure, the quantitative structure, and their mutual correspondence on students' performance in solving constant rate problems. The work presented in this paper is part of this research.

METHOD

Following the analytic categorization we prepared for this study 21 different rate problems, each representing one of the types of problem as defined in Yerushalmy et al. (1999). A questionnaire containing four problems, randomly selected for each participant, was administered in 17 different classes of ninth graders who had already learned to solve rate problems by a function approach within the VisualMath curriculum.

These same problems were administered in another 17 classes of ninth graders who had learned to solve rate problems by the equation-unknown strand (which below we call the non-functional approach). About 100 students of the two populations solved each problem. In this paper we refer only to four combinations of two situational structures and two quantitative structures (Table 1).

The pair of problems 3 and 4 have the same quantitative structure of the type: $v_1=$given, $v_2=$given $t_1=t_2$, $s_1-s_2=$given, while the pair of problems 1 and 2 share another quantitative structure of the type: $v_1=$given, $v_2=$given $t_1=t_2$, $s_1+s_2=$given.

</tr>
</tbody>
</table>

The pair of problems 2 and 3 share the same situational structure: two vehicles driving in the same direction at the same time). Problems 1 and 4 both share another situational structure: (two vehicles driving towards each at the same time). Students' performance was scored as correct or incorrect. A correct model was either formed symbolically (a correct equation), graphically (reading the solution from accurate graphs), or numerically (reading the solution from a table of values).

FINDINGS

Following the traditional observations of algebra word problems, we started by analyzing what effect the quantitative structure had on students' performance in each population. For the function approach students, no significant difference was found between the two quantitative structures of problems 3 and 4, and problems 1 and 2 (Table 2).

</tbody>
</table>

Table 2: Percentage of correct solutions in the two quantitative structures

This was not the case for the non-functional approach population (correctness x quantitative structure significant: p(χ²(13.948;1))=0.001<0.01). Among these students the problems with the quantitative structure v₁=given, v₂=given, t₁=t₂, s₁-s₂=given seemed easier (with 63% success) than the problems with the quantitative structure v₁=given, v₂=given, t₁=t₂, s₁+s₂=given (with only 44% success). The latter structure is reported as problematic in other studies (Mayer, 1982; Clement, 1982) because of the relational proposition involved in it (one traveled 45 km more than the other). The higher success (64% against 44%) with this problematic structure within the function approach population might be explained by their use of graphs of functions to describe the situation. This visual representation of
the processes might have helped to state correctly the algebraic relations among quantities and form a right algebraic model (Hall et al., 1989).

A similar analysis was conducted for the situational structures of the pairs of problems 2, 3 and 1, 4 (Table 3). No significant differences were found in the two populations.

</tbody>
</table>

Table 4: Percentage of correct solutions to the four problems by the function approach students

We assume that the combination of the specific correspondence of the quantitative structure and the situational structure of problems 1 and 3 were responsible for the results. For each function in this case, a point and a slope are given, which make it possible both accurately to graph and explicitly to describe the linear function symbolically. We termed such combinations between the situational structure and the quantitative structure canonical (Yerushalmy and Gilead, 1999). The situational model of problems 2 and 4 can only be sketched, not drawn by accurate graphs. Thus the symbolic model (the equation) cannot be fully described by the given quantities when phrased according to the situational model. A symbolic representation would have to use a parameter or another independent variable in addition to the time-
independent variable, and the solution cannot be determined by straightforward comparison of two functions \( G(x) = F(x) \) as it can be determined in the canonical problems. This quality of the four rate problems is detailed in Figure 2.

Figure 2: The contribution of each quantitative structure to information about the two functions in each visual situational structure

Analyzing the performance of the function approach students according to the canonical and non-canonical terms, we found (Table 5) significant differences (\( p \{ \chi^2(117.222;1) \} = 0.001 < 0.01 \)).

<table>
<thead>
<tr>
<th>Type of combination</th>
<th>Function approach Percentage of students who built a correct model</th>
<th>Non-functional approach Percentage of students who built a correct model</th>
</tr>
</thead>
<tbody>
<tr>
<td>Canonical</td>
<td>89% (n=207)</td>
<td>50% (n=224)</td>
</tr>
<tr>
<td>Non canonical</td>
<td>36% (n=186)</td>
<td>57% (n=192)</td>
</tr>
</tbody>
</table>

Table 5: Percentage of correct solutions to canonical and non-canonical problems.
Differences among the non-functional approach students (table 5) were not found significant (\( \chi^2(2.209;1) = 0.137 > 0.05 \)).

Performance on canonical problems was significantly (\( \chi^2(73.473;1) = 0.001 < 0.01 \)) better (89%) within the function approach population than within the population of the traditional solution approach (50%). However, performance on non-canonical problems was significantly (\( \chi^2(17.687; 1) = 0.001 < 0.01 \)) better (57%) within the population of the traditional solution approach than within the function approach population (36%).

Thus, the multiple representations that is one of the foundations of the function’s approach students were taught to use, was especially helpful in problems in which the equation could be explicitly derived from the situational model. It was less helpful, and we conjecture that it was even an obstacle, where the symbolic model (equation and solution) could not be directly derived from the situational model. An informal review, of different "function approach to algebra " texts that we conducted, revealed that the majority of constant rate word problems are of the canonical type, while in the traditional approach texts canonical and non-canonical types are interwoven. The findings have implications for the use of graphic tools (e.g; Graphic calculators) that most sequences of function approaches to algebra suggest, as an exploratory support for solving word problems. These tools might prove useful and helpful only for the canonical problems.

**SUMMARY**

The paper discussed the possible impact of the domain of functions on the ability and the difficulty to solve rate problems in algebra. Some of the problems (the canonical ones) turned out to be significantly easier by the function solution approach than by the traditional solution approach. The non-canonical problems proved more difficult within the function solution approach. This finding that the categorization of word problems seems to be curriculum-dependent may represents a more general challenge for emergent research on curricular change. New curricula may help to eliminate known pedagogical obstacles, but may also generate new unexpected ones. And new curricula may have to revise the previously used set of tools for analyzing students’ knowledge.

MICHAEL'S COMPUTER GAME: A CASE OF OPEN MODELLING

Ronnie Goldstein (Open University, UK) & Dave Pratt (University of Warwick, UK)

We report on work from the Playground project, in which young children (6 to 8) are designing their own computer games using a specially built iconic language to represent rules that determine the behaviour of objects in the emerging game. We report on one child's development of a maze game to illustrate how conventional modelling theory might be extended to encompass situations in which children legitimately construct and reconstruct the problem being modelled and in which children are simultaneously learning about the potential and utilities of the modelling tools themselves. We conclude that a framework for such modelling needs to acknowledge the complexity of activity and to incorporate new perspectives on validation and on modifying the goals.

Introduction

The notion of modelling that interests us describes the activity of creating and testing a model that represents critical elements, including typically the mathematical structure of a problem or system. Much of the research on modelling activity involves the use of software; indeed Schecher (1993) proposes that model building software be recognized as a category of tools in its own right, and defines this new category as:

"... context-free software tools that support the user in representing a part of the 'touch-and-show' reality in the form of an abstract, quantifiable system of parameters and their relationships (the model), which predicts the behavior of the real system.” (p. 162)

Such software has been used by students to explore ready built models (for one of many examples, see White, 1984) and to express the learners’ own ideas for models that represent a particular situation or problem. (this distinction is discussed by, amongst others, Bliss & Ogborn, 1989.)

Our interest in modelling stems from our work in the Playground Project: we are studying young children (6 to 8 years old), as they use specially designed software to make their own computer games. Our focus is on the way young children express their ideas for games through the articulation of rules. We wish to modify or extend modelling theory to encompass situations like ours where the learner possesses considerable control over the nature of the problem: the child is involved in problem posing, an activity that falls outside the classical modelling cycle as expressed in Figure 1.

We also hope to adapt the modelling cycle by acknowledging the central role of tools in shaping the activity. Our starting point owes much to the situated cognitionists (Lave, 1988) in that we regard tools and learners to be in a dialectical relationship; that is to say, as the learners become more familiar with the tools, they become aware
of new opportunities and utilities of those tools. Through using the tools, the learners re-construct their understanding of them. This shapes the way that the learners think about their solution to the problem, and, where problem posing is legitimate, the problem itself.

In summary, we aim to illustrate the evolutionary nature of a form of modelling that encompasses conventional modelling activity but adds to it two important processes: (i) an openness that makes it legitimate to change the problem being modelled, and (ii) an interleaving of learning about the tools themselves.

Our approach

We report the work of one child, Michael, who is 7 years old. He has been building a maze game using Pathways, one of the pieces of software being developed in the Playgrounds project. Pathways is driven entirely through the use of icons with the intention that it is accessible to very young children. The software allows children to choose from many different background screens and to place a number of objects on the screen. The objects can be given various shapes and they can be made to move automatically or to be dependent on the joystick or the mouse. A significant feature of the software is that objects can be given rules that determine their behaviour when the game is played. An underpinning hypothesis is that young children can create complex behaviour by teaching objects a relatively small number of simple rules expressed in an iconic language. An object can hold several rules. For example, the pathways in Figure 7 apply to the walls of a maze and they express the rules: ‘When I touch the tiger, I reveal a rabbit’ and ‘When I touch anything, bounce off me’ (i.e. any other touching object should bounce away from the object that holds the rule).

Children move from defining rules to playing the game by clicking a switch that turns the game on but they can return at any time to making rules by switching the game off again.

The game evolutions are captured in clinical interviews, in which we work as participant observers alongside pairs of children (usually pairs, though in the episode reported in this paper Michael is working on his own). The children are between 6 and 8 years of age. The interviews normally last between 1 and 1.5 hours. Game evolutions usually extend across 4 or 5 such interviews.

The data for the research are transcriptions of the recordings on videotape of the children’s activity, captured from their computer screen and from discussions between the children and the researchers. Also, there are many versions of the emerging game, saved at regular or significant moments.

Evolution of a Maze Game

This episode began towards the end of the second session with Michael, who was building a type of maze game in which the player controls the tiger with a
joystick and tries to ‘catch’ the rabbit (see Figure 2) at which point the rabbit disappears as if eaten by the tiger. He has built a timer (in the top right corner of the screen), which counts the time that has elapsed since the game was switched on. The game contains several pieces of wall (the blue strips) but so far Michael has not given the walls any rules. This episode describes how Michael’s game evolved to include rules for the walls. (Note: In the transcribed sections below, M refers to Michael and R to the researcher(s) who were present.)

At the beginning of this episode, Michael played the game and found that the tiger passed straight through the walls. Michael wanted to turn the walls into barriers.

1. M: Can we make it not be able to go through?
2. R: There is something we can try on that but let’s worry about that a bit later.
3. M: Would it be the bounce button?
4. R: Yes. How did you know about the bounce button?
5. M: When I was searching.

Michael had remembered some earlier exploration in which he had come across an icon for bouncing. When this icon is used in a rule, anything else that touches the object with the rule bounces off that object. Michael opened up the pathways for one piece of wall and began to enter each element of the wall’s rule: ‘When I am touching the tiger, bounce off me’ (Figure 3).

Michael checked this rule by playing the game but found that the tiger passed straight through the wall. The researchers explained that there was a conflict in Michael’s rules: Michael had already written a rule for the tiger which meant that it was controlled by the joystick and so the tiger did not know whether to follow the joystick or to bounce off the wall. In fact, the tiger would momentarily bounce off the wall but then immediately pick up the position of the joystick again. Michael was not content.

6. M: I wish it would just not go through ... it wouldn’t really be a proper maze because the idea is that you can’t go through stuff like walls and stuff. That’s the whole point of mazes.

With some encouragement from the researcher, Michael began to consider alternative solutions that would resolve the bouncing conundrum. He considered penalising the player somehow when the tiger collided with a wall.

7. M: If you touched the wall, I was thinking ...Oh, I’ve actually just had an idea. It changes its speed. It speed goes up so it’s harder to control. So basically it goes, “Oh no I’ve touched the wall”. It gets faster and faster and faster.

The researcher explained that the speed of the tiger was controlled manually by the joystick, and so any programmed change to the speed of the tiger would in any case be overridden by the player.
8. M: I've just thought of the worst one ever. The game stops.

Michael entered the rule: 'When I touch the tiger, I stop the game' into a blank pathway for one piece of wall (Figure 4). He then copied this rule for each of the other pieces of wall.

Michael kept this rule for the walls for most of the remainder of his time working on the maze game. During this time he concentrated on other aspects of his game. By the time we pick up the story once more, Michael has changed the walls into circular obstacles (Figure 5). He has also added two extra rabbits, each of which moves automatically and bounces off the walls.

Michael had created this effect by applying the earlier idea of bouncing off the walls to the rabbits. Thus, each circular obstacle contained the pathways in Figure 6.

The second rule can be read: 'When I touch anything, bounce off me'. Michael had already learnt that the tiger was controlled by the joystick and could not (visibly) be made to bounce off the walls, so in effect only the rabbits would now bounce off the obstacles.

However, Michael was still worried about his first rule, which made the game stop too often. He wanted to penalise the player some other way when the tiger collided with an obstacle.

9. M: Can I make ... oh yeah ... I could change that rule (pointing to a circle) until ...make it, could I make it one rabbit appears every time you touch it?

The researcher suggested that Michael could start with some hidden rabbits and make them appear when the tiger touched an obstacle.
10. M: ...also when you ... like you can destroy one, you can get one but then you go in ... and you catch one, it appears again but, would that happen? The researchers asked for clarification.

11. M: Well, tiger gets the rabbit but then he accidentally goes into a ball and the rabbit appears again, sort of.

12. R: Oh I see, one that’s been eaten appears.

Michael decided that since he has six obstacles and three rabbits, he could allocate two obstacles to each rabbit, so that whenever the tiger touched an obstacle it would make a particular rabbit appear and, if that rabbit was not already hidden, nothing would apparently happen.

Michael erased the ‘I stop the game’ icon from the pathway of one of the obstacles. With some help, he found an icon for ‘I show’ and inserted it into the rule (see Figure 7) and he made sure that the correct rabbit was included in the rule. Michael repeated this process for each obstacle.

Discussion

We have noticed three very different phases of activity in the pupils’ work. These phases have no clear order and they are often not distinct from one another.

Phases of activity

1. Game-oriented activity (G): There are some points during the sessions when the main focus of the students’ work is on the game itself. When the pupils are in G their thinking is focused on the final outcome of their efforts, i.e. the game they are designing. They are concerned with issues such as the context for the game, the background screen, what happens, who controls which objects, how many players are involved and how any victory is accomplished. Lines 6, 7 and 8 above are comments from Michael at times when his thinking was clearly game-oriented.

2. Tool-oriented activity (T): There are other stages during the pupils’ activity when they need to learn about the tools that they are using. Whenever computers are used, some time needs to be devoted to understanding the software and how it operates. This is quite normal and there are bound to be stages when the pupils have to find out how to change the background picture on the screen or which particular icons in which order might be used for one of their rules. In line 5 Michael refers to a tool-oriented stage when he was “searching”, by which he means he was exploring the software.

3. Rule-oriented activity (R): The pupils create particular rules for particular objects in their game to make things actually happen when the game is played. Michael has
given a rule to the walls in his game so that when the tiger touches any of them it will bounce, rather than carry on in the same direction (Figure 2). Later he changed the rules for the walls (which had become circles) so that when the tiger touched one of them a new rabbit was made to appear (Figure 6). When the thinking is clearly focused on a rule to be included in the game, we say it is rule-oriented activity.

Complexity

Michael's activity highlights two issues that have implications for how we think about the modelling cycle.

1. Order of the phases: It must already be clear that there is no prescribed order for the three phases (G, R and T) described above. For instance, the students are engaged in game-oriented activity when they use the icon in the toolbar at the foot of the screen to switch their game on. This might happen at any stage, either for the sheer fun of it or to validate their changes. Thus the place of G in the complete picture cannot be determined in advance. It is also evident that T and G might occur in either order: on occasions students learn about a particular tool before they attempt to use it in the game (line 5); at other times they learn about a new tool because its need has become evident in the game (activity leading up to the rule in Figure 7). The preferred approach will vary with the student and with the particular situation.

2. Links between the phases: The complexity of the phases is also attributable to the close links that exist between them. Activity in G often suggests new possibilities for R (see the text leading up to and including line 1). In lines 6, 7 and 8 Michael is in G but he is moving towards R because he is starting to think about particular rules. During the course of this short extract he uses the phrase "If you touched the wall" which is very similar to the one used by the software's mouth when it is applied to certain rules. Students need to learn to think about their game's rules formally in the language of the software so they can change the game and Michael has started to do this very early. There is, however, no clear link in the data that has been collected between T and G and this leads to the hypothesis that R is critical within Pathways and an equivalent mode needs to be found for other situations that depend on the acquisition of tools.

Modelling

Our analysis of Michael's work highlights several features that are similar to those in the conventional modelling cycle. We see analogies between the real and model worlds of the conventional modelling cycle with Michael's game-oriented and rule-oriented activity. We also recognise the processes of interpretation and validation. Furthermore, in describing the complexity of the interleaving of the different phases of activity, we are observing no more than has been reported by several other researchers who have commented on the lack of the linearity implied by the conventional modelling cycle (Lesh & Doerr, 2000). Because of the commonality between Michael's activity and modelling theory, we believe it is productive to consider the episode as a case of modelling. Nevertheless in the next two sections we
wish to elaborate on some aspects of the data, which strike us as different from conventional modelling.

**De-goaling**

Michael resolved the conflict over bouncing by changing the game so that it simply stopped whenever the tiger touched a wall (line 8). Michael forged new insights into the utility of the tools involved in trying to make the tiger bounce and this caused him to redefine his objective. Later he adopted the bouncing idea for the rabbits (lines 9-13) and so changed the aim of his game once more. A feature of the above episode is that, during his tool-oriented activity, Michael often sought out new possibilities, and exploited new discoveries. In an earlier incident, Michael explicitly recalled his prior experimentation (lines 2-5) and subsequently used the bounce stone during a phase of rule-oriented activity in order to create the effect of walls as boundaries (Figures 3 and 4).

We refer to the process of changing the aim of the game as de-goaling. The purpose of the activity, as understood by Michael, was to create a computer game. This explicit purpose made legitimate, indeed encouraged, de-goaling, a process that is not normally associated with modelling.

**Validating**

Another feature of Michael’s activity is the way in which he validated his ideas. The move from R to G was often triggered by the need to validate his recently expressed rules. In the rule-oriented activity that preceded line 6, Michael had formulated a bouncing rule (Figure 3). He validated this rule by playing the game. On this occasion, the validation was initially negative – the rule did not work – but subsequently very positive since he found new ways of resolving the dilemma as discussed above.

Similarly, the creative game-oriented activity in which he imagined disappearing and re-appearing rabbits (lines 9-13) is stimulated by the validation process (playing the game) that triggered a dissatisfaction with the game stopping repeatedly.

We are struck by the natural way that Michael moved from the model-world of rules to the ‘real’ world of his game because of the constant need to validate his progress and the legitimacy of changing the problem being posed, his maze.

**Open Modelling**

The feature of de-goaling and the nature of validation lead us to believe that we should regard Michael’s activity as a variation of conventional modelling. We refer to the type of modelling illustrated by Michael’s activity as open modelling. Open modelling describes activity where the learner is encouraged to reformulate creatively the problem itself as a result of learning about the utilities of and potentials for the modelling tools. In the literature on conventional modelling, concerns have been expressed about the lack of evidence of validation strategies when children are expressing their own models (Doerr, 1996). Matos (1995) reports on 10th grade students using spreadsheets to model the length of paper in a roll of given diameter. Matos found that the spreadsheet’s use was transformed during the activity: the
software started as a tool for expressing models but became the reality within which
the students worked. As a consequence, Matos’ students hardly ever referred back to
the problem after the initial stage. Validation rarely occurred in the conventional
modelling cycle. In contrast, Michael engaged naturally and almost continually in
validation processes. The creative challenge of de-goaling provides a drive to move
between real and model world activity. There is some evidence that, because of the
legitimacy of changing the problem being modelled (i.e. de-goaling), validation
occurs more naturally and takes on a more positive and creative role in open
modelling than it does in conventional modelling activity reported by other
researchers.

STUDENTS’ CONCEPTIONS OF CUBIC FUNCTIONS

Pedro Gómez, Cristina Carulla

Universidad de Granada, Spain • University of los Andes, Colombia*

This paper explores some aspects of students’ conceptions of cubic functions of the form \( f(x) = a(x - h)^3 + k \). This was done by analyzing students’ responses to a problem dealing with family of functions. On the basis of these answers, a series of hypothesis was formulated. These hypotheses were corroborated with a second group of students who solved the problem and were asked to correct and comment a pre-arranged solution to it. It was found that an important proportion of students develops a consolidated and invalid conception of the cubic function with special characteristics concerning its domain.

Introduction

In this study we wanted to explore some aspects of students’ conceptions of cubic functions of the form \( f(x) = a(x - h)^3 + k \). We did so by considering the performance of a group of university students solving a problem dealing with graphics of cubic functions. Our purpose was to describe some characteristics of the students’ graphics and to explore, on the basis of those graphics, some aspects of the students’ conceptions of the cubic function. The study was done in two phases. During the first phase, we constructed a set of categories that enabled us to characterize the students’ graphics and we formulated some conjectures concerning the possible conceptions that were behind that behavior. During the second phase, working with a different group of students, but the same problem, we confirmed the previously found characterization for the graphics and were able to test the proposed conjectures. We formulated as well a partial description of the students’ conceptions of this type of cubic function.

In what follows we discuss some conceptual aspects concerning the understanding of the notion of function, in general, and of the cubic function, in particular. We then describe in detail the instruments we used to collect, codify and analyze the students’ performance. Finally, we present the results found and draw some conclusions.

Understanding of the notion of function

The understanding of the notion of function has drawn some attention recently (Harel & Dubinsky, 1992; Tall, 1991; Romberg et al., 1993; Leindhardt et al., 1990). In particular, Sierpinska (1992) has produced a list of acts of understanding and epistemological obstacles related to the notion of function. For example, an act of understanding concerning the representation of functions is the discrimination between different means of representing functions and the functions themselves. An epistemological obstacle concerning the graph of a function is that the graph of a func-

* The research reported in this paper was partially supported by the Foundation for the Development of Science and Technology of the Colombian Central Bank.
tion is a geometrical model of the functional relationship. It does not have to be exact and can contain pairs \((x,y)\) such that the function is not defined for \(x\).

The notion of \textit{representative} (Schwarz & Dreyfus, 1995) has become important as technology is used more widely in the teaching of functions. This notion has to do with the fact that a given function can have multiple representatives within a given representation system. For example, \(f(x) = (x - 2)^2 + 3\) and \(f(x) = x^2 - 4x + 7\) are two representatives of the same function. Likewise, a function can have an infinite number of representatives in the graphical representation system, depending on the range and scale used for the axis.

The process of understanding can be seen as proceeding by “states”. Each state corresponds to a certain partial knowledge (a \textit{conception}) that has worked with previous experience and that allows the student to feel comfortable while solving tasks. For a given type of problems a conception can correspond to either a valid or invalid version of the mathematical knowledge at stake. We will say that a conception (valid or invalid) is consolidated whenever the student having it “feels comfortable” putting it into play while solving problems. As it will be explained later, this sense of “comfort” can be observed through the coherence of the answers of the student to a series of related questions. On the other hand, a conception can be in an unconsolidated state. When this happens, partial knowledge has not been established and the answers of the student do not follow a coherent pattern.

\textbf{Understanding of the cubic function}

There is little research made on the understanding of the cubic function. Curran found that students exhibit links between their understanding of the graph of a cubic function and their understandings of the graphs of linear and quadratic functions (Curran, 1995).

We considered a specific form of the cubic function: \(f(x) = a(x - h)^3 + k\). We did so, because the precalculus course under study followed a strategy of teaching translations and dilatations in the construction of graphs of functions. The general form of the cubic function \(f(x) = ax^3 + bx^2 + cx + d\) is introduced later on.

We were interested in exploring some aspects of the students’ conceptions of the cubic function. In particular, we wanted to see if it was possible that students develop consolidated but invalid conceptions concerning the domain and range of the function. This interest came from a first phase of the study in which students were asked to solve a problem concerning family of cubic functions (the problem is shown later). We found that many students draw graphs similar to those shown in table 1.

The proportion of answers of these types made us think that they could be a consequence of an invalid and consolidated conception of the cubic function, instead of simply being a consequence of drawing mistakes or specific circumstances related to the specific problem at hand. This conception could be expressed as follows:

\textit{The domain and range of the cubic function is a proper subset of the real numbers and can be seen as an interval around the inflection point of the function.}

We felt that if a student has this kind of conception, then he/she could agree with situ-
Table 1: Types of graphs produced by students

- If the inflection point of the function is on the y-axis or close enough to it, then the graph crosses that axis (Graph types 3, 4, 5, 6).
- If the inflection point of the function is not close to the y-axis, but it is not too far away, then the graph of the function has the y-axis as one of its asymptotes (Graph type 2).
- If the inflection point is far enough from the y-axis, then the graph of the function has other asymptotes (Graph type 1).
- If the inflection point of the function is far enough from the x-axis, then it does not cross that axis (Graph type 3).

In order to test these hypotheses we decided to work with a different group of students and the same problem. This was the second phase of the study.

Context and data collection
The study was done with first-semester students of a Precalculus course in a private university in Bogotá, Colombia. This course was taught on the basis of a curriculum innovation that involved graphic calculators (Gómez et al., 1996). The course concerns an introduction to the study of functions with special emphasis in the relationship between the symbolic and graphical representation systems and problem solving. One fourth of the course deals with linear functions, followed by the study of quadratic, cubic, polynomial, rational and radical functions. Special attention is given to the graphical role of the parameters in the different possible symbolic representations of a function.

Some results are already known concerning this curriculum innovation. Mesa and Gómez (1996) found no differences in some aspects of understanding between the stu-
dents who took the traditional course and those who took the curriculum innovation. Gómez and Rico (1995) found that the students of this group participated more actively in social interaction and in the construction of the mathematical discourse, changes that can partially be attributed to a different behavior of the teacher. Even though she changed her behavior, Valero and Gómez (1996) found that the teacher could not change completely her beliefs system. Carulla and Gómez (1996) found that the teachers and researchers who participated in the curriculum innovation underwent significant changes on their visions about mathematics, its learning and teaching. Gómez (In press) found that the effects of technology use on achievement depends on the way it is integrated into the curriculum.

The problem used was one of the problems scheduled to be done at the time cubic functions were taught in the course. We wanted to explore whether students of this new group produced graphs similar to those found in the first group; and whether those graphs were a consequence of a consolidated but invalid conception of the cubic function. In order to perform this exploration, we collected and analyzed three different types of information: 1) the answers of the students to the problem; 2) the way students corrected and commented a solution to the problem produced by us that contained most of the mistakes corresponding to the consolidated and invalid conception; 3) the comments made by the students to a series of statements related to the above solution and to the hypotheses presented earlier.

The last two instruments were designed in order to make sure that the mistakes found in the graphs were not a consequence of drawing problems and to induce the students to put into play their conceptions under different circumstances concerning the same problem. The problem proposed to the students was the following.

1) Assume that $a = 1$. The figure shows the plane $h$–$k$ plane, where the point $(h, k)$ represents the cubic function $y = (x - h)^3 + k$. Draw in different cartesian planes $x$–$y$ the functions or family of functions corresponding to a) $A$; b) $L_1$; c) $L_2$; and d) $L_3$.

2) Assume that $h = -2$. The figure shows the $a$–$k$ plane, where a point $(a, k)$ represents the cubic function $y = a(x - 2)^3 + k$. Draw in different planes $x$–$y$ the functions or family of functions corresponding to e) $A$; f) $L_1$; g) $L_2$ and h) $L_3$.

The following is an example of the solution to the problem that the students were
asked to correct and comment and the statement they were expected to comment.

1) a. The point A corresponds to a graph whose inflection point is \((-1/2, -2)\). Its symbolic representation is:

\[ y = (x + 1/2)^3 - 2. \]

The graph does not cross the y-axis.

The following are the rest of the graphs and statements that were proposed to the students for correcting and commenting on.

1) b. The graphs do not cross the x-axis.

1) c. The graphs seem to have two asymptotes.

1) d. Some graphs cross the y-axis and others do not.

2) e. The graph has restricted domain and range.

2) f. Some graphs do not cross the y-axis. The domain is the same for all the functions.

2) g. For big values of y the graphs join each other.

2) h. Those graphs with big enough value of k do not cross the x-axis.

Analysis

For the solution of the problem the students were divided in two groups: 13 students were asked to solve problem 1 and 9 students, problem 2. All students were asked to correct the solution proposed and to comment on the statements proposed. We calculated the following percentages:

▲ The percentage of students that, having produced a graph, drew a graph of
one of the types expected, as described in table 1.

\[\text{\textbullet For each answer corrected, the percentage of students that marked it as correct.}\]

\[\text{\textbullet For each statement commented, the percentage of students that accepted it as valid.}\]

Furthermore, an analysis of each student's answers was made on the basis of his comments to the statements. The purpose of this analysis was to explore the coherence of the comments of each student to the series of statements, and be able to conclude about their conceptions. We considered only those students who commented at least three statements. We considered that a series of answers were coherent if at most one comment was contradictory with the other comments (from the point of view of their validity).

Results
Table 2 shows the percentage of students that, having produced a graph, draw a graph of one of the types expected, as described in table 1.

Discussion
The results show that students of the second group continue drawing graphs of the
types found with the first group of students. When asked to correct the pre-arranged solution, all students marked as correct all the invalid answers proposed to them. However, when asked to comment on the statements proposed, the reactions of the students differed. Many answers were found in which students did not agree with the statements. Nevertheless, this was not a consequence of a "random" reaction from the students to the statements. The analysis of each students' comments to the series of statements show that the students can be categorized into three groups: those with a coherent and invalid series of answers, those with coherent and valid answers, and those with incoherent answers. The relevant point here is that the group with coherent but invalid answers represents an important proportion of the total group. This leads us to think that many students can develop a consolidated and invalid conception of the cubic function of the form \( f(x) = a(x - h)^3 + k \). However, our hypothesis concerning the range of the cubic function is not clear, given the results to questions 2g and 2h.

Conclusions

There might be many reasons why students develop this type of conception of the cubic function. From the mathematical point of view this seems to be a natural situation. Since cartesian planes are traditionally drawn with the same scale in both axis and the cubic function grows rapidly, the part of the domain of the function that can be "seen" in the graph is usually a subset of the real numbers. Furthermore, it seems that most textbooks and teachers tend to consider cubic functions for which \( a \geq 1 \).

Teaching and textbooks do not help either. We found that the textbook used in the course did not present graphs in which it could be seen that the domain were the real numbers. Furthermore, when checking some teaching materials drafts from one of the teachers, we found graphs similar to those drawn by the students.

It is very likely that this problem exists with quadratic functions as well. As a matter of fact, when performing informal interviews with the students, one of them justified the "asymptotic" behavior of the cubic function as being the same as the one for the quadratic function. In this sense, one can say that there is a link between the understanding of the quadratic and the cubic function. However, even though we do not have data to justify, we think that this link is broken when quadratic and cubic functions are compared to linear functions, a fact that would not corroborate Curran's results in this respect.

One may argue that the problem proposed to the students was about family of functions and not about the domain and range of the functions. Therefore, students could have been more concerned about answering the questions and correcting the answers proposed with respect to what they considered relevant in the problem and this might be the reason why all of them marked as correct all the answers proposed to them. However, this was not the case with the statements they had to comment on. Those statements referred to the graphs themselves and made no direct connections to the text of the problem.

Finally, technology might have played a role as well. The "window" problem identified by Schwarz and Dreyfus with their "representative" concept might induce stu-
students to construct their invalid conception. This is a somewhat paradoxical situation given that graphic calculators and computer software allow students to easily change the scale and range of the axis. However, this could be evidence of the fact that students do not take advantage of those features.

The learning difficulties found in this study would not be very important if they could be interpreted as a consequence of drawing problems related to the specific context of the task at hand. However, as we have found elsewhere (Carulla & Gómez, 1997), when technology is involved, students tend to construct their understanding based mainly on the graphical representation of the concepts. This might be the reason why we found these consolidated and invalid conceptions.

Relationships between embodied objects and symbolic procepts: an explanatory theory of success and failure in mathematics

Eddie Gray and David Tall

Mathematics Education Research Centre
University of Warwick, UK
<E.M.Gray@warwick.ac.uk>, <David.Tall@warwick.ac.uk>

In this paper we propose a theory of cognitive construction in mathematics that gives a unified explanation of the power and difficulty of cognitive development in a wide range of contexts. It is based on an analysis of how operations on embodied objects may be seen in two distinct ways: as embodied configurations given by the operations, and as refined symbolism that dually represents processes to do mathematics and concepts to think about it. An example is the embodied configuration of five fingers, the process of counting five and the concept of the number five. Another is the embodied notion of a locally straight curve, the process of differentiation and the concept of derivative. Our approach relates ideas in the embodied theory of Lakoff, van Hiele's theory of developing sophistication in geometry, and the process-object theories of Dubinsky and Sfard. It not only offers the benefit of comparing strengths and weaknesses of a variety of differing theoretical positions, it also reveals subtle similarities between widely occurring difficulties in mathematical growth.

Introduction

The theory presented here builds on work that has developed steadily over the last two decades (Gray, 1991; Tall & Thomas, 1991; Gray & Tall, 1994; Tall, 1985, 1995). But it is not a simple restatement of earlier theories. A simple switch of viewpoint is seen to reveal powerful insight into very different ways in which individuals construct mathematical concepts. To gain insight into this viewpoint, we consider the situation in which embodied objects are perceived by and acted upon by individuals. (The precise nature of embodied objects will be discussed in more detail shortly, but essentially they begin with human perceptions using the fundamental senses, and become more mentally based through reflection and discussion over time.) Our viewpoint then compares the developing embodied meanings of the objects and their configurations with other mental constructions relating processes and concepts through the use of symbolism. Our purpose is to compare the meaning embodied in the objects and their configurations on the one hand with process-object abstraction on the other. We seek a theory with the power of both explanation and prediction of the varied nature of cognitive development throughout mathematics. We require a viewpoint that is theoretically sound yet has a simple and practical meaning relevant to the spectrum of practitioners from teachers of young children to university mathematicians.
One of our hypotheses is that the theorised encapsulation (or reification) of a process as a mental object is often linked to a corresponding embodied configuration of the objects acted upon (which we henceforth refer to as base objects). We observe that the embodied configurations are more primitively meaningful than the encapsulated mental objects and yet lack the flexibility and power of the distilled essence of the symbolism that links dually to both mathematical concept and mathematical process. The consequence is that the embodied approach can give fundamental meaning to mathematical ideas but that such embodied representations prove to be complex to handle when they are applied to increasingly sophisticated problems. Progress to more subtle levels of mathematical thinking requires eventual access to the powerful and compact use of symbolism. We observe that a practical, real world understanding of simple mathematics can very well benefit from a focus on the operations on the base objects, and such a perspective is satisfactory, even insightful in everyday situations. However, an exclusive focus at this level can act as an epistemological obstacle barring the way to the more sophisticated theory that is required for subtle technical and conceptual thinking. As was observed in Gray, Pitta, Pinto & Tall (1999), those students who consider only their perceptions of embodied objects remain at a more primitive level, whilst those who succeed move on to more sophisticated levels, with an easy movement forward to focus on the symbolism or back to consider the configurations of the base objects. Some of those with a developing hierarchy maintain the full range (being 'harmonic' in the sense of Krutetskii (1976)), others become successful by focussing on the higher levels (increasingly ‘analytic’ according to Krutetskii), losing contact with the real world and becoming ‘formal’ thinkers (Pinto & Tall, 1999).

**Embodied objects**

We take the notion of ‘embodied object’ to begin with the mental conception of a physical object in the world as perceived through the senses. Examples include a Jersey cow, a hamburger, a paper bag, geometric objects such as triangles, arrays of objects such as the dots on a domino, the drawing of a graph of a function, a Venn diagram, and so on. In addition to our direct perceptions through our physical senses, we also think about what we perceive, compare our sense of one embodied object with another and share these ideas with others. In this way our perceptions take on an increasingly subtle meaning. On the one hand our mental conception may be in the form of a “skeleton” or a prototype, having general properties that provide a basis for communication until the addition of specific properties lead to the particular. (For instance, the word ‘dog’ may bring to mind a domestic animal with fur that barks; but as we consider new information, such as a dog whose fur is cropped into artistic shapes, we might then home in on a poodle, or to a specific poodle belonging to a friend.) On the other—and this is highly relevant to the development of mathematics—our perceptions may become abstractions which no longer refer consciously to the specific objects in the real world. An example of the latter is the idea of a ‘straight line’ which is initially seen as a line drawn with a tool such as a ruler that makes it ‘look straight’. By talking about the idea we move on to
consider a mental concept that is 'perfectly straight', 'having no width', 'arbitrarily extensible in either direction'. None of these properties is true of an actual line in the real world, but it is based on real-world perception and can only be constructed mentally by building on the human acts of perception and reflection. In this way we see an increasing sophistication in the notion of 'embodied object' that begins with sensory perception and is refined in mental thought through the use of language to give increasingly refined precision and hierarchies of meaning. This gives an increasingly sophisticated conception of embodied objects in a general manner which has been specifically described by van Hiele (1985) with reference to geometric objects.

We use the term ‘embodied object’ in a manner similar to the theory of Lakoff and his colleagues who speak of ‘embodied cognitive science’ (Lakoff & Johnson, 1999; Lakoff & Nunez, 2000). However, we note that Lakoff’s theory does not explicitly use the notion of ‘embodied object’—the term does not appear in the index of either Lakoff & Johnson (1999) or Lakoff & Nunez (2000).

Our approach makes a closer analysis of the nature of mathematical concepts and sees a significant distinction between embodied objects (such as a triangle or a graph) on the one hand and the symbols of arithmetic and algebra on the other. The latter symbols act as pivots between processes and concepts in the notion of procept (Gray & Tall, 1994), providing a link between the conscious focus on imagery (including symbols) for thinking and the unconscious interiorized operations for carrying out mathematical processes. In particular, we empathize with Dörfler (1993) who claims that, although he can imagine five objects, nowhere in his mind can he imagine a mental object for the number ‘five’. From the perspective we are adopting in this paper, we agree that the imagery for the number ‘five’ is not an embodied object, although a mental image of ‘five fingers’ clearly is. This emphasizes that thinking involving embodied objects is likely to differ significantly from the kind of thinking involved in the successful development of arithmetic and algebra. However, it does not mean that we cannot call a number an ‘object’ to manipulate, simply that it is not an embodied object. In fact, our linguistic use of number as a noun—‘five is a number’—gives it a semblance of being an entity, even though this is no more an embodied object than the gerund ‘running’ in ‘running is good for you’. We refer to a number as ‘it’, we operate on ‘it’ and with ‘it’ in arithmetic and—far more important—the symbol for the number allows us to switch flexibly between mental concept and mental process.

Encapsulation of procedure - process - procept

Gray & Tall (1994) adopted the distinction between procedure and process of Davis (1983, p. 257) whereby the term procedure is a step-by-step algorithm in which the individual needs to complete each step before taking the next. A process occurs when one or more procedures (having the same overall effect) are seen as a whole, without needing to refer to the individual steps, or even the different procedures. For example, "count-all", "count-on", "count-on-from-largest", "known fact", are all different procedures for the process of adding two numbers. When the symbols act freely as cues
to switch between mental concepts to think about and processes to carry out operations, they are called procepts. These can be composed and decomposed at will to derive new facts. For instance, 8+6 may be calculated by decomposing 6 into 2+4, composing 8 and 2 as 10, and 10 and 4 as 14, or as decomposing 8 into 4+4, then recomposing 4+6 as 10, and then the other 4 plus the 10 makes 14. More particularly, it is now relatively easy to see the implications of the distinctions we make between the process of addition and the concept of sum. The former suggests doing the arithmetic whereas the latter emphasises a proceptual structure that consists of a theory of related procepts, including the base objects on which the processes act, the symbols as process and object, and the concept image related to the use and meaning of the procepts. Thus, in the example above, the procepts are symbolised whole numbers with the related process of addition; the base objects are initially physical objects, but then become figural objects and later become redundant as they are subsumed in a counting process which is itself compressed into the concept of sum.

It is clear from this discussion that the spectrum of procedure-process-procept is not a classification into disjoint classes; we explicitly mentioned the ambiguity of the symbolism as process or concept in the title of our paper (Gray & Tall, 1994). It is a categorization into a spectrum of improving sophistication in which the categories blend one into another, even regressing on occasion to a more primitive case. One of us remembers adding up marks in mathematics examinations and getting to ‘know’ most of the required facts, yet regressing to add 89 and 2 with a quick count-on as '89, 90, 91'. What matters with the increasing sophistication is that a ‘process’ usually (but not always) may be performed by a specific finite procedure (a counter-example lies in the general process of convergence to a limit). A ‘procept’ relates to a thinkable concept and a process carried out by its corresponding procedures.

What is clear, however, is the steady development of entities operated on, from physical objects including fingers, to imagined fingers or configurations of counters, to mentally operations with the number symbols themselves. The increasingly sophisticated arithmetical knowledge developed by children (see Steffe et al., 1983) is exemplified by an increasing detachment from immediate experience, the development of different aspects of counting and a change in the form of unit counted. Within four of the counting types, the perceptual, figural, motor and verbal we may see the gradual shift in the nature of the base object from a perceptual unit to a mental embodied object. Cobb (1987), has suggested that it is “only at the level of abstract counting that number words or numeral signify conceptual entities that appear to exist independently of the child’s actual or represented sensory motor activity” (p.168). We suggest that it is at this stage that the transition from process to concept can occur that forms the basis for understanding the numeration system. Though the system is straightforward for those who understand it, it remains a source of difficulty for many, particularly when shifted beyond whole numbers and extended to decimals. We suggest that it is the formation and reliance upon embodied configurations in the whole number context that is the basis for this difficulty. The recognition of proceptual structures provides the flexibility.
Sophistication and a spectrum of performance

Figure 1 (expanded from figure 1 of Gray, Pitta, Pinto & Tall, 1999) shows the possible outcomes of different levels of sophistication from pre-procedure through to procept. It shows that a problem requiring only a routine procedural solution will distinguish between failure and success only in terms of the change from pre-procedure to procedure. The availability of different routes at the process level introduces the possibility of alternative methods allowing checking for possible errors in execution, even to an underlying unconscious feeling that something is wrong when an error is made (Crowley & Tall, 1999). The procept level moves to a higher plane where the symbols act dually as process and concept, allowing the individual to think about relationships between the symbols in a manner which transcends process alone.

For example, we may recognise that the procedure ‘add 3 to a number and double the result’ and the procedure ‘double a number and add 6’ both give the same process. Symbols can be effective for these two procedures in terms of the expressions \((3+n)\times2\) and \(2\times n+6\), or the more standard notations, \(2(3+n)\) and \(2n+6\). These all represent the same input-output process operating on the (value of) the number \(n\). A student still at the procedure level might find these various expressions and their procedural meanings a considerable barrier to understanding expressions as processes.

![Figure 1: A spectrum of performance (taken from Gray, Pitta, Pinto & Tall, (1999, p.121)).](image-url)
Refocusing – a possible explanation

How does this process of refocusing from operations on physical objects, to operations on mental entities, to operations with mental entities occur. A probable solution is given by Edelman & Tononi (2000, p.57) who report many studies that show that initial problem solving causes activity in a wide range of brain centres, measurable using brain scans, but, as the solution processes become more routine, the required brain areas become fewer as alternatives are no longer required. Edelman and Tononi hypothesise that conscious thought requires a combination of both high correlation between different areas of the brain (which they term ‘integration’) at the same time as there is a range of possible choices to make (termed ‘differentiation’). Routine mathematics becomes unconscious because it requires little differentiation in parts of its activity, only coming to the surface when a particular decision must be consciously made. Thus it becomes possible—but not inevitable—that the focus on the basic objects being manipulated becomes less necessary, and the links, first to inner perceptions, then to increasingly unconscious processes, gives a natural sequence of development for the human brain.

The relationship between embodied objects and encapsulation of processes

It is at this stage that our theoretical positions begin to diverge from both embodied object theory and process-object theory. The former could be a viewpoint in which all mathematical concepts are embodied objects. Such a view fails because the concept of number is not an embodied object, although the concept of ‘five things’ is. In saying this we misinterpret Lakoff and his colleagues who say that all thought is embodied rather than all we think about is embodied. However, we consider it important to lay the ghost of the idea that all mathematical concepts are conceived as embodied objects. For several years now (for example, Tall, 1995; Gray et al 1999; Tall et al 2000), we have been homing in on three (or perhaps four) distinct types of concept in mathematics. One is the embodied object, as in geometry and graphs that begin with physical foundations and steadily develop more abstract mental pictures through the subtle hierarchical use of language. Another is the symbolic procept which acts seamlessly to switch from a ‘mental concept to manipulate’ to an often unconscious ‘process to carry out’ using an appropriate cognitive algorithm. The third is an axiomatic concept in advanced mathematical thinking where verbal/symbolical axioms are used as a basis for a logically constructed theory. (Here the fourth type of concept might occur by distinguishing between those concepts evolving from embodied objects and those from encapsulated processes (Tall, et al, 2000).) Expanding the theory based on ‘perception, action and reflection’, we see the different kinds of mental entities arising as in figure 2 (overleaf).

We begin by considering the classical situation where the individual performs operations on embodied objects. We have already considered the case of number concepts where the base objects are physical objects and the encapsulated concepts are number concepts represented by number symbols. Here we note an interesting fact. Because the counting process operates on physical objects, the seemingly abstract
concept of number, theoretically formed by a process of encapsulation, already has a primitive existence in the physical configurations of the base objects. It is by elaborating this simple idea that we come to a distinct view of the role of base objects in the formation of the higher order encapsulated concept. Essentially we see this role of the base objects as a stepping stone to the higher order concept, whilst at the same time having specific meanings for some individuals that act as epistemological obstacles preventing the hierarchical development that is essential for progress to more sophisticated mathematics.

Consider, as a second example, the idea of 'rate of change' and the subtle mathematical process of differentiation and its related concept of derivative. Here we see the picture of a graph as an embodied object that represents the function concept visually. It can be drawn and seen either with a pencil or with a wave of the hand in the air. This embodied action conveys the sense of the changing gradient of the graph as it changes slope. It proves to be natural for many students to develop an insight into the changing gradient by simply 'looking along the curve' and plotting the visual numerical value of the (signed) gradient as a graph. This can be done visually and enactively without any numerical calculation or symbolic manipulation. The more formal ideas can come (shortly) after the fundamental embodied activity has been constructed with support from the bodily movement of the individual.

This brings us to our major difference with theories of process-object encapsulation, particularly formulated in the sequence action-process-object-schema (Czarnocha et al, 1999; Sfard, 1991). Our observations of human activity reveal that the 'encapsulated object' is not simply produced by 'encapsulation' or 'reification' of process into object, but is greatly enhanced by using the configuration of the base objects involved as a precursor of the sophisticated mental abstraction.

This is not to say that the higher sophistications of calculus and analysis always remain consciously linked to fundamental embodied objects. They don't. The connections may remain but become unconscious, so that the brain can move on to focus on essential details selected as the basis of axiomatic development. This starts with formal definitions (based on useful, generative, properties) and continues by a process of formal deduction of theorems. Each established theorem then becomes available as a concept for use in the proof of later theorems. Different students learn formal mathematics in different ways. Many do not develop beyond their existing embodied
perception. Some build on their concept imagery, modifying and extending their conceptual hierarchy to grow naturally into the formal ideas. Others have grown in sophistication and no longer evoke conscious links to their embodied sense of the world, extracting meaning from the formal definitions by formal deduction (Pinto, 1998).

In this way we see abstractions rooted in embodied objects of the biological brain providing a basis not only for geometric thought in a developing van Hiele sense, but also a foundation for symbolic process-object encapsulation and on to axiomatic thought.

ANALYTIC-SYNTHETIC ACTIVITIES IN THE LEARNING OF MATHEMATICS

Valery A. Gusev, Moscow Pedagogical State University,

Ildar S. Safuanov, Pedagogical Institute of Naberezhnye Chelny

We consider the well-known in psychological literature, but not yet sufficiently investigated in application to mathematics education mechanisms of thinking – the analytic-synthetic activities. Examples of using such means of mental activity as «synthesis» and «the analysis through synthesis» in solving geometric and algebraic problems are given. From these examples, one can deduce that various problems require various aspects of analytic-synthetic activities, and the most complicated means of such activity – “analysis through synthesis” can be developed only as a result of serious and specially designed teaching. The important task of mathematics education is to develop an effective system of teaching pupils to use all means of analytic-synthetic activity.

In this theoretical essay we will consider the well-known in psychological literature, but not yet sufficiently investigated in application to mathematics education mechanisms of thinking – the analytic-synthetic activities. The theoretical framework of our paper is Soviet activity approach in psychology and, particularly, S. L. Rubinshtein’s conception of means of mental activity, or mental operations (S. L. Rubinshtein, 1989, p. 377). S. L. Rubinshtein (1958, p. 28) wrote: “The process of thinking is first of all the analysing and the synthesising of what is resulted in the analysis, then processes of abstraction and generalisation which are derivatives of analysis and synthesis. Regularities of these processes and their interrelations with each other are essentially basic interior regularities of thinking”.

Analysis (in the ancient Greek decomposition, partition, dissection) is a procedure of mental, and frequently as well real dissection of a subject (phenomenon, process), of a property of a subject (subjects) on its components; extraction from a subject of aspects of its study; drawing out of a subjects their sides, properties, relations between them.

The analysis frequently is represented as multistage process. Something, reached as a result of the initial analysis, becomes then subject of the deeper analysis in the next stage. This passage from one level of the analysis to other, deeper level, is determined by the requirements and character of new tasks arising during the process of cognition.

Synthesis (in the ancient Greek junction, compiling, integration) is a mental combination of parts and sides, extracted by the analysis, in some new mental unity, in which the typical features of the analysed subject are fixed. The synthesis is
connected with the simplification of what is analysed, with the detection in a subject of essential internal connections constructing the mental unity, with obtaining new piece of knowledge.

The synthetic activity of generalisation and meaning-making of the results of the analysis together with the analogy and other means of mental activity is a powerful tool of the discovering new truths, of obtaining principally new scientific results; of constructing revolutionary ideas creating new landmarks and directions in the development of sciences.

The synthesis reproduces the analysed subject, but is connected with the improvement, enrichment, deepening of that knowledge about a subject as a whole, which we had before the analysis. Synthesis already uses methods of that scientific theory, within the framework of which the analysis is produced, and, hence, those idealisations and abstraction, on the basis of which that theory is constructed. As a result of the analysis and synthesis the subject is reproduced in its essential and necessary relations and with that degree of the precision and adequacy, which is determined, on the one hand, by the contemporary state of the science and experimental technique and, on the other hand, by the character of the problem of research.

Thus, the synthesis is a procedure, inverse with respect to the analysis, but with which the analysis is frequently combined and intertwined in practical or cognitive activities. The analysis and synthesis are studied by such sciences as psychology, epistemology, logic, pedagogy and didactics of various disciplines.

Historically, the analysis was considered as a path (method of thinking) from the whole to the parts of the whole, and synthesis as a path from the parts to the whole. Therefore, analysis and synthesis are practically inseparable from each other. They accompany each other, complete each other, constituting the united analytic-synthetic method. The analysis assumes synthesis, and the synthesis is impossible without the analysis.

The analysis and synthesis as the methods of scientific knowledge play the important role in mathematical research. Similarly, extremely great is their role in mathematics teaching, in which they appear in the different forms: as methods of the solution of problems, of the proof of the theorems, of the study of properties of mathematical concepts etc.

Some of synthetic methods of solving problems involving geometrical constructions (methods of geometric loci, of similarity) were known still by ancient Greek geometers, and the distinction between analytical and synthetic methods was introduced to mathematics by Euclid. He considered the analysis and synthesis as two kinds of the "syllogistic" method of proof. In the thirteenth book of the "Elements" Euclid wrote: "In synthesis we begin with what is already proved, and come to the inference or to the knowledge of what is necessary to prove" (Euclid, 1956).
One can also find the definitions of the analysis and synthesis in the works of Francois Viete, who remarked that “there is a way of investigating the truth in mathematics, and the invention of that way is assigned to Plato; Theo has named it “analysis” and has defined as follows: “we consider the required as known and pass from a corollary to a corollary until we are convinced in the truth of the required; the synthesis consists in the following: proceeding from known, we, from a corollary to a corollary, come to the discovery of the required” (Yushkevich, 1970).

In the didactics of mathematics the terms “analysis” and “synthesis” traditionally meant two oppositely directed courses of reasoning, usually used in problem solving and in proving of theorems; the analysis is the reasoning directed from what is required to find or to prove to what is given or established earlier; the synthesis is the reasoning in the opposite direction.

Kolyagin et al. (1975, p. 52) wrote that “nowadays one understands the analysis as the means of thinking, leading from the corollary to the reason generating that corollary, and the synthesis is understood as the means of thinking, leading from the reason to the corollary generated by this reason”.

Giving much attention to the means of thinking “analysis” and “synthesis”, we certainly understand, that the mental activities are not reduced to these means only. The importance of such means as abstraction, concretisation, generalisation, analogy etc. for thinking in general and for mathematical thinking in particular is well known and widely admitted.

The analysis and synthesis can be combined with each other.

S. L. Rubinshtein distinguished the important form of the analysis – one which is carried out through synthesis. The essence of such analysis is the following: “the object of thinking is being repeatedly included in new connections and thus it arises in new appearances, with new qualities fixed in new concepts; thus, new contents are repeatedly taken out of the object, it turns repeatedly to new sides; new properties of the object come to light”(Rubinshtein, 1958, p. 98-99).

Thus, the important means of thinking arises: “the analysis through synthesis”. Its role in psychology is connected with the detection of new qualities, sides and properties of objects. Therefore, this means is connected to the creative processes. S. L. Rubinshtein (1976) named this means «a quintessence of thinking». In our view, the possession of this means of mental activity is the highest level of person’s development in general and her/his mathematical development in particular.

As a result of the using of means of mental activities «synthesis», «analysis» and «the analysis through synthesis» the special kind of intellectual activity – analytic-synthetic activity is born. This new kind of activity, in its turn, generates various analytic-synthetic methods of reasoning and problem solving in teaching/learning mathematics.
We will illustrate the essence of means «synthesis» and «the analysis through synthesis» by examples of problem solving.

The first example is a problem which can be solved by «pure» synthesis.

**Problem 1.** The perimeter of an isosceles triangle is equal to 1 meter, and the base of the triangle is equal to 0.4 m. What is the length of the lateral side (fig. 1)?

![Fig. 1](image)

**Solution:**

We will denote properties by the letter P with appropriate numbers. We have:

P1: the triangle ABC is isosceles (given).

P2: the perimeter of a triangle ABC is equal to $AB + AC + BC = 1$ m (given).

P3: $AB = 0.4$ m (given).

P4: $AC = BC$ (from P1).

P5: $AC = BC$ =? (it is required to find).

Compare the properties.

P6: $0.4$ m + 2 $AC = 1$ m.

P7: $AC = 0.3$ m (P6).

Thus, in this problem we, deducing corollaries from the condition, come to the answer. This is the most simple example of the use of synthesis.

In the next problem the synthesis is accompanied by the analysis.
Problem 2. FOX: OX = 5. Find numeric values of the letters in this equality.

Solution:
We begin with synthesis, i.e. with deriving corollaries from the given equality.
P1: FOX: OX = 5 (given).
P2: FOX = 5 OX (P1).
The further reasoning is based on the possibility of the representation of a number as a sum of digit summands.
P3: 100 F + OX = 5 OX (P2).
Here we have distinguished OX, i.e. have used the analysis in addition to the synthesis. We remark also, that OX is a two-digit number. Further:
P4: 100 F = 4 OX (P3).
P5: 25 F = OX (P4).
P6: 25 F is a two-digit number (P5).
Now the analysis will be used once more. It is necessary to answer a question: for what numbers F, the number 25 F is two-digit? It is easy to find, that there are only three possibilities: F = 1, F = 2, F = 3. Hence the answer is: FOX can be deciphered in three ways: 125, 250, 375.
In this example synthesis was accompanied by the simple, but very essential for finding a solution analysis. Therefore, it is possible to name the mental activity used in this solution «synthesis through analysis».
Finally, we will consider two examples (geometric and algebraic) of application of the most advanced and complicated means of mental activity – «analysis through synthesis».

Problem 3. Prove that the triangle ABC, in which bisector coincides with a median, is isosceles (fig. 2).
Solution:

P1: $\angle ACD = \angle BCD$ (i.e. $CD$ is a bisector).

P2: $BD = AD$ (i.e. $AD$ is a median).

P3: The triangle $ABC$ is isosceles (required to prove).

From P1 and P2 nothing can be received, and other data is not present. What should one do in such case? There is a necessity in the analysis, and the analysis here is rather difficult.

It is necessary to prove, for example, the equality of sides $AC$ and $BC$ of the triangle $ABC$. What is necessary to know (to prove) for this purpose? The answer to this problem is rather difficult for the 7-th grade pupils of the Russian schools, where this problem is offered.

The more mathematically gifted pupils can use the sign of an isosceles triangle: the triangle is isosceles, if its base angles are equal. The idea is to construct, taking advantage of the equality of angles $ACD$ and $BCD$, an isosceles triangle with the same angles and with a lateral side equal simultaneously to $AC$ and $BC$. Thus, one can think about the inclusion of angles $ACD$ and $BCD$ and sides $AC$ and $BC$ into new connections, so that the equality of sides $AC$ and $BC$ becomes revealed. For this purpose it is possible to draw a segment $DE$ on the prolongation of the segment $CD$, so that $DE=CD$, and, considering equal triangles $EAD$ and $CBD$, one can show that the triangle $CAE$ is isosceles and, hence, $AC = AE = BC$ (fig. 3).
The solution of this problem is a vivid example of the application of the analysis through synthesis. The analysis leads us here to the necessity of the rather complicated additional construction.

In the following problem the analysis through synthesis is applied to solving a non-standard algebraic problem.

Problem 4. Find natural solutions of the equation:

\[ P1: 1 + x + x^2 + x^3 = 2^y. \]

Solution:

We begin with synthesis, trying to transform this equation.

\[ P2: 1 + x + x^2 (1 + x) = 2^y \quad (P1). \]
\[ P3: (1 + x^2) (1 + x) = 2^y \quad (P2). \]

What more can be deduced from this representation of the equation? One can read it as follows: the product of two natural numbers (\( x \) is a natural number, hence, 1 + \( x^2 \) and 1 + \( x \) are also natural) is equal to the non-negative integer power of 2. In which case is it possible? Obviously, it is possible only when factors are also integer non-negative powers of 2. Thus, we have

\[ P4: 1 + x^2 \text{ and } 1 + x \text{ are integer non-negative powers of } 2, \text{ or, more concretely:} \]
\[ P5: 1 + x = 2^m, \text{ } m \text{ is a non-negative integer number.} \]
\[ P6: 1 + x^2 = 2^n, \text{ } n \text{ is a non-negative integer number.} \]
\[ P7: x = 2^m - 1 \quad (P6). \]
\[ P8: (2^m - 1)^2 = 2^n \quad (P6, P7). \]
\[ P9: 2^{2m} - 2x2^m + 2 = 2^n \quad (P8). \]

Note that if \( n > 0 \) then both parts of the equality can be simultaneously divided by 2. Consider separately the case \( n = 0 \). In this case \( x = 0 \), but thus equality contradicts to the condition of naturality of number \( x \). Therefore, \( n > 0 \). We have

\[ P10: 2^{2m-1} - 2^m + 1 = 2^{n-1} \quad (P9). \]
\[ P11: 2^m (2^{n-1} - 1) + 1 = 2^{n-1} \quad (P10). \]

All the transformations we accomplished are rather simple, however, it might seem unclear, for which purpose we obtained the equality P11. Here the analysis through synthesis has been accomplished, which has lead to the equality in which for all but one values of parameter \( n \) there appears an even number in the right part and odd one in the left part.
Now we will consider, for which values of $m$ and $n$ this equality is possible. Obviously, $n$ does not exceed 1 (if $n > 1$, we have an even number on the right and an odd one on the left), and $m$ is greater than 0 (if $m = 0$, the number on the left would not be integer). As we have established above, $n > 0$, therefore, $n = 1$, whence $2^m (2^m - 1 - 1) + 1 = 1$. Hence, $2^m - 1 = 0$, whence $2^m - 1 = 1$ and, hence, $m = 1$. Finally we obtain $m = 1, y = 2$.

In this non-standard and rather difficult example there are three subtle moments (ideas): 1) one should see the conclusion P4; 2) denotations P5 and P6; 3) when transforming the left part of equality P8, it was necessary to foresee the purpose, that on the right and on the left there should appear expressions with values of different parity for almost all values of parameters.

In these examples, one can see that various problems require various aspects of analytic-synthetic activities, and the most complicated means of such activity – “analysis through synthesis” can be elaborated only as a result of serious and specially designed teaching. The important task of the theory of mathematics education is to develop an effective system of teaching to all means of analytic-synthetic activity, including the most difficult one – analysis through synthesis.

RELEARNING MATHEMATICS - THE CASE OF DYNAMIC GEOMETRICAL PHENOMENA AND THEIR UNEXPECTED CARTESIAN REPRESENTATIONS

Nurit Hadas and Abraham Arcavi - Weizmann Institute of Science- Israel

Abstract This study describes the processes underwent by two mathematically sophisticated students during the investigation of geometrical phenomena with Dynamic Geometry. The investigation took place in an environment which included a computerized setting and ad hoc designed investigations to provide opportunities to deal with unexpected outcomes. In such an environment and in order to make sense of what they did and found, the students reviewed and enhanced their knowledge and thought processes, consolidating connections, establishing new ones, and developing new ways of work.

Introduction

In the last decades, there were considerable advances in the design of computerized environments to promote different and possibly more powerful ways of learning mathematics. Papert (1980) conceived the idea of "microworlds" in which students had the possibility to talk mathematics and to construct their ideas by designing. Pea (1986) defined "cognitive technologies" as a tool which may help transcend the limitations of the mind, supporting fundamental changes in the thinking processes. DiSessa (2000) described new "literacies" as rearranging "the entire intellectual terrain" (p. 19) making advanced knowledge more accessible.

In line with these and many others, our starting point rests on the broad assumption that computerized technologies enable students to approach, learn and understand mathematics in ways that were not possible before. There are many research studies reporting about learning in such settings (e.g. Kaput, 1992; Schwartz et al., 1993). Our focus is on "re-learning" (in the sense of Arcavi & Nachmias, 1989): we explored how students (and teachers) revisit and enrich their known mathematics in ad-hoc designed learning environments. In this paper, we briefly describe such an environment, and we present a case of two mathematically sophisticated students at the end of secondary school working with it. The mathematical topic of the exploration was familiar to the students, and they had all the needed pre-requisite knowledge to succeed, and they did. However, as in previous studies with students learning mathematical topics for the first time (Hadas & Hershkowitz, 1998, 1999, Hadas et al., in press), in this study the re-learning process of these students was led by their need to produce explanations of surprising findings which contradicted their expectations. We present data from their work and analyze the ways in which their prior knowledge and school habits (uses of procedures and formulae, repertoire of functions, expectations, courage to integrate and discuss intuitive ideas, etc) were engaged and changed during their work.

The environment

In our study, by learning environment we mean: (a) a Dynamic Geometry (DG) microworld with the possibility of juxtaposition and use of multiple representations (geometrical drawings, measurements, Cartesian graphs) and (b) specially designed geometrical investigations (involving unexpected outcomes) presented through a
coherent sequence of open ended tasks (leading students to make and check conjectures and explain results not in line with their conjectures).

The following is one such sequence of tasks which includes two parts. The first deals with the area variation of an isosceles triangle (with equal sides of length 5 units) as a function of (i) the variable base (task 1), (ii) the variable angle between the two equal sides (task 2), and (iii) the variable altitude to its base (task 3). In the second part, the investigation turns to the area of a scalene triangle (sides of length 4 and 5), again, as a function of the variable third side (task 4) and as a function of the variable altitude to it (task 5).

Firstly, students are requested to examine the variation visually by dragging, measuring, and hypothesizing about the main graphical characteristics of the expected Cartesian graph of the relationship (domain, range, increase, decrease, maximum, symmetry, graph shape etc.) and to relate these to the geometrical features at stake (for a full description and analysis of the tasks, see Arcavi & Hadas, 2000).

After the students propose hypothesis/predictions, they are asked to make use of the software (Geometry Inventor, 1994) in order to draw the graph in real time, as they drag and change the triangle. Then they are requested to compare the graph on the screen with their predictions, and to explain the findings. Here, we concentrate on data from tasks 1 & 5, which in our experience are almost certain to produce surprises, contradictions and a subsequent motivation to search for an explanation.

The students

MI and US, 12 graders at the time of this study (age 17), were friends who studied together in the same advanced mathematics class, at the highest level of their last year in a prestigious (public) secondary school. They had had at least two years of calculus, geometry and algebra. They worked through the sequence of tasks described above in the presence of an interviewer who asked them questions to clarify what they said and requested for explicit verbalizations of their thought processes. At the end, they talked very openly about their views of the experiment in relation to their school experiences. The interview was videotaped and almost fully transcribed.

Framework for the analysis

Our analysis of the relearning focuses on three interrelated components:

- The role of prior knowledge - How pieces of the students’ entrance knowledge determine what students see (and thus possibly hinder progress), and at the same time, how their knowledge is refined and enhanced by their experiences in this environment.

- The role of the views of the subject matter and on “doing” mathematics.

- The role of real time experimentation - How the objects of their observations and the features of the software support the change in their knowledge and in turn how the growth of their knowledge support new uses of the software?
Data and Analysis

At the beginning, MI and US correctly worked out the values of the domain of the variable base (0 -10). When they turned to the range, without any prompt, they said:

US: between 0 and..., a right angled triangle will be the largest.
MI: When it is 90, its five... [inaudible, maybe “squared”] divide by 2.
US: its 25/2.

Later, US explained this conclusion:

US: I simply saw it is 12.5, the only variable [between the two equal sides] is α and when the angle is 90° the sine is 1, and if it is not 90° then the sine value is less than 1 and that decreases the area.

The calculation they used (“$5 \text{ squared divide by two}$”) corresponds to the formula side-times-side-times-the sine of the enclosed angle which was the most common for them from their trigonometry course. Then they were asked to predict the graph of the area as a function of the triangle’s base.

US: It is growing like... [traces with his hands a parabolic shape with a minimum], ...you have to use a theorem...
MI: Why not linear?
I: A nice question.
MI: If it is the base times the altitude over 2 it must be linear... but the altitude decreases and the base increases... Anyway, that means that is not linear, but it is not parabolic either, I think.
... for a parabola there must be here a quadratic function, and I don’t see it.
US: He is right, shall I explain?
I: Yes.
US: I am not sure, just a second... Suppose I define the length of BC as x, so how do I find the area? I divide it by two and draw the altitude, I can do x times the altitude...

US and MI brought many knowledge resources to this problem: they identified the maximum area correctly and efficiently. Their repertoire of functions was beyond the prototypical (“It is not linear, but it is not parabolic either”). The connections between the graph and the formula were properly and spontaneously invoked (“for a parabola there must be here a quadratic function, and I don’t see it”). They could use another area formula (“Suppose I define the length of BC as x...”).

We propose that in this part of the session, their actions and discussions were clearly determined by their looking of how to apply what they already knew (which they did and quite successfully). They switched from one formula to another according to the context, and spontaneously discussed why the function is neither linear nor quadratic. However, they made almost no use of the environment and the findings it may suggest as a source of information or insight. One obvious reason for that, is their lack of previous experiences with a dynamic software. But, we claim that another, more subtle reason for not relying on the environment was their implicit views on doing mathematics. Their actions and discussions revealed a “formalistic approach”, (e.g. finding quickly what is easy to find -the maximum- via a known calculation, attempts to invoke 'ready-to-go' procedures – “you have to use a theorem...” - and proceeding to a “secure” building of a symbolic model, as the only basis to envision...
the characteristics of the graph rather than from the features of the situation observed on the screen.

Their initial reliance on displaying and using their knowledge and their initial reluctance to use the dynamic environment, was confirmed by MI and US themselves, when they were debriefed after the interview. They mentioned that at school they “simply follow the formulae”, sometimes even “without understanding”.

In the following exchanges, they gradually began to rely more on the information provided by their experimentation with the software in order to produce qualitative arguments.

US: Symmetry? I don't think that there will be symmetry, here there will be higher values [points to the zone in the graph up to the maximum area value] and here ["after" the maximum] it will come down slowly.
I: Why do you say so?
US: I imagine the rate of change
I: You imagine it from seeing it?
US: From sort of physical vision, not formula or anything.
I: MI, do you agree?
MI: It looks like it first grows a lot and then it decreases a lot.
I: So you agree with non-symmetry here?

For the first time, in order to predict the shape of the graph, they abandoned the formulae. Instead, they relied on their visual perception of the area variation in order to predict how the rate of change should be reflected on how the graph should look like. They seemed to agree on the qualitative difference between rates of change on both sides of the maximum. However, MI made a surprising comment which reflected the interference of his symbolic knowledge.

MI: No, I think it will be symmetry because again if we consider the formula side times side times the sine of the angle between them, then, kind of, if sinus from 0° to 180° is symmetrical. From looking at it as it seems...
I: So it looks like that but it is not like that. Is that what you say?
MI: Yes. Also usually functions like these are symmetrical. I think on the basis of what...

Two strong reasons made MI disregard what he had just “saw” and to reject their agreed qualitative conclusion about the asymmetry of the graph. The first is the knowledge of the formula for the area which focus on the angle as the independent variable (in which case the graph is indeed symmetrical) and not the base. From what they said later, we learn that their school experiences did not include calculus problems in which students model the same dependent variable as a function of different independent variables. Thus, in this case, MI could not disentangle what he imagined as symmetrical (a function of the angle) from the situation he is investigating (a function of the base). The second is related to MI's views of their past practices of mathematics, rather than to a dominant piece of prior knowledge: the area functions they have met were symmetrical. Prior knowledge and past school practices “join forces” here in order to reject a qualitative correct observation.

After drawing the graph with the software (see figure 1), the interviewer asked them
whether they got what they have expected, and they both laughed:

MI: No, absolutely not.
I: Does it make sense?
US: I said the opposite... I thought it was non-symmetrical from an absolutely non-mathematical view. I imagined the side varying and I imagined the increase and saw that at first the area increases with a fast rate and when it decreases, it decreases with kind of a slower rate, therefore I thought it is not symmetrical...

MI: It does not, it does not make sense... Why it is not symmetrical?

US focuses on why the asymmetry he mentioned before turned out to be the opposite of what they obtained. Whereas, MI was very puzzled by the asymmetry itself. Later on, when discussed the algebraic representation, he returned to his dilemma:

MI: I know that in order to get a symmetrical graph, the maximum value ought to be when the angle between the equal sides is 60°, and it is at 90°, but from the point of view of the formula it still does not make sense to me.

When they obtained the graph for task 2 (Figure 2a below), MI realized that his expectation of symmetry was right, but it referred to the area as a function of the angle and not as a function of the base. MI realized that a dependent variable can be a function of two different independent variables, and thus settled his dilemma. Figures 2b and 2c show the graphs they obtained for tasks 3 and 4. Their expectations were correct and made them feel comfortable with both the environment and their work.

In task 5 (investigating the area of a scalene triangle of sides 4,5 and x, as a function of the altitude to the variable side), MI and US found another point of confrontation with their previous knowledge and habits of learning presenting another opportunity for the creation of new connections. Firstly, they predicted that the graph would be similar to the three graphs they already saw in the previous tasks.

MI: why should it be different than before?
US: I don’t think that it makes any difference if the triangle is isosceles or not.

But, at this point and in contrast to their work on the first task, they felt the need to experiment before making a final prediction. After discussing the domain of variability of the altitude and the range of the area, US suggested to use the DG tool to measure the altitude AD while changing the triangle. As US dragged the vertices on the screen and drew his predicted graph on the worksheet MI suddenly took the
mouse from US, dragged the figure on the screen and looked unsatisfied.

I: What disturbs you, MI?
MI: It is like we have a double domain. You have a certain length [of the altitude AD] here and also...
US: Something is wrong, it is returning back, the altitude values are growing from 0 till 4 and then, if you continue, it is going back.
I: I want to understand, does it change your prediction about the graphs’ shape?
US: It is not the graphs’ shape, I am trying to solve MI’s question. It is a function. It is a graph that satisfy some sort of function so it can’t be that there are two images for the same pre-image, two different values of the area fitting the same value of the altitude. It simple can’t be.

In order to strengthen the argument, MI measured:

MI: For 3.12 you have the maximum [10 square units] and also this area [2.18]. [He produced by dragging the two situations on the screen one after the other, as seen in figure 3.]

![Figure 3](image)

We note that at this point, MI and US used freely the DG environment to challenge their own initial prediction (“why should it be different from what happens with an isosceles triangle”). However, what they found seemed unnatural and different from their school experiences with “nice” graphs, let alone those who do not represent functions. (Reluctance from relationships which are not functions is described in detail in Even, 1993.) Thus when the interviewer asked them again if they want to correct their predicted graph, they requested to draw the graph with the software, at once, instead of risking a prediction. Although they already knew that “it will return back” (see figure 4) they were surprised and laughed:

MI: How come that we didn’t guess it.
US: It is very surprising.

MI’s comment can be interpreted in at least two different ways. It may mean that given their analysis, they could have guessed the shape of the graph. However, judging from the somehow ironic tone of his voice, he could have meant that this graph is something impossible to anticipate.

Then they tried to reflect on their prediction and explain the result.

US: It is as MI said, for the same altitude there are two area values.
MI: And this fits what we see here.
US: In one case the altitude is inside the triangle and in the other outside.

But they were still concerned.

MI: It is impossible to write it as a function.
US: I never saw a graph that does not satisfy the definition of function...
MI: After what we have said ... it is not so surprising.
The interviewer suggested using the algebraic representation. As they were used to do so, they had no problems in writing two symbolic expressions for the two situations
\[0.5x\sqrt{(25-x^2)} + \sqrt{(16-x^2)}\] and \[0.5x\sqrt{(25-x^2)} - \sqrt{(16-x^2)}\]. When they proceeded to make sense of how these expressions depict the situation, their comments seemed to add another layer of meaning in connection to the geometrical phenomenon.

MI: Looking at the graph, the functions meet when the altitude length is 0 or 4. 4 is not the maximum of the function, it is the maximum of the altitude. At 4 it will be the same in the two formulas, the value of \(\sqrt{16-x^2}\) is 0.

**Discussion**

We take the data above as an illustration of what it may mean to re-learn a known mathematical topic within a new dynamic environment which creates the need to settle results contradicting expectations. MI and US have not seen these tasks before. However, from their school experience, they were used to explore several types of functions and solve max-min problems by modeling and using calculus tools (e.g. derivatives). Thus the mathematical topic of their exploration was very familiar to them, and the following are some of the characteristics of their re-learning process:

- The unfulfilled expectation of symmetry (in task 1) and the non-function (in task 5) created engaging dilemmas. In task 1, MI’s correct envisioning of the variation as a function of the angle, affected what he saw when the variation was a function of the basis. In task 5, their notion (and repertoire) of functions did not allow a non-function to depict a situation. In the first case, their knowledge helped them realize that the same dependent variable can vary according to different independent variables (something they were not used to but were able to understand and experience). In the second case, their knowledge and ability to produce a symbolic model and make sense of it, coupled with their initial qualitative analysis led them to accept the surprising graph as the right representation. In both cases, they enlarged their repertoire of functions.

Therefore, we can say that the students previous knowledge which seemed to hinder their learning was also the basis of their re-learning. Their knowledge was precisely the basis upon which meaningful dilemmas were created. They were able to integrate the DG tools in order to: (a) produce qualitative arguments, (b) make connections between different representations and (c) resolve their dilemmas and apparent “contradictions”.

- The students approach to the first task indicated habits of work and views of mathematics clearly established by their school practices. As their work progressed, they started to use the tool to allow themselves to operate differently from what they were used to. Later, in task 5, they incorporated the dragging and graphing options to support more qualitative reasoning. They began to think about the predicted graph not only in terms of what kind of formula it is tied to, but also on how the graph has to reflect the features of the situation using the dragging and measuring tools offered by the software.

CHILDREN’S GRAPHICAL CONCEPTIONS: ASSESSMENT OF LEARNING FOR TEACHING
Constantia Hadjidemetriou and Julian Williams
University of Manchester

We report a study of 14-15 year old children's graphical conceptions and misconceptions using a diagnostic instrument developed from the research literature to suit the UK National Curriculum. Rasch measurement methodology was used to develop the instrument with a pilot sample and the final instrument and resulting scale is here evaluated and reported based on the full sample of 425 children. The result is that a hierarchy of responses is confirmed, each level of which is described as a characteristic performance including key misconceptions. We compare this with previous work on graphs and functions, explore a small group of teachers' knowledge and discuss the applications of the work in schools in the present stage of the programme.

Introduction and background
This study builds on previous work on misconceptions in children's graphical thinking, and especially in their interpretations of graphs (Clement, 1985; Even, 1998; Janvier, 1981; Kerslake, 1993; Sharma, 1993). Unfortunately, as Leinhardt et al (1990) said, “of the many articles we reviewed almost 75% had an obligatory section at the end called something like ‘Implications for teaching’ but few dealt directly with research on the study of teaching these topics” (p. 45). We would add that the ‘teaching implications’ drawn from research on the psychology of learning mathematics are in any case in general problematic: for many reasons these implications rarely impact on practice. Williams and Ryan (2000) argued that research knowledge about students' misconceptions and learning generally needs to be located within the curriculum and associated with relevant teaching strategies if it is to be made useful for teachers. This involves a significant transformation and development of such knowledge into pedagogical content knowledge (Even, 1998) which requires its own study. In particular teachers need to know at which stages of their development pupils are likely to exhibit the researched misconceptions and errors and where in the curriculum they are relevant. Ryan and Williams (2000) produced such data for errors scattered across the curriculum. The present study develops this work by focussing in depth on the area of ‘graphical understanding and interpretation’ relevant to years 9 and 10 of the mathematics curriculum, and by connecting the research with teachers’ knowledge of these misconceptions. In particular this study:

- developed an instrument from the research literature to assess children's learning and misconceptions on a scale related to their curriculum, which we claim is a prerequisite for transforming this knowledge into professional practice, and
explored the development of this into an instrument for assessing teachers’ pedagogical content knowledge.

The development of the assessment instrument involved the tuning of, or the development of, diagnostic items from the research literature on graphacy to fit the school curriculum. This developed from an analysis of the key work in the field of children’s thinking, identifying items which related appropriately to:

- slope-height confusion: the height is a distracting feature when interpreting the slope (Clement, 1985);
- linearity-smooth prototypes: pupils tend to sketch linear graphs and expect some form of reasonableness, such as ‘smooth’, ‘symmetrical’, ‘continuous’ (Leinhardt et al, 1990);
- the ‘y=x’ prototype: pupils’ tendency to construct the y=x graph;
- the ‘Origin’ prototype: graphs are drawn through the origin;
- graph as ‘picture’: many pupils, unable to treat the graph as an abstract representation of relationships, appear to interpret it as a literal picture of the underlying situation (Clement, 1985);
- co-ordinates: pupils’ tendency to reverse the x and the y co-ordinates and their inability to adjust their knowledge in unfamiliar situations (Kerslake, 1993);
- scale: pupils prototypically read a scale to a unit of one or ten (Williams and Ryan, 2000).

Originally it was also intended to incorporate the misconception related to misinterpreting time-dependent and time-independent graphs (Hitt, 1998), but the items did not work effectively with our sample in the pilot and this was dropped from the study.

The scaling of the test provides a measure on which pupils, item-difficulty and errors can be located (following the methodology described in Ryan and Williams, 2000 and Ryan et al 1998). The pilot study, previously reported in Hadjidemetriou and Williams (2000), involved:

- interviewing 4 teachers about these items to confirm their curriculum relevance;
- testing 50 pupils, identifying errors and development of a possible hierarchy into a measurement ‘scale’ using Rasch methodology, and
- interviewing the children who made the expected errors to validate the error categories as significant misconceptions in the children's reasoning which are in accord with the literature.

This paper reports the confirmation of the instrument in the main study of 450 pupils, and the beginnings of our research into teachers’ related pedagogical content knowledge (the instrument and report of the pilot will be found at http://www.man.ac.uk/cme/ch).
Method

The two study samples (pilot: n=50 and main: N=425) were all of year 10 pupils in the North West of the UK, whose teachers were interviewed (n=4 and N=12) to check that the test was regarded as fair and valid. The test results were subjected to a Rasch analysis in the usual way, including the coding and analysis of errors on the same scale as the items. (For a summary of this method see Williams and Ryan, 2000: the Rasch scaling is the modern stochastic development of the Guttman scaling model used in the CSMS studies in Hart, 1981). The result is a single difficulty estimate for each item and an ability estimate for each child consistent with the Rasch measurement assumptions, (only 4 mark points fell outside a model 'infit' tolerance of mean square 0.7 to 1.3 in the pilot, and one in the main study). Several items were modified between the pilot and main study, as described in detail in the pilot report in Hadjidemetriou and Williams (2000). The main study data was used also to scale the 'common' errors on the same scale (using the average ability parameter of the children who made the error). We are aware of the debate in mathematics education about the nature of such hierarchies: we accept that there may be serious dangers in fixing such constructs which may make improvements in curriculum and methods difficult. On the other hand teaching in the UK is dominated by a national curriculum which is so structured, and the engagement of teachers in practice requires us to adapt to this.

In addition to the test analyses, we drew on interviews with groups of children about the test items to gain some insight into the cause of the errors and their relation to significant misconceptions. In these interviews children were selected who made the interesting errors and discussions were organised in groups which allowed us to confirm our diagnoses of the children's thinking (along the lines described in Williams and Ryan, 2000). Furthermore we interviewed teachers and asked them to complete a questionnaire in which they were asked to suggest how difficult their children would find the items on the pupils' test, and to suggest likely errors and misconceptions the children would make. This data is used here to explore the validity of the research data on misconceptions and also the state of knowledge of this small group of teachers.

Results

The table below (Table 1) shows the resulting hierarchy of children's performance and thinking. A comparison with CSMS results reveals a comparability between the CSMS levels 1 and 2 and our own levels 1 and 2. The underlined statements in the figure are common to the hierarchy that Kerslake assembled (Kerslake, 1981; Sharma, 1993). However the emphasis is different in our test, because we included many more items which involved interpretation and sketching of graphs within contexts involving understanding of rates of change and associated misconceptions. Therefore our hierarchy at level 3 branches from the relatively common levels 1 and 2.
Interviews with children to validate the instrument

The main purpose of the pupil interviews was validation of the test, in particular our interpretation that the errors in the test are symptomatic of the misconception discussed in the literature. In this section we illustrate with interviews of a couple

Table 1: Hierarchy of performance and errors
of children’s slope-height confusion in relation to their errors in interpreting a graph of the growth of girls and boys in their teenage years. From the graph presented it can be concluded that the girls at age 14 are bigger (graph height) but the boys are growing faster (graph slope). The item (question 7 of the test) was developed from one of from Janvier’s, and is designed to probe for slope-height confusion:

INT: So ‘which group is growing faster at the age of 14’. You have ‘girls’ and why did you choose girls?
Nicole: Went up 14 and it’s more than the boys.
INT: It is more...
Nicole: It is more than the boys at the age of 14.
INT: Right, and what do you understand when I am asking you ‘which group is growing faster at the age of 14’?
Nicole: Which one is growing faster, which one is heavier.
INT: Which one is heavier. All right, is that what you understand Sara?
Sara: Yeah yeah
INT: Which group is growing faster? You went for the one which is growing, who is...
Sara: Heavier
INT: Heavier. So you put girls.
Sara: Yeah

Later when asked to interpret the curve of the graph for boys’ growth, Sara effectively explained that their growth was slow up to the age of 12 and then grew fast, then stopped:

Sara: They grow quite quickly
INT: Quickly? Till which age do they grow quickly?
Sara: ’Till about 12
INT: 12. And then what happens after 12?
Sara: They are growing even quicker.
INT: Even quicker. And then?
Sara: The line just like … stops.

The interviewer subsequently confirmed that both girls Sarah and Nicole thought that the ‘girls’ were growing faster and would not change their minds. It seems clear that the classic ‘slope height’ confusion operated, in that the height of the graph serves as a powerful distractor in interpretation of the graph, leading to the error we sought to confirm.

Interviews and questionnaires with teachers

In the main study the test was given as a questionnaire to the teachers with instructions that they should record their perception of the difficulties of the items on a Likert scale, and suggest misconceptions students might have that would cause difficulty. We built a rating scale from these data and the item-perception-difficulty measures that resulted were correlated with the children’s actual difficulty as estimated by the test analysis (rho = 0.395). In addition we sought to confirm the teachers’ responses through informal interviews, where we also began to explore their teaching practices.
However, the teachers' estimates were significantly awry on a number of items (see figure, in which teachers' ratings of difficulty were scaled on a rating scale analysis, and plotted against 'actual' scaled values of the pupils difficulties).

The 'discrepant' items were examined for face validity and found perfectly acceptable as test items. However, the teachers' mis-estimation of their (relative) difficulty could be explained by one of two reasons:

(a) in at least three items the teachers underestimated the difficulty for the children because they apparently misunderstood the actual question themselves, i.e. they had the misconception the item was designed to elicit, or they had a limited understanding that did not receive full credit; or

(b) on two items the teachers' overestimated the difficulty because they did not realise the children could answer the question without a sophisticated understanding of gradient.

In the questionnaire and interviews, the teachers were encouraged to list the misconceptions that children might exhibit. Here we summarise the misconceptions mentioned by the 12 teachers we worked with:

Table 2: Misconceptions mentioned by 12 teachers in interview or in the questionnaire

Conclusions and discussion

We have developed an instrument and a hierarchy describing children’s graphical thinking and misconceptions which respects their curriculum and is regarded as valid by the, admittedly small, sample of teachers involved. The hierarchy summarised in the chart in this paper suggests how more and less sophisticated pupils behave with graphs and what their main misconceptions are. This is linked approximately at the lowest levels with the hierarchy for graphs described by Kerslake, but covers the literature on graphical interpretation.

The evidence causes us to doubt whether teachers are aware of the common misconceptions the instrument reveals in this field, and we believe that many teachers would benefit from using the instrument in their teaching. In our current work we are investigating this. In small numbers of observations of lessons, we have not yet seen teaching which takes account of the major misconceptions spontaneously.

We are aware of the criticism that the misconceptions children exhibit may arguably be strongly associated with the particular problems they are presented with and the tools they are given to handle them with. Indeed Roth’s work (see http://www.educ.uvic.ca/faculty/mroth/Papers Available) has shown that even expert scientists exhibit misconceptions when presented with tasks which demand interpretation in contexts outside their familiar experience. We agree also with Ainley (2000) that graphical work in general and interpretation skills in particular become transparent or fused when children embed them in their activity or social practice. This is entirely consistent with our other work (eg, Wake et al, 2000; Williams et al, in press) which suggests that experts interpret and use graphs effortlessly in their daily practice, when the graph as a semiotic tool is fused with its interpretant. Nevertheless we believe that learning to interpret graphs in new contexts is an important, if demanding skill, which requires its own practice. The difficulty of research on mathematics in use is that only rarely do we see mathematics actually being learnt rather than used.
We therefore persist in believing that work in academic settings which purports to represent unfamiliar situations is a valuable part of the curriculum, and that children’s difficulties therein need charting and pedagogical attention. In the next stage of our work we will examine more closely teachers’ use of such diagnostic instruments and how they might develop their practice in this respect.

**References**

A short instructional unit was constructed to promote awareness of problem structure. The instructional unit included problem mapping, schema abstraction and analogical problem composition. The unit was tried with students and teachers. In this paper we report the results for 75 students, in 8th grade and 11th grade. It was hypothesized that following instruction students would improve in constructing analogical problems and would be less affected by context in sorting problems. The change in the sorting task was mostly in the expected direction but was not significant. Both age groups improved in problem construction but the change was significant only for the 8th graders.

Word problem solving was considered an Achilles’ heel in mathematics education. In the last decade, however, it is perceived as an opportunity to acquire understanding of mathematical structures.

Traditionally, algebra problems were organized in topics such as transportation problems, or work problems (Mayer, 1981). These methods resulted in the categorization of problems by context in students’ minds. Nowadays math educators promote the development of meaningful knowledge through the construction of connections between mathematical ideas (Hiebert and Carpenter, 1992). These links can be achieved, according to English (1997), through a process of analogical reasoning.

Analogical reasoning in problem solving occurs when previous problem solving experience (source) is transferred to a new problem solving situation (target). Such transfer requires, first of all, good understanding of the structure of the source problem (Gentner, 1983). As it turns out, this is not sufficient and more conditions have to be met. The transfer process includes three crucial and related actions that have to be performed: recognition of a potential problem to transfer from, abstraction of source problem structure, and mapping of corresponding elements and relations in the source and target problems.

Quite a lot of researchers detail conditions that promote transfer. Some of these works suggest, for example, that the abstraction of a general schema is facilitated by comparison and mapping of several examples in
different contexts, and by the use of a combination of simple and complex examples (Gick and Holyoak, 1983; Reed and Bolstad, 1991; English and Halford, 1995).

In this work we try to promote the abstraction of problem schema by asking children to compare elements of pairs of problems, and requiring a generalization of problem components. We then ask them to compose analogical problems of their own. The task of composing a problem subject to given constraints is usually used for detecting students’ conceptions (Rowell & Norwood, 1999). We use it here as a part of the instruction unit and view it as an important tool in encouraging focus on structure.

It should be noted that structure, much like schema, has different definitions. Reed (1987) defines similar-structure algebra problems as problems that have the same equation. Weaver and Kintsch (1992) suggest that equations play a lesser role and that the dominant factor is some deeper conceptual structure.

In this work we used problems that have the same equation and the same conceptual structure as examples of similar-structure problems. We use the terms analogical and isomorphic interchangeably to denote similar-structure problems. The construction of problem space and similarity tasks that test whether context or structure affect children’s conceptions was based on ideas from Reed’s (1987) work on a structure-mapping model.

METHOD

The study was conducted in the course of the school year. It took 6-7 class sessions and consisted of three parts: a pretest, an instructional unit, and a posttest. Both pretest and posttest included a problem sorting task and an analogical problem composition task.

The purpose of the sorting task was to identify the criterion children use in categorizing problems. Students were given 12 problems created by the product matrix of 4 context categories: transportation, work, pipes, and mixtures, and 3 different problem structures.

Using Reed’s (1987) terms, three types of relations exist between these problems:
Isomorphic (or analogical) problems – same structure, different context
Similar problems – different structure, same context
Unrelated problems – different structure, different context
According to the research hypothesis children were expected to sort by context in the pretest. A shift towards sorting by structure was expected in the posttest as an outcome of applying the instructional unit.

A problem composition task, given several times along the study, checked children’s ability to write an isomorphic problem to a given (or composed) source problem. The composition task had a significant role in the instruction. It was expected that children would perform better in this task in the posttest, and that this would be part of the explanation for the change in the sorting task.

The study sample consisted of 100 participants, studying or teaching mathematics, including: 75 students (61 students in 8th grade and 14 students in 11th grade); 12 student-teachers in mathematics; 13 mathematics teachers in middle school and high school. In this paper we report the results for the 75 middle school and high school students. We focus on the analogical problem composition task, and discuss the changes in students’ performance.

The instructional unit was especially designed for the study and consisted of different types of activities:
1. Mapping between two given problems
2. Abstraction of problem components
3. Practice in writing analogical problems
4. Matching a general schema to a given problem

Examples of some of these tasks are detailed in the following section, as a part of the description of individual children’s performance.

RESULTS
We will present quantitative results and proceed with examples that demonstrate the change in problem composition.

In the pretest sorting task students identified (put in the same category) more similar problems than isomorphic problems as being related. This trend was significant in the 8th grade group. Following instruction the 11th graders identified fewer connections between similar problems than they did before instruction, and both groups identified more connections between isomorphic problems than they did before instruction. These changes are in line with our hypothesis, but they are not significant.

Table 1 presents percentages of students who successfully composed an isomorphic problem in the first composition task (a simple problem given in the pretest), and in the last task (a complex problem given in the posttest).
Table 1: Isomorphic problem composition before and after instruction.

<table>

<td>67%</td>
<td>80%</td>
</tr>
</tbody>
</table>

* significant difference

A comparison of problem composition in the pretest and posttest shows a significant change for 8th grader, where the difference in performance was 34%. In the 11th grade the difference in performance was 13% and non significant. However, as will be discussed later, the problem composition tasks included problems that differed in structure. As the student progressed, the structure for which he was asked to build an analogical problem became more complex.

It is interesting to note that the change in 8th grade occurred mainly for the girls. In the pretest 17% of the girls and 50% of the boys could construct an isomorphic problem. In the posttest 65% of the girls and 75% of the boys could compose an isomorphic problem.

The shift in ability to construct analogical problems can be seen in the work of an 8th grader and an 11th grader. It should be noted that with the students, for instructional purposes, we used (and defined by examples) the term similar problems instead of isomorphic problems.

Hilla’s case (8th grade):

Table 2: Hilla’s first problem composition task.

<table>
<thead>
<tr>
<th>task</th>
<th>Source (given)</th>
<th>Composed by Hilla</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pretest: compose a similar problem using machines that produce parts.</td>
<td>Two persons started walking one towards the other on foot and at the same time from 2 different cities, the distance between which is 96 km. One person was walking at the rate of 5 km/h, and the second at the rate of 3 km/h. How much time will it take before they meet each other?</td>
<td>Two machines in a factory that produces parts were operated at the same time. One machine works at the rate of 25 km/h and the other works faster than the first by 5 km/h. I have no idea how to continue this.</td>
</tr>
</tbody>
</table>

During the instructional stage Hilla improved gradually and managed to compose a part of the analogical problems correctly. In the last task, which presented a complex source problem, she exhibited good structure analysis (as seen in Table 3).
Table 3: Hilla’s last problem composition task.

<table>
<thead>
<tr>
<th>Posttest Task: write a similar problem with different context (not specified)</th>
<th>Source</th>
<th>Composed by Hilla</th>
</tr>
</thead>
<tbody>
<tr>
<td>When a student reads a favorite book at the rate of 50 words/min it takes him a certain amount of time. Once he read for 8 minutes at his usual pace and then increased it to 60 words/min and finished 2 minutes earlier than usual. How much time does it usually take him to read the book?</td>
<td>A cyclist usually rides at the rate of 10 km/h. After 12 minutes of riding at his usual pace he increased it to 14 km/h. How much time did he ride if we know that he arrived 4 minutes earlier?</td>
<td></td>
</tr>
</tbody>
</table>

Hilla is also able to specify the similarity between the problems: *They both deal with the same thing that starts at a certain rate and changes to a new rate.*

Stav’s case (11th grade):

Table 4: Stav’s first problem composition task.

<table>
<thead>
<tr>
<th>task</th>
<th>Source (given)</th>
<th>Composed by Stav</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pretest: compose a similar problem using machines that produce parts.</td>
<td>Two persons started walking one towards the other on foot and at the same time from 2 different cities, the distance between which is 96 km. One person was walking at the rate of 5 km/h, and the second at the rate of 3 km/h. How much time will it take before they meet each other?</td>
<td>Two machines in a computer factory produce CD-s. One produces 4 records/hour and fills up a CD case in 16 hours. It works 24 hours and then rests. The other machine produces 6 CD/h and it too works for 24 hours. How much time will it take the machines to fill up the same amount of cases?</td>
</tr>
</tbody>
</table>

Stav’s composed problem, presented in Table 4, is different in structure from the given problem. Stav does not really use the simultaneous work of the machines. There is no focus on a certain amount that is produced by the two machines working together.

The main change occurred on composing one of the problems in the instructional session task presented in Table 5.
Table 5: Stav’s problem composition during instruction.

<table>
<thead>
<tr>
<th>Task: Compose a similar problem.</th>
<th>Source (given)</th>
<th>Composed by Stav</th>
</tr>
</thead>
<tbody>
<tr>
<td>Back and Forth</td>
<td>A person leaves the city of Bally riding his bikes for 2.5 hours at the rate of 20 km/h he gets to the city of Gat. He does the way back on foot and walks for 10 hours from Gat back to Bally. What is his walking rate?</td>
<td>Yesterday a student was preparing his homework at the rate of 16 problems per hour for 3.5 hours. At what rate did he work today to finish the same amount of problems, if it took him 6.5 hours?</td>
</tr>
</tbody>
</table>

Stav solved his own problem by writing and calculating: \((3.5 \times 16)/6.5 = 8.6\) and writing the answer in words: The student solved 8.6 problems per hour.

While Stav managed to perform well on the Back and Forth (see Table 5) problem, another 11th grade student, Jenny, exhibited some interesting difficulties. Jenny wrote: A student prepares his homework in the afternoon and checks his work again in the evening. If he prepares his work at a rate of 1 problem per minute it takes him 10 minutes. But when he checks his work at the rate of 2 problems per minute it takes him 5 minutes. How many problems were there?

Jenny wrote: \(5 \times 2 \times X = 10 \times 1 \times X\) She realized that the same person is doing two similar actions, each at a different rate. She also used (correctly) the same total production: in both cases the same amount of problems is used. However, she did not have a good mapping strategy for creating an analogical problem, as a result she had trouble in choosing the unknown.

In the above examples students composed an isomorphic problem to a given problem. Another type of task involved mapping problems. Students were given examples of pairs of isomorphic problems, and asked to map their elements. Following several examples they were asked to compose a pair of isomorphic problems and map their elements. In this task Sagi, an 8th grader, wrote the problem pair presented in Table 6.

Table 6: Sagi’s composed pair of isomorphic problems.

<table>
<thead>
<tr>
<th>Sagi’s 1st problem:</th>
<th>Sagi’s 2nd problem:</th>
</tr>
</thead>
<tbody>
<tr>
<td>The Truck: A truck travels on a 100 km track. It travels in the rate of 50 km/h. How much time will it take it to finish the track?</td>
<td>The Fisherman: A fisherman has to catch 100 fish. He catches them at the rate of 50 fish per day. How many days will it take him to catch 100 fish?</td>
</tr>
</tbody>
</table>
Sagi map of the corresponding problems' elements is detailed in Table 7.

Table 7: Sagi's problem mapping.

<table>
<thead>
<tr>
<th>The Truck</th>
<th>The Fisherman</th>
</tr>
</thead>
<tbody>
<tr>
<td>distance -</td>
<td>total number of fish</td>
</tr>
<tr>
<td>rate of driving -</td>
<td>rate of catching fish</td>
</tr>
<tr>
<td>number of hours -</td>
<td>number of days</td>
</tr>
<tr>
<td>In this problem we calculate:</td>
<td>In this problem we calculate:</td>
</tr>
<tr>
<td>Distance/ rate = time</td>
<td>Amount/ rate = time</td>
</tr>
</tbody>
</table>

Sagi's example demonstrates very good performance of a young child on a problem composition task, which, as will be further discussed, is not an easy task for students (or, in fact, also for teachers).

DISCUSSION

Using a short instructional unit this research tried to change students' focus in problem solving from context-centered to structure-centered. The instructional unit included several ideas suggested by different researchers, such as mapping between problem elements and comparing given examples. In addition to these, we tried another task, different in nature, but also more difficult, the task of writing an isomorphic problem. As it turned out, when problem structure was simple, such as a rate x time = production, a third of the 8th graders and two thirds of the 11th graders could compose it with some instructional guide. When problems became more complex, it apparently became more difficult to perceive a complete picture of problem structure and compose a problem of the same structure. This is not surprising in light of what is mentioned in the introduction, that understanding of the source problem structure is a necessary condition for analogical reasoning.

Although the tasks were difficult, some change in the direction of more attention to problem structure and less to context similarity occurred. The students' awareness of structure was also expressed in class discussions, and brought up in a follow up questionnaire.

The instructional unit together with the pretest and posttest took very few class sessions, and can be considered as an exploration of the power of the unit's task. In view of the effect of this short experience, we suggest to use these tasks and construct a more comprehensive program.
REFERENCES

In this paper we report on a longitudinal study where we investigated whether there are differences in 3 – 4 year-old children’s tendency to focus on numerosities, and whether these differences are related to the children’s development of cardinality. It was found that the two groups of children at the age of three formed on the basis of their spontaneous tendency to focus on amounts of objects differed in their development of recognising and producing small amounts. Those children who spontaneously regarded the numerosities as relevant factors in the test situations developed faster in cardinality related skills than those children that focused on other features in the tasks.

Introduction

Recent research in cognitive, comparative and developmental psychology supports the position that infants have biologically primary quantitative abilities, which encompass their implicit understanding of numerosity, ordinality, counting and simple arithmetic (for a review, see Geary, 2000). However, in these studies on infant abilities there seems to regularly appear a small group of children who do not present these quantitative abilities at all.

In the research on the development of exceptional skills it has been established that the amount of deliberate practice as well as the age at which it is started is related to the level of performance (Ericsson & Lehmann, 1996). The child’s social environment influences the ways in which he/she engages with the mathematical world around him/her. Also the differences in opportunities the child finds in his surroundings to practice pre-mathematical skills might explain the differences in the development of early mathematical skills of children. The world could appear to be full of numerosities and opportunities for practising early mathematical skills to some children, whilst others focus on other features in the environment and involve themselves much less with pre-mathematical ideas. According to Ginsburg et al.’s (1999) observational studies, 5 year-old children deal with mathematical activities as much as 45 percent of their time of free play in day care, of which 11% is enumeration.

In the development of cardinality a child moves from innate, preverbal counting system called subitizing to fluent usage of traditional counting in determining numbers of objects. Counting skills enable the child to recognise and produce bigger amounts than innate capability of subitizing does. “The cardinal number word refers to the whole set of entities and tells how many entities there are, that is, describes the manyness of the set” (Fuson, 1988, 5). The concept of cardinality grows out of
children's experience with counting in a manner similar to that in which a symbolic concept of print grows out of children's experiences with the alphabet. Cardinality requires both explicit knowledge of the relation between numbers and quantity, and the attentional procedures for focusing on that which is counted (Bialystok & Codd, 1997.) According to Schaeffer, Eggleston, and Scott (1974), cardinality results from the integration of two prior processes: subitizing and counting. Among other primitive processes, subitizing provides the basis for acquisition of the number concept and orients a child to the numerosities of sets (s)he experiences (English & Halford, 1995, 60). Subitizing, or enumeration of small sets up to about four elements, is a rapid and accurate pre-attentive process, which requires no explicit teaching, and possibly little or no experience (Gallistel & Gelman, 1978; Sathian et al., 1999).

A major step in early mathematical development is learning to count. Counting enables the child to make quantitative determinations of amounts, rather than relying on perceptual or quantitative judgements. Cardinal situations and counting are, at first, separate and different situations for children, but are gradually connected when children understand that counting is not an isolated activity, but has a result (Fuson, 1988, 206.) The remarkably slow development of cardinality and counting skills (e.g. Fuson, 1988; Wynn, 1990) could be explained by major differences in preverbal and verbal counting systems (Wynn, 1992a, Wynn 1992b). One potential explanation for the differences in pre-schoolers mathematical skills (see, e.g Reusser, 2000) might be children's different amount of spontaneous dealing with mathematical activities.

In the present study, we followed up children from the age of 3 to the age of 4 years in terms of spontaneous focusing on numerosities and cardinality. This study investigates whether there are differences in children's focusing on numerosities, and whether the groups formed on the basis of differences in focusing on amounts differ in their development of cardinality. Our hypothesis is that the differences in spontaneous focusing on amounts might indicate the children's overall tendency to focus on numerosities in his/her surroundings, and this could cause considerable differences on the amounts of practice in enumeration and counting skills. So, those children who do not regard numerosities immediately as relevant factors in the tasks would not develop as quickly in recognising and producing small amounts.

Method

Participants

39 children (18 girls and 21 boys) from the city of Turku participated in this one year follow up study. The children's mean age at the start of the follow up was 2 years and 11 months (s=1,5 months). The children were tested for the second time when they were on average 3 years and 5 months (s=1,5 months) old, and for the third time when they were on average 3 years and 11 months (s=1,5 months) old. The children attended seven day-care centres located in the middle-class areas of Turku at the beginning of the follow-up period.
Procedure and tasks

The video-recorded tasks were presented individually in a familiar room of the child’s day-care centre during the morning. The carrot task took approximately 5 minutes and the caterpillar/pig task about 10-15 minutes, depending on the child’s skills.

Spontaneous focusing on numerosities was assessed at the beginning of the follow up by the carrot task and the spontaneous focusing section of the caterpillar task. Cardinal tests were presented at the age of 3, 3½ and 4 years. At the beginning and in the middle of the follow up period the cardinal section of the caterpillar task was presented, and in the end of the follow up a modified but parallel version of the caterpillar task, called the pig task, was performed.

**Carrot task**

The experimenter placed two similar cuddly toys in the form of ”bunnies” and then a plate of 5cm long ”carrots” on the table in front of the child. The bunnies and the carrots were identified together with the child. The experimenter asked the child, “Look at what I do. I do this, this. Now, you do what I did.” While saying “this”, the experimenter lifted two carrots, one at a time, into a row in front of the experimenter’s bunny. The child imitated the experimenter as well as (s)he could and placed carrots in front of his/her bunny.

The amounts of carrots in the items were 2, 1, 3, 4, 5, ...10. If the child did not lift as many carrots to his/her bunny as the experimenter did, the failed quantity was repeated. After two failures with the same quantity, the experimenter returned once again to the previously successful quantities. In every case the first items with two, one and three carrots were presented to the child.

**Caterpillar task**

The materials in the caterpillar task were a black sack, a small (17cm x 14cm) box, ten sewed green fabric “caterpillars” (length 60cm), who had either 1,2,3... or 10 legs (length 6cm) every 2.5cm. Feet were 3.5cm in length. The one-legged caterpillar had its leg in the middle, the two-legged caterpillar had a leg in the middle and a leg 2.5cm from the other leg. This was the way in which all the caterpillars’ legs were situated. There were also 24 red socks in the small box, which were elastic and suitable for the caterpillars. In the task, a child sat at a table. The experimenter sat to their left, and the sack that contained the caterpillars was on the experimenter’s left. The box with the socks was placed on a tall stool on the opposite side of the table at the beginning of the task.

The caterpillar tasks did not to assume that the child would use any verbal number words. The child had to determine the number of objects (legs on the caterpillar), keep it in mind for few seconds and pick up the same amount of objects (socks) and bring them to the original objects (legs). The tasks enabled the child to spontaneously use either subitizing, estimating or counting to solve the items. The child could check.
the original number of legs on the way whilst picking up the socks, if s/he wanted to. The location of the caterpillar and the box of socks prevented the use of one-to-one correspondence. The child could not easily see the legs of caterpillars when standing next to the box of socks.

In the spontaneous focusing section of the caterpillar task the experimenter asked the child what clothes (s)he put on when (s)he goes out (e.g. hat, gloves, shoes and socks). Then the experimenter told the child about the sack, in which there lived a family of friendly caterpillars. The caterpillars were about to go out, but first they needed to put on socks. After introducing the first 6-legged caterpillar, which already had socks on, the experimenter showed, by pointing to the legs one at a time, that there was a sock on every foot of the caterpillar. The child was told that was the way that the other caterpillars should be dressed too. The 6-legged caterpillar “waited” in the sack and the 2-legged caterpillar was lifted from the sack. The child was asked to bring the caterpillar as many socks as the caterpillar needed from the box on opposite side of the table. All the socks that the caterpillar needed were to be brought in one go. After bringing the socks, the child was asked if (s)he had brought the correct number of socks. Then the experimenter put the socks on the caterpillar and asked if the caterpillar was ready to go. If the child did not bring exactly two socks for the caterpillar, the item was repeated to make sure that the child considered the amount of legs as a relevant factor in the task. The spontaneous focusing on amounts was assessed from these two trials in the first section of the caterpillar task.

The cardinal section of the caterpillar task was conducted immediately after the spontaneous focusing section by advising the child to bring exactly as many socks as the caterpillar needed if the child had not brought the right amount of socks for the caterpillar. This was to make sure that all the children understood that it was necessary to focus on the amount of legs and socks in this task.

The caterpillars were presented in the order 2, 1, 3, 4, 2, 5, 6, 1, 7, 8, 2, 9, and 10, where the numbers represent the number of legs of the caterpillars. The one- and two legged caterpillars were presented between the sequence of test caterpillars for two reasons: to motivate and relax the child with easier tasks, and to break the growing order of test caterpillars. If the child did not bring the right number of socks for the caterpillar, the failed amount was repeated, and if the child failed twice with the same amount, the previous successful amount was repeated. The amount at which the child got both attempts right determined the level of the child’s performance.

**Pig task**

The materials in the pig task were a flat box, where the sows stayed, a small (17 x 14cm) box for pigs, 12 plastic sows (length 60cm), which had either 1,2,3... or 12 teats (length 3.5cm) every 2cms. The teats were located similarly to the legs of the caterpillars. There were also 24 piglets in a box on the opposite side of the table. The child and the experimenter sat as in the caterpillar tasks at a table.
In the pig task, the experimenter told the child about the sows that stayed in a box, and needed help. The child was asked, if s/he knew how sows feed little pigs, and the 6-teated sow, who nursed six pigs was introduced. The experimenter showed that this was the way in which sows feed their pigs: a piglet suckling at every teat. The children were instructed to help the other sows feed their piglets. The 6-teated sow went back to feeding her piglets in the box, and the 2-teated sow was lifted from the box. The child was asked to bring as many piglets as the sow could feed from the box on the opposite side of the table. The pig task continued in a manner similar to the caterpillar task. The maximum amount of teats the sow had was 12.

Analyses
It was carefully observed if the child immediately focused his/her attention on the numerosities of objects instead of other features in the first items of the tasks. The child was considered as spontaneously focusing on numerosities, if (s)he produced the same number of carrots as the experimenter had produced, or if (s)he immediately brought the same number of socks as there were legs on the caterpillar in the first items of the caterpillar task. The child was considered as not spontaneously focusing on amounts if (s)he did not focus on the amount of carrots, and either tried to imitate the way in which the experimenter lifted the carrots, or concentrated on feeding the bunny. Consequently in the caterpillar task the lack of spontaneous focusing on amounts appeared if the child did not pay attention to the number of legs and socks and brought either a handful of socks or just one sock for the first 2-legged caterpillars.

Cardinality was analysed from the cardinal section of the caterpillar task and the pig task. The carrot task could not be used because those children who did not focus on the number of carrots in the task obviously considered the whole task as an imitation of movements or feeding task instead of producing the same number of carrots for the bunny. After the child’s first attempts in the caterpillar task, it was made clear to the child that the number of socks was a relevant factor in the task.

The level of a child’s skills of recognising and producing numerosities was determined through successful trials in bringing socks for the caterpillar. The child had to succeed twice with the same number of legs to be considered as capable of producing the given number of socks. The task was finished after two failures at the same amount.

Results
Spontaneous focusing on numerosities
The children of this study had differences in spontaneous focusing on numerosities. There were 14 children who did not spontaneously focus on numerosities in either one (11 children) or both tasks (3 children), called the non-spontaneous group, and 25 children who focused immediately on numerosities in both tasks in the beginning of the follow up, called the spontaneous group. Four children did not focus on the amount of carrots in the carrot task, and 11 children did not focus on the numbers of
legs and socks in the caterpillar task. Those children who did not focus on the amounts either imitated the movements of experimenter, concentrated on feeding the bunny, or brought only one sock or a handful of socks to the 2-legged caterpillar. In the caterpillar task, 10 children out of those 11 who did not focus on the amount of legs and socks in the first item started focusing on the number of legs when advised, and proving that they were capable of recognising and producing the amounts of one and two.

Cardinality

To examine the question of whether the non-spontaneous group of children differed from the spontaneous group in their cardinal skills during the follow up period we investigated their achievements in cardinal tests (see Figure 1.).

![Figure 1. The results of the non-spontaneous and spontaneous groups in cardinal tests in the age of 3, 3½ and 4 years.](image)

Separate 2 x 3 (group x age) ANOVAs with repeated measures were performed for their performance, together with Tukey's HSD tests, from 3 to 4 years of age. The main effects of group (F(1,37)=7.18; p=0.011) and age (F(2,74)=21.20; p<0.001) were statistically significant. The non-spontaneous group displayed weaker skills in cardinal tests and the children's skills developed during the follow up period. Symptomatically significant (F(2,74)=2.92; p=0.060) interaction of Group x Age in performance suggest that there were developmental differences in cardinal skills between the groups. The spontaneous group developed faster than non-spontaneous group in recognising and producing small amounts.

In spite of the slight trend of differences in the groups' performances in favour of the spontaneous group, Tukey HSD tests revealed that there were no statistically significant differences in the groups' results at the age of 3 and 3½ years. However, after 12 months, group differences began to appear. The cardinal skills of the non-spontaneous group were weaker (p<0.001) when the children were 4 years old. The results of group comparisons were confirmed by Kruskall-Wallis's non-parametric test.
Discussion

The children of this study had differences in their tendency to focus spontaneously on numerosities. The spontaneous group of children (25 out of 39 children) interpreted the carrot and the caterpillar task instantly as numerical and focused their attention to the amounts in the tasks. Those children (14 out of 39) who did not spontaneously focus on the numerosities in the tasks when they were three years old, developed more slowly in cardinality than those who immediately perceived the task situations in terms of various numbers of objects or events. The spontaneous group outperformed the non-spontaneous group at the age of four years unlike than at the age of 3 and 3½ years in their skills to recognise and produce small amounts.

According to the results, it seems that there are significant differences in the ways in which children pay attention to numerosities in situations and these differences in the amount and the quality of spontaneous activity might be of great importance for the children’s later development of number concept. The fact that all the children except for one in the non-spontaneous group were able to bring the 2-legged caterpillar two socks when advised to focus on the amount of legs in the caterpillar task, supports the idea that spontaneous focusing on numerosities is a separate process from enumeration. It is possible that every child manages to deal with numbers within their subitizeable range once they realise that number of objects in the situation is a relevant feature for his/her action. What causes these differences in the ways that children interpret their perception is a subject for a later study, where the follow-up of children will begin earlier than in this study. This should be investigated because this study raises the question of whether the differences in the spontaneous tendency to focus on numerosities produce differences in the development of cardinality, or vice versa. There is also a question about the nature of spontaneous tendency to focus on numerosities: is it inherently different in children, or as a result of social support? Could there be such differences in the linguistic skills or subitizing range of the children, which would explain the different development of cardinal skills?

In Hannula’s (2000) study it was reported that the spontaneous group of this study tried to use more counting to solve the caterpillar task at the age of three years (64% of the children) than the non-spontaneous group of children (21% of the children). Considering the long time (e.g. Fuson, 1988; Wynn, 1990) that counting skills take to develop accurately, it is plausible that the spontaneous group of children was further in their development of counting skills at the beginning the follow up, though the levels of children’s performances did not differ. It is a common phenomenon in the development of skills that the level of performance does not rise immediately, but after a training phase, when a more advanced and demanding strategy is mastered. In this case the spontaneous group of children would have focused on numerosities more often, because the quantities of objects had become more meaningful to them. Even so, the differences in the skills of spontaneous and non-spontaneous groups in the beginning of follow up do not eliminate the possibility of spontaneous numerical tendency to have a significant role in the development of cardinality. The effects of
differences in the amount of training quantitative skills produced by spontaneous activity could still derive to different developmental profiles in early mathematical skills. Therefore, our preliminary hypothesis for future studies is that spontaneous tendency to focus on numerosities serves as one of the building blocks for the child’s early numerical development, possibly besides innate quantitative abilities.

SELF-ESTEEM AND PERFORMANCE IN SCHOOL MATHEMATICS:
A CONTRIBUTION TO THE DEBATE ABOUT THE RELATIONSHIP BETWEEN
COGNITION AND AFFECT

Izabel Hazin, Jorge Tarcísio da Rocha Falcão

This research work was aimed to analyze the relationship between cognitive and affective aspects in the particular context of mathematical education. Self-esteem was chosen to represent affective pole involved in this process, while mathematical performance at school was focused in terms of performance in a specific mathematical evaluation test. Data collected suggest empirical evidence for a connection between the level of self-esteem, interaction patterns and mathematical performance inside the pairs, high-level self-esteem pairs with cooperative patterns of work performing clearly better than low self-esteem level subjects. These data seem to reinforce the idea that it is not possible to split children difficulties at school in a dichotomy of cognitive and affective aspects.

1. Introduction

The theoretical question about the place of affectivity in mathematical sense-making activities emerged strongly in previous research efforts of our research group (see Da Rocha Falcão and cols., 2000; Brito Lima & Da Rocha Falcão, 1997; Da Rocha Falcão, 1996), and is the main motivation of this research. These two poles of human psychological functioning cannot, of course, be scientifically addressed in such generic terms; because of this, the first step in operationally building this research enterprise was the translation of “affectivity” and “mathematical activities” is better-delimited and narrower representative variables. On the other hand, we share the perspective of V.A. De Bellis and G.A. Goldin about the affective system as including changing states of feeling (local affect) as well as more stable, longer-term constructs (global affect) (De Bellis and Goldin, 1999, pp.250; italics added). We are here particularly interested in the sphere of the so-called global aspect, concerning "(...) emotions about and within emotional states, emotions about and within cognitive states, and the monitoring and regulation of emotion (De Bellis and Goldin, op. cit., pp. 250; italics added).

Self-esteem was then chosen as representative of the global-affective sphere, since this complex process can be seen as a component of the general representation that someone has of himself/herself (Palacios & Hidalgo, 1995; Aberastury & Knobel, 1992). This representation has a more conceptual pole, the self-concept, and an affect-evaluative pole, the self-esteem. The data shown here try to offer empirical evidence of a connection between self-esteem and performance in school mathematics; this attempt, in fact, intend to go further, offering evidence for the debate about connections between affect and cognition in psychology. This debate is a hard theoretical task; since René Descartes, there is a strong tradition of splitting human nature in rational/spiritual aspects (res cogitans) and somatic/emotional/animal aspects (res extensa) (Descartes, 1973). This philosophical and epistemological background nourished theoretical
systems in psychology stressing one of these poles (in detriment of the other one), without an integrative approach showing the functional interconnection between affectivity and cognition. Two important theoretical systems in psychology are good examples of this Cartesian heritage: Piagetian genetic epistemology and Freudian psychoanalysis. Cognition, from a Piagetian point of view, is related to a biological need of equilibration, where affective aspects are seen as "combustible" for logical structures (the "engine"): "(...) affectivity is considered as the energetic pole of behavior" (Piaget, 1980, pg. 135). Freud, for his turn, will stress unconscious pulsional (libidinal) aspects as central in the theoretical explanation of human behavior, viewing cognition (or epistemophilic motivation) as a derivative of libidinal impulse by sublimation or neurosis (Freud, 1973). There are certainly other important theoretical contributions addressing this specific aspect of an integrative view of human behavior (see, for example, Henry Wallon, Erick Erikson and Donald W. Winnicott's works on child development); none of them, nevertheless, seem to propose empirical data concerning specific aspects of cognition (i.e., specific knowledge domains or conceptual fields) taking into account affective aspects as constitutive, not merely adjuvant. The present research work tries to contribute in this direction, showing empirical evidence of the interaction between self-esteem and school achievement in mathematical problem-solving tasks.

2. Procedure

The sample of this study was initially constituted by 81 students of the 5th grade (elementary level) of a public school from Recife (Brazil), with ages varying from 12 to 14. This specific school level was chosen because it represents the first important moment of clear school difficulties in mathematics for Brazilian children (Ministério da Educação e do Desporto-Brazil, 1995). This initial sample was submitted to the HTP (House, Tree, Person) Test, used here to access levels of self-esteem among the students, according to administration criteria proposed by E. Hammer (Hammer, 1991). We could then arrive to a research sample of 20 students showing low or high levels of self-esteem (see Figure 1 below for examples of HTP data). These students were put together in pairs, controlling gender and self-esteem, as illustrated by Table 1 below. These ten pairs of students were submitted to a set of 20 evaluation questions in school mathematics, created specifically for northeastern Brazilian children (NAPE Evaluation Test – for more detailed information, see Neves e Souza, 1997). These questions addressed aspects considered important by Brazilian educational authorities for this school level, and are briefly described in Table 2. Both the achievement as well as the problem-solving strategies and difficulties in the NAPE Evaluation Test were analyzed, together with descriptive data like constitution of pairs concerning gender and self-esteem level (according to the procedure described in Table 1 below) and patterns of interaction and leadership showed by the subjects during problem-solving sessions. This set of data was
analyzed with the help of multidimensional descriptive tools (cluster analysis of nominal data; for more detailed information about these statistical descriptive multidimensional procedures, see Rouanet, Bernard & Le Roux, 1990); results are described in the next session.

Subject N: drawing occupying more than 1/3 of the paper, presence of details in the body, presence of the soil and additional elements (sun, clouds, flowers) (Obs: this drawing was originally produced with color pencils).

Subject R: drawing occupying less than 1/3 of the paper, few details in human body, absence of the soil (Obs: this drawing was originally produced with black pencil only).

Figure 1: Drawings of a person produced by two subjects considered, respectively, as being examples of high-level (subject N.) and low-level (subject R.) self-esteem, according to Hammer (op. cit.) classificatory propositions for HTP analysis.

3. Results

Two descriptive multidimensional clusters of pairs of subjects were obtained from data analyzed (see Figure 2 below). These clusters represent a hierarchical classification of the pairs of subjects according to two sets of information: classification 1 was obtained from descriptive data concerning gender and self-esteem level in the composition of the pair, interaction and leadership patterns verified in the pair interactions during problem-solving activities, and need of help from the teacher during problem-solving. Interpretation of this first classification showed that two descriptive variables combined, level of self-esteem (LSE) and pattern of interaction of the pair (INT), could explain the partition obtained (the other variables having low contributions to the general variance of the data, i.e., contributions under the average value of explained contributions; this interpretation was confirmed by correspondence factor analysis). The first of these variables, LSE, admitted three analytical categories concerning the composition of the pairs in terms of self-esteem level of each subject: a) high-high; b) low-low; c) high-low.

![Diagram](image)

**Figure 2:** Hierarchical classificatory trees produced from data issued of pairs of subjects

The variable INT, for its turn, had equally three analytical categories concerning the patterns of interaction showed by the pair during problem-solving activities: a) Strong cooperation between subjects, with dialogues and step-by-step sense making in problem-solving procedures; b) One of the subjects is clearly the "guide", thinking aloud in order to share with the other subject his/her procedure; this other subject supports and encourages the first one; c) One of the
subjects ignores the other, working alone and silently, the ignored subject accepting this scenario. Classificatory tree number 0 shows two main clusters of pairs (and an isolated pair [number 10], which will be referred latter): the first one is formed by pairs 2, 4, 5, 6 and 9, and the second one being formed by pairs numbers 1, 3, 7 and 8. The first cluster is formed by three LSE high-high pairs, one low-low and one high-low; the second cluster is formed by two LSE low-low pairs and two high-low; the first pair was strongly characterized by INT pattern type (a), while the second cluster was characterized by INT pattern type (c). Briefly, we can interpret the partition obtained in terms of two groups characterized respectively by low self-esteem, combined with important difficulties in interaction between subjects of the pair (cluster 2: 1, 3, 7, 8), and high self-esteem, combined with good interaction pattern (cluster 1: 2, 4, 5, 6, 9). It is important to observe that this is not a pure partition (since there are pairs more and less representatives of the partition scheme), but the most suitable one, in terms of the contribution to the total explained variance of the analyzed data. In this context of analysis, the pair number 10 is explained as a member of cluster 2, since clinical analysis of protocols shows the same LSE and INT characteristics of this cluster. The exclusion of this pair from cluster 2 seems to be explained by very peculiar and strong characteristics detected in clinical analysis, specifically a clear INT pattern type (b) and a very strong dependence to the teacher during the problem-solving session.

Classification 0, for its turn, was obtained from data concerning the performance of pairs along the problems of NAPE Evaluation Test. The categorization of these data took into account the specific groups of mathematical aspects (in accordance with summary reproduced in table 2 above). The same multidimensional classificatory algorithm used for classification 1 analyzed these data, and the partition obtained showed a very interesting result: this partition is almost identical to the first one, these two classifications being produced by different set of data. The interpretation of classification 2 showed that the partition obtained is strongly explained by aspects that could be summarized in terms of difficulties in solving 6 of the 20 problems (the other 14 problems showed an irrelevant contribution to the partition obtained); cluster 1, formed by pairs numbers 2, 4, 5, 6 and 9, showed very few difficulties, while cluster 2, formed by pairs numbers 1, 3, 7, 8 and 10, showed important difficulties, summarized by table 3 below. A global interpretation of the main differences between clusters 1 and 2 of the second classification seems to indicate that the cluster 1 is clearly able to capitalize help from the teacher, and also from discussion inside the pairs; cluster 2 has important difficulties in dealing with formal representations like graphics, numeric systems and school algorithms. The partition obtained in classification 2 reproduces almost perfectly the previous partition obtained in classification 1, based upon self-esteem and patters of interaction inside the pairs; this result offers empirical support to a possible connection between the two sets of data.
Relevant questions of NAPE Evaluation test | Pattern of problem-solving shown by cluster 1 | Pattern of problem-solving shown by cluster 2
---|---|---
**Question 8:** Question involving fraction \([G6]\) | Has some difficulty in considering part-whole relations, but arrives to the solution after help offered by the teacher. | Absence of one specific pattern for this question.
**Questions 9 and 10:** Questions involving the comprehension of statistical graphics \([G7]\) | Can easily discuss and solve these questions. | Important difficulties in interpreting graphic representation even after teacher’s help.
**Question 14:** Question involving the comprehension of the numerical decimal system of notation \([G4]\) | Shows comprehension of the numeric-decimal system. | Has difficulties in dealing with intermediary zeros in transposing four-digit numbers from current language to algorism representation.
**Question 17:** Problems of multiplicative structure \([G2]\) | Has some difficulty in making explicit the multiplicative structure of the problem, and in explaining how to solve it, but arrives to the solution. | Absence of one specific pattern for this question.
**Question 19:** Question involving the use of operational algorithms \([G3]\) | Shows comprehension of the numeric-decimal system, and of the algorithmic procedures related to this system. | Difficulties in intermediary operational steps of the use of algorithms (especially when dealing with division).

4. Concluding remarks

This study tried to offer empirical evidences to the need of taking into account both affective and cognitive aspects in the research about mathematical learning. Efforts were made, first of all, in proposing clearly defined variables in order to arrive to a replicable study. As a result of this effort, the affective pole was operationally defined in terms of self-esteem, which cannot be considered as covering affectivity in its complexity, but seems to be an important aspect of global affect (De Bellis & Goldin, op. cit). This variable was analyzed together with other descriptive variables, and an important relation between self-esteem and interaction patterns was detected. On the other hand, mathematical activity was operationally defined in terms of performance in a specific evaluation test, what is certainly a narrow sample of mathematical performance, but is a perfectly public, explicit tool in the context of research.

The two very similar partition of subjects obtained as a function of descriptive variables like self-esteem and interaction patterns and performance in the NAPE Evaluation Test is a first empirical evidence of a possible connection between performance in school mathematics and affective aspects. This connection is still a very tentative interpretation, since we cannot assume a
causal relation in any direction, neither we can discard the role of other intervening variables not addressed by this study. Interaction patterns, an aspect already explored in previous research (see, for example, Leikin and Zaslavsky, 1997), appears here in contact with self-esteem, and this empirical connection certainly deserves additional research.

Affect is undoubtedly a difficult aspect to take into account in the context of research and theorizing in psychology of mathematics education. Nevertheless, data collected here reinforce the need of taking mathematical learning into account as a human activity, impregnated of fears, self-evaluation, social roles and interaction possibilities.

References

This paper reports on a study of Year 3 children's addition and subtraction mental computation abilities, and the complexity of interaction of cognitive and affective factors that support and diminish their ability to compute proficiently (accurately and flexibly). In particular, the study investigated the part played by number sense knowledge (e.g., numeration, number facts, estimation and effects of operations on number), metacognition, memory and affects (e.g., beliefs, attitudes). It found that proficient mental addition and subtraction was a consequence of the integration of all factors, but that accurate mental addition and subtraction could occur when some factors were impoverished if there was compensation.

Skilled mental computers are disposed to making sense of mathematics; they use a variety of strategies in different situations (depending on numbers and context) (Sowder, 1994). Thus, proficiency in mental computation involves both accuracy (achieving the correct answer) and flexibility (using a variety of strategies as efficiency requires). This paper looks at why some children are more proficient (more accurate and flexible) at mental addition and subtraction than others. In particular, a fundamental aim was to identify factors, and relationships among factors, that influence this proficiency.

Research on mental computation has proposed specific connections among mental computation and aspects of number sense, in particular, number facts and estimation (e.g., Heirdsfield, 1996). Other research relating to computation (in particular, children's natural strategies) has reported connections with numeration (e.g., place value) and effects of operation on number (e.g., Kamii, Lewis, & Jones, 1991).

Relationships have been posited between mental computation and affects (e.g., Van der Heijden, 1994), where affects cover beliefs (with respect to mathematics, self, teaching, and social context), attitudes (including self efficacy and attribution) and emotions (McLeod, 1992). Beliefs about the nature of mathematics can be manifested in a student's disposition - mastery orientation or performance orientation (Prawat, 1989). In relation to computation, mastery oriented students would aim for understanding and flexibility. Here, monitoring, checking, and planning might be evident. Whereas, performance oriented students would tend to aim to complete a task as quickly as possible, and not attend to understanding and reflection.

Proficient mental computers are flexible in their choice of strategies. Such effortful, reflective and self-regulatory behaviour should involve metacognition (e.g., Sowder,
Metacognition can be considered to have three components: metacognitive knowledge (knowledge of own thinking), metacognitive strategies (planning, monitoring, regulating and evaluating), and metacognitive beliefs (perception of own abilities and perception of a particular domain) (Paris & Winograd, 1990). It is believed that metacognition, particularly metacognitive knowledge, is domain specific or even task specific (Lawson, 1984).

With regard to memory, Hope (1985) argued that superior short term memory was not necessary for proficient mental computation; rather, interest, practice, and knowledge were more important factors. Heirdsfield (1999) found that a superior short term memory was unnecessary for a student who was accurate and flexible with mental addition and subtraction. A well-connected and accessible knowledge base and efficient mental strategies were sufficient for the student. However, Heirdsfield also found that the mental image of pen and paper algorithm strategy always used by accurate/inflexible students tended to place heavy demand on short term memory.

Two aspects of memory seemed to be significant for mental computation: retrieval of facts and strategies, and concurrent calculation. Hunter (1978) suggested that the first aspect, demand for retrieval of facts and strategies, is met by long term memory. In his study of expert mental calculators, Hunter posited that these experts not only build up vast resources of numerical equivalents (e.g., number facts and other more complicated numerical equivalents), but also a vast store of ingenious strategies. In this way, complex calculations can be handled more easily by accessing long term memory for facts and strategies, thus eliminating the need for massive calculations and demands on temporary storage. However, his model did not account for the second aspect, concurrent processing of calculations. To encompass this, a model for working memory (Baddeley, 1992; Logie, 1995) consisting of a central executive, a phonological loop and a visuospatial scratchpad has been proposed. The central executive provides a processing and co-ordinating function, including information organisation, reasoning, retrieval from long term memory (access), and allocation of attention. The phonological loop (PL) is responsible for storage and manipulation of phonemic information, for instance, rehearsal of interim calculations. The visuospatial scratchpad (VSSP) deals with holding and manipulating visuospatial information. This may involve representation of numbers in the head, or positional information of algorithms.

In summary, research on mental computation and number has proposed connections among mental addition and subtraction, number sense (e.g., number facts, estimation, numeration, effects of operations on number), affective factors (including beliefs, attributions, self efficacy, and social context in classroom and home); and metacognitive processes. Further, it appeared that memory might have an effect on mental computation.
The study

The research consisted of two studies, a pilot study and a main study. Both studies were based on interviews developed to investigate mental computation (strategies and accuracy) and other aspects that were identified from the literature. The findings of the pilot study informed the main study. For the purposes of this paper, findings of both the pilot and main studies will be combined.

Subjects. The subjects were Year 3 students from two Brisbane independent schools that served high and middle socioeconomic areas. The students (13 in all) were selected (from a population of 3 classes, 60 students in all) after participating in a structured mental computation selection interview. As proficiency in mental computation was defined in terms of both flexibility and accuracy, both these factors were considered when selecting the students. As a result of their performance on the selection items, students were identified as accurate and flexible (4 students), accurate and inflexible (2 students), inaccurate and flexible (3 students), and inaccurate and inflexible (4 students).

Instruments. The students participated in a series of semi-structured clinical interviews that: (1) addressed mental computation strategies, number facts, computational estimation, numeration, and number and operations, (2) investigated metacognition and affect; and (3) administered memory tasks. The number sense, metacognition and affect tasks have been described elsewhere (Heirdsfield & Cooper, 1997). The memory tasks (Lezak, 1995) consisted of: (1) the Digit Span Test, a test of short term recall that requires verbal rehearsal and/or verbal recall; (2) a modified version of a short term retention test; and (3) a mazes test that addresses the central executive, for example, planning and decision-making.

The Digit Span Test specifically addressed the phonological loop (Gatherole & Pickering, 2000). Evidence from research investigating working memory in six- and seven-year old children found that existing visuospatial tests did not actually measure visuospatial memory (Gatherole & Pickering, 2000). Therefore, for the purposes of this study, no specific tests addressing visuospatial memory were administered. However, evidence of this component of memory was sought from observations of students’ responses as they computed mentally. In a similar manner, evidence for the utilisation of the phonological loop and the central executive came from witnessing students’ rehearsal of interim calculations, students’ self-reports of “seeing things/numbers in the head”, evidence of planning and choosing strategies, and other elicitations.

Interview procedures. The students were withdrawn from class to a quiet room in the school for the interviews. For most students, the series of interviews took four sessions of twenty minutes each. All interview sessions were videotaped.

Analysis. Students’ responses on the interviews were analysed for: (1) accuracy and strategy choice for mental addition and subtraction (which, in turn, was used to
determine flexibility, the use of a variety of strategies); (2) knowledge and strategies for
numeration, number facts and computational estimation, and knowledge of the effects of
operation on number; (3) metacognition and form and extent of affects; and (4) scores
and strategies on memory tasks. For the purposes of identifying flexibility, mental
computation strategies were classified using a scheme (based on Beishuizen, 1993;
Cooper, Heirdsfield, & Irons, 1996; Reys, Reys, Nohda, & Emori, 1995) that divided
strategies into the following categories: (1) separated (e.g., 38+17: 30+10=40, 8+7 = 15
= 10+5, 40+10+5 = 55); (2) aggregation (e.g., 38+17: 38+10=48, 48+7 = 55); (3)
wholistic (e.g., 38+17 = 40+17-2 = 57-2 = 55); and (4) mental image of pen and paper
algorithm – following an image of the formal setting out of the written algorithm (taught
to almost automaticity in the schools the students attended).

Each student’s ratings for number sense, metacognitive, affective and memory factors
were summarised. These summaries were combined for each of the computation types:
accurate and flexible, accurate and inflexible, inaccurate and flexible, and inaccurate and
inflexible to produce a composite figure to represent that type. Factors were identified
as commonly present (representing), varying and not present for each type. Analysis
then moved from within types to across types to identify factors which by their presence
or absence would show a relationship to accuracy and flexibility. Analysis focused on
what was not present during failure as well as what was present during success.

Results

In this study, accurate/flexible mental computers employed a variety of efficient mental
strategies to alleviate demands on working memory, while accurate/inflexible students
resorted to one automatic strategy (mental image of pen and paper algorithm). Only one
other student reported using automatic strategies. She was an accurate/flexible student,
but her “automatic” strategies included a variety of efficient mental strategies. Inaccurate/flexible students also employed a variety of strategies (but low level
strategies), while inaccurate/inflexible showed little in terms of strategies. This last
group of students possessed poor knowledge, metacognition and memory.

Comparing accurate/flexible and accurate/inflexible students’ responses, accuracy in
mental computation was found to relate predominantly to fast and accurate number
facts. Those students who scored poorly in the number facts test (slow and/or
inaccurate) were inaccurate in mental computation. This would make sense, as fast and
accurate recall of number facts from long term memory would result in less load on
working memory, when more complex calculations are involved. Thus, fast and
accurate number facts were found to be essential knowledge for accuracy in mental
addition and subtraction.

In contrast, comparing accurate/flexible and inaccurate/flexible students’ responses,
flexibility in mental computation was found to relate to a mixture of factors, to number
facts strategies and numeration, and, in part, to understanding the effects of operations on number, and metacognition. Fast and accurate number facts were not found to be related to flexibility (inaccurate/flexible students often had poor number facts). Students who were flexible in mental computation employed a variety of efficient number facts strategies (derived facts strategies) in the number facts test. Some students (particularly those who were flexible/accurate) applied some number facts strategies to mental computation strategies. In the case of flexible/inaccurate students, using derived facts strategies in the test did not help them in mental computation, as derived facts strategies were not used in interim calculations – instead, count was often used.

Efficient mental strategies (e.g., wholistic and aggregation) were found to require good numeration understanding. Lower level alternative mental strategies (e.g., separation) also were found to require some numeration understanding (canonical and noncanonical). However, accurate/inflexible students, who tended to use the mental image of pen and paper algorithm strategy, did not require the same level of numeration understanding, although a threshold knowledge was essential for procedural understanding (e.g., canonical understanding). Inaccurate/inflexible students were found to have very poor numeration understanding.

The relationship of flexibility to understanding of number and operation was not so straightforward. Students who exhibited good understanding in number and operation were found to employ high-level strategies (e.g., wholistic). It appeared that both numeration and number and operation understanding was required for successful employment of the wholistic strategy. Research has found that an understanding of the effects of operation on number would be important for efficient mental computation (e.g., Reys, 1992). In particular, understanding how changing the addend and subtrahend affects the result of addition and subtraction examples is the basis of the ability to employ some wholistic strategies.

Similar to number and operations, the effect of metacognition on mental computation was mixed. In this study, metacognition was not directly related to either accuracy or flexibility, although accurate/flexible students showed evidence of metacognitive strategies, especially monitoring and checking. Research findings support a relationship with flexibility, that metacognition aids skilled mental computers (e.g., McIntosh, Reys, & Reys, 1992; Sowder, 1994). The reasons for this study not showing a clear relation between flexibility and metacognition might lie in the young age of the students and their lack of metacognitive knowledge (in particular, their unawareness of their metacognitive strategies). On the other hand, the students were able to verbalise their metacognitive beliefs (perceptions of their abilities).

Neither accuracy nor flexibility was found to be related to estimation. This finding was in contrast to the findings of Reys, Bestgen, Rybolt, and Wyatt (1982) and Heirdsfield
In the present study, even the most accurate/flexible mental computers did not exhibit proficiency in estimation. One reason could be the students were too young to have developed estimation strategies. Estimation is not part of Queensland’s present Year 3 syllabus (Department of Education, Queensland, 1991). Heirdsfield (1996) found that, even in Year 4, most students with estimation strategies had developed them from out of classroom experiences.

Exceptional short term recall and retention were found not necessary for mental computation; however, threshold levels were necessary. These findings support those of Hunter (1978).

The expert (mental calculator) goes quite a way to meet these demands (of working memory), partly by the speed and quality of working, and partly by devising calculative methods which evade an excess of interrupted working. (p. 343)

Of course, poor working memory resources might contribute to a poor knowledge base in long term memory and poor connections between this knowledge, resulting in the diminished performance of inaccurate/inflexible students. Further, these students scored poorly on the working memory tasks. Thus, working memory might be a stronger influence of proficiency in mental addition and subtraction than the evidence of this study showed. To check this requires a look at the different tests used in the memory component of the interviews.

The results for Digit Span Test indicated that, for most students (other than inaccurate/inflexible), the phonological loop could support retrieval of number facts from long term memory, and holding and rehearsal of interim calculations. However, inaccurate/flexible students did not have number facts in long term memory, so the phonological loop could not retrieve these. The results from the other tests indicated that the visuospatial scratchpad only supported strategies such as the mental image of pen and paper algorithm, which meant there was little evidence of the use of the visuospatial scratchpad for accurate/flexible students, even though it was expected that some numbers would be represented in some visual form. However, because of their age, the students using strategies other than the mental image of pen and paper algorithm, might have been unaware of their use of mental imagery (or so preoccupied with their strategies, that they could not remember using any mental imagery).

Conclusions

The study showed that students proficient in mental computation (accurate and flexible) possessed integrated understandings of number facts (speed, accuracy, and efficient number facts), numeration, and number and operation. These proficient students also exhibited some metacognitive strategies and possessed reasonable short term memory and executive functioning.
Where there was less knowledge and fewer connections between knowledge, students compensated in different ways, depending on their beliefs and what knowledge they possessed. Accurate/inflexible students used the teacher taught strategy of mental image of pen and paper algorithm in which strong beliefs were held. Combined with fast and accurate number facts and some numeration understanding, their familiarity (almost automaticity) with this strategy enabled the students to complete the mental computation tasks with accuracy. Working memory was sufficient to use an inefficient mental strategy accurately. The visuospatial scratchpad was used as a visual memory aid. The inaccurate/flexible students compensated for their poor number facts and minimal and disconnected knowledge base by using a variety of mental strategies in an endeavour to find one that would enable them to reduce the difficulty of calculation. Although their limited numeration understanding and memory (including executive functioning) were sufficient to support the development of some alternative strategies, these were not high level strategies. In particular, access to wholistic strategies was only partially successful. Finally, the inaccurate/inflexible students who exhibited deficient and disconnected understanding tried to compensate by using teacher-taught procedures (similar to the accurate/inflexible students), but they were unsuccessful, as they possessed no procedural understanding and also had poor working memory.

The importance of connected knowledge for proficient mental computation demonstrates the need for teaching practices to focus on the development of an extensive and integrated knowledge base. Students can and do formulate their own strategies, but do not always use them accurately. Therefore, students should be encouraged to formulate their own strategies but in a supportive environment that assists them to use strategies appropriately. Because of memory load, students should be permitted to use external memory aids (e.g. pen and paper) to assist mental computation. This has a second payoff in that efficient mental strategies are, at times, also efficient written strategies. By having students formulate mental strategies, they have to call upon number sense knowledge, thus acquiring connected knowledge while they develop computational procedures. This is in contrast to students using teacher-taught procedures, which require little connected knowledge.

A STUDENT'S UNDERSTANDING OF MATHEMATICAL INFORMATION

Milan Hejný, Nadia Stehliková
Faculty of Education, Charles University, Prague

The paper was supported by grant GACR No. 406/99/1696.

The possible causes of elementary and secondary students' difficulties with grasping arithmetic information embedded in a word problem are studied using the "decompose and reconstruct" experimental setting (modified from one type of message games) and theory of meaning making. Concepts of elementary datum and elementary image are defined for research purposes. Seven obstacles inhibiting a student's grasping of the word problem or making its grasping impossible have been identified and analysed.

1. Introduction and framework

In everyday life, numbers play many different roles (Verschaffel, De Corte, 1996, Freudenthal, 1983): to quantify (cardinal aspect), to identify an object's location in a sequence or in a group (ordinal aspect), to measure, to reckon, or to name things. The better the student's discernment of these roles, the more effectively he/she can use his/her arithmetic knowledge in everyday life and the better is his/her insight into the world of arithmetic.

The diversity of number notions in real world is most richly reflected in word problems. Many studies have dealt with the classification of addition, subtraction, multiplication and division situations (e.g. Vergnaud, 1983, Nesher, 1988, Verschaffel, De Corte, 1996, Verschaffel, Greer, De Corte, 2000). The effect of the format of a word problem (verbal or pictorial) on the solution to the problem has been studied e.g. by Minato, Honma, Takahashi (1993). A student's ability to pose (word) problems was studied by English (1997) before and after a carefully prepared teaching programme which brought to student's attention all aspects of word problems (their structure, context, semantic relations, their "critical information units", etc.). The readability factors in the ordinary language of mathematics texts for (second language) learner are investigated in Adetula (1990) and Prins (1997). Prins (1997) identified a variety of phenomena influencing readability and consequently a student's solution to a problem stated in words. The following are particularly related to our research: difficult vocabulary, text structure, obscure information (i.e. confusing information, culturally biased contexts, contradictory and senseless information).

We hypothesise that the core of the difficulties that (not only) Czech and Slovak students have with word problems lies in their inability to grasp them, i.e. to transform (to model) a situation described in words into the language of equations. A teacher trying to "teach" students to solve word problems often presents them with instructions how to transform a particular type of problem (e.g. word problems on common work, on age, on filling up a swimming pool, on movement, etc.) into equation(s). These instructions, however, replace, rather than promote real
understanding. They may help a student solve a standard task but they do not enable him/her to create a clear and rich image of a situation.

We have been observing and analysing processes of students’ grasping of situations described in words for many years. In this contribution, we shall present one type of such analysis, based on the atomisation of numerical information and the corresponding number image.

2. Methodology
2.1 Instructional Setting
In our research, the centre of attention is a set of students’ semantic images of a number(s). Its starting point is our pedagogical experience – a database which we have acquired through classroom observation and/or experiments. The experimental setting used in this research has been designed as a modification of an instructional setting used in our experimental teaching for the development of a student’s ability to grasp a mathematical text.

The setting, tentatively labelled “decompose and reconstruct”, belongs among so called message games and is based on the following sequence of students’ activities: student A gets a certain mathematical text, for instance a word problem, and he/she will decompose it into a set of elementary information units (by an elementary information unit, we mean a sentence or a phrase including one number); student B then tries to reconstruct the original text from them. For instance, this instructional context was used in a game based on the familiar game Chinese Whispers. Groups of four take part, each group has two “decomposers” and two “reconstructors”. They work on their own. A teacher prepares text T and everyone is given the number of words of T and the number of words a decomposer can use. The teacher hands over to the student A a text which will undergo a series of transformations.

\[
\begin{align*}
T & \rightarrow T_1 \rightarrow T_2 \rightarrow T_3 \rightarrow T_4 \\
A & B C D
\end{align*}
\]

Where \( T_i \) are texts, \( d = \) decompose, \( r = \) reconstruct and letters A to D stand for students.

Each team is evaluated according to the information value of their texts \( T_4 \), i.e. to what extent the information of text \( T_4 \) corresponds to that of the original text \( T \).

A similar setting was investigated in the plenary panel in PME20 (Puig, Gutierrez, (eds.), 1996, pp 53-84). One pair of students was first asked to solve a presented word problem and then to write a message explaining their solution to their friends that have to solve a similar problem, without using any number in the message (later specified as “to write it in mathematics using mathsymbols”). The second pair of students was then asked to solve their problem according to the method described in the message.

2.2 Experimental Setting
The instructional setting “decompose and reconstruct” has been modified for
research purposes and used in research in two ways. First, pairs of students took part in experiments during which one of them was given a text and asked to decompose it into elementary information units so that there was exactly one number in each unit. Then the second student was asked to reconstruct the original text. Experiments were recorded and observed by experimenters.

Second, experimenters chose fourteen concrete word problems from Czech, Slovak and Polish textbooks (some of them will be given below as examples) and decomposed them into a list of elementary information units. In some cases, the decomposition was done by other people as well, e.g. by students and teachers. During this process, the need arose for the specification of basic concepts, e.g. the concept of decomposition itself or the concept of elementary information unit. For instance, during an interview one student decomposed the following information “I have 25 crowns in my piggy-bank”, which we considered to be elementary, into two elementary information units “I have a twenty-crown note in my piggy-bank” and “I have a five-crown coin in my piggy-bank”. In other words, the quantity of 25 crowns, which was considered as one number by most students, was regarded to be two numbers.

To get a more complex picture, some of the analysed word problems were given to students and their solutions were recorded.

2.3 Definitions of Concepts and Our Assumptions of Understanding Texts

Karl Popper (Lorenz, Popper, 1994), in line with Bertrand Bolzano, speaks about three worlds: the World of Objects (mass and energy), the World of Culture (everything created by the humankind) and the World of Mind (everything which is present in the minds of individual people). In concordance with this view we will consistently distinguish between information which belongs to the World of Objects and image, evoked by the information, which belongs to the World of Mind. These two concepts are interconnected through a pair of projections:

\[
\text{grasping} \quad \text{information} \rightarrow \text{image} \\
\text{articulation} \quad \text{image} \rightarrow \text{information}
\]

The wide space of information will be narrowed down to numerical information embedded in the World of Objects. Such information will be called a datum. Let us specify the basic terms of our considerations even further.

By an elementary datum, we mean a statement which
(a) includes at least one known or unknown number (i.e. the question in the word problem will be considered an elementary datum, too),
(b) has an unambiguous and if possible also briefly described connection to the world of objects, and
(c) cannot be further decomposed.

For instance, the statement “I bought things for 18 crowns” is an elementary datum, while neither “16 is an even number” nor “Peter had one more crown” nor “in the classroom there are 5 girls and 11 boys” are elementary data; the first one has
no connection to the real world, the connection of the second one is not clear (we do not know with whom Peter is being compared) and the last one can be further decomposed.

The concept of elementary datum has two components: (1) a number or numbers, (2) its (their) embedding in the world of objects. By grasping an elementary datum, an elementary image originates. The concept of elementary image has three components. Besides (1) and (2), it also includes its location in the mind of a concrete person.

By the decomposition of text \( T \) we mean a sequence of data \( D_1, D_2, ..., D_k \) such that each number (known or unknown) of text \( T \) is contained in exactly one of these data and the semantic meaning of a number in the text \( T \) and corresponding data \( D_i \) is the same. The inverse process to decomposition is the reconstruction of the text. The decomposition is considered to be good if it is brief and if someone else is able to reconstruct the original text or at least its mathematical layer from it.

We have seen that decomposition is a subjective activity – two persons can make two different decompositions of the same text. Moreover, the above characterisation can rarely help us to decide which of several decompositions made by teachers or students is the best. Yet, the given characterisation helps us both in analysing and describing the investigated cases.

The process of decomposition has brought to light several interesting phenomena which play an important role in a student’s grasping of a mathematical text and may sometimes function as obstacles in this process.

3. Some Phenomena Elucidating a Grasping Process

In this section, we will describe seven phenomena identified as important elements in some grasping processes.

3.1 Non-verbal Information

By non-verbal information, we mean information whose main carrier is a picture, table, graph, scheme, etc. The importance of this kind of information is emphasised by the fact that pictorial information often appears at a pre-school and early school age and thus plays a key role in the process of developing a student’s attitude towards mathematics. The example of non-verbal information is the picture in example 1 below.

Non-verbal information can be characterised with five criteria.

1. Adequacy: information falls into a student’s experience.
2. Comprehensibility: information is presented in such a way that a student is able to create its image for him/herself.
3. Non-ambiguity: information does not allow for several different interpretations (see the next section).
4. Memorisibility: information as a whole and its individual parts contribute to its holding in a student’s memory.
5. Motivation: information increases/decreases a student’s personal interest.
What we call non-verbal information falls into the category of (external) representations which has been given a considerable attention (e.g. Verschaffel, De Corte, 1996) and it can be a source of serious learning difficulty as “such devices do not speak for themselves” and “their meaning must be constructed by the learner” (Becker, Selter, 1996) and as will be seen in the section below.

3.2 Vague (Ambiguous) Information

Example 1 (Kováčik et al, 1995):

I purchased three things for 18 crowns.
Draw them.

When asked by their teacher, both Eve and Mike said that a roll costs 2 crowns and cheese 8 crowns.

It appeared that contrary to other students who gave various different interpretations of the picture Eve and Mike had the same image of the picture. This assumption proved to be wrong. Later when solving the problem, they disagreed. Eve saw the picture as a shop window offering six different kinds of goods. In view of this image, she included the case 5+5+8 (two bananas and cheese) in her solution. Mike, who understood the picture as a set of six different things, rejected this solution and gave only solutions in which each object was used once (like 2+5+11 = a roll, a banana, yoghurt). This illustrates the fact that a person’s image is a multilayered concept. Two images which seem to be the same in one layer may differ in another. Thus we can say that the information in the picture is vague (ambiguous).

Vague (ambiguous) information can be seen from two points of view. (a) From a mathematical point of view it allows for different interpretations than that of the author. (b) From the didactic point of view it allows for two different but meaningful students’ interpretations. We consider the latter vagueness to be desirable at school. We agree with Byers (1998) that “we tend to react to every presence of ambiguity by attempting to remove it rather than by working with it” which is often the case of both the authors of mathematical textbooks and teachers in the Czech Republic. The rich discussion which began over Eve’s and Mike’s interpretations can be very informative because:

1. it improves a student’s sensitivity to possible ambiguity in the presented information, it teaches him/her not to be content with a protetic interpretation (e.g. to use a key-word strategy solution (Verschaffel, De Corte, 1996)) but rather analyse it critically,
2. it shows students that the same situation can have several different interpretations and that the solution to any problem must begin with the specification of the situation (i.e. choosing one of the possible interpretations),
3. it helps overcome a widely held belief that a math problem has always one clear solution.
The prerequisite is that the teacher him/herself (1) finds the problem clear, (2) can see what different interpretations it can have, (3) is willing to monitor students’ discussion.

3.3 The Word “About”

Example 2 (Repás et al, 1997): A bar of chocolate costs 12 crowns. A teacher bought 29 bars. He paid for the chocolate about ... crowns.

Example 3 (Cernek, Repás, 1998): My 10 steps are about ... metres.

In examples 2 and 3, the word “about” plays an important role. It indicates approximation. But while in example 3, it confirms the fact that there is no right solution to the problem, in example 2 there is an exact solution. In other words, in example 3 approximity is related to the result and in example 2 to the solving process. Students’ solutions to the problems from examples 2 and 3 revealed four possible interpretations of the word “about”:

1. I am to find an exact result and round it off (the answer was about 350).
2. I am to guess the result (i.e. 30·10=300).
3. I am to show how well I can guess the comparison of the lengths of “step” and “meter”.
4. I am to experiment – I am to pace 10 steps and measure the distance. I can repeat the process and find the average.

The word “my” in example 3 shows that there is no given answer, that the result will be individualised. This phenomenon can be called subjectivity of information.

3.4 Comprehensibility

Example 4: The match ended with the result 3:2. In half-time, the score was 0:0. How many goals did the home team score?

As assumed above, the information is comprehensible for a student if he/she is able to create an image of it for him/herself. This phenomenon applies primarily to a student’s image rather than to information written on paper. The same information can be comprehensible for one person and less comprehensible for another (e.g. Jane knows that one number means the number of goals of the home team and the second that of guests but she does not know which is which which became clear when she was asked to decompose the text) or totally incomprehensible.

3.5 Hesitation

By hesitation, we will mean a psychological state of an individual who is forced to decide a matter important for him/her but he/she lacks the necessary information.

Examples: (a) a student cannot remember whether 0 was assumed to be a natural number, or (b) if \( \pi = 3.14 \) is an exact equality or not; (c) a student does not know if the formula for the area of a triangle \( A = \frac{1}{2} b h \) holds for the obtuse-angled triangle; (d) a student solves the problem in Example 3 and hesitates if 8 metres would not be considered by the teacher as wrong.
The examples (a) and (b) concern isolated facts which must be remembered and the reason for hesitation is memory failure. The third one is different. The student should be able to use his/her knowledge to resolve the problem, e.g. by relating the area of a triangle to the area of a quadrilateral. The last case is sad because the source of the student's problems is not his/her ignorance but fear that he/she would not guess the teacher's expectations right (see didactic contract – Brousseau, 1997). It is not a rare case in Czech schools. Consider the following example which highlights the difference between a mathematical and didactic conceptions of mathematics.

Example 5 (Kovácik et al, 1995): Ela took less than 17 steps. How many steps could she take?

The problem is in word “could”. A mathematician can see no problem – the result can be any number between 0 and 16. However, the reaction of a student who believes that there must be a single correct answer to each problem can be different. He/she can be bewildered by this question.

3.6 Implicit information

Again, this phenomenon depends on the reader's experience. The space of implicit information can be classified according to two criteria:

1. **What** is hidden – a number, its meaning or relation.
   Examples: (a) a number is hidden in the words “double-headed”, “kilo” (meaning one kilo), “week” (one week or seven days), “goalless” (it hides either one number – no goal was scored in the match – or two numbers – guests scored 0 goal and the home team scored 0 goal);

   (b) the meaning of a number is hidden in the label “the result was 3:2” (it is partly hidden for Jane above);

   (c) the relation is hidden in the group of words “gross, nett, tare” as in the word problem “If gross weight is 58 dg and net weight is 35 dg, what is the tare?” (Demby, Semadeni, 1997).

2. The *carrier* of the implicit information – it can be a word, a group of words, a sign, a picture, a table, etc.

4. Conclusions

The “decompose and reconstruct” setting has been used in our experimental teaching for improving a student’s ability to understand the text of word problems. It's research modification described above has been continuously elaborated. First, we try to standardise the techniques of analysis of material acquired through the “decompose and reconstruct” setting, second, we are looking for its other variants. The list of the seven given phenomena is being enriched by other phenomena and restructured.

A serious problem which has not been addressed in our research so far is how to apply this method in practice, how to convince teachers of its efficiency. In this respect, we direct our attention at university students – future teachers.

Pathway between Text and Solution of Word Problems

Sara Hershkovitz and Pearla Nesher
Centre for Educational Technology and Haifa University, Israel

Solution of a word problem begins with the given text. The students' task is to discover the mathematical model that will lead them to the correct solution. We endeavored in our study to detect the text representation by analyzing the students' repetition of the text on the one hand and their mathematical solution on the other hand. While revealing the representation mechanism, we analyzed the performance of students who were successful, as well as those who failed in the mathematical solution of the problem. The findings demonstrate that the solvers have their own representation of the given text that affects both their retelling and the mathematical solution.

Theoretical Background
A solution of a mathematical word problem begins with a given text. The processes involved in reading the text, are linked on the one hand to text comprehension and discovering the formal mathematical model on the other hand. Comprehension in this context means building a representation of the textual information. According to Gick (1986) there are three major stages in solving a problem: constructing a representation of the problem, searching for a solution and implementing the solution. Our main interest in this study is the first stage, constructing the representation.

One method of revealing the construction of representation is to ask the students to retell the text they have read. The retelling can provide evidence of how the student has interpreted the original text. Kintsch (1986, 1994) and Verschaffel (1994), employing this methodology in their studies, found the source for subsequent erroneous solutions in the manner the solver represented the text. Thus, the subsequent erroneous solutions are reflected in the retold text. The solver, instead of retelling the original text, which may be too complicated for him, relates a simplified version of the story. For example, a relative quantity might become an absolute quantity.

Reading a given word problem, the student relates to the textbase in order to build a situation model (Kintsch 1986, 1994). To elaborate it to a mathematical model requires understanding of the situation described in the text and using mathematics to complete the missing data in the given text.
Similarly, Bilsky (1986) demonstrated that the context and the goal of reading a text affect the way the subject constructs the representation of the text. She found that the manner in which a subject views the text, whether a “math problem” or a “story”, was decisive regarding the text representation. Similarly, Anderson and Pichert (1978) found that shifting perspectives on the same text (second recall) add additional information and recalls less irrelevant information, thus adopting a new perspective led subjects to invoke a schema that provided implicit cues for the different categories of story information.

Numerous evidence exists for schemas directing comprehension and representation Reed (1999), Marshall (1995). A schema provides a framework for integrating new information into old knowledge in order to construct a general structure for a variety of specific instances.

The purpose of our study was the verbal text and its representation. The method used was retelling. We endeavored in our study to detect the relationship between the text representation and the mathematical solution by analyzing the retelling. While revealing the representation mechanism we analyzed students who were successful as well as those who failed in the mathematical solution of the problem.

In analyzing the retelling of successful solvers, we also noted what Raney et al. (2000) wrote about the model of text repetition effects in which wording is represented in an abstract, context-independent manner, whereas the situation described by the text is represented in an episodic, context-dependent manner.

Method
The texts used in our study were three word problems, typically given in math classes, all of which lead to two-step solutions. Forty-nine fifth and sixth grade Israeli students, who had already studied such problems, were individually interviewed in a single 45-minute session.

Task description:
Three word problems were presented to the students:

Problem No. 1: I have a book with 320 pages. I have already read 80 pages of the book. How many days are needed to finish reading the book if every day I read 60 pages?

Problem No. 2: In the morning the seller distributed the roses equally into 6 vases. How many roses did he place in each vase if
during the day he sold 120 roses and at the end of the day he saw that 60 roses were left?

**Problem No. 3:** For the journey lunch-boxes were prepared for all participants. Each lunch box had 5 pieces of fruit of which 2 were apples and the rest were plums. In preparing the lunch-boxes 240 plums were used. How many participants received lunch-boxes?

For each of the three problems each student was asked to read aloud the text (original text) of the word problem, to retell it (first retelling), and then to solve it. After the solution he was asked again to tell the story (second retelling). The complete record of the session was used in our analysis.

**Method of analyzing the session records**

Our initial analysis was performed on two levels: 1) Deviation of the repetitions from the original text, and 2) Correct or incorrect solution. Regarding deviation from the original text, we classified it into four major categories:

a) Changing the wording **without changing the schema** of the text.

For example, in this category Yael retold problem No. 2 in this way: *There was a seller. He received roses and equally distributed them in vases. During the day a lot of people arrived and bought a lot of roses. Then he found out that 60 roses were left?*

b) Changing the order or the flow of information of the original text.

*For example, in this category Michal retold problem No. 2 in this way: A seller sold 120 flowers and 60 flowers were left. The flowers (those sold and those left) were in 6 vases. How many flowers were there in each vase?*

c) Accurately retelling the original text.

d) Changing the text so that it describes a different schema.

*For example, in this category Joseph retold problem No. 1 in this way: There is a book with 320 pages. Up to now I have read 80 pages, one day I read 60 pages. How many more pages do I have to read?*

**Findings**

In Table No.1 we can see the distribution among the above four categories of deviations from the original text in the repetition, and the correctness of the solution for each word problem.
Table No. 1: Deviation from the Original Text and Correctness of the Solution.

<table>

<td>14 (16) (29%-33%)</td>
<td>4 (8%)</td>
</tr>
</tbody>
</table>

* Due to any reason

We can see in Table 1 that very few students are included in category (c) in which the subjects retold the original text exactly. This means that most students engaged in some elaboration while retelling the original text, thus supporting the findings of Raney (2000) that the wording is abstract.

What is the difference between those who rephrased the text and correctly solved the problem and those who rephrased the text and erred? Those who succeeded in solving the task, did not change the basic schema of the text. Their variations were of two kinds: (a) changing the wording without changing the schema, and (b) changing the order of the text. Those of category (a) usually added details to the description of the situation (episode) taken from their general world knowledge, which were not mentioned in the text.

For example there were students who told about the people who came to buy the flowers, or added some information about the flower-seller. This also conforms to the findings of Raney et al. The situation described in the text is represented in an episodic context-dependent manner. Once the subjects grasped the situation they were ready to add their own details. On the other hand, frequently the wording was changed to express the original semantics.
Those included in category (b – of the correct answer) also preserved the text schema, but elaborated on the text in a way so as to help them detect the mathematical model.

Michal, who changed the flow of problem 2 (see explanation of category b above), immediately began to solve the problem and claimed: “first I have to know how many flowers he had in the morning, the sold flowers and the left ones $120+60$. Only then can I find out how many flowers he placed in each vase. I have to do $180:6=30$”

Six students belong to both categories (a) and (b). For example, Johnny in problem No. 3, rather than adding to the story some details from his world knowledge, also solved a part of the problem in the course of retelling it.

In this way he retained the problem’s underlying structure while changing its surface structure.

Johnny’s repetition was:

A member of the entertainment committee, or somebody else, I don’t know exactly who, prepared the lunch-boxes for the journey the committee organized. In each lunch box they put 5 pieces of fruit of which there were 2 apples and 3 plums. 240 plums were needed to prepare all the lunch-boxes. How many children got lunch-boxes?

While solving the problem he wrote 2 math expressions as follows:

\[ 3 + 2 = 5 \quad \text{and} \quad 240 : 3 = 80 \]

He summarized “80 children will get lunch-boxes”.

He continued and said: “Now I can find out how many apples were needed as well ($80\times2=160$).”

All those who solved the problems incorrectly, also consistently changed the schema of the text in their repetition (category d). As found by Kintsch (1986), the changes they made in the text fitted their erroneous mathematical solution. Moreover, when asked to give the second repetition (after the solution) they were again consistent in their story,

The second repetition fitted their erroneous solution.

Changes in the schema were also of two kinds:

1. Those who entirely changed the mathematical model (e.g. from multiplicative to additive),

For example: Joseph, whose repetition was demonstrated for category (d), changed the problem from two different structures (additive and multiplicative) to two similar structures (two additive
structures). He continued to solve the problem by solving the expressions: \(80 + 60 = 140\), and \(320 - 140 = 180\).

2. Those who changed the relationships of the sets involved in the situation text (Bilsky, 1986). For example, Shay retold problem No.3 as follows:

*Lunch-boxes were prepared. There were 5 fruits in each lunch box, of which 3 were plums and 2 were apples.* Shay continued to speak aloud while solving: \(240:5=48\) and said:

"240 are all the fruit. Each child received 5 fruits".

In this case the 240 plums were changed into 240 fruits, so that it would be reasonable to distribute 240 fruits - 5 fruits per each child, which was not the original question.

**Discussion:**
It is clear that the first step in the problem solving process is constructing a representation of the situation. This process does not take place in a vacuum, but is strongly affected by its context (Bilsky 1986, Bransford and Johnson 1972).

Verschaffel et al. (1994) described the role of real world knowledge in the different phases of problem solving. Beginning with the initial phase of problem understanding, modeling that precedes the computation, and the final phase in which the result of the computational work is interpreted and evaluated. We also tried to trace the students’ representation of the text read by asking them to retell the text. We examined their solution (thus, their modeling) and we noted their solution by asking them to retell the text again after their solution.

We found some students who retold the text precisely. According to Fletcher & Chrysler (1990): "The most superficial level of representation, called surface memory, captures the exact wording of a text. This representation is viewed as a product of highly automated lexical and syntactic process." All those students solved the problem correctly. They probably found no reason to change the wording and they immediately saw the mathematical model, which led them to the correct answer.

According to Fletcher & Chrysler (1990), in studies on reading, accurate repetition of the text is viewed to be the lowest level. In mathematics, we have thus far been unable to relate the precise retelling to a low level of understanding. In our sample, those who retold the text exactly did not support the claim that they were on a lower level.
Most students changed the wording while retelling the given text. We believe that this occurs while the student is constructing the situation model of the given textbase (Kintsch 1986). Fletcher & Chrysler (1990) add, “the final level of representation is referred to as the situation model. This representation results from processes that integrate the information conveyed by the text with a reader’s or listener’s prior knowledge and produce the most lasting trace in long memory. The situation model corresponds to the equivalence class of all experiences that convey the same situation.”

We found evidence that most students do not “translate” the textbase directly into a mathematical expression. In order to construct the situation model from a given text, the student has to invoke qualitative considerations, which are necessary for constructing the situation in his mind. He frequently adds details not originally mentioned in the text but taken from his world experience (Nesher 1980). Anderson et al. (1983) claim that “the content schema embodies the reader’s existing knowledge of real and imaginary worlds. What the reader already believes about the topic helps to structure the interpretation of new messages about the topic.” We found that all students in our sample who built a richer text by adding detailed information, did so because it was useful for them in order to construct a complete understanding of the text, and thus they correctly solved the problems.

Another path from the original text to correct solutions was found when students changed the original order of the text. This happened in problems in which the numbers given in the text were not in the same order they appeared in the mathematical expression. In this case the students changed the order so that the numbers appeared in their retelling in the same order they were supposed to appear in the mathematical expression.

All students who failed to solve the problems changed the text into another situation, mostly to a simpler one. These changes related to changing the text so that it described different mathematical structures. Kintsch (1986) and Verschaffel (1994) found this type of behavior in simple one-step additive problems. In our study, in accordance with theirs, the students felt comfortable with the changes they made. This was consistent even in the second repetition made after they already solved the problem. When they had to interpret and evaluate their solution, they did not feel that they were referring to another story. Once again, we would note that solving a word problem is not a matter of a direct solution. Zwaan and Radvansky (1998) found similar findings in
relation to other expertise domains. In the path that leads from a given text to its mathematical solution, the situation model plays a crucial role. This model is constructed by the solver after reading the given text and adding interpretations based on his world experience.

We believe that our findings might have pedagogical implications, as teachers could gain some access to the students’ internal representations by asking them to retell the text. This may be particularly helpful in tracing the source of erroneous solutions.

DESIGNING SOFTWARE TO ALLOCATE APPROPRIATE DEMANDS ON MEMORY AND AWARENESS

Dave Hewitt
School of Education, University of Birmingham, UK

I begin by considering the division into necessary and contingent which exists within philosophy and discuss ways in which this can be applied to the mathematics curriculum (the divide having been re-named arbitrary and necessary). By looking at implications of this divide, I develop a pedagogic approach which clarifies when a teacher’s role is to assist memory and when it is to educate awareness. I consider how this approach has informed the development of one of the dynamic geometry computer files in the package ACTIVE GEOMETRY.

Arbitrary and necessary

Within philosophy there is a divide made between those things which are logically true and can be derived in some way from other truths, and those which cannot be so derived and where some sort of choice is possible. The former are known as necessary and the latter as contingent. Kripke (1996, p36) expressed the divide as follows: If [something] is true, might it have been otherwise?... If the answer is ‘no’, then this fact about the world is a necessary one. If the answer is ‘yes’, then this fact about the world is a contingent one. In my application of this divide to mathematics education (Hewitt, 1999), the issue of whether the question why? can be suitably answered can be an alternative tool for deciding whether a ‘fact’ might be considered necessary or not. Within Nozick’s (1984, pp140-141) discussion of statements concerning the principle of sufficient reason, he wrote:

Let us state the principle of sufficient reason as: every truth has an explanation. For every truth p there is some truth q which stands in the explanatory relation E to p... When any other truth holds without an explanation it is an arbitrary brute fact.

Using a combination of Nozick and Kripke, if the question why? can be answered by providing an explanation which shows that this ‘fact’ could not have been otherwise, then this ‘fact’ is one which is necessary, otherwise it is arbitrary. I have chosen to use the term arbitrary rather than contingent since within education a student is rarely party to the moment when some people were aware of choice and had reasons for making the choice they did. So rather than being party to this choice, students are presented with the ‘fact’ in a text book, or by a teacher, some decades or centuries after the choice was actually made, which makes it appear arbitrary. For example:

Student: What is the name of a 2D shape which has four sides the same length?

Teacher: A rhombus.
Student: Why?
Teacher:....

Consider how you might answer the student's question before reading on.

Personally, I do not know why such a shape is named a rhombus I just accept the use of the name as a social convention within the English speaking mathematics community. I suspect there were reasons why this name was chosen at the time, but for me, working on mathematics today, I merely have to accept the term in order to communicate with colleagues successfully within the field of mathematics.

Walkerdine (1990, p2) wrote that Saussure is credited with recognizing the importance of the fact that the relationship between the signifier and the signified is arbitrary; that is to say, conventional rather than necessary. Names are signifiers and all names are arbitrary in my usage of the word. Names are the result of choices, as are conventions. Thus all names and conventions within the mathematics curriculum are arbitrary and as such are to be accepted rather than understood by a student. This is because there are no reasons for why any of these have to be how they are. Different choices could have been made which would have resulted in different names and conventions without affecting the mathematics of the situation at all. Only the language of description would have been changed. For example, there is no reason for why the x co-ordinate must be written before the y co-ordinate. It could have been the other way round and none of the mathematical properties concerning co-ordinates would change, only the way in which they are described.

I will now consider how a student may come to know the arbitrary. I am usually known as Dave Hewitt but I also have other names between Dave and Hewitt in my full name. What are they? Consider this before reading on. These other names are arbitrary and the only way in which it is possible for you to know them is to be informed by someone who already knows them, such as me, or perhaps an official document which has them written down. Students cannot know for sure how a co-ordinate is written unless they consult someone who knows. They can invent plenty of ways of writing co-ordinates, but if we expect them to learn what is a convention within the mathematics community, then those students will have to be told of the convention. This gives a clear role for both students and teachers: students need to be told, accept and memorise the arbitrary; teachers will need to inform and offer ways to practise the use of the arbitrary.

The name of the shape in Figure 1 may be arbitrary but there are other things about the shape which are not. The shape has certain properties, such as sides which are the same length, which I can work out and not have to ask someone else who knows. This is an example of something which is not arbitrary but necessary. There is an explanation which I can provide which convinces me that the sides must be the same length. There is no choice about the matter, it is a property which has to be so.
Figure 1. What properties has this shape?

Not everyone may be able to become aware of the property of equal length sides. A student who does not know about Pythagoras’ Theorem may struggle to know for sure that the shape has this property. So the necessary is not available for all students to know as necessary. Whether students can come to know a property will depend upon the awareness they already have of the mathematics involved. If they do have sufficient awareness, then that awareness can become educated in the process of finding out that this property of the shape must be true. It is the role of a teacher to consider the awareness of students and make choices about what are appropriate challenges for certain students. Whatever the situation though, properties of shapes are not arbitrary and so I propose as a guiding principle that therefore they are not to be told. Instead, either particular properties are considered not to be within the awareness of the students and so will not form the focus of a lesson, or they are accessible to the awareness of students and so an activity needs to be provided to educate students’ awareness so that they can come to know that these properties must be true.

Figure 2. When to inform and when not to inform.

Figure 2 summarises the differences between arbitrary and necessary. In particular, the arbitrary is in the realm of memory and a teacher’s role is to assist students in memorising. The necessary, however, can be known through awareness and so a teacher’s role is not to inform but to devise activities which help students to educate their awareness as I have just mentioned above.

The necessity of the sides being the same length in Figure 1 is based upon some information which is provided or assumed, such as the drawing itself, the assumption...
that the corners lie exactly on grid points, it is a square grid, that we are in Euclidean geometry, etc. These I describe as *givens* and provided certain givens are accepted, there are situations where there is underlying necessity which comes as a consequence of these givens. It is working on what is necessary where mathematics really lies. The arbitrary is for ease of communication and is not mathematics itself. Sadly, too much attention is often paid to the arbitrary when mathematics is to be found in the necessary. Richard Feynman (1988, pp13-14), a famous physicist of the 20th century, gave the following story:

One kid says to me, “See that bird? What kind of bird is that?”
I said, “I haven’t the slightest idea what kind of bird it is.”
He says, “It’s a brown-throated thrush. Your father doesn’t teach you anything!”
But it was the opposite. He had already taught me: “See that bird?” he says. “It’s a Spencer’s warbler.” (I knew he didn’t know the real name.) “Well, in Italian, it’s a *Chutto Lapittida*. In Chinese, it’s a *Chung-long-tah*, and in Japanese, it’s a *Katano Tekeda*. You can know the name of that bird in all the languages of the world, but when you’re finished, you’ll know absolutely nothing whatever about the bird. You’ll only know about humans in different places, and what they call the bird. So let’s look at the bird and see what it’s doing – that’s what counts.” (I learned very early the difference between knowing the name of something and knowing something.).

The linking together of memory and awareness is often exhibited by skilled practitioners. Bird watchers attend to properties of birds and with the noticing of certain properties (size, markings, birdsong, etc.) comes the name of the bird, and likewise mathematicians attend to properties of the shape in Figure 1 and the word *rhombus* or *parallelogram* appears to come as if from thin air. Walkerdine (1990, p3) posed the question how do children come to read the myriad of arbitrary signifiers—the words, gestures, objects, etc.—with which they are surrounded, such that their arbitrariness is banished and they appear to have that meaning which is conventional? The arbitrary signifier *rhombus* only gains an (apparent) meaning when the relevant properties are associated with the word within a student’s mind. As Saussure (1974, p75) said in relation to the signifier and signified coming together to form a ‘sign’: *Both terms involved in the linguistic sign are psychological and are united in the brain by an associative bond*. It is only when the name and related properties are brought together through association that the name stops having the sense of arbitrariness (in the usual English use of the word) and takes on an apparent meaning. This issue is developed within the next section where I consider some pedagogic decisions involved in the development of a software file.
An example of bringing together the roles of memory and awareness: the design of a dynamic geometry file

Dynamic geometry software, such as Geometer's Sketchpad and Cabri-Géomètre, has offered new ways for students to engage with geometry. The possibility of movement and the focus on properties, especially concerning geometric relationships through construction, has brought new pedagogic possibilities (for example, see Laborde, 1995, and Jones, 1998). Some files for Geometer's Sketchpad have been commercially available (for example, Exploring Geometry with the Geometer’s Sketchpad from Key Curriculum Press) which generally take the form of demonstrating dynamically a mathematical property or setting up a mathematical construction where the locus of a point, for example, is to be explored. The emphasis on these files is on the mathematical content. The Active Geometry files available from the Association of Teachers of Mathematics (ATM) for either Geometer’s Sketchpad or Cabri-Géomètre II consider ways in which parts of the UK National Curriculum can be directly addressed through dynamic geometry software without the need for students or teachers to know about construction techniques. I will consider one of these files, Quadinc, and discuss some pedagogic issues which underpin the design of the file.

Quadinc has a quadrilateral whose corners can be moved to any point on a square grid. As a corner is moved, so the properties of the quadrilateral change and names associated with the quadrilateral may also change as a consequence. For example, Figure 3 shows the quadrilateral ABCD. Such a shape is usually assigned the name square, however, it is also a trapezium (accepting an ‘inclusive’ definition for a trapezium), parallelogram, kite, cyclic, rhombus and a rectangle. All these names appear on the screen. If corner B is moved one grid space to the right then all the names disappear except for trapezium. Thus all the names associated with the particular quadrilateral appear on the screen and change dynamically as the quadrilateral is changed dynamically. At any given positioning of the quadrilateral, the associated names are displayed alongside. Thus the file provides the arbitrary – the names – by simply having the appropriate names displayed. However, the file does not attempt to explain or define any of the names. This is similar to situations that all young children face when they learn their first language. Words appear (are said), and appear within a context. The fact that certain words appear frequently (such as no or yes) means that a child has an opportunity to recognise them, and improve the way in which that child says the word through checking against the way adults say the word. The fact that words are said within context gives a child the opportunity of developing meaning for those words. Within Quadinc, mathematical meaning will come from a student considering the context within which the word rhombus, for example, appears. The power to abstract rules and meanings from examples is one which all children have used when learning their first language and which can be utilised in learning mathematics as an older child. Ginsburg (1977),
Bruner (1960) and Gattegno (1971) have all made references to the powers that very young children use in learning their first language and yet these are rarely called upon by many traditional teaching approaches.

Quadinc informs students of what is arbitrary – the names. It leaves to the students’ awareness those things which are necessary – properties and relationships. In fact some properties are given, namely the length of sides and interior angles at the top of the screen. This has been done in order that attention can remain at the level of properties such as this angle is the same as that rather than attention having frequently to be taken away to the level of calculation such as the use of Pythagoras and trigonometry. There would be many students for whom the requirement to use Pythagoras, for example, to calculate lengths of sides would exclude them from knowing the lengths of sides since they may not be aware of Pythagoras or such calculations may be difficult to carry out. Choosing to provide the lengths and angles means that noticing properties such as equal length sides now becomes accessible for such students. Thus this is a pedagogic decision to make the task of finding properties associated with names more accessible when it may not otherwise have been or have required attention being taken onto a sub-task for a considerable period of time. For example, Ginsburg (1977, p164) wrote about a similar issue regarding the task of noticing commutativity when the sub-tasks of actually carrying out calculations take up so much time and attention for some students:

Over the years, they work 6+7, 7+6, 7x6, 6x7, 7÷6, 6÷7. At first, the very act of calculation may be so difficult that they focus attention only on individual problems. They concentrate on getting the correct sum for say 6+7 and so they cannot notice that 7+6 yields the same
result. Or it is so hard for them to do $7 \div 6$ that they cannot see that $6 \div 7$
gives a different answer.

If it is desired that students' attention is with the results of such calculations so that
the issue of commutativity might be noticed, then asking some students to also carry
out the calculations may result in attention being taken away from where it is
required since the task of calculating may be sufficiently challenging in itself. For
similar reasons, there is a button which can be double-clicked which will show on
the screen a circle going through the corners A, B and C. It is necessary that such a
circle exists (allowing for certain 'degenerate' cases such the circle having infinite
radius) but providing it makes the property of cyclic become highly accessible since
a student need only attend to whether the fourth point, D, lies on the circle as well.

There are many possible activities which a teacher may provide which help to focus
a student's attention on to properties of the quadrilateral. Several are included within
the activity tasks in *Active Geometry* of which a section brief section regarding the
exploration of a rhombus below is given as an example:

See if you can state a rule which makes a quadrilateral a rhombus, where the
rule is *only* about:

a) the lengths of the sides;

b) the direction of the sides;

c) the angles inside the quadrilateral;

d) the diagonals of the quadrilateral (use the *Show diagonals* button);

e) the angle bisectors of the quadrilateral (use the *Show angle bisectors*
button).

(Note: not all of these may be possible)

Check each rule *carefully* to see whether any quadrilateral which obeys the
rule *must* be a rhombus. One idea is to pass on your rules to someone else and
see whether they can find a quadrilateral which obeys the rule but is not a
rhombus. If they find one, then you need to think again about your rule.

Through such activities the names are practised (in order to assist memory) whilst
attention is placed with properties and relationships (in order to educate awareness).
The simultaneity of names and properties appearing and disappearing together helps
develop an associative bond between the names and the properties of the
quadrilateral. The appearance of a name indicates that associated properties are
present within the quadrilateral. The student's role is to abstract from examples
which properties remain the same when a certain name appears on the screen.
Meanwhile the use of the name itself is being met and practised again and again.
Summary

Viewing the mathematics curriculum in terms of arbitrary and necessary can assist in clarifying the role a teacher has with respect to whether or not to inform students of certain parts of the curriculum. It also helps the way in which software is developed so that what is arbitrary is provided and is practised whilst working on the necessary. This way memory is assisted whilst awareness is educated. This contrasts with the use of tests as the main method of practice (where awareness is rarely educated) or treating properties as things which have to be memorised as well (thus placing a burden on memory as well as not educating awareness). Asking students to use memory for the arbitrary, and awareness for the necessary, means that students in mathematics classrooms can begin to use the powers they used so effectively as young children, such as the power of abstraction.

MEASURING GROWTH IN EARLY NUMERACY: CREATION OF INTERVAL SCALES TO MONITOR DEVELOPMENT

MARJ HORNE  
AUSTRALIAN CATHOLIC UNIVERSITY

GLENN ROWLEY  
MONASH UNIVERSITY

There is a need to measure learning and quantify growth. This is particularly important when looking at any curriculum developments and programs to improve teaching and learning. One off assessments (e.g. TIMSS) provide a basis for comparisons but do not inform curriculum, teaching or an understanding about the learning process. This paper reports on the development of a scaling process that allowed the assessment to be driven by a model of learning and mathematical development rather than the statistical process. The process then allowed the scales to be transformed to interval scales enabling growth to be investigated and comparisons to be made between groups.

When the Early Numeracy Research Project (ENRP) began at the start of 1999 there was a need to develop a comprehensive and appropriate learning and assessment framework for early numeracy. Drawing upon Australian and overseas research on young children's mathematics learning, the ENRP team developed a framework of the key “Growth Points” in the early learning of mathematics. For teachers these growth points, from a number of mathematics curriculum areas, can be used to describe children's numeracy development and to inform their teaching. For example, those in the Number area include Counting, Place Value, Addition and Subtraction, and Multiplication and Division. The process of development of the framework and its associated assessment interview is described more fully elsewhere (Clarke, Sullivan, Cheeseman & Clarke, 2000; Clarke, Gervasoni & Sullivan, 2000).

The purpose of the framework was to inform teachers in their planning and implementation of curriculum and to provide a basis for assessment which would enable children’s mathematical development to be monitored. The assessment was to provide information for the research team on the development of aspects of numeracy, but it was also to inform teachers, enabling them to learn more about the thinking and development of individual children in their classes and to plan their teaching accordingly. Assessment, in the form of a 30-40 minute task-based interview, was developed based on this framework. The nature of this assessment is essentially different to the one off standardised assessments.

- It is developed from a structure of mathematical development rather than from a content base.
- It does not require all children to answer all the same questions but is rather structured so that students stop answering questions within a domain once there is a lack of success.
• It allows for a focus on the approaches the child uses as well as the answers given.
• Its purpose is to inform teaching as well as to provide information on children’s mathematical development.

Data collected from interviews with over 5000 children in each of March and November in 1999 and 2000 have led to minor modifications of the framework and enabled monitoring of some aspects of children’s mathematical development. To date, 4-6 Growth Points have been developed for each domain. It is possible that more Growth Points could be added, as the research and the interview protocols are extended to higher grade levels.

The ENRP is a large scale project looking at a whole school approach to school improvement in early numeracy. It is a developmental project with a team of researchers working with all teachers of early numeracy in the 35 trial schools. One aspect of investigating the development of early numeracy is to compare growth between students in the 35 trial schools which have been chosen to be representative of region, size and socioeconomic indicators and the matched 35 reference schools, at each of the grade levels involved. Another purpose is to study growth and inform teachers of the way children learn and their numeracy development. Such comparisons are obviously facilitated by the use of an interval scale of measurement. While the growth points were chosen to be important ideas and are not exhaustive but rather a set of sign posts, they were not chosen with any interval properties in mind.

One approach which has been used to look at underlying scales with interval properties in recent years has been Rasch modelling (Andrich, 1988; Pirolli & Wilson, 1998). The data from the interview are not the equivalent of students answering items on a written test as the interview within a domain ceases when errors are made so the children do not all answer the same set of questions, and, although some questions may be common, the full range is not appropriately sampled. Although Rasch models do allow for missing data, the cutting off of the questions once lack of success is experienced makes the use of Rasch modelling problematic.

The study of growth with such a large number of children and many domains would be enhanced by the use of an interval scale. Without an interval scale, growth differences between children are only clear when the starting points are the same. An interval scale would enable more appropriate analysis of such a large amount of data. This paper looks specifically at a new approach to the development of interval scales and reports some findings based on those scales.

Analysis

A large sample of students has been involved in the two years of the project – to date 8681 students from 68 schools balanced with respect to region, size and socioeconomic indicators. Not surprisingly, the frequencies of responses in each domain of the interview strongly suggest that the growth points do not form an
interval scale. Figure 1 shows the distribution of Growth Points for the domain Counting in two successive years. The distributions are irregular, but consistent from year to year. The uneven distribution suggests that Growth Point 2 spans a wider range of performance than Growth Points 1 and 3 on either side. Similar patterns occurred with other Growth Points. The stability of these patterns over successive years indicates that they reflect a property of the measurement scale, rather than arising from peculiarities of the samples. Essentially, the implication is that the student development from Growth Point 1 to 2 may not be the same as that from 2 to 3, etc. While this is generally true of achievement test scores, it inhibits making comparisons between the growth of one group and the growth of another, unless they start at the same point. A key purpose of the ENRP is to demonstrate growth to teachers in a way that is meaningful to them, and to find how this growth is enhanced by the whole school approach and professional development that the project offers. For this reason, we have investigated adjusting the location of the Growth Points along a scale of achievement so that they represent achievement within a domain on a scale with interval properties.

![Figure 1. Distribution of growth points for the counting domain in March 1999 and March 2000.](image)

Creating an interval scale

The major assumption that is made in the scaling process that follows is

*that the nature of the distribution of learning in the population of children in the first three years of school is normal.*

The measurement of other attributes of a person such as height, with a cohort like this one, do approximate a normal distribution. As long as there is a continuum of learning in the domain, beginning before children commence school and extending beyond grade 2, the spread of children within the domain should approximate to a normal distribution. We can then regard the Growth Points as indicators of an underlying normal distribution, cut into slices of unequal width. The sample of students used is wide enough and representative enough that, given the above assumption, there is an underlying normal distribution of performance. It is not uncommon for researchers to assume a normal distribution for a measure, even when
there is no particular reason to expect it. We emphasise that in this case, the assumption is not made lightly. The justification for this is that the sample is large, and that the schools have been selected to be representative with respect to geographic area, school size, and socioeconomic indicators. The test is whether scaling from two different populations yields similar sets of scaling points.

This adjustment of the location of the Growth Points along a scale was done by standardising the scores, then re-scaling them using the mean and standard deviation of the original set of Growth Points. With this process it is reasonable to expect similar scaling points from populations that differ in mean and standard deviation. In detail the steps were

1. We chose the median student to be representative of the growth point then calculated the proportion of students below, thus giving a cumulative frequency distribution. This means that below the median student were half the students on that growth point plus all students on lower growth points.

2. Assuming a normal distribution, we found the z-score of the median student for each growth point by using the probability from the relative cumulative frequency. The probability of being below the median student in a growth point is the number of students below (calculated in step 1) divided by the total number of students. This was then looked up on a normal distribution table to give a z-score for the median student representative of the growth point.

3. We translated this z-score back to a distribution with the same mean and standard deviation as the original data.

The Trial and Reference Group data from the March 1999 interviews were rescaled in this way. These are two large populations (n = 3639 and 1219, respectively) representing a wide range of geographic regions and socioeconomic characteristics. Table 1 shows the transformations, as applied to these two populations.

</table>

* Rows are shaded for n < 50. With so few people in the score range, the accuracy of the scaling may be problematic.

Comparison of the scaling from the two distinct populations indicates that it matters little which population is used to scale the Growth Points. For example looking at the scaled growth points for growth point number 2 in table 1 shows the scaled score for the trial schools to be 2.016, only just above the hypothetical growth point 2, while for the reference schools the scaled growth point at 1.989 was only just below. The
difference between the two independent populations for this growth point was only .027. For 5 of the 6 Growth Points shown here in Table 3, the difference is less than 0.10 in magnitude, and the remaining one arises from a Growth Point with small n (less than 50, shaded in Table 3.) and has a difference of about 0.25. We assert that the process we have adopted yields results that are relatively invariant across populations, provided there are sufficient data at each Growth Point.

The scaling process yields scores that can be mapped onto scales with any size units. Given that teachers and others may still wish to interpret growth information and mean scores in terms of the Growth Point scales with which they are familiar, a case can be made that the most suitable mapping is onto a scale in which the two endpoints remain fixed, and the intermediate points are adjusted. Table 2 shows the results of such a scaling in the column labelled Scaled Growth point 0-6 Scale, using the entire March 2000 cohort, including the grade 3 and 4 children, (Trial and Reference schools) as the scaling population. The process followed was the same as the one above to give the growth points in the column headed Scaled Growth Point but with a fourth step included that stretched the scale from 0 to 6 while maintaining its interval nature. Again looking at the hypothetical growth point 2 in Table 2 the scaled growth point obtained by using the original process but the different population was just above at 2.08. One the re-scaling has been done to set the lower and upper growth points at 0 and 6 this scaled score becomes 1.83, just below the 2.

Table 2: Scaling of growth points for Counting: trial and reference schools, March 2000

Use of the scaled Growth Points

One of the ways in which the research data might be used is to compare groups. With some confidence in the interval properties of the re-scaled Growth Points, we are now in a position to reach conclusions about relative growth, even from comparison groups that have different starting points. Figure 2 shows growth on the Counting domain. The growth over the 1999 and 2000 academic years is apparent, as is the slower growth over the 1999-2000 summer break. Comparisons across cohorts show the gap between grade levels. In each case the graphs are in pairs showing trial and reference schools in a particular cohort. For example the upper two graphs on the left are the cohort of students that began in grade 2 in 1999 and in 2000 were in grade 3 and thus were not tested as they were no longer part of the project (a small sample was tested in 2000 but not as part of the main project). The two lines below
these represent the cohort of students who began in the project as grade 1 students in March 1999 and were tested in Nov 1999 and in March and November of 2000. It can be seen that in the trial and reference schools grade 1 students were very similar at the beginning of 1999 but that the growth in the trial schools was greater during both 1999 and 2000.

The interval scales can now be used to compare growth for investigating successful aspects of the program and to inform teachers of growth for their students and classes. The scales have enabled investigations such as the growth is typical in a year and the extra growth that occurred as a result of the ENRP program provided in schools. Teachers involved in ENRP understand a scale of measurement framed in terms of Growth Points, and welcome information about achievement in this form. Until we were confident that Growth Points could be manipulated into an interval scale, we were unable to provide this information in a way with which we could feel comfortable. Because the transformation described previously is fairly close to the unscaled Growth Points, we can present information about means and variances in terms of scaled Growth Points, and remain confident that this information will not mislead users who interpret them in terms of understanding and skills possessed by their students. Because they are close this also means that we can refer to the growth points as whole numbers knowing that they are close to the scaled values. In terms that are readily understandable by teachers in the project, we can say that typical gains for students in Reference Schools are a little less than one Growth Point per year in Counting, but a little more than one Growth Point per year for students in Trial Schools. Very little of this gain occurs between November and March, a good part of which is summer holidays.

The differences found between trial and reference schools are statistically significant. Rowley and Horne (2000) reported an analyses of variance using the scaled March
achievement as the covariate with the independent variables of schoolcode, grade level and ENRP participation (i.e. Trial versus Reference Schools). For all six domains used in both years, they found a significant ENRP main effect, indicating that the effect of ENRP on achievement can be detected, over and above that of prior achievement, school attended and grade level. A repeat analysis done with the year 2000 data supported the same findings.

Finally, the interval properties of the scaled Growth Points allowed us to test the applicability of particular models to the data. In this example, the models included, separately at each grade level, in logical-temporal order:
- The school that the child attended (as represented by the matched pair of schools, one Trial and one Reference school)
- The child’s prior (March 1999) achievement
- The provision of ENRP Professional Development in the school.
Regression analysis allows us to ask whether each of these in turn produces a significantly better-fitting model than those that precede it. In essence, this tells us how well is achievement in November predicted by the school attended, achievement in March, and by whether or not the school participates in the ENRP Professional Development program. And finally, we can also see how much difference does the ENRP Professional Development makes by using the re-scaled growth points.

Table 3: Regression coefficients for provision of professional development for Counting

</table>

Table 3 shows the unstandardised regression coefficients for ENRP Participation in the full model, which includes School, Prior Achievement, and ENRP Participation. These coefficients may be interpreted with some precision as the expected advantage in achievement, assessed in Growth Points, that students gain through their school’s participation in the ENRP program. In general, students may expect to gain from 25 percent to 48 percent of a growth point per year more if their school participates in ENRP program.

Conclusions

In this paper, we have presented the construction of interval scales based on a set of protocols for one-to-one interviews of children in their first three years of schooling that can be used to assess their development on curriculum-relevant domains of mathematical learning. Because of the nature of interval scales, the assessments obtained are useful for assessing and charting growth.
Using the Growth Point Scales in this way, we have shown some representations of growth in achievement, and demonstrated a modest but consistent advantage in achievement from participation in the ENRP program. This rescaling process has provided data which has been used for comparisons to investigate differences between groups looking at the success of programs and, perhaps more importantly, to look at children’s development in early years numeracy.

The scales for separate domains are referenced to Growth Points within each domain, but not to each other. Future use of the data will enable typical growth in the domains to be investigated. At the start of grade 2 before the project began, for example, students were typically at Growth Point of 3 in Counting, but just at growth point 2 in Multiplication and Division. Equally, a typical year’s growth is approximately one Growth Point in Counting, but only half that in most other domains. While these comparisons are possible we also do not want to lose sight of the many other developments which are not measured by these interview based scales. The comparisons now possible are being used as one aspect of deciding on case studies to be carried out in 2001.

Acknowledgements
The main team of researchers involved in the ENRP includes D. M. Clarke (director), J. Cheeseman, B. Clarke, A. Gervasoni, D. Gronn, M. Horne, A. McDonough, P. Montgomery, G. Rowley, and P. Sullivan. All of this team have been involved in the research presented here.

PROGRAMMING RULES: WHAT DO CHILDREN UNDERSTAND?
Celia Hoyles, Richard Noss, Ross Adamson & Sarah Lowe
Institute of Education, University of London, UK

Abstract
We are working to build computational worlds where children can play, design and program videogames. Videogames represent rule-based systems which are expressible in non-textual animated ways. We describe the different ways children (aged 7 to 8 years) articulate a simple rule they have programmed themselves. The results indicate that rule expression is shaped by the type of prompt to make the articulation (to predict, describe or to explain), the narrative context of the game and the medium of expression (computational, spoken or written).

Background
This study concerns children’s understandings of rules they have constructed by programming a computer, in the general context of building their own video games. There is much research into children’s understanding of causal evidence and logical reasoning, much of it undertaken in the field of developmental psychology. Since the 1970’s, evidence has accumulated that children rarely argue solely on the basis of universal laws of logic or domain-independent abstract rules. There are different interpretations as to why this might be the case: that children call up pragmatic reasoning structures derived from experience in context (Cheng and Holyoak, 1985), or that their arguments are derived from knowledge and the way it is structured (Ceci, 1990). How far children are aware of the logical necessity of even their correct conclusions is still a matter of debate.

Following a careful analysis of children’s naturally occurring arguments, Anderson, Chinn, Chang, Waggoner, & Yi (1997) report that children tend to omit parts of the logic of their argument (premise, warrant or conclusion), to be cryptic when mentioning the known or obvious, and elliptical when expressing their position, giving no more information than was necessary. Nonetheless, they conclude that the children’s arguments were logically complete: that is, the framework used was not inconsistent with deductive logic. The fact that everyday language is likely to be only a partial indicator of reasoning calls into question how children’s reasoning might best be investigated. Anderson et al. report that children used words such as ‘because’, ‘so’, and ‘therefore’, in arguments which included modus ponens; so simple reference to linguistic pointers is no infallible guide to logical reasoning.

Aside from research on children’s logical understanding, we briefly allude to a further strand of research which is an important source for our analysis. This concerns the literature on learning by designing, creating and debugging meaningful ‘external’ artefacts (the constructionist paradigm, Harel and Papert, 1991) and our own work (Noss and Hoyles, 1996). However, an assumption behind our work had been that the expression of complex ideas and its communication to a computer necessitated collections of symbols in the form of textual strings and it was this need for symbolic representation that was crucial for mathematical learning. This
assumption is somewhat anachronistic, as we have begun to explore the potential of programming within a non-textual environment in which programs are created by directly manipulating animated characters and animations themselves are the source code of the language.

The study forms part of the Playground project (http://www.ioe.ac.uk/playground) in which we are giving children (aged 6 to 8 years) the opportunity to construct creative and fun computer games (see also Harel, 1988 and Kafai, 1995) and at the same time, offer them an appreciation of — and a language for — the rules that underpin them. Broadly, we conjecture that through designing, building and playing their own computer games, children will think differently about ideas like causality and inference, and will find new, more formal and complete ways to express their thoughts about rules. Given the age of the children, it is obvious that we cannot expect them to build symbolic representations of rules. Rather we have based our work on ToonTalk (Kahn, 1999) where programming involves the ‘training’ of animated robots by example, and essentially without text. The conditions which determine subsequent performance of the actions at run time can be generalised or specialised after the training has taken place.

Our research is framed by two questions: i. How is children’s understanding and expression of rules mediated by a programming language in which the rules are available for inspection and change and ii. How far do children’s descriptions of the rules they have programmed throw light on their understandings of causal reasoning?

The Meaning of a Rule

What do we mean by rules in the context of young children building their own computer games? As long ago as 1932, Piaget was interested in games as complex systems of rules and endeavoured to trace the development of the practice and consciousness of rules in young children (Piaget, 1932). He concluded (largely through an analysis of boys playing marbles), that between ages 7 and 10 years, children were unable to codify rules, although they were able to play games according to social conventions. A conscious realisation of the rules of their games and seeing that they could be changed, Piaget argued, only developed at age 11–12. For Piaget (and Vygotsky as well), what changes over time is the explicit recognition of the rules of a game.

In our early interviews with children (aged 6 to 8) we asked them to tell us about their favourite games (both on and off the computer) and the rules of these games. We found most only described constraints (“you mustn’t hit other children”) and not the actual rules designed into the game. From our case studies of the children programming their own games, we have noted that children have indeed become more aware of rules, but also that they adhere to different types of rules that we have categorised as follows:

Player rules – a regulation that must not be transgressed: “You must not hit the sides of the maze.”
Player goal – a maxim or formula that is generally advisable, but not compulsory to follow: “Score as many points as you can”.

System rules – a generalised statement that describes what is true in most or all cases: “When Theseus touches the minotaur with the sword then he will die”.

Our interest focuses on children’s understanding of the universal system rules that are hard-wired into the computer game (that is, built by programming). Clearly, any programming environment brings its own complexities: e.g. how the rule is expressed in the language, and how virtual ‘phenomena’ like “dying” are translated into programmable actions (like “disappearing”)?

We have engaged in two types of studies to investigate children’s understandings of rules: i. extended case studies tracing the evolution of both games and the children’s understandings of the rules (see Goldstein & Pratt, submitted); ii. clinical task-based interviews which probe how children think about rules (in this case, conditions and actions), and the extent to which the expression and application of rules are mediated by the tools available (as well as what light this may throw on existing developmental sequences). The clinical interviews were based around tightly controlled, pre-designed tasks with specific aims (in contrast with the largely exploratory and open computer activities that characterised the case-study work). As well as interacting with the computer, the children, working individually or in pairs, completed worksheets. A researcher, who made metacognitive prompts to probe descriptions, predictions, and expectations, was present with each pair. All the interviews were audio-taped and transcribed. We report on one of the task-based interviews which we conducted with 9 children aged 7/8 years. The interviews took about one hour.

A Task-based Interview: The Cat and the Milk

The aim of the task was to probe children’s thinking while programming a simple rule that involved a sequence of condition and action, ‘if touching a particular object then do something’. The first part of the task involved constructing a rule with a warrant between a condition and action that had a common-sense explanation (“if a cat touches the milk it meows”) followed by an application in a less realistic setting.

The children were given the scenario illustrated in Figure 1, in which the cat had already been programmed so that it could be moved about with the mouse. In ToonTalk, this means that a robot had been trained to move with the mouse and placed on the back of the cat. This piece of pre-written ‘code’ we call a behaviour: it can be saved on its own but is also transferable to any object, to make it move.
similarly. The children's task was to program a robot (to put on the back of the cat) so that if the cat touched the milk carton it would meow. After this, we wanted the 'move with mouse' behaviour to be transferred to the milk carton, so it could be moved (a fantasy element) while leaving the meowing behaviour on the cat.

The researcher's role was to ask the children to describe what they observed on the screen, to explain what was happening and to predict what would happen after programming the new rule. The following prompts were used as guides:

<table>
<thead>
<tr>
<th>Description/explanation.</th>
<th>Imagine you have to describe what is going on the screen to a friend who cannot see it: What can you see? What is happening? Why is it happening?</th>
</tr>
</thead>
<tbody>
<tr>
<td>Build the rule and describe it.</td>
<td>What can you see? Is it working? What does it do? (so a friend can know)</td>
</tr>
<tr>
<td>Add rule and predict what will happen.</td>
<td>What will happen? When will it happen? Why will it happen?</td>
</tr>
<tr>
<td>Use rules/behaviours in other contexts</td>
<td>What will happen? When will it happen? Why will it happen?</td>
</tr>
</tbody>
</table>

Specifically, the researcher asked the following questions:

After playing with the cat: "Why can you move the cat about?" (explanation)
After training the robot: "Describe what it would do" (description)
After putting the behaviour on the back of the cat: "Do you think the cat is going to meow or not when it touches the milk?" (prediction)
After trying out the new rule: "What is happening (when they move the cat)? Why?" (explanation)
After taking the move behaviour from the cat and giving it to the milk: "What do you think will happen when the milk touches the cat?" (prediction)
After testing it out: "What is happening? Why?" (explanation)

**Analysis**

After the data was transcribed, we grouped the children's explanations of causality into two general categories. The categories were devised partly from theory (see Donaldson, 1986), but also as a result of a pilot study conducted in 1999.

**Category A: Student-centred explanations**

A1. Real World (Physical laws): using analogies of everyday events or real events, "it does that as it is a ball and balls bounce."

A2. Intentional World (Psychological laws): giving the characters motivations and intentions, "cats hate meat so they growl."

A3. Fantasy (Personal Imagination):

   i. shared narrative about the game, "the witch casts a spell on you so you die."

   ii. idiosyncratic.
Category B: Formal computer-centred explanations

These include explanations by reference to the logic of the system or according to the inevitable outcomes from programming. It is possible, however, to distinguish these explanations along a general-specific dimension:

B1. Explanations derived from prior knowledge of general computer systems.

B2. Explanations derived from knowledge of computer games.

B3. Explanations derived from general features of the Playground environment: “there is a behaviour on the back of the bear”

B4. Explanations derived from specific aspects of the programming environment: “the rule is programmed so the robot plays a sound when the bear is touching the cheese”.

Results

We present the main types of response to each of the questions and illustrate them with quotes from the children. We also annotate each type of response with a conjecture which is informing our current observations.

Explaining what was observed on the screen: After experimenting with the scene, all the children were asked, “Why do you think the cat is moving?” Four children responded in a way that could be categorised as formal, but general since in ToonTalk all objects are moved by a virtual hand (B3). An example is:

I: Why can you move the cat about?
Joe: Because that’s the main thing really.
I: What do you think makes it move?
Joe: Your hand.
I: What makes him move up then?
Joe indicates the mouse.

Another example from Hazel:

I: Why do you think the cat can move?
Hazel: Because you’re moving the mouse so it moves the cat as well.
But the fact that neither chose to talk specifically about the behaviours on the back of the cat that made it move, maybe explains their later ‘psychological’ (A2) as opposed to ‘formal’ responses, for example:

I: Why can you move the cat about?
Joe: Because it’s a creature.
In contrast, the responses of five of the children were categorised as formal/specific; they clearly made the connection between actions on the screen with programmed behaviours.

I: Why do you think the cat is moving?
Sophie: Maybe she already has the behaviour.
However, it was only on inspecting the behaviour in the course of the interview that most children were able to appreciate the mechanism involved. For example, having looked at the back of the cat, Sophie was more specific in her explanation:

_Sophie:_ 'Cos it's got that behaviour 'I move with mouse'.

**Conjecture 1:** Children need to link observations with behaviours as a first step to explaining the outcomes of the rules they have observed.

**Describing a new rule:** After the children had trained a robot to instantiate the rule, 'if touch milk, then meow', we asked them to label the robot so another child would know what it did.

Four children omitted the condition in their descriptions, as illustrated by:

_I:_ First we have to type a label that describes what it does.
_Alice:_ Meows!
_I:_ Jane, is that what you want?
_Jane:_ Meow!

Three children were unsure what to write and wanted to add comments like "this is a fantastic game", while the remaining two wrote complete descriptions. When the behaviour or rule was 'contextualised' by putting it in the back of the cat, _all_ the children correctly described it verbally e.g:

_I:_ If somebody ... found your cat, how would you describe it?
_Sophie:_ It meows when... um... it touches the milk carton...

However, when _writing_ a description, their labels varied from uninformative "Fofo" (2 children), to action-only "Meows" (3), to explicit/complete but contextualised, "When the cat touches the milk it meows" (2) to decontextualised and complete, "It meows when it touches the milk." (2). These disparities between what children programmed, what they said and what they wrote, was characteristic of other rule descriptions.

**Conjecture 2:** Children are better able to articulate explicitly all the parts of a rule when it is programmed, and/or contextualised in a realistic situation, but the completeness of their expression varies with the medium.

**Predicting the consequences of a rule as programmed:** We asked the children to predict what would happen when the cat with its new behaviour was moved about the screen. Six children predicted correctly: e.g.

_I:_ Before we play the game, when you move the cat around, what do you think will happen?
_Sophie:_ When it touches the milk carton it's going to make a cat noise.
_I:_ And when it touches the cake, what will it do?
_Sophie:_ Nothing.
_I:_ Try it and see... why is that, by the way?
_Sophie:_ Because we've made a behaviour about the milk carton and not the cake.
Strangely, even after constructing their program and giving it the cat, the others were unable to predict what would happen with any confidence.

I: Now, without you having to press the space bar or do anything, do you think the cat is going to go meow when it touches the milk?
Hazel: No!
I: No, why not?
Hazel: Maybe we have to do a bit more stuff to get it to do it. [...]
I: Do you think that cat is going to meow when it touches the milk?
Both: No!
I: Why not?
Joe: Because we haven't ... we've done something wrong.

Conjecture 3: Even after having constructed a rule explicitly and articulated it in natural language, children may be unsure of its consequences; that is not appreciate its inevitability.

Predicting the implied consequences: We then asked the children to put the ‘move behaviour’ on the back of the milk carton (instead of the cat) and predict if they will hear the meow sound when the milk touches the cat. All of the children were either completely certain this would not happen, or were very unsure about it:

I: If you move the milk so that it touches the cat, will you hear a meow sound?
Hazel: No, because we haven't told it to do that.
I: We haven't told what to do what?
Hazel: We haven't told the milk . . . when it touches the cat, say the milk runs around, we haven't told it that when it catches the milk [cat? CH] it says meow.
I: We haven't told the milk that when it touches . . .
Hazel: We haven't flipped the milk over and when, so we haven't wrote when you touch the cat it will say meow.

It seems that the implications of the rule (that is, the symmetry of the formal relation of touching) did not ‘transfer’ to an unfamiliar situation of milk moving.

Conjecture 4: Programming the rule correctly and seeing its consequences, does not necessarily lead to a formal understanding of all the rule’s implications.

Explaining what was observed on the screen: After seeing what actually happened and hearing the meow when the milk was moved to the cat, all the children began to appreciate the symmetrical nature of touching, albeit often with an element of psychological causality:

Jane: I know why. 'cos the cat is touching the milk, and the milk is touching the cat.
I: When you move that milk to the cat, what happens?
Jane: Meowing.
I: Now, who's meowing?
Jane: The cat.
I: Why does the cat meow?
Jane: Because he likes the milk!

PME25  2001
Conjecture 5: Playing with the rule and observing its implications, begins the process of appreciating the logic of the implied consequences of a new rule.

Conclusions
Overall when the mechanism of the behaviour is articulated and ‘connected’ to an object, children are better able to explain and predict what is happening in their game and come up with a rich mix of formal, narrative and psychological explanations. Yet even if children program a rule correctly, they may not express it completely in spoken or written language, especially in a decontextualised form. More interestingly, children may not predict the implied consequences of a formal rule they have programmed, particularly when the narrative does not ‘make sense’. This suggests that the formal means of expression may not yet be fully integrated with verbal and written articulations. We have noticed that with more experience, children are able to integrate their various descriptions and to make simultaneous and multiple interpretations of what is going on – in terms of the narrative requirements of the game (the cat needs the milk to be healthy) and the formal requirements of the rules they program into the game.

3 We should note here that there are many facets to a game other than rules, which are just as important in game construction and play, namely constraints, descriptive and declarative aspects.
4 We recognise here that there may well be an element here of lacking confidence in their programming skills.
Investigating of The Influence of Verbal Interaction And Real-World Settings In Children’s Problem-Solving And Analogical Transfer

Hsin-Mei E. Huang  Department of Elementary education, Taipei Municipal Teachers College, Taiwan, R.O.C. edith131@ms47.hinet.net

Abstract
Eighty fourth-grade children in mixed-ability dyads were randomly assigned to four experimental conditions: with and without real-world settings and verbal interaction with peers. Dyads of children were asked to solve two daily mathematical problems in the first phase. Three weeks later children solved three daily mathematical problems as delayed transfer tasks after completed the first tasks. The results show that verbal interaction accompanied with real-world settings situation is the most effective way to improve children’s performance in problem-solving. Either verbal interaction or real-world settings helps children’s analogical transfer rather than solving problems individually without any real-world settings. Moreover, children tend to mix addition, multiplication and counting to solve problems through verbal interaction with peers and tasks.

Introduction and theoretical Framework
It’s plausible that a stronger connection between school mathematics and everyday mathematics will enhance mathematical competencies and learning (Streefland,1991). Therefore, one of the focal points within problem-solving research is the impact of real-world settings and how children apply their skills and knowledge through verbal interaction with peers to find respective answers in solving everyday mathematical problems.

According to Piaget’s theory, the young children are constantly experimenting with objects, language and situations to understand more about the world (Rogoff, 1990). A child is supposed to be an active experimenter who discovers facts and relationships when s/he is presented with materials and situations that encourage the design of his own experiments. This will in turn lead to deeper and more long-lasting knowledge than will a rote memorization of facts presented by teachers or in textbooks. Furthermore, everyday mathematics should be thought of as a process of knowing in which the same activity (arithmetic) takes different forms across situations and occasions (Lave, 1988). Thus the practices and the problem context in which people engage are supposed to be important for problem solvers, especially for the young learners.

The goal of making mathematics meaningful to students is to connect their everyday life understanding, in particular where arithmetic is concerned, to formal learning (Freudenthal, 1991; Streefland,1991). Strategies and patterns of problem-solving, initially are supported by situations and contexts, which in the long run are
superseded by abstractions. Therefore, even though the practices and contexts of everyday mathematics differs from contexts of school mathematics, it is expected that students are able to transfer their mathematical competence in everyday context to do similar arithmetic in school or test contexts. Empirical studies have found that people can carry out new procedures or solve novel problems that are quite similar to those on which they had previously learned (Vousniado & Ortony, 1989). This study will explore the effects of real-world settings on children solving problems and applying their knowledge from a previous setting to novel and formal mathematical problems.

According to a number of models in cognitive science, cooperative verbal interaction with peers is a fundamental component in cognitive processes that operates at a deep level of conceptual understanding, for instance analogical reasoning in solving mathematical problems (e.g., Huang, 1997), as well as mathematical operations skills and application skills (e.g., Fuchs, Fuchs, Bentz, Phillips & Hamlett, 1994). From the social cognitive point of view, when students interact with their peers, they are exposed to new strategies, terminology and ways of thinking about problems, which may in turn affect their problem-solving behavior. For children as well as for their social partners, engagement in shared thinking yields the opportunities for development of greater skill and understanding (Rogoff, 1990).

Although some research found inconsistencies and contradict challenges in peer verbal interaction (e.g., Orsolini & Pontecorvo, 1992; Webb, 1989), the usual findings from empirical support for the premise is that one-to-one discussion environments might remove many of the barriers that prevent students from asking questions and learning actively (e.g., Fuchs et al., 1994; Fuchs, Fuchs, Hamlett, Phillips, Karns, & Dutka, 1997). Studies showing positive interactions and learning between high- and low-achieving classmates have incorporated thorough training in how to interact constructively (e.g., Fuchs et al., 1994; Fuchs et al., 1997; Graesser & Person, 1994). Therefore, casing this study within the context of same-age, good-and-poor dyads, the researcher expected to examine the effect on cooperative verbal interaction in dyads accompanied with/without real-world settings in solving daily mathematical problems and delayed transfer tasks.

The purpose of this study is to examine how verbal interaction and real-world settings affect children’s skills in solving daily mathematical problems and analogical transfer. Children’s strategies in solving multiplicative problems through verbal interaction with peers and tasks were also analyzed. In light of previous work on the importance of verbal interaction and real-world settings, the hypothesis supposes that either verbal interaction or real-world settings would significantly
influence children problem-solving as opposed to solving problems individually without verbal interaction and real-world settings. Furthermore, the other hypothesis is that there is an interactive relationship between problems-solving conditions and solvers.

**Method**

*Subjects.* Eighty fourth grade children participated in this experiment. They were selected randomly from a public school in Taipei city, Taiwan. Subjects had been taught and had experience in verbal interaction and problem solving with small groups cooperatively in daily mathematics courses. All subjects worked in mixed-ability pairs. Therefore, good and poor solvers in this study were determined based on the mean of subjects’ achievement in the previous semester’s mathematics course. If a subject’s score was higher than or equal to the mean score, s/he was defined as a good solver. If a subject’s mathematics achievement score was lower than mean score, s/he was defined as a poor solver.

*Design of the study.* There were two problem-solving phases included in this study. The first phase was focused on dyads of children in solving two multiplication problems. The second phase was focused on children’s transfer of learning in solving three novel multiplicative problems. The contexts of problems designed in this study were derived from children’s daily life and Taiwanese society. The item difficulty index and item discrimination index of the five problems had been tested from 97 forth grade students. They were randomly selected from a public elementary school in Taipei, Taiwan. The values of item difficulty index of these five problems were from .39 to .50. The values of item discrimination index of these five problems were from .58 to .96. The idea of problem settings and arithmetical structures of these problems are referred to the research of Franke (1998) and Ruwisch (1998). The mathematical structures contents of the five problems are listed on Table 1. The design, materials and procedures in two phases are illustrated as follows.

A. *The first problem-solving phase.* 1. Task problems. Two multiplicative problem-solving settings were provided. In the first problem setting, called “Class Camping”, the children were required to buy items for a camping trip with 30 classmates. In the second situation, called “Lantern Festival”, children were required to buy colored envelopes for pasting on three different sizes of posters for Lantern Festival. Children had to determine the number of packages of items needed for solving these two tasks and write down their answers on shopping lists. Both “Class Camping” and “Lantern Festival” problems have similar arithmetical structures but differing in contexts. The underlying mathematical contents of “Class camping” and “Lantern Festival” are numbers and area, respectively. 2. Experimental conditions. The problem-solving situations were designed differently.
shows, three problems in delayed transfer tasks have similar structural features but differing in superficial features.

C. Evaluation. Multiple evaluations (on a scale of 0-5) of written responses of each problem item were used. If a subject wrote the solutions on the shopping lists correctly, s/he was given a full score of 5 on each item.

Results

Table 2 shows the summaries of means and standard deviations of four experimental conditions in two problem-solving phases. A one between-subjects ANOVA indicated group comparison on performance. The results revealed that the difference among four conditions was significant, $F(3,76)=7.02$, $p<.001$. The Tukey posteriori comparison analysis among the four experimental conditions suggested that there was a significant difference between I&D and I&ND, as well as I&D and NI&ND. There was no difference among I&ND, NI&D and NI&ND. The hypothesis is partially supported by the results. It suggests that cooperative verbal interaction with peers accompanied with real-world settings simultaneous would significantly improve children's performance in solving daily mathematical problems.

In terms of analyzing good and poor solvers of the four experimental conditions in solving transfer task problems, the data was analyzed with a two (good Vs. poor solvers) and four (four experimental conditions) ANOVA. The results indicated that the significant interaction effect was not found with $F(3,72)=2.56$, $p<.06$. The hypothesis is not supported by the results. However, a significant main effect of experimental conditions was found with $F(3,72)=7.77$, $p<.001$. The results of follow up analysis and the Tukey posteriori comparison analysis for the four experimental conditions suggested children in I&D, I&ND, and NI&D conditions outperformed those in the NI&ND condition. Moreover, there was significant difference between good and poor solvers with $F(1,72)=37.30$, $p<.001$. As shown in Table 3, good solvers
demonstrated better analogical transfer performance than did poor ones.

Children's verbal interaction with peers in the discussion groups (I&D and NI&D) when they solved the "Class Camping" and "Lantern Festival" problems were collected and analyzed. Children's strategies used in solving problems were transcribed from videotapes and audio tapes. Two raters categorized children's problem solving strategies from the transcripts. The consistency between the two raters with the result of Kappa analysis was .57, p<.001. Table 4 shows the types of children's strategies in solving multiplicative problems.

Ten kinds of strategies were categorized from the children's peer interaction. Children's strategies used in solving daily mathematical problems are as follows: 1. Computation using multiplication and division directly. Around 34.6% of the children determined the multiplier then applied multiplication algorithm as well as applied division directly to obtain the quotient. 2. Computation using addition and multiplication. About 3.8% of the children determined the needed amount and applied multiplicative facts and then added up the products. 3. Computation using multiplication and subtraction. About 11.5% of the children applied multiplicative facts to get the product then used the product to subtract the known number. 4. Computation using addition, subtraction and multiplication. Around 2.6% of the children used composite units in repeated addition and used multiplication partially, and then used the known quantity to subtract. 5. Computation using addition, subtraction, multiplication and division. About 2.6% of the children used the mixed computation. 6. Applying counting, addition and multiplication. About 25.6% of the children used skip counting by threes, twos or ones to determine the needed amount. 7. Repeated addition. About 14.1% of the children used a specific number as a unit to add up the numbers until the needed amount. 8. Counting by ones or twos. About 2.6% of the children accomplished computation by counting. 9. Children drew units or drew using a ruler on the given posters then counted the total squares to get the number of items needed. About 1.3% of the children used
this strategy. 10. Calculation in head. About 1.3% of the children did not show any
arithmetical strategies but stated the answer directly.

Discussion & Implication

Findings in this study clearly support the superiority of verbal interaction
accompanied with real-world settings for children working on solving mathematics
problems and analogical transfer. If either verbal interaction or real-world settings
are provided separately, it is not sufficient to improve the children’s performances
particularly on their first time solving a specific problem. This may have been due to
two reasons. First, a constructive discussion in the process of problem-solving was
not found in all dyads. This was concluded from observation of peer discussion
during problem solving. Some good solvers tended to solve problems on their own
without verbal interaction with poor partners. On the other hand, several poor
solvers tended to rely on their partners’ explanation without questioning and
analyzing. Second, children in the four conditions were able to deal with the items
that represented figures shown on worksheets. Consequently, the effect of real-world
settings did not significantly improve the children’s performances. Although it was
shown that the lack of either verbal interaction or real-world settings is sufficient to
improve the children’s performances on first time problem-solving, it did reveal
quite a significant improvement on children’s transfer performances.

With respect to the good/poor contrasts, the findings demonstrate the accuracy
of transfer problem-solving was higher for good solvers rather than poor solvers.
The good solvers seem to provide more procedural explanation, demonstration or
checked work. Such instructional style is similar to tutoring and would in turn
promote solvers’ performances (Fuchs et al., 1994; Fuchs et al., 1997; Graesser &
Person, 1994) as appeared in transfer superiority. It is possible that poor solvers
tend to watch and listen to their partners with little opportunity to analyze and apply
their partners’ explanations. When comparing a good solver’s in-depth learning with
a poor solver’s passive learning, it is not surprising to find that the poor solver’s
performance is inferior to the good one’s.

In terms of the strategies applied in solving multiplicative problems, children
seem to tend to mix addition, multiplication and counting to solve problems. A lot of
fourth grade children might have been aware of the commutative principle of
multiplication and the inverse relationship between multiplication and division.
Some children counted each item one by one instead of count in multiples. Such
perceptual counting is also found in lower graders (e.g., Franke, 1998; Ruwisch,
1998)

Results of this study suggest possibilities for improving children’s problem
solving. Effective training of peer tutoring and conceptual explanation during
for each of the four experimental conditions. Subjects in dyads were assigned to the four conditions randomly. All subjects were provided with written and oral descriptions of the problems when they came in the experimental condition. The four experimental conditions are illustrated as follows. i. Items and Discussion (I&D): Children (n=20) were provided with real-world items and were encouraged to discuss with peers and work cooperatively. Children discussed cooperatively the purchase of the items in a fictitious store. ii. Items and No Discussion (I&ND): Children (n=20) were provided with real-world items but were not permitted to discuss with their peers. Children determined individually how to purchase the items in a fictitious store. iii. No Items and Discussion (NI&D): Children (n=20) were encouraged to discuss with their peers and work cooperatively without any real-world items. iv. No Items and No Discussion (NI&ND): Children (n=20) individually determined how to purchase the items according to the problems shown in the task without any real-world items and peer discussion. Videotapes and recorders were used to gather children’s verbal interaction during solving problems. Analysis of variance indicated that the subjects’ previous math achievement in the four conditions was not significantly different before the actual experiment began $F_{(3,76)}=.07, p>.05$.

B. The delayed transfer problem-solving phase. Three word problems were presented on worksheets as delayed transfer tasks and were tested three weeks later after children completed the first phase of problem-solving tasks. As Table 1
solving mathematical problems (e.g., Fuchs et al., 1994; Graesser & Person, 1994) are needed for increasing children's abilities to provide complete explanations and work in constructive, interactive fashion during instruction.

Reference
This study analysed the language of three boys, aged 5, who were engaged in play that was judged to have a high degree of mathematical content. The boys were selected because of the diversity of their language. One was relatively taciturn, one used a great deal of language but of limited complexity, and one used complex language that appeared to describe and lead his thought and that of others. Analysis suggests that the last of these three has the skills to succeed at school while the other two will need help in expanding their language to describe and advance their concepts.

Introduction

Students' ability to discuss mathematical activities and express mathematical thinking is crucial in current methods for teaching and learning mathematics. Teachers rely on children’s language to decipher their thought so that mathematics instruction can be built upon the children’s existing. Teachers must pay attention to children's conversations (e.g., Gooding & Stacey, 1993; Solomon & Nimerovsky, 1999), their answers to tasks set by teachers (e.g., Brodie, 1999), and their self-talk. Yet there is considerable variation in the specificity with which different students discuss their mathematical activity. Gooding and Stacey explored the nature of discussion in groups of 10 and 11 year-old students who did or did not gain in understanding in cooperative problem solving. The unsuccessful groups talked less than did the successful groups and used a smaller proportion of explanations. Unsuccessful groups used hardly any explicit mathematical discussion while successful groups named and discussed key mathematical aspects of their problems.

While teachers at all levels of school need to understand children’s thinking, teachers in children’s first year of school may have the most difficulty in coming to an understanding of what their students know. It is hard for these teachers to make appropriate judgements because many students do not use the same terms as their
teachers do, may use the same terms in different ways, or may be unable or unwilling to talk about what they know.

One guide to young children's concepts can be found in observing their play. A study by Ginsburg and colleagues (Ginsburg, Inoue & Seo, 1999) has demonstrated that mathematical thinking can be identified in a large portion of the play of 4- and 5-year-old children. Although this is important information, teachers have little time for an extensive analysis of individual children's play, and are generally dependent on children's language to understand their concepts.

The study by Ginsburg and colleagues involved an intensive analysis of the play of 80 children who were from lower, middle and high-income families in New York City and who attended pre-school facilities. The investigators videotaped individual children for 15 minutes during times designated as free play. Then each 1-minute period of these videotapes was coded for the presence of five mathematical concepts: magnitude comparison, enumeration, pattern and shape, spatial relations, and dynamics. Overall, these mathematical concepts appeared in about 45% of the 1-minute episodes. This was true for children from lower income, middle income and upper-income homes. Play with blocks, Lego™, or jigsaw puzzles was found to be particularly rich in mathematical concepts.

When these children were interviewed about addition and subtraction, differences in performance and underlying concepts were seen among children from different economic backgrounds (Ginsburg, Pappas & Seo, in press). In general, the upper income children showed a somewhat higher level of mathematical thinking and metacognition. This may have been related to their use of language.

The case studies reported here are an early step in a wider analysis of the ways in which children from this study use language in the course of their mathematical play. Understanding the nature and uses of language in free play may help teachers gain insight into children's mathematical thinking, foster their language development, and encourage language use in mathematics instruction.

In examining children's mathematical language, we considered the views of both Piaget and the Vygotsky. On the one hand, there is evidence (e.g., Jordan,
Huttenlocher, & Levine, 1994) that children often have mathematical competencies they cannot express in words. As Piaget maintained, there is a sense in which thought precedes language. At the same time, Vygotsky (1978) discusses two ways in which language may facilitate intellectual growth: intrapersonal speech in which children use language to plan a solution or to control behavior, and interpersonal language to share ideas and to stimulate development, as when a more competent peer provides assistance in the zone of proximal development. In this study, we considered both Piaget and Vygotsky’s perspectives. One purpose of this analysis was to see if patterns of language use could be seen that would form the basis for analysis of the rest of the sample and thus provide recommendations for teaching.

Case studies

Three boys, aged 5, were selected for exploration of mathematical language employed in free play. They were selected because they all demonstrated a high level of mathematical concepts in their play, but differed in their language. They were: (1) Nigel, an African American who was building a “roller coaster”, (2) Franco, an Hispanic American who was building a robot and then a tower with Lego, and (3) Isaac, a European American who was helping to make a large jigsaw puzzle of a train. All spoke English. Franco’s family spoke Spanish at home.

Table 1 shows the mathematical codes assigned to each minute of play observed for these three boys. Mathematics was coded in five categories: Magnitude Comparison (MC), Enumeration (EN), Pattern and Shape (PS), Spatial Relations (SR) and Dynamic or exploring the process of change (DY). Where more than one code is given, the first code is the one that was judged to dominate that episode. These codes are based on observations of behaviour and do not necessarily imply that any language was employed.

Nigel and Isaac were coded as engaging in play with a mathematical content in 14 of the 15 one-minute periods (93%), and Franco was coded in engaging in mathematical play in all of the 15 minutes coded (100%).

Nigel was relatively taciturn in this episode. He spoke in only 7 of the 15 minute intervals, making a total of 14 intelligible utterances. Six (42%) of these utterances were judged to have a mathematical content. Each utterance identified as mathematical related to the type of block he needed or had found. Examples included "There it is, two" (judged to be self-talk, as no one else was in the vicinity, and enumeration) and "Gimme one of these blocks" (instruction to another boy, enumeration). His longest utterance involved a complaint to the teacher that someone had upset his structure: "Ms M, look what he's done. You've broke my roller coaster, I don't like it."

Franco was talkative, and spoke in all of the minute episodes, making a total of 47 utterances, 18 (38%) of which were judged to have mathematical content (one containing two categories). A feature of his utterances was that he used many non-specific terms to accompany his play. For example while talking about adding blocks to parts of his structure he said, "R, Lookit, I did it over there and I put over there and I put over there." He was employing concepts of position, but could not be understood by someone who was not present. Most of his utterances related to his building but he also exchanged comments about his father's bicycle and sharing. Most of his comments drew attention to his activity or structure. The following utterances came
from minutes 14 and 15. Codes are given beside each utterance considered mathematical, to give a picture of the analysis.

“Long bigger, long bigger, long bigger” (while building his tower) [Description, MC]

“I still more bigger, I still more bigger” (comparing his tower with R’s) [Description, MC]

“I put mine bigger. You see, I told you” [Description, MC]

“Wanna see mine is bigger?” (to R) [Question MC]

“No Matthew had it first.” (claiming a block for M)

“No, no Matthew, we are making robots. I’m show you. Put yours next to mine” (persuading M to join his Lego with his) [Instruction, SR]

“Look Matthew, it’s long bigger” (showing the taller tower to M) [Description, MC]

Isaac was also talkative. He spoke in all of the 15 minute sessions, making a total of 61 utterances, 22 (36%) of which had mathematical content. When not commenting on the task, he sang, discussed a television cartoon, or made noises into the microphone. While Nigel’s utterances tended to be the minimum that would get what he wanted, Isaac’s were more complex, expanding ideas from one sentence to the following one. His self-talk included both repetition of a previous statement, “We have to take it apart and build it all over again”, and reading aloud from the box “Over five feet long, thirty-eight [pieces], age four and up. Wow!” The following sample is from minute 1 of his transcript.

“Guess we need a little help. Excuse me. Are we making pieces? I don’t know. Are we making any pieces?” (watching 3 children working on a puzzle)

“Okay, that goes in the caboose” (has joined in working on the puzzle) [Instruction SR]

“And the caboose is in the back.” [Description SR]

“We’re making a real big train, just like a real train actually.” (taking more pieces from the box) [Description MC]

“Looks like a real olden-day train. This looks like a real olden day train, for good”
(singing) “just like I love you...this goes away”

Judgements were made on what would be considered emergent mathematical language. For example, “one” could be classified as a pronoun or enumeration depending on the context. Time sequences were not classified, nor were iterations or the concept of ‘broken’ which could be a precursor to part-whole, although an argument could be made for including all of these as early stages of mathematical language. Mathematical language was classified by its function, as self-talk, instruction, questions, or comments. Table 2 gives the number of utterances with a mathematical content by function and mathematical code.

**Interpretation**

The number of episodes of play considered mathematical was similar for these boys, as was the proportion of their utterances judged to have a mathematical content. The differences noted were qualitative. There was a marked difference in the variety of mathematical contexts that the boys spoke about and in the complexity of the structure of their language.

Nigel’s limited use of language is interesting in itself, although it makes it difficult to judge his competence. His play covered three spheres of early mathematics, and he used language for two of these. His limited language did include evidence of specific nouns, modifiers, and logical connection between sentences in an utterances not...
classified as mathematical, that in which he complained to his teacher about someone breaking his roller coaster. However, his limited use of language, if typical, could make him like the students in Gooding and Stacey’s groups who did not learn in cooperative groups.

Franco was not fully fluent in English. His play was very rich in early mathematical concepts, with a greater number of mathematical episodes being identified than for the other boys. While his play in this episode covered four categories of mathematical ideas, he used language to describe only two of these. The fact that he talked a lot is likely to be an advantage, as he was practicing putting the process of comparison into words. In this episode he showed a limited vocabulary for mathematical concepts, using pronouns for both processes and objects. While all three boys used pronouns when the object of their play was self evident, the other two also used nouns and modifiers. Franco only occasionally used a noun and used no modifiers. He used no words to describe either dynamic changes or pattern and shape.

Isaac’s play covered four mathematical categories, and he used language for all of them. This sample gives many examples of his analytic thought. His sentences showed continuation of ideas that became more specific in succeeding utterances. The nature of his self-talk suggests that he will continue to generate ideas, so that his concepts grow with minimal external influence.

The language of three boys gives us initial insights that will be explored further with the full data. It appeared that descriptive language supported thinking for all three boys and, in Isaac’s case, questions and instructions led both his activity and possibly thinking for him and for others. Nigel and Franco demonstrated more concepts than they talked about and there was less evidence that it led their activity. Although two boys used some self talk, it is difficult to judge the extent to which this may have led thinking.

The presence or absence of attributes that Gooding and Stacey found in the conversations of successful groups indicates the relevance of these factors in the language of young children. Studies of functional grammar suggest that the analytic nature and logical connectedness of language is the aspect that enables students to be
successful in classroom discourse. The size of vocabulary is known to be a good predictor of success in school, and this is likely to be true in mathematics as well. All of these are factors that can be fostered in good teaching. We know that all of these boys exhibit mathematical concepts in their everyday behavior and it is important for teachers to be aware of what they know. Two of them are likely to need more help in using words to describe mathematical objects and activities and ask relevant questions.

UNIVERSITY MATHEMATICS TEACHING – WHERE IS THE CHALLENGE?
Barbara Jaworski – University of Oxford

Data from university mathematics tutorials were analysed on characteristics of teaching using a construct 'the teaching triad', derived from analyses of secondary mathematics teaching. Elements of 'management of learning', 'sensitivity to students' (from both affective and cognitive perspectives) and 'mathematical challenge' were sought and rationalised with earlier manifestations of these elements. Meanings were derived which made sense in the university context, taking into account the particular culture of university mathematics teaching and expectations of tutors and students. Whereas at first there seemed little challenge on which to remark, a reconceptualisation of challenge allowed an alternative perspective to be offered. The paper reports on this perspective and looks critically at processes and strategies in teaching mathematics at this level.

Ways in which teachers offer and enable students to tackle appropriate challenges are important to students' engagement with mathematics and their development of mathematical concepts. Teachers' sensitivity to students' affective and cognitive needs is seen to be closely related to the effective nature of challenge.

The research reported here involves an analysis of tutorial teaching from a project – called the Undergraduate Mathematics Teaching Project (UMTP) - designed to characterise university mathematics teaching in first year tutorials. Analysis has been done using the teaching triad, a construct deriving from earlier research into classroom mathematics teaching at secondary level (Jaworski, 1994) and used, subsequently, as a device to analyse teaching and as a developmental tool by teachers (Note 1). The triad has also been used to analyse the activity of mathematics teacher-educators in the professional development of mathematics teachers (Zaslavsky & Leikin, 1999)

Theoretical Background

The UMTP was rooted in theory relating to mathematical learning at university level; in particular the difficulties experienced by students at this level (e.g. Tall, 1991; Nardi, 1996). It is distinct in its fine-grained focus on tutor-student interactions and tutors' expressed thinking relating to these interactions. It draws on previous research into secondary mathematics teaching, with a focus on teaching activity, its relationship with students’ mathematical activity, and the associated thinking of the teachers in their planning of interactions with students (Jaworski, 1994).

So, for example, research into university learning suggests that students have difficulty in conceptualising cosets of groups, and relating them to notions of conjugation in groups (e.g; Dubinsky et al, 1994; Burn, 1998). We have shown how one tutor struggled with his students' lack of understanding of these concepts, and ways in which he personally addressed them and constructed his teaching to

1 See Jaworski and Potari (1998), Potari and Jaworski, forthcoming
2 The research was funded by a grant from the Economic and Social Research Council (ESRC) number R 000 22 2688
It was conducted in collaboration with Elena Nardi (Univ. of East Anglia) and Stephen Hegedus (now Univ. of Massachusetts). See also Jaworski, Nardi and Hegedus, 1999; forthcoming; and Nardi, et al, forthcoming.
overcome them. As a result of such analyses, we were able to offer a number of indications for a theory of mathematics teaching at this level (Jaworski et al, forthcoming; Nardi et al, in preparation)

Current analysis of tutorial approaches is using the teaching triad with three inter-related elements: management of learning, sensitivity to students (from both affective and cognitive perspectives) and mathematical challenge. Briefly, ML describes the teacher's role in the constitution of the classroom learning environment. This includes classroom groupings; planning of tasks and activity; setting of norms and so on. SS describes the teacher's knowledge of students and attention to their needs; the ways in which the teacher interacts with individuals and guides group interactions. MC describes the challenges offered to students, to engender mathematical thinking and activity, in tasks set, questions posed and metacognitive encouragement. These domains are closely interlinked and interdependent. Analysis, reflexively, categorises tutorial data in relation to these elements and reassesses the meaning of the elements with respect to the data.

Methodology
The methodology of the UMTP was reported in detail in Jaworski et al (1999). Briefly, from interview data, factual summaries, or protocols, were constructed that were then analysed, using tested coding systems, for their teaching characteristics. Commonly occurring codes were inspected against key episodes from the data, selected for their significance by the researcher gathering the data. Sections of data highlighted by the codes were analysed in fine-grained detail to seek insights into teaching issues including teachers' decisions in conducting of tutorials and their relation to the particular mathematics that was the focus of observed tutorials (largely analysis and abstract algebra, with some topology and probability).

Subsequent analysis of tutorial data followed that of interview data, by a production of tutorial protocols: each a summary of the activity of the tutorial. Coding of these protocols, led to identification of (a) typical patterns of interactions; and (b) instances where activity or dialogue might be characterised by elements of the teaching triad. Particular episodes were identified to typify examples of (a) and (b) and these were studied in greater depth from the full tutorial text.

Typical patterns of interaction
The lecture-tutorial culture in mathematics in this university requires students to tackle problems set in a lecture and give written solutions to their tutor for comments. Tutors' marking of the solutions forms the basis of tutorial activity

In analysis of activity in tutorials, the codes, tutor explanation, tutor as expert, tutor questioning were abundant. Tutor explanation [TE] was usually a straightforward exposition of some aspect of mathematics. Tutor as expert [TEx] included the offering of key methods of solution, or proof, or mathematical tricks or routines that are perceived to be part of what one tutor expressed as the "mathematical armoury" that students need. Tutor questions were mainly of three types: enquiring about students' thinking or difficulties [QS]; specific mathematical questions relating to the
mathematics being addressed [QM]; and prompting or leading questions directed at filling gaps in an argument [QA]. The following episode represents these patterns. The codes are illustrated in the transcript, and used in the microanalysis of the episode in relation to the teaching triad. The mathematical focus is a question concerning the orders of elements of the group $A_4$. Students (two here) have shown difficulty in their solution to the question, and the tutor is highlighting aspects of the concepts that he perceives as important. Voices of the students are not distinct.

**Episode 1: Words from tutorial transcript**

1. T The first thing is what's the order of $A_4$? [QM]
2. S It's 12
3. T So if $H$ is a subgroup of $A_4$; - we quite often write $\leq$ to mean subgroup of [TEx] - if $H$ is a subgroup of $A_4$, then what can we say about the order of $H$? [QM]
   [Tutor writes as he talks. Students observe, listen and respond.]
4. S It must be a factor of 12
5. T Right, so what are they [QA]
6. S 1, 2, 3, 4, 6, 12
7. T And what result did you use to deduce that? [QS] Pause (10 secs) [Inaudible words omitted]
8. S Lagrange’s Theorem
9. T That's the one. So we now know what sizes to look for: 1 and 12 are dead easy. Right? Order 1, $H$ just has to be the identity. Order 12, it has to be all of $A_4$. Those are easy.
   [Students make ‘understanding’ noises: ah, mm]
   Order 2. A little while ago, you worked out that there was only one Cayley table for groups of order two. Another way to look at this is what orders of elements can you have? Well, in fact we’ve already proved this, haven’t we here? [Reference to an earlier question and solution] 2 is prime; a group of prime order must be cyclic, so any of these would have to be generated by an element of order 2, and any element of order 2 will generate one of these. So the subgroups of order 2 are precisely $e$ and an element of order two. [TE]
   Three. The same argument works. [A few inaudible words omitted here]
   Four Now what orders could elements have inside a group of order 4. [QM/A]
10. S 2, 1, 4
11. T Is there any element of $A_4$ of order 4? [QS] Pause (5 secs)
12. T No, there isn’t. They come in one of three types
   [Tutor continues with an explanation of subgroups of order 4, and moves on to subgroups of order 6. Student participation is of a similar degree to that recorded above.]
13. T So, there's no subgroup of order 6.
   The two reasons that this is interesting are that first of all you can have several subgroups of the same size; the other thing is there may be a size which by Lagrange’s theorem is allowed for a size of subgroup, but for which there is no subgroup. [TE] Neither of you wrote this but some other people did, they wrote, by Lagrange’s theorem there must be a subgroup of size n for every n that divides the order of the group. And that’s not true. Here was an example. Right. [TEx]

3 We might argue about distinctions between QM, QS, and QA; and between TE and TEx. It is hard to find clear distinguishing examples in one piece of dialogue. The insertion of the codes here is indicative only of their use and meaning.
A considerable part of tutorial activity can be characterised in the form exemplified above. Of course details change. Different bits of mathematics cause different problems for different students, and different tutors interact with their students in idiosyncratic ways. The pauses in the dialogue above are short compared to those of another tutor, who usually waits a much greater length of time (20-30 secs in some cases) for his students to say something; and much shorter than some tutors who wait hardly any time at all. “Answering own questions” is one coding category of tutor activity, in which a question is asked by the tutor, and almost immediately the tutor supplies the answer. It is a rhetorical form in which the question is an almost seamless part of tutor exposition of the concept. Tutors clearly want to offer their students good explanations of the mathematics they consider important.

After observing and recording this tutorial, the researcher interviewed the tutor, starting with a question about his tutorial agenda. The protocol reads as follows:

Researcher: You mark their work. How does this form your tutorial agenda?

Tutor: It tends to be that all of them have made the same mistakes, so it helps to form a scheme of help, e.g. noticing that they all believed the converse of Lagrange’s theorem to be true. Then, once this general scheme is formed, you have to tailor it individually, e.g. noticing that a particular student is writing left cosets for right and that gives her odd results.

[TEACH; REC STU PRO; KNOW STU]

The bracketed words, e.g., [TEACH; REC STU PRO; KNOW STU] are part of the coding system used to analyse interview protocols. They characterise the associated dialogue as being about planning for teaching, recognising students’ problems, and knowledge of students. These were some of the most commonly occurring codes in the analyses of interview protocols. They indicated common elements of tutors’ thinking about planning and teaching of tutorials. In this case, the teaching focus, on Lagrange’s theorem, is designed around students’ misconceptions of the truth of the converse of the theorem, and particular errors in tackling associated questions. Tutor’s knowledge of students’ particular needs comes from marking their work, and seeing them in tutorials. An important part of the coding of both interview protocols and tutorial protocols, is a rationalisation of the two, providing insights into how a tutor interprets his thinking about teaching into practice in the tutorial.

Characterising elements of activity or dialogue using the teaching triad.

The teaching triad arose from teaching that engaged students overtly in questioning and inquiry in mathematics (Jaworski, 1994). A teacher’s questions that challenged sensitively the particular thinking of a student were seen to be fruitful in enabling conceptual development. In micro-analysis, harmony between sensitivity and challenge was seen to be a characteristic of a successful teaching interaction. Micro-analyses were then scrutinised against a macro-analysis taking into account wider sociocultural issues of the learning environment (Potari and Jaworski, forthcoming).

In the episode above, at the micro level, management of learning, ML, is evident in the tutor’s recognition of difficulties and planning of the focus of the tutorial to address these difficulties [Interview protocol]. Sensitivity to students, SS, (influencing ML) is seen both at an affective level, basing the focus in aspects of
mathematics that are clearly relevant to students difficulties, and at a cognitive level, focusing on the example that will highlight clearly the concept that the tutor wants students to consider (converse of Lagrange’s theorem). The tutor’s questions invite student participation, but in some cases this is of a minimal degree [statements 2, 6, 10], and in others, students seem unable to respond. The tutor often waits for a response [7, 11] and sometimes supplies the answer himself [12]. The dialogue seems to encompass little mathematical challenge, MC. Largely, questions seek students’ knowledge of particular mathematical results and teacher exposition provides the substance of the interaction. Any challenge is left to the students themselves in making sense of concepts in their own personal study.

At a macro level, mathematical enculturation might be seen as a tacitly agreed basis of interaction. Students have met Lagrange’s Theorem – one of them is able to name it in response to a prompt from the tutor. However, it is important mathematically that they perceive the difference between theorem and converse, both in terms of Lagrange, but as a consideration in theorems more generally. The tutor’s choice of example might be seen as a clever management strategy, enabling students to perceive truth relations between a theorem and its converse. In this we might discern a (tacit) element of challenge. Students are being confronted with a challenge to their perceptions, and it is up to them to go away and make sense of it.

An alternative pattern of interaction

The episode that follows is chosen to show an approach that seems to incorporate challenge in a different form. Unusually the tutor here was also the lecturer of the Abstract Algebra course, so he had, himself, set the problems on which the students worked, including a question about quotient groups. In the lecture, a theorem had been proved and the lecturer had asked the student to prove for themselves its converse. This in itself is potentially a mathematical challenge for the students who tackle it. The tutor is working with two students, one of whom is ill (S1) and does not say much. The tutorial protocol and coding for the episode read:

**Tutorial Protocol**: Tutor asks S2 a question. S2 explains at the board. Tutor offers advice and asks questions when S2 gets stuck. S1 offers suggestions. When S2 has finished his proof, tutor explains a quicker method he [the tutor] would have used.

**Coding**: tutor questioning [QS/M/A]; student-led explanation [SE]; tutor-students interaction [TSI]; tutor as expert [TEx]; rapport between tutor and students [R].

**Episode 2: Words from Tutorial Transcript**

Conventions: () inaudible words omitted; ... repetitive or irrelevant words omitted. The episode transcribed here is 10 minutes of the tutorial.

1  T: You did the part of question 3 I did in lectures, but the part I left as an exercise, namely the converse, er, you forgot about (students laugh). [R]
One wants to show that for a congruence ... - well its an equivalence relation, - that satisfies \( g_1 \sim k_1 \) and \( g_2 \sim k_2 \Rightarrow g_1 g_2 k_1 k_2 \); and \( g \sim k \Rightarrow g^{-1} \sim k^{-1} \)
So its an equivalence relation that respects the group operations inversion and congruence ...
we’re told that H is a normal subgroup of G and we’re given this equivalence relation by \( g_1 \sim g_2 \) if and only if they represent the same coset. So lets try proving these two things.
Let's say we want \( g_1 g_2 = k_1 k_2 \) and this means saying that \( g_1 H = k_1 H \) and \( g_2 H = k_2 H \). Then this means saying that \( g_1 g_2 H = k_1 k_2 H \). [On board is also written \( g_1 g_2 \sim k_1 k_2 \).]

I said in lectures, although you may not remember, that the work had been done already because the quotient group is well defined, you can actually multiply cosets together in a well-defined fashion. ... Why do you think those cosets at the end are equal? 

2 S2: Well for the things we're getting at the top — from \( g_1 H = k_1 H \) [T: yes] you can say that, for any \( h \) in \( H \), \( g_1 h = \) [SE]

3 T: Go on, go for it [tutor invites him to the board. S2 writes, talking as he writes] [R]

(The next portion of the tape is hard to follow as symbols are being written (evidenced by noise of chalk on board) but not necessarily articulated. The researcher's fieldnotes (FN) help with what was written. Reconstruction is as faithful as possible under these circumstances.)

4 S2: If you've got \( h \) and \( l \) in \( H \), then this one tells us that \( g_1 h = k_1 l \) (pause for some \( l \) in \( H \) (S2 and tutor say this together) and same sort of thing for the twos, (he writes \( g_2 h = k_2 l \)) (pause) [SE]

5 T: call it \( h' \) and \( l' \), well, call it \( l' \), you might want the same \( h \) as () (pause) [TE]

6 S2: erm (pause)

7 T: well what's a general element of the left hand side downstairs look like? [QS]

8 S2: erm that's gonna be \( g_2 g_2 \) and that's the same \( h \) [chalk on board and inaudible speech:

FN suggest he writes \( g_1 g_2 h \) and wants to continue with \( k_1 k_2 \) ] [SE]

9 T: well, just expand - don't write \( k_1 k_2 \) now - keep expanding ...what you had there - so we can rewrite that can't we ... [TE]

10 S2: well \( g_1 \) and \( g_2 \) can be combined to another \( g \) [SE]

11 S1: Can't you write as something else, can't you say \( g_2 h = k_2 l' \) [SE]

12 T: Yes, go for that I'd say [R]

13 S2: Say that \( k_2 l' \) equals (pause, hesitancy) can you say from that one, that is equal to er (pause) \( k_1 \) (pause) before, that was only true cause that was in \( H \) [SE]

14 T: well you know now that

15 S2: [inaudible, but FN give us the following symbols: \( g_1 g_2 h = g_1 k_1 l' \)]

16 T: you haven't really written much up there yet that requires, uses, normality. The fact that \( e H \) is normal means that \( k_2 l' \) can be written in a different way. (Pause) [TE]

17 Together: T: \( k_2 l' \) S2: some other thing - \( k_1 \) T: \( k_2 \) S2: Yes.

18 T: OK, so its \( g_1 l'' \), let's say, \( k_2 \) -- and what is

19 S2: so that \( g_1 \) T: Yes S2: \( l'' \) from this Together: is \( k_1 h'' \)

20 T: \( k_2 \) and then that is equal to [TSI] [R]

21 S: erm, same sort of thing, because of normality we can say that this is something else

22 T: oh, yes, you, why not go the other way

23 S2: depends what we're aiming for

24 T: well exactly, we're aiming for a \( k_1 k_2 \), so why not instead swap them round [TSI]

25 Together: \( k_1 k_2 h''' \) OK [FN indicate that on the board now is the following:
You did the very hard work of essentially proving that multiplying cosets of a normal subgroup is well defined. I'd have been perfectly happy if you'd assumed that. [TEx] OK? So you've got that out, and that is absolutely fine, but, I'd have been happy with this: You've got two cosets — that coset's the same as that, that coset's the same as that; so $g_1 H g_2 H = k_1 k_2 H$, and these cosets multiply to give that $[g_1 H]$ and these cosets multiply to give that $[k_1 k_2 H]$ [i.e. $g_2 H = k_1 k_2 H$] and that's all I was expecting. [TE]

In the same way suppose $g=k$ and $g=g_2 h$, so they have the same inverse in the quotient group and what is the inverse of this, we know it is represented by the inverse of the representatives [FN: writes $(gH)^{-1} = (kH)^{-1} g^{-1} H = k^{-1} H$ $g^{-1} = k^{-1}$] so that would have done. So that was all really I wanted. What you proved was that multiplying cosets is fine when you have a normal subgroup; which is a good point to remember. [TE, TEx]

[Tutor now quickly explains the proof as he would have proved it] [TE]

So it's a bit simpler ... rather than getting lost in algebra. [TEX]

The episode, while largely managed by the tutor, splits into 3 parts: (a) [I] in which tutor creates the problem-solving environment, stating the problem, and clarifying its context and parameters; (b) [2-25] in which we see tutor-students interaction: one student, mainly, constructs a solution with support from tutor instructions [5,9], questions [7,22], comments [12, 14, 16, 18], prompts [20, 22, 24], and expert input [16]. At points tutor and student seem to think together [17, 19, 25]; and (c) [26-27] in which we see the tutor in expert mode, explaining and demonstrating. Part (b) seems rather different from the style of interaction represented in Episode 1. There is evidence of student involvement in activity and thinking. Although we see in this episode, as above, considerable TE and TEx, there are new elements. Students join in the discussion in a more active way, encouraged by the tutor. Parts of the tutorial are student-led, albeit with tutor participation. Interaction is less responsive on the part of the students and more generative. There seems to be rapport between tutor and students which implies a degree of trust built up through experience of working together.

The teaching strategy of inviting a student to the board is a familiar practice here. In one interview this tutor acknowledged it might feel threatening to a student, but that students had come to realise that he would provide helpful support.

"I do promise to help; or will help ... they actually know I'll start them off. They won't just be stood at the board and me twiddling my thumbs. I might, after a few seconds, like 30 seconds, or something like that, or perhaps even less if they're looking panicky, I would suggest, er. "Well, OK, write down, what's the first line? What's it mean to say that?"

So, the intervention of the tutor shown above is a considered approach to encouraging students' participation in the mathematics of the tutorial. As such, it seems to constitute mathematical challenge, sensitively handled, albeit a challenge to think publicly, rather than to tackle a particular mathematical question. MI in Episode 2 seems more sophisticated than in Episode 1 in that it incorporates a teaching strategy that not only addresses the tutor's mathematical issues, but does so in a way that the students are seen, overtly, to be involved in the thinking. There is
evident struggle to express ideas, and present them in accepted forms. Tutor interjections might be seen as tutor imposing his own explanations or expertise, but alternatively they can be construed as supportive input (*affective sensitivity*), according to his own words. As they are generally pertinent to the immediate thinking of the student they are also sensitive in a cognitive domain.

**Concluding Remarks**

In our tentative theory of pedagogic development/awareness (Jaworski et al, forthcoming; Nardi et al, in preparation) Episode 2 is characterised at a higher level than Episode 1, indicating more sophistication of pedagogic awareness in addressing students’ mathematical conceptualisation. However, a central part of the tutor role is seen widely as inducting students into appropriate ways of seeing and thinking mathematics. We see, above, examples of the various strategies that tutors use, which seem to form their pedagogical repertoire, and to be a practical manifestation of pedagogic thinking. Challenge to students is often implicit in the pedagogic approach, leaving its interpretation up to the students themselves. However, the second episode is more indicative of *harmony* in sensitivity and challenge. In previous research, harmony has been shown through teachers’ questions being related to students’ thinking, and through development of students’ metacognitive activity [Note 1]. Here it is part of the teaching strategy (*ML*) that challenges students (sensitively) to address mathematical concepts. Further research might explore critically the relationship of harmony to students’ conceptual learning.

*My sincere thanks to Kate Watson for her contribution to data analysis*

Visualisation in Geometry: Multiple Linked Representations?
G. Kadunz (Klagenfurt) & R. Sträßer (Bielefeld/Gießen)

At a first glance, geometry seems to be the most appropriate field for visualising problems and supporting its solutions. The paper looks into this statement by analysing the role of multiple (sometimes: linked) representations, especially in computer environments like Dynamical Geometry Software (DGS). Using a prototypic example, the essay throws some doubts on the above optimism and gives reasons for a more sceptical evaluation of the role of visualisation in geometry and its learning.

1 The field of interest and related literature
Visualisation is a continuous field of interest within the PME community (see the plenary session by Dreyfus 1991, the plenary panel in 1992, pp.3-191ff of the PME16-proceedings, or the papers of the research forum in the 1999-proceedings, pp. I-197ff). “Imagery and Visualization” since long is a category in the “index of presentations by research domain” in the PME-proceedings. It is also a constant field of interest in the broad community of mathematics education research (see for instance the handbook edited by Zimmermann&Cunningham 1991).

At a first glance, geometry is an easy domain for studying visualisation because, traditionally, geometry is THE mathematical domain where imagery abounds. It is often described as the field where icons, imagery and their inherent relations are studied - but: research in geometry education seems not to have an accepted description of the role of visualisation in geometry. Even historically we find times when geometry relies on visualisation via numerous drawings which alternate with periods or authors widely refusing the use of diagrams (see e.g. the well-known case of Lagrange’s introduction to the “Mécanique analytique”).

2 The focus of the study and its framework
Within the field of visualisation and geometry, the paper tries to better understand the role of the variety of (sometimes, especially in computer environments: linked) representations of a geometrical problem in order to better understand visualisation in the field of geometry. The (non-surprising !) guess that this also throws some light on a more general idea of visualisation will not be treated here (for this, see Kadunz 2000).

The framework of the essay is the idea that -for the purpose of the study- it helps to distinguish between a human being (sometimes: a learner) and mathematical (in the essay normally) geometrical knowledge which are linked by external and/or internal representations (for this concept of representations see e.g. Goldin 1992). Consequently, the reader should not infer any special position of the authors with respect to epistemological questions (like for instance the adherence or degree of adherence to constructivism) from this study.
3 A prototypic example

3.1 The problem

Segment AE is the diameter of a circle with centre C, B and D are midpoints of the segments AC and CE. With respective circles around B and D through A and E, we come to a configuration represented in drawing 1a. How to construct a circle which only touches the circles around B, C and D (for a "solution" see drawing 1b).

3.2 The drawing

Drawing 1a is an easy construction task with points, segments, circles and their names - the signs of standard elementary geometry. The fourth circle touching the first three circles may be arranged using ruler and compass or appropriate geometry software (like Dynamic Geometry Systems -"DGS"). A DGS-solution could place the centre M on the mid-perpendicular of segment AE (as a variable point on the perpendicular) and an additional point H in the intersection of the circle around C and the mid-perpendicular. Dragging M then arranges an appropriate circle with centre M through H to touch the circles around B and D.

3.3 An algebraic solution

The problem solver can use drawing 1b as a plan for an exact construction: Because of symmetry, the centre M of the fourth circle must be on the mid-perpendicular to segment AE - giving rise to a numerical solution if the radius of the circle is known. As the circles around D and M have only one point in common, the intersection and points D and M have to be collinear - offering a right-angled triangle DCM (see drawing 2). With R as radius of the circle around C and x as radius of the circle with

[Diagram 1a, Diagram 1b, Diagram 2]
centre M, we come to the equation (*) below and its easy and simple solution of x=R/3.

\[(*) \ (x+R/2)^2 = (R-x)^2+(R/2)^2\]

The algorithmic transposition of the formula could even be handed over to a Computer Algebra System (CAS) - and drawing 3 gives the commands for the CAS-"Derive".

\[\text{SOLVE}\left[\left(\frac{x}{2}\right)^2 - (\frac{R}{2})^2, x\right] \Rightarrow x = \frac{R}{3}\]

By concentration onto the algebraic solution of the equation (*), the original problem disappears. The equation does not tell its genesis and could be given as a drill-and-practice problem on equations without showing its geometrical origin. This is the price to pay for the use of the algorithmic solution - and only the unexpected result x=R/3 (only one solution of a quadratic equation - and a "simple" one!) may motivate the question why this special result had to be calculated. The algebraic solution does not offer a clue to an answer of this question and may come as a surprise because it can hardly be anticipated from drawing 1a/b. On the other hand, the algebraic solution by means of the Pythagorean theorem offers no clue or interpretation of this rather "simple" solution. Even the effective construction does not offer a hint to embed the solution x : R = 1 : 3 into a broader geometrical context. Nevertheless, it is easy to end the construction by using the mid-perpendicular of AE and a circle around A with radius 2R/3 for finding the centre and then the radius of the inscribed circle.

3.4 A geometric solution

The solution using the algebraic information x=R/3 did not offer a geometrical interpretation for the solution. So we look for a way to cope with the construction of a circle tangent to three other circles. Within the range of elementary geometry, a productive method to cope with problems like these is the inversion of circles and we will use it to explore the problem - even if inversion is no more part of the elementary school geometry. With DGS and its power to group chains of constructions by means of a "macro"-definition, by means of modularising a construction, we have a chance to solve the problem (we will not elaborate on inversion because of the abundance of appropriate literature on this topic; see for instance Lindner, 1999, pp.336-341; Coxeter, 1989, pp.104-117).

Let us take the "large" circle with centre C as the circle of inversion. The circle around M and tangent to the other three circles is transformed into a circle tangent to the images of the other three circles. The images of the these
three circles are the circle of inversion itself and two tangents (straight lines !) to the circle of inversion (!!). In short: as images of the circles around B and D we have perpendiculars f(B) and f(D) to segment AE through A and E because they touch the circle of inversion in A and E and go through the centre C of inversion.

Now the image of the circle C_M with centre M (a circle again!) has to touch these two perpendiculars and the circle of inversion. Its centre f(M) must be on the mid-parallel between f(B) and f(D). Consequently, the image of the fourth circle has the same radius R as the circle of inversion. The construction of it is very easy and the inversion of it immediately gives the solution C_M of our problem. Symmetry adds the other solution (as in drawing 5).

The only information lacking now is the value x = R/3 of the radius of the circle C_M - and one could even doubt the necessity of knowing the numerical value because the construction is already finished. But inversion can inform us about this radius with the following argument: The image f(C_M) has the same radius as the circle of inversion around C. If one additionally constructs a circle around C with radius 3R, this circle will (obviously!) touch the image f(C_M) of the solution of our problem. The image of this larger circle around C also has to touch the circle with centre M and has the same centre as the circle of inversion.

If we consult the definition of the inversion, this image has to have a radius of R/3 - hence our solution as well.

With this, we solved the problem by means of geometry in a double sense: We found, we geometrically constructed the circle around M we looked for AND we deduced its radius from the characteristics of the inversion. Inversion was the key to our geometrical solution.

4 On visualisation in geometry

If we look back to the solution process, we can clearly distinguish three phases: At first we constructed an "empirical" solution using the drag-mode of the DGS, this offered a clue for the second phase, namely an algebraic calculation for the radius of the inscribed circle (and a consecutive construction of it).

The third phase deliberately put aside this numerical/algebraic solution while inversion offered a purely iconic, geometrical solution with the length of the radius as an additional information from a careful analysis of the inversion.

4.1 Traditional representations

The succession of the different phases is clearly marked by the use of different types of representations: at first, the solution is sought in the "register" of geometrical,
icnic representations (for the concept of “register” see DUVAL 2000), we “visualised” the problem. Unfortunately, this only leads to an empirical solution (the drag-mode solution), but also produces the drawing, the graphical representation which opens the door for the second representation: the algebraic, symbolic description of the problem. In some sense, the algebraic description hides the initial problem, but offers powerful means to solve it - namely: the transposition of equations - and a surprisingly and numerically simple solution. The effective construction in the iconic representation “degenerates” to a mere technical process. It was exactly the change of register, the change of representation which made possible a solution of the problem. The interplay of the iconic representation of the empirical “solution” and the symbolic representation of the situation (via equations) and its rule governed manipulation produced the exact and elementary solution of the problem.

But this change of representations (from iconic to symbolic registers), the algebraic solution of the problem and its iconic realisation have a severe deficit: The symbolic representation put aside and masked the initial problem, offered a general and effective solution - but no clue to understand this solution in terms of (synthetic, iconic) geometry. Having found a symbolic solution, we now looked for an iconic one, i.e. after the change from iconic to symbolic representation, we turned back to the iconic representation to “understand” our solution in terms of geometry. The driving force of this return to geometry may have been the simplicity of our algebraic solution (or the love of geometry and consequently a search for a geometrical solution). In all, the symbols of the algebraic result made us go back to icons and forced us back into geometry. And with the use of a somewhat more advanced tool like inversion, we came across a “purely” iconic solution and could even give a geometrical reason for the simple algebraic result.

4.2 Representations with DGS
In both “icons phases”, the first as well as the third phase of the solution process, the special features of DGS were of special help: In phase 1 the drag-mode helped to produce the empirical solution. If we additionally go into technical details of Dynamic Geometry Software, we come across a representation behind the iconic representation on screen: invisible for the user, but nevertheless essential for DGS, there is a “second” representation inside every DGS “behind” the visible representation on screen. Parallel to the construction of the user, DGS save all input (like position, shape and measures of the constructed objects), including information on relations between parts of the geometrical construction. This representation is kept hidden from the “normal” user – but makes possible the drag-mode by the quick and iterated recalculation of the whole construction depending on the position of basic objects. The high calculation power of modern hardware enables the computer to produce a quasi-continuous movement on screen when varying basic objects of a construction. Following the functional dependencies of the other objects, the DGS produces an actualisation of the representation on screen following the new position of basic elements. The visible iconic representation is internally controlled by an invisible
algebraic representation of relations. This algebraic representation in return obviously depends on the position values of the user input for basic objects. It is this power which – on the other hand – in some sense prevents the problem solver from searching for more general, geometrical means to solve the problem because the power of the algorithms of analytic geometry make the drag-mode so simple and comfortable. As a consequence, the user is kept inside the icons of geometry – the concepts simulated by the drag-mode remain blind, whereas the solution in phase 2 is conceptually void. Nevertheless, the surprisingly simple solution is a good reason to continue working on the problem.

For an effective realisation of the inversion in phase 3, the macro-functionality of the DGS is crucial. To state it in more general terms: The offer of a modularization of the solution by means of appropriate “macros” (like “inversion of a circle or straight line at a given circle of inversion”) is crucial for an effective and swift construction in phase 3. Traditional paper&pencil constructions would be very tedious and time consuming (and be definitely out of reach in a normal school context already because of a lack of exactness). With macros, more general: a cognitively appropriate modularization of the construction, the iconic register becomes more manageable and flexible to use it in as tentative, but rule-governed way as we are used to when transforming equations.

So the third phase of the solution is characterized by a constant change between the iconic representation of the problem and its solution, represented by the drawing, and the reflections and theoretical concepts (mainly from the geometrical inversion) to further the solution process. The drawing is (re-)structured by means of conceptual entities (“modules”) like “inversion of a line / a circle at a given circle of inversion”. These modules are used to guide the continuation of the construction by “offering” new concepts/modules to advance the solution process. On the one hand, they offer a possibility to an economical construction, hiding those objects which are only intermediate states of a given construction (like a mid-perpendicular if only a midpoint of a segment is to be constructed). In addition to that, they give way for a look onto the overall structure of a complex construction, hiding those elements which conceptually are not needed for it. In some sense, they do the same job in a geometrical construction as algebraic expressions (“terms”) do in algebraic transformation of equations. So they deeply influence the conceptual understanding and making of a (complex) construction. In our example, the modules act as links between the actual drawing and the geometrical theory of inversion, sometimes even motivating the use of additional modules. They are “only” heuristical tools which - in contrast to algorithms - offer hints how to continue the solution, they do not prescribe the next step (as would have to do algorithms). Within this complex, heuristical process, an iconic solution is embedded into the geometrical theory.

4.3 On visualization
From a more or less phenomenological angle, the first two phases of the solution are clearly different: the first one is marked by iconic, whereas the second phase heavily
relies on symbolic manipulation. Icons offer an elementary heuristic to prepare for the second symbolic phase. Using elementary algebra, symbols produce a numerical solution, which can easily be transformed into an (iconic) construction. Following a simple, traditional visualisation concept, the first phase "visualises" the problem, while the second phase brings into being a non-visual, algebraic solution. Such a traditional concept of visualisation is inappropriate to fully understand the third phase, but opens a way to describe the interaction of "external" representations as opposed to "internal" representations (for the distinction cf. Goldin 1992).

We now concentrate on the third phase to understand the solution. On the one hand, we find constructions in the sense of traditional geometry. On the other hand and at turning points of this phase, we interpreted our constructions by means of concepts from the theory of transformation geometry, especially the theory of inversion. We condensed parts of the drawing into a distinct "Gestalt", a module which could be understood as an instance of a concept from inversion theory. So we linked the iconic representation with a conceptual one, the construction was seen as an external representation of the concepts of inversion, which were the respective internal representation. And DGS-macros could additionally represent these concepts as simple software commands. Software offered (or could offer) an additional external representation of the theoretical concepts. The solution process was a constant to-and-from between external representations (on paper and/or machine-based) and internal, conceptual representations. Concepts grounded the solution process because they linked the solution with a geometrical theory – and led to the development of new icons and images which had to be interpreted within the theory of inversion to further the solution process. Looking onto the external, iconic representation had a heuristical function to decide which concepts were appropriate to bring forward the solution process. With a decision on the "next" concept to use, an algorithm - with necessity – defined the next iconic representation which in turn grounded the next heuristical step. This process of constant move between iconic and conceptual representations lasted until a complete and satisfactory solution was reached.

The interaction between the two representations (internal/symbolic and external/iconic and linked by the problem solver) can be taken as an enlarged concept of visualisation. This view of visualisation is characterised by a continuous interaction of perspectives, a constant change to be decided on using geometrical knowledge (and – in learning, especially school contexts: the support of a an external mediator, for instance a teacher). Visualisation is constant interaction of iconic, external and other (external and/or internal) representations.

5 Consequences for research
For (research within the field of) geometry, especially school geometry, the above view on visualisation can "explain" some difficulties: If change between different representations is a, if not the key to progress in a problem solution, the only type of geometrical representation, the iconic one, and its continuous use will not advance the solution process. Geometry as such, inherently, has to overcome a specific difficulty:
Already working in an iconic mode does not offer a chance to change representations to make available different registers to bring forward the solution process. Taken in a more constructive way, developmental research in geometry teaching and learning should deliberately further the change of representations, especially leaving the realm of geometrical, iconic representations and has to diligently analyse the consequences of such an effort.

More globally, research on visualization must look into both directions of change of representations - and not only analyze the change from other, especially symbolic representations to iconic ones. A perspective on visualization not only taking into account one direction of a necessarily two-way process to and from visual, iconic representations is needed to better understand the links between multiple representations, to better understand visualization.

References
This study uses an activity theory approach to explore artefact mediation within a middle high school lesson relating to the reduction of fractions. The first part of the paper discusses the main concepts, including the Bakhtinian concept of ‘voice’. These are then applied to outline the activity system of a classroom - episodes of which are analysed in greater detail. Artefacts including the ‘teacher voice’, the expression ‘simplest terms’ and various strategies for calculation are identified. It is argued that the choices made by the students reflected the playing out of an hypothesised contradiction between use values and exchange values lying at the heart of the lesson.

The point of departure for this study is the belief that mathematical knowledge is dependent on both the mind and society (Gerdes, 1985; Bishop, 1988; Lave and Wenger, 1991; Nunes, Schlieman & Carraher, 1993; Bloor, 1983; Solomon, 1989; Cobb, 1994; von Glasersfeld, 1995; Walkerdine, 1988, 1994). A common finding/assumption associated with this view is that mathematical thinking is not valid by virtue of correspondence with what is factual (the so called Platonist view) - rather, its truth value depends on its coherence with what is already taken to be true and with what works. These concerns (coherence and utility) throw into focus the questions of how mathematical tools are generated and related to a problem situation and, if all knowledge is situated, how knowledge can be transferred from one site to the next. Related to these larger questions is the issue of how mediating artefacts facilitate the construction of mathematical knowledge within the local domain of a mathematics classroom. It is this topic which is the immediate focus for this paper.

In the next section a theoretical framework for the paper, drawing on activity theory (Scribner, 1997), is set out. Following this, the paper illustrates its main ideas with an examination of transcripts depicting interactions within a middle school classroom. Tensional qualities within situated artefacts are then discussed, and this leads to the conclusion.

‘Mediating artefacts’ in the processes of knowledge use

The idea of cognitive mediation develops from the work of Vygotsky. In *Mind and Society* (1978), for instance, he enriches the simple idea of stimulus-response processes by introducing a third element described by him as a second order stimulus or “mediated act”. For Vygotsky, the mediating act “possesses the important characteristic of reverse action (that is, it operates on the individual, not the environment)” and in so doing "permits humans, by the aid of extrinsic stimuli, to control their behavior from the outside. The use of signs leads humans to a specific
structure of behaviour that breaks away from biological development and creates new forms of a culturally-based psychological process" (italics in the original, p 40). In Vygotsky's work, signs are an instance of psychological tools, and in the work of later theorists (for instance, Leont'ev, 1981) these are subsumed into a larger category of cultural-historical artifacts associated with the physical, social and cultural context of knowledge production and use. What is especially interesting about Vygotsky's formulation is that mediating artifacts are not merely technical components of task performance - but they "transfer the psychological operation to higher and qualitatively new forms" (p 40). In other words, mediating artefacts transform knowledge in the course of their operation (Wertsch, 1985); thus, knowledge use and knowledge production are seen as interrelated on the Vygotskian view.

These insights have given rise to an 'object oriented' cultural-historical approach to human cognition (Leont'ev, 1981). In Engeström's analysis (1987), for instance, 'subjects' collaborate within an activity driven by a common motive or 'object'. Activities are mediated by tools, rules, and other social characteristics such as the community and division of labour specific to action. However, the object is characterised by internal or primary contradictions and these are played out across multiple domains of mediation leading to an expansive redevelopment of the object and subsequent re-mediation of the activity system.

In addition, because communicative events call up socio-historical processes and thereby express value positions as well as systems of belief and historical placement, an important artefact within an activity is the Bakhtinian concept of 'voice'. When applied to the classroom, for instance, this means we can sensibly talk about the "voice of the teacher" - and mean by this an artefact within the dialogue which both shapes and is shaped by activity. For Bakhtin, when two voices are in dialogue a "hybrid construction" of utterances is produced. By this he means that "an utterance that belongs, by its grammatical (syntactic) and compositional markers, to a single speaker, but that actually contains mixed within it two utterances, two speech manners, two styles, two 'languages', two semantic and axiological belief systems" (Bakhtin, 1991, p. 304, cited Wertsch, 1985, p 227; Engeström, 1995; Wells, 1996). Hybrid constructions such as these facilitate the trajectory of the object on its developmental path.
Looking at the data

In order to illustrate the ideas introduced above, I have selected four excerpts from a corpus of observed mathematics middle high school classroom interactions (Episodes, A, B, C, and D) obtained as part of a larger project (Clarke, in press). These involve the teacher, Mrs R and two students, M and D. Prior to the action depicted, Mrs R requires her class to do questions (a) - (e) of the following list taken from a work sheet entitled the ‘Ratio pep test’.

Reduce to simplest terms

As the class settles down to this task, she calls forward to the blackboard a number of students including M whom she says “like to work ahead” (also see A1 below). Here she illustrates certain algebraic techniques (see Episode A below) useful in undertaking items (f) - (i) which she then sets for this subgroup and sends them back to their desks to begin work. M takes up his position with D and the two commence to work collaboratively (Episodes B, C, D). In the course of this we see M and D checking their progress with Mrs R (Episode B) and making progress through the exercises (Episodes C and D).

Episode B starts with M concerned about his response to (h) which was ‘1.5’.

**Episode B**

<tr>
<td>B12</td>
<td>M: Thank you. [T goes to A and L’s desks]</td>
</tr>
</tbody>
</table>

Episode C occurs shortly after the preceding episode. In this M and D engage on the topic of what is the correct response to question (e) which asked for a reduction to simplest terms of 5:5.
Episode C

C1 D: Five to the ratio of five, is one.
C2 M: This was [inaudible], I don't know.
C3 D: One over one.
C4 M: No, we've got to reduce to simplest terms.
C5 D: Yeah, it's just one. The five over five one.
C6 M: It's just one to one.
C7 D: Yeah.

In analysing these episodes, the first step is to examine M's statement to D "no, we've got to reduce to simplest terms" (C4).

Already in B1 M’s exclamation “oh, I’ve got to reduce to the simplest terms” coincides with expressions of hesitation, frustration and uncertainty(B1 - B5). This suggests that the voice used in C4 derives from elsewhere - I argue a hybridisation of the ‘teacher’ voice and the imputed voice of the text which required students to “reduce to simplest terms”. In C4 the form of M’s retort resembles the teacher’s response given to M previously in B11 - “no, because it’s a ratio”. On this earlier occasion the teacher expressed a reservation concerning the legitimacy of the form of a response M gave to exercise question (f); in C4 M expresses the same kind of concern (albeit in relation to D’s work), and does so in a similar way. In particular, the function of the voice for each instance (B11 and C4) is to progress problem solving attempts by redefining the problem into an alternative version of the question under examination. In B11 this was achieved by drawing attention to specific features of the question asked - the importance of ratio form. In C4 this was achieved by emphasising the salience of the need for “simplest terms”. This shows that M’s utterance in C4 ventriloques the teacher’s voice in B11. However, C4 also ventriloquises the imputed voice of the text for the text actually requires students to express in “simplest terms”. Further, it is noted that M when in C4 M says to D “no, we’ve got to reduce to simplest terms” words crucial to his meaning are left out. From the context it is possible to tell that he means “No, we’ve got to reduce the ratio to simplest terms”. Indeed, because he leaves the words the ratio out D is quite legitimately able to respond “Yeah, it’s just one”(C5). It is concluded that, for M, the term “simplest” does not function strictly as a mathematical term, but as a tool used to think and perform tasks in accordance with the expectations of the mathematics lesson.

This example illustrates how M and D adopt and synthesise the vocal and textual media in which they are immersed; and use the artifacts so synthesised to reconfigure the problems they encounter in their progress towards accepted outcomes. These relations are expressed in the top triangle of Figure 1. Further, it is clear that the character of this kind of intersubjective knowledge was reflexive in that Mrs R and
the students shared knowledge relating to the lesson and shared the knowledge that
this knowledge is shared. In the section following, I propose to consider more
closely the development of this intersubjectivity and, in particular, explore the issues
of tensions among mediated artefacts.

---

**Figure 1: Model of the classroom activity system**

**Tensions among artefacts**

Episode D occurs immediately after Episode C.

**Episode D**

[Question (a) reduce to simplest terms: 4/12]

D1 D: It's one third, the top one, then there's—that's one third as well. [pause] What's the forty one?
[referring to question 1 (c) reduce to simplest terms: 16/40] Four over. [M writes 1/3]

D2 M: That's not right, the ...

D3 D: Divide it by four, it's, yeah. [M writes 4/]

D4 M: No. It's got to be two over five. [writes 2/5]

D5 D: Yeah, two over five. I knew that one. I was just [inaudible]. [writes 2/5]

D6 M: Oh sure you did, that's what they all say.
[Question 1 (d) reduce to simplest terms: 240/300]

D7 D: Um, two-forty, yeah, three hundred divided by two-forty.

D8 M: Hang on, twelve, so we'd have twelve ...[pause - writes 12/]

D9 D: No, that ... it's divided by it, right? That's one ...

D10 M: ... over four [interrupting - writes 4]. Four divided by ...

D11 D: ... or one third.

D12 M: ... it's going to be three over one. [writes 3/1]

D13 D: Why?

D14 M: 'Cause, it's just going to be the opposite. Look.

D15 D: Yes.

D16 M: Times twelve.

D17 D: 'Cause that's bigger number. Yep.

D18 M: Um. Um. Two forty over three hundred. Um, two four 'o' divide—no.

D19 D: Three hundred.
In this episode M and D exhibit evidence of four strategies (S₁, S₂, S₃ and S₄) relating to the task of simplifying fractions, as follows. In S₁ a fraction a/b is reduced to the form 1/n where n is the natural number for which either b = na or a = nb. D uses this strategy in D7 and D9 - it gives him the correct answer to (a) and a wrong answer to (b). S₂ provides a necessary condition for any reduced form: if a/b is reduced to c/d and if a>b, then c>d. This test enables M to state in D2 by inspection that D’s response to (b) must be wrong (see also D14). Strategy S₃ is to divide both the numerator and denominator by a common factor (D3 - D5, and D8, D10 and D12), thereby determining a reduced fractional form. Finally, S₄ deals with the case where the natural number n as in S₁, does not exist. In this case factors of a, say n₁ and n₂, are sought such that a = n₁n₂ and there exists a natural number n₃ such that b = n₂n₃. The reduced fraction is then written as n₂/n₃. We see S₄ applied in D18 - D30. In D18 and D20 M carefully checks that strategy S₁ does not apply. Then he uses S₄ twice: first in order to reduce 240/360 to 40/75 (D20 and D22); and second, with D’s help, in order to reduce 40/75 to 8/15 (D23 - D30).

Of these strategies, of course, S₂ is correct only in the limited cases to which it applies, and S₃ is a correct general strategy; S₁ and S₄ are both false. My focus in the following is on S₄. Where does come from? Preceding their work together, a number of other students including M who like “to work ahead” (Mrs R’s words) is gathered at the board in the front of the classroom. Here Mrs R rehearses a series of algebraic manipulations working towards a cancellation algorithm involving algebraic expressions. Her method (a sample is illustrated below) involves an intricate construction of pronumerals and arithmetic operations involving factors.

Episode A

A1 T: Just working ahead a little bit? OK, guys I’m going to think of two numbers. OK? Oh, come on Alistair. Now stand over here because. See, Dale, we’ll talk behind their back, you see. And so will L. Over this side guys, over this side. See if you can see. You stay, the small ones can stay here, you go over there. OK. All right, that’s it, that’s fine. Just squat down. OK. Now, I’m going to think of three numbers, right?, x is going to be 7, y is going to be 9, and uh, m is going to be 3. OK? Now I’m going to multiply x by 5. I would write it as 5x. OK? I’m going to multiply y by 5, how would I write it?

A2 Ss: 5y.

A3 T: OK. And I’m going to multiply m by 8.
A4 Ss: 8m.
A5 T: All right. Now, I'm now going to divide x by 5. Now what's going to happen if I do that?
A6 Ss: Be the same number.
A7 T: Ah. It's going to go back to the same number. All right. I'm now going to take this, um, I multiplied m by 8, I'm now going to divide it by m. What am I going to be left with?
A8 S51: Eight.
A9 T: Um. Is it?
A10 S52: Yes.
A11 T: Right, m is 3, 8 times 3 is 24, divided by 3, brings it back to 8. Do you notice that this one you told me brought it back to 7. Seven times—5 times 7 is 35, divided by 5 is 7. Good. And this one here you told me went to 8. Now can you see a pattern?

At the conclusion of this instructional episode, students are instructed to return to their seats and do the entire question set - that is, including those questions (f) - (i) she requested the general class to "cross out". Mrs R’s figuring in this episode and M’s construction of S₄ are comparable in their intricacy and in their emphasis on the multiplication and division of factors. Whether M takes more than these kinds of manipulations from Mrs R’s work is unclear - nevertheless, in his choice of S₄, M exhibits a motivation to engage in a similar kind of exploration of factors relevant to the questions considered. It emerges that in his subsequent work with D, M expresses a stronger preference for the erroneous and more convoluted S₄ rather than the correct and apparently more straightforward, S₃. M seems to find the form of S₄ more appealing than the substance of S₃. What can explain this apparently anomalous situation?

My approach is to analyse the tensions among mediating artefacts within the activity system of the classroom, as set out in the application of Engeström's model of the activity system in Figure 1, above. At the heart of my argument is the assumption that there is a tension within the core of the lesson itself - namely, a primary contradiction between the ‘use values’ and the ‘exchange values’ of mathematics learning (Engeström, 1987, 1991, 2000). In the classroom, use value is associated with getting the answers correct; exchange value, with being seen by the teacher and other students as "liking to work ahead" (as Mrs R put it) or not being “a dumb person” (as the students put it). This primary contradiction is played out as a tension between the correct strategy S₃ on one hand, and the choice of the status conferring though erroneous strategy S₄ on the other. What this analysis shows is that ‘the lesson’ observed is more than merely a mathematics lesson - it is also a lesson about the social standing of mathematical knowledge, and about how critical value sometimes attaches to the forms of knowledge (such as are evident in S₄) rather than its substance (as in S₃). This paper therefore highlights the importance of recognising contextual and axiological variables when analysing cognitive events in the classroom.

Engeström, Y (1991) Non scolae sed vitae discimus: toward overcoming the encapsulation of school learning. Learning and Instruction, 1, 243-259
Based on classroom observations and interviews over two years, this study reports on the different ways two teachers incorporated use of a computer algebra system into their teaching of introductory differential calculus. Factors that contribute to successful CAS teaching were monitored: teaching approach, preference for representations, and use of technology. In the first trial the teachers adopted distinctly different ways of using CAS. In the second trial, these differences persisted, but they made some changes. In response to new knowledge about the testing, one teacher extended his focus on rules by teaching new CAS procedures. In response to new students, the second teacher reduced CAS use for routine symbolic procedures while continuing to use it to support conceptual understanding.

Background

It is generally acknowledged that teachers' classroom teaching practices are influenced by their underlying beliefs and knowledge about mathematics and mathematics teaching. Reporting on a professional development project during which teachers explored learning and teaching with computer activities, Noss and Hoyles (1996) monitored changes in the ways the teachers used Microworlds technology. These changes served as a 'window' on the teachers' mathematical beliefs and pedagogy. Noss and Hoyles observed that "there is a mutually constructive relationship between what teachers believe and what they do" (p.201). They maintained that while changing their pedagogy, "Teachers are not pushed arbitrarily by 'constraints'. Neither are they free agents" (p.201). The present study provides a detailed description of how such changes in teaching with technology come about and how they are linked to changes in teacher knowledge and beliefs.

Attempts have been made to classify teaching practices and to relate them to teachers' knowledge and beliefs. Shulman (1986) distinguishes between teachers' content knowledge (understanding and organization of knowledge of specific topics) and content pedagogical knowledge (knowing ways of presenting knowledge to students, including representations, and understanding what makes the learning easy or hard). These types of knowledge are interconnected (Even & Tirosh, 1995). Fennema and Franke (1992) describe other types of teacher knowledge; pedagogical knowledge (knowledge and planning of teaching procedures, behaviour management and motivational techniques), knowledge of students and knowledge of institutional constraints.

Teacher content knowledge impacts on teaching practice which in turn impacts on student learning. Jablonka and Keitel (2000) believe that teachers with highly developed content knowledge are "more flexible in structuring content for teaching
and in discussing students' ideas" (p.120). Gutstein and Mack (1998), in a study of teaching fractions, show that a teacher’s teaching decisions and practices were derived from the depth of her interrelated knowledge of content, pedagogical content, and of students.

Kuhn and Ball’s (1986) model of teaching practice was commended by Thompson (1992), in a comprehensive survey of teachers’ beliefs and conceptions, "as constituting a consensual knowledge base regarding models of teaching" (p.136). The model identifies four different teaching practices linked to particular beliefs about mathematics and goals for teaching, and characterized by related teaching styles.

1. Learner focused: mathematics teaching that focuses on the learner’s personal construction of mathematical knowledge;
2. Content focused with an emphasis on conceptual understanding: mathematics teaching that is driven by the content itself but emphasizes conceptual understanding;
3. Content-focused with an emphasis on performance: mathematics teaching that emphasizes student performance and mastery of mathematical rules and procedures;
4. Classroom focused: mathematics teaching based on knowledge about effective classrooms. (Kuhn & Ball, 1986, p.2)

The relationship between teaching styles and student achievement for teaching with technology is a topic of current interest. For example, student success (i.e., improved conceptual understanding) on calculus courses taught with technology is attributed to the adoption of student-centred teaching practices within a constructivist perspective (Keller, Russell & Thompson, 1999; and others). Kendal & Stacey (1999 & in press) use the word privileging (originally used by Wertsch, 1990) to describe a teacher’s individual way of teaching. It includes decisions about what is taught and how it is taught including: what is emphasised in the content (what is stressed and what is not stressed), what representations are preferred and ignored, the attention paid to procedures and concepts, rules and meaning, and how much is explained or left to students to work out for themselves. Privileging reflects the teacher’s underlying beliefs about the nature of mathematics and how it should be taught. It is derived from an interplay of teachers’ beliefs and interrelated knowledge sources (content, content pedagogical, pedagogical), is moderated by institutional knowledge about students and school constraints, is manifested through teachers’ practice and attitudes, and is highly influential in student learning. Privileging has several components and in this study of the teaching of calculus with technology, we focus on teacher choices about:

1. Teaching approach (evidenced by teaching method and style using Kuhn and Ball’s classification above).
2. Calculus content (evidenced by representations of differentiation taught).
3. Use of technology (evidenced by the nature of use of the CAS calculator).

This study reports on the three aspects of each teacher’s privileging during the teaching of an introductory calculus unit. It monitors the changes that occurred over the two years and explores the impact of new knowledge and a new situation on the
changes in technology privileging, linking them to each teacher's beliefs and pedagogy.

**Method**

In two successive years, Teachers A and B volunteered to teach the same 25 lessons on introductory differential calculus course to their Year 11 classes (16-17 year olds). They were both experienced teachers of mathematics and had used graphics calculators in their classrooms for several years. They participated in the development of the teaching program that focused on numerical, graphical and symbolic representations of derivative and links between them (see Kendal & Stacey, 1999) and integrated the use of a CAS calculator (TI-92).

*Observation of lessons during teaching trials 1 and 2.* Half the lessons in the first trial, and every lesson in the second trial were observed and audiotaped. Teacher behaviour was closely monitored (e.g., time spent on each type of differentiation activity, the nature of every teacher-student interaction, and attitudes displayed towards calculus, technology and students) and a comprehensive checklist of 52 observations was completed immediately after each lesson. Finally, a privileging profile (with three components) for each teacher was developed. It consisted of teaching approach (style & manner), calculus content (the representations of differentiation they chose to teach), and ways the CAS calculator was incorporated into their lessons (frequency & nature of use). The nature of calculator use was classified as functional (primarily to get answers), pedagogical (primarily for learning) or neutral.

*First interview after the first teaching trial.* Nine months after the first trial and ten weeks prior to the commencement of the second trial, each teacher was interviewed separately, to identify their personal knowledge of differentiation. This also provided a basis for comparison with the privileging that occurred during the second trial. During the interview the teachers were asked to discuss their proposed solutions (and to predict their students' responses) to a set of problems most of which would be included on the students' tests six months later. A wide spectrum of teacher characteristics was monitored including: personal knowledge of multiple representations of differentiation; awareness of alternative ways to solve differentiation problems; preference for representation; attitude towards the CAS calculator; personal CAS calculator use; knowledge of students; awareness of subtle school pressures and explicit constraints; and evidence of teaching methods and teaching styles.

*Second interview after second teaching trial.* Ten weeks after the teaching second trial, a second teacher interview was conducted to substantiate the privileging identified by observation of lessons during the second trial. Teachers were asked to reflect about their teaching practices, particularly the way they had used the CAS calculator to support conceptual understanding of the concept of derivative.

The following results summarise observations from all of these sources.
Results

Teacher knowledge

Personal teacher knowledge of calculus (differentiation). During the first interview, Teacher A knew how to differentiate symbolically (using algebraic rules) and graphically (finding the gradient of the tangent at the point), and how to translate between the two representations. He nominated up to two different differentiation strategies to answer particular test items, reasoned successfully about numerical derivative (limiting value of a difference quotient), reasoned with difficulty about graphical derivative and was unable to reason about a symbolic derivative. Teacher B performed symbolic, graphical and numerical differentiation and translated between the three representations of derivative. He nominated up to four different differentiation strategies to answer particular test items, and reasoned successfully about numerical, graphical, and symbolic derivatives.

Overall, Teacher A displayed less depth and less integrated knowledge about the concept of derivative than Teacher B who displayed deep, holistic, and integrated knowledge. This was reflected in both trials by Teacher A’s focus on teaching rules and Teacher B’s focus on developing students’ understanding.

Institutional knowledge. During both trials, the teachers were cognizant of the fact that although their students could use the CAS calculator for the trial tests, they would not be permitted on school examinations to be held in three months time and on official state school examinations in fifteen months time. They were also aware that the style of assessment on trial test 1 was similar to the official school examination (based mostly on the symbolic derivative) and whereas for trial test 2, the assessment involved numerical, graphical and symbolic derivatives.

Three components of teacher privileging

1. Privileging related to teaching approach during both trials

Teaching method. Teacher A mostly taught rules for procedures and during both interviews talked about routines to solve problems. In contrast, Teacher B emphasized understanding of the concept of derivative. He employed enactive representations and encouraged students to use visualization techniques. During the first interview he solved each problem several ways, explained his use of different representations and made sense of each answer. During the second interview he talked about conceptual understanding: "Getting the tangent idea through to them, what the gradient actually represents, what the derivative represents and the relationship between them - I think we’ve done very nicely with the calculator."

Teaching style. Teacher A lectured his students who were expected to copy down his lesson notes. In contrast, Teacher B orchestrated discussions between ‘student and teacher’ and ‘student and student’ and his student-centred teaching style fostered student construction of meaning. In both trials, Teacher A’s teaching approach (which emphasised student performance and mastery of mathematical rules and procedures) is classified as Content-focused with an emphasis on performance (using
Kuhn and Ball’s (1986) model). Teacher B’s approach which emphasised conceptual understanding of content and student construction of meaning is classified as Content-focused with an emphasis on conceptual understanding. This involves the "dual influence of content and learner. On one hand, content is focal, but on the other, understanding is viewed as constructed by the individual" (p.15).

2. Privileging of calculus content

During the first trial and in the first interview, Teacher A focused almost exclusively on the symbolic derivative. However, during the second teaching trial, he expanded his use of representations to include graphical and numerical derivatives. This came about after the first interview during which he realized that the students’ assessment would involve numerical and graphical differentiation, unlike the tests in first trial that were essentially symbolic. In consequence, during the second trial he decided to include the numerical and graphical representations of derivative.

During both teaching trials, Teacher B consistently stressed the symbolic derivative and involved the graphical derivative in explanations. Although during the interview he personally demonstrated ability to differentiate numerically (i.e. use a rate of change or difference quotient), he actively rejected teaching about the numerical representation in the second trial. He explained that this was because he believed that his students were a low attaining group and would not be able to cope with three representations of differentiation (i.e., he made changes because of knowledge of new students).

3. Privileging of technology

In the first trial, Teacher A linked the CAS calculator to an overhead projector and frequently demonstrated symbolic procedures to the students and allowed them to use CAS freely. He avoided using graphs. In the second trial, he taught his students the additional CAS numerical and graphical differentiation routines (described as functional use by Etlinger, 1974) and provided them with a step-by-step flowchart of corresponding CAS calculator procedures. In addition, he used the calculator to explain the links between the numerical and graphical derivatives (described as pedagogical use by Etlinger, 1974)

I’d say, when you see these words it means between two points, and when you see this word that means at a point. . . [I am] giving them strategies. . . and we did it [used dynamic graphing program] to understand the straight line against the curve.

In the first trial, Teacher B used graphs freely but noticeably controlled student use of the CAS calculator for symbolic procedures. In the second trial, he actually reduced his functional use of the CAS calculator while maintaining his pedagogical emphasis on the symbolic and graphical links.

It’s [the CAS] good for discovery because it takes a lot of the hack work out of teaching for understanding but you still need to teach pen and paper skill. I think there are certain skills that the kids have to have, even if you can use the technology.
I think the kids have to have the [algebraic] skills as well, without the technology. I think that’s essential for their understanding. It’s not sufficient to just use the calculator; they have to have the understanding of what’s behind it.

Table 1 below summarizes Teacher A and B’s privileging demonstrated during the first trial lesson observations (reported by Kendal & Stacey, 1999) and the changes in their technology privileging that occurred during the second trial.

**Conclusions and discussion**

Teacher A’s personal knowledge of differentiation was limited and the interviews revealed he believed his main responsibility was to help students pass examinations. During both trials, his teaching approach involved teaching rules and procedures
using a lecture style of delivery. He focused on symbolic differentiation because he believed this was exact (stated in first interview). He appreciated the symbolic power of CAS, enjoyed using it himself, and encouraged his students to use it for symbolic procedures. During the first interview, which occurred between the two teaching trials, Teacher A realized for the first time, that the second trial assessment would involve multiple representations of differentiation. He responded to this "new" institutional knowledge by expanding his repertoire of calculator procedures to include numerical and graphical differentiation. In addition, his initial preference for the symbolic representation had an unexpected consequence - he gave a stronger emphasis to numerical differentiation. He showed his students how to use CAS procedures to substitute into functions to find ordered pairs and create a difference quotient calculation. This usually gives an 'excellent' approximation to the gradient of the tangent (and curve) and Teacher A led his students to believe it was exact. He also believed that with CAS, graphical differentiation was "exact".

Teacher B’s knowledge of differentiation was deep and holistic and he believed that it was his responsibility to foster student understanding. During both trials, his privileging included teaching approaches that supported conceptual understanding using a student-centred style of delivery. He believed that the symbolic representation was the most powerful and useful for his students but he limited their use of CAS in order to prepare them for future examinations without it. However, to support student understanding, he adopted the graphical representation of derivative (gradient) using the CAS calculator. He also showed gradients enactively, and encouraged his students to visualize graphs of symbolic functions and derivatives. From the first to the second trial, Teacher B’s privileging was essentially stable but he reacted to "new" knowledge about his students: that the second group was algebraically weaker. In the second trial, he totally rejected the numerical representation, believing they could not cope with three representations. He also reduced their opportunity to individually differentiate symbolically with CAS (but allowed pedagogical class activities) strongly believing they needed practice with by-hand symbolic differentiation to cope with future examinations.

Both teachers, in response to new knowledge, made changes to their technological privileging in ways that were consistent with their own beliefs and knowledge. These results are consistent with other research. For example, Tharp, Fitzsimmons, and Brown Ayers (1997) showed that teaching style tended to be unchanged by the addition of technology. In their study, after an initial attempt at more enquiry based learning using a graphics calculator, teachers with a rule-based (procedural) view tended to revert to their procedural style of teaching, whilst teachers who were not rule-based remained more likely to focus on student conceptual understanding and thinking.

The institutional constraints and teachers’ knowledge or assessment of the needs of their students were important determinants of the change in privileging for both of our teachers from the first to the second trial. The constraints of the assessment
system were important for both, although in different ways. Teacher A was more accepting of aims the research project, allowing students to use CAS and adding new techniques in response to new knowledge of expectations of students. Teacher B was always more concerned that students developed by hand skills and rejected some of the aims of the research trial for a group he assessed as weak.

As hand-held CAS calculators are now becoming more affordable and easily incorporated into the teaching of mathematics in secondary school classrooms, the issue of teachers changing their pedagogy for more effective teaching with technology is becoming increasingly urgent.

EFFECTIVE TEACHERS OF SECOND LANGUAGE LEARNERS IN MATHEMATICS
Lena Licón Khisty, University of Illinois at Chicago

This paper presents an overview of findings of an ongoing project to identify teachers who demonstrate effectiveness in teaching mathematics with minority second language learners. The objective of the study is to better understand the processes of instruction that contribute to positive student achievement in the subject. The study rests on the assumption that the teacher is a critical factor in student learning given the teacher’s role as a more experienced other and as the engineer of learning environments. Data for the study include classroom-based observations and videotape analyses of teachers from two different geographical sites. This discussion will summarize the common characteristics among the teachers. Findings strongly suggest that key elements in teaching cannot be taken for granted.

In many classrooms, in primary through secondary level schools, in various parts of the world, there are a growing number of students whose home language and/or more proficient language is other than the dominant language of instruction. These students are second language learners (SLL); they enter school needing to develop or improve academic proficiency (Cummins, 1981) in the dominant language of institutions, government, and power. In many contexts, these same students are members of groups who have a history of underachievement and underrepresentation in educational areas that are particularly associated with basic social prosperity and advancement. In countries such as South Africa, the educational issues and success of the majority of second language learners are strongly connected to the country’s overall political well-being. In the United States, the ethnic and linguistic demographics of classrooms have significantly changed over the last thirty years; so much so that a teacher can no longer assume that all students will speak English or will be sufficiently proficient in all modes of the language to participate fully and equally with other students who are native English speakers. This discussion will focus on the USA context; however, as just noted, the findings and implications of this work extend to other contexts and other SLL groups.

The work presented here is primarily concerned with issues related to the educational achievement of Latinos, and specifically students of Mexican descent. In the USA, this group is disproportionately low-income, has one of the highest rates of non-completion of high school and has had a long history of underachievement in mathematics. Consequently, the improved schooling of Latinos, particularly in mathematics is a major concern for the educational community. In the recent decade, there has been much discussion about the relationship among Latinos’ predominant characteristic as English language learners, communication processes in classrooms, and mathematics achievement (Secada, 1992; Khisty, 1999). Indeed, there are clear and obvious connections between the clarity and comprehensibility of mathematical
talk (both oral and written) in a second language and a student’s ability to function with the talk to learn mathematics. In essence, a linguistically and culturally sensitive learning environment is highly relevant to second language learners’ success in mathematics (Ortiz-Franco, Hernandez, & De La Cruz, 1999). We know generally what constitutes these effective learning environments. For example, connecting student experiences to mathematical problems makes them easier for second language learners to comprehend (Khisty, McLeod, & Bertilson, 199?). However, we still do not know enough about how teachers actually enact these supportive learning environments. A study was conducted to identify effective teachers of mathematics with second language learners, specifically Latinos, in order to better understand the classroom processes that seem to contribute to students’ learning of the subject. This discussion draws upon part of the study and focuses on common characteristics found among a group of teachers. Two teachers who were found to be exceptional will be highlighted specifically by examples from their classrooms.

Theoretical Framework
The study is based on some key assumptions. First, that learning is a social activity; that higher psychological functions originate in human interactions and activity (Vygotsky, 1978). Second, these sociocultural activities are mediated through the use of cultural artifacts, tools, and symbolic systems, especially language, thereby implying a reciprocal relationship between the cultural and the intellectual. What is important here is that how and why these artifacts are used mediates how humans come to think with them (Moll, 2000). Third, sociocultural activity, or interaction, forms the context in which children participate and from which they appropriate tool use and cultural thinking. From this, we can assume that the “more experienced other” with whom children interact is highly relevant to their learning. The “more experienced other” is the person (be it parent, teacher, older sibling or peer) who initiates and assists the “less experienced” ones in learning; it is the “more experienced other” who provides the relationship between development and the cultural resources or tools that produce that development (Moll, 2000). However, this perspective does not suggest interaction or activity as an imitative set of dynamics. In former views of teaching, the teacher was seen as the subject and agent and the learner as the object and patient. On the contrary, if we observe normal human interactions, we can see that there is joint activity with teacher and students as co-constructors of the interaction. In summary, as Moll (2000) points out: “Social relationships are the key to the mental and personal development of individuals. The very mechanism underlying higher mental functions is a copy from social interactions” (p. 30).

Given the foregoing, the focus of the study was on the teacher, defined as the “more experienced other”, and the primary person in the classroom from whom students would appropriate critical aspects of mathematics learning. It was further assumed that by observing effective teachers, it would be possible to identify key aspects of their instruction as they enacted them. Teaching is such a complex activity
that often teachers are not aware of all of what they do or say as they instruct. Furthermore, there are times when there is incongruence between what one says one believes about instruction and what one actually does. Ongoing observations of teachers during instruction would more accurately capture the relevant elements.

Methods and Data

This work began several years ago in one middle-size city in the west coast region of the USA and was continued in a large urban area of the Midwest. Both areas have large populations of Latino second language learners, and many schools (at all levels) could be found to have enrollments that were very near 100% Latino. In both areas, a search for effective teachers of mathematics with Latino second language learners began with identification of schools that had high standardized test scores in mathematics. Principals in these schools then were asked to recommend teachers who had demonstrated consistent ability to develop students to do well on the tests in this subject. Once a pool of teachers was identified, they were initially observed to determine if they fit a profile of effectiveness. Effective was determined on two levels. First, did the teacher have a history of significantly moving students ahead academically, i.e., having students who scored at or above grade norm? Did students with this teacher demonstrate significant growth in mathematics as measured by standardized tests? Second, did the teacher model instruction that was consistent with general notions of best practices? Interestingly, there were not many schools in either area that both had high populations of Latino second language learners and high test scores in mathematics. Generally, most teachers who were initially identified produced occasionally only small gains or had students who usually fell just short of a standardized norm.

A pool of five teachers was finally selected for observation. All teachers had a history of their students gaining two to three grade levels during the year with them. In all cases, most of the teachers’ students entered below grade level and left, a school year later, one to two grades above norm on a standardized test. One teacher was at second grade, two were at fifth grade, one was at sixth, and one was at eighth grade. Each teacher was observed using fieldnotes and was also videotaped for at least twenty hours of mathematics instruction. Some observations were conducted on consistent days to capture a fuller development of a mathematical concept and the rest were done intermittently to capture different parts of the school year’s teaching and learning. While other types of data were collected as supporting or elaborating documents, the videotapes are the primary source of data. The videotapes were analyzed for relevant patterns in the teachers’ instruction without any a priori determined set of elements. Teachers were informally interviewed about their instruction when additional clarification or elaboration was warranted. This discussion focuses on common characteristics or elements shared by all five of the teachers.
Shared Characteristics of Effective Teachers

The five teachers of this discussion shared some striking similarities in their instruction of mathematics with second language learners. The teachers did not teach in the same school or know each other. Two of them were fluent in Spanish but only one taught primarily in Spanish. The different use of Spanish was due to school program demands and not to the teachers' belief of the importance of the primary language in learning. The other teachers only spoke English but used various methods to incorporate Spanish in the classroom in order to facilitate students' learning. All of them had ten to fifteen years or more of experience teaching with second language learners. Only two of them had a concentration of college coursework in mathematics or mathematics teaching. In what follows, I will describe the aspects of their teaching of mathematics that seem particularly relevant to students' success. Examples from two teachers in particular, one second grade and the other fifth grade, will be used to highlight some of these characteristics.

Writing mathematics. First, at a time when reforms in mathematics have emphasized connections between this subject and other disciplines (NCTM, 2000), very little has changed in terms of using writing to develop mathematical concepts and understandings. Yet writing is clearly a process that can support and advance student thinking. It helps to bring order out of chaos in one's thinking (Halliday & Martin, 1993). In these classrooms, writing mathematics was a constant and natural part of the mathematics curriculum. In the second grade classroom, the teacher used writing addition and subtraction problems to teach not only mathematical literacy, concepts, and skills, but also general emerging literacy skills. Practice spelling lists included mathematical terms and students learned letters, sentence structures, and conventions such as punctuation in the context of reading and composing their own mathematical word problems and explanations. For example, when students completed composing their problems, they brought their work to the teacher who sat a group of students' desks. She would read aloud each piece of writing and comment on both the fluency of the writing and the mathematics in the problem. She also edited the writing with language corrections and send the student back to make the necessary revisions. All writing was kept in a student's own writing book, and often, a student's piece of work would be used to demonstrate to the whole class some particular aspect of writing and the structure of language they all needed to learn.

In a fifth grade class, after some work on developing understanding of a particular concept, for example, finding the missing leg of a right triangle, students had to write to a fictitious person telling them how to do a problem using the concept (Chval, 2000). This writing was revised at least five times with each draft having dialogue-type comments from the teacher. These comments were usually in the form of questions from the teacher asking for clarification on specific aspects of the problem solving process. All comments from the teacher were detailed and clearly designed to guide the student's thinking and writing mathematically. It was not until the final draft
that comments referred to issues of conventions of writing such as choice of words, spelling, and punctuation. Examination of samples of student writings over the several drafts strongly suggests how powerful writing and teacher’s guidance through the process can be in learning mathematics (Chval, 2000).

**Mutual support among students.** Another characteristic among all the teachers was their development of mutual support among the students. All the teachers preferred to have students work with each other in pairs and encouraged the fluid movement of students such that, as needed, a student might move to join another pair to form a group of three or several students might form a larger group. Consistently, what determined the movement among students was the need to seek additional input on how to solve a problem or to get an additional check on the correctness of the answer. Sometimes a problem was so difficult that several students gathered to figure it out. Two things are particularly significant about this. First, the organization of students is different from what is often thought of or enacted for active learning and groupwork. Too often, teachers’ understanding of groupwork means that students are organized into groups of three to five students who are to work together on a problem. The study’s teachers felt that groups of three or more students hindered learning since mathematical problems were usually a task that could be accomplished individually thus not fitting the nature of groupwork. However, they did believe that good learning came from students talking together. Second, because of this belief, the teachers’ focus became not the organization of students but rather students’ sense of responsibility to help one another understand the mathematics. Therefore, a good deal of time was spent setting and reinforcing this culture. In the following example from the fifth grade teacher (Chval, 2000), we can get a glimpse of the development of this culture:

Teacher: Alejandro wasn’t participating because he never asked for help. So somebody over here. Anybody. You move around. I’m only one person. Move around quietly and ask each other. You can teach each other. Walk around. Help each other. I can’t help all of you at the same time.

This kind of norm was not something taken lightly; in fact, establishing it was an integral part of the overall curriculum. All students were socially identified as having particular skills and expertise that could be tapped; at the same time, all students had to take initiative to help if someone else seemed to be having trouble. The organization of students into groups became secondary to the idea of mutual sharing of knowledge and willingness to help others learn.

**High expectations.** All the teachers also had high expectations for their students that were actually manifested in the curriculum. Much has been said over the last several years about the importance of high expectations for improving the learning of underachieving minority students (e.g. Dusek, 1985). However, too often this is a hollow belief with little evidence of it in teaching. This was not the case with these teachers. For example, the fifth grade teacher began the school year with problems revolving around a right triangle such as finding a missing leg when other sides are known. The year was spent on other themes in geometry such as measuring circles and
rectangles. This is extremely unusual work for fifth grade minority students who too often start the school year one to two grade levels below norm—as was the case with this particular class. Many years experience conducting staff development with practicing teachers has demonstrated to this author that teachers tend to misinterpret the educational dictum of “beginning with what the students know” to mean starting with mathematical basics. Too many teachers would have decided that geometry was too advanced for the students and would have taught a remedial program. This teacher like the others in the study defined her task as supporting and guiding her students in such a way that they would grasp whatever curriculum she gave them. That the students were below grade level norm did not deter her from teaching an “advanced” curriculum. Interestingly, like the other teachers’ classes, outsiders assumed these students were part of a gifted class (Chval, 2000). While the idea of high expectations for students seems like an outdated one, these teachers demonstrate that it is still highly critical for the success of minority second language learners in mathematics.

**Contextualization of mathematics.** The teachers in this study were all very skillful at contextualizing mathematics. They saw contextual support as a critical tool for developing students’ comprehension of mathematical ideas and practice, and accomplished it through a combination of all of the following: drawings, concrete objects, stories that came from students, students’ experiences, and presenting everything said in written form so that students did not rely on listening for learning. Students in all the classes spent a good deal of time constructing models such as making three dimensional geometric shapes or cutting paper to show operations with fractions. In one example, in order to reinforce the ideas of perimeter and area, the fifth grade teacher had students stand next to some grouped tables in such a way that their bodies only touched the perimeter of the tables. Then the students were asked to sit on the tables so that they did not touch the perimeter and touched only the area. Such physical demonstrations were a frequent activity to ensure that students both would not forget the ideas being taught and would have a physical image to support the ideas. It is easy to assume that contextualizing mathematics is a good thing but not critical to mathematics learning. These teachers believed just the opposite. Contextualization in as many ways as possible was deemed to be the key to their students’ comprehension, and therefore their learning. Creating a highly contextualized learning environment is also a key principle of effective instruction for second language learners in general (Cummins, 1986). Therefore these teachers were integrating what they knew about learning in second language with their mathematics teaching.

**Pedagogic talk.** While some of the teachers used only English for instruction and others used both Spanish and English, they were all highly mindful, but not necessarily conscious, of their pedagogic talk. They used their talk such as probing questions and statements, both oral and written, as a tool for learning much like manipulatives. They all recognized that their students had thoughts about what they were learning but did not have words to describe those thoughts. Their task was to give the students the means to express their thoughts. However, the teachers believed
this occurred by students appropriating what they frequently heard. Consequently, the teachers’ talk was very deliberate but not unnatural; it also was very rich in terms of vocabulary, and students after a time could be heard using the same words and phrases appropriately. For example, the fifth grade teacher in one lesson used the word “congruent” over forty times but not in a repetitive manner. In the following excerpt, again, we can get a glimpse of how “congruent” is brought into students’ environment and repertoire.

Tch.: I have two congruent triangles here. Two equal parts, two exact triangles. I want only the area of my original triangle, ACB....[several teacher and student exchanges occur] Would you please read that, Julia?

Julia: The triangle and its...

Tch: Congruent

Julia: Congruent [struggling]

Tch: Look at that word everyone. Congruent. What does that mean? [students offer explanations which the teacher incorporates into her talk. Several exchanges later]

Tch: They appear to be congruent to each other. I agree. They appear to be congruent. But this one and this are not congruent, are they?

All the teachers also were exceptionally skillful in guiding their students’ thinking by the use of key questions, ones that would challenge and extend students’ thinking. Overall, there were few lower level fact or knowledge questions. In this example, the class as a whole is reviewing how they solved finding the area of a rectangle. A student has offered only the correct numerical answer, and the teacher responds in a supportive manner: “I don’t care what the number is. What does that number represent? What does it mean?” Such emphasis on asking for meanings punctuated all of the teachers’ talk to an overwhelming degree. It should be noted that these types of questions served to both develop students’ thinking

Conclusions

The purpose of this discussion was to highlight common characteristics of teachers of minority second language learners, teachers who had a clear record of being effective in significantly improving their students’ learning of mathematics. The findings point to the importance of engineering supportive and linguistically sensitive learning environments, and that teachers’ talk is critical to this process. However, it is not just any talk but talk that is carefully and meaningfully used as a teaching tool. It is talk that encourages students’ positive appropriation of mathematics thinking and knowing. The teachers in this study also point to how important it is to integrate knowledge bases. In one way or another, they drew on principles of effective second language acquisition and literacy development, and incorporated these principles into their mathematics teaching. Observations of these teachers also suggest that it is important to ensure that teachers garner accurate images of innovations. These teachers did not adopt the too common version of groupwork that is often found in classrooms whereby three to five students are physically gathered to work together.
They, instead, recognized that the essence of groupwork centers around students talking with one another to share knowledge. This meant developing students to understand how important it is to support each other. Lastly, in essence, these teachers demonstrated that it is very viable to teach underachieving students as if they are gifted, that these students do not have to start at the very beginning because they did not learn the first time around. Ideas such as manifesting high expectations for students by teaching them advanced skills may be “old hat” in terms of research, but the effects of low expectations operate still in classrooms.

LINKS BETWEEN INTUITIVE THINKING AND CLASSROOM AREA TASKS

Gillian Kidman
Centre for Mathematics and Science Education,
Queensland University of Technology, Kelvin Grove, Australia

This paper investigates the links between intuitive area integration rules and classroom area tasks in students 9 to 13 years of age. The study used rectangular and near rectangular regions of varying areas and perimeters, as well as common classroom area tasks. Information Integration Theory and functional measurement procedures were used to reveal the students' intuitive additive and multiplicative rules. It was found that intuitive judgement rules are strongly linked to a students' responses to and success on common classroom area tasks.

Area is the most commonly used domain of measurement and the basis for many models used by teachers and textbook authors to explain computational strategies (Hirstein, Lamb & Osborn, 1978; Woodward & Byrd, 1983; and Baturo & Nason, 1996). It is also a concept that textbooks commonly used in Australia either fail to define or, often (for example, Blane & Booth, 1989), discuss with the apparent assumption that students already understand it.

This apparent lack of definition, and an emphasis on formulae, seems to be contributing to the documented confusion between area and perimeter (Kidman, 1999; Kidman & Cooper, 1996a; Outhred & Mitchelmore, 1996; Clements & Ellerton, 1995; Bell, Costello & Kuchemann, 1983; Hirstein, 1981; Hirstein, et. al. 1978; Bell, Hughes, & Rogers, 1975). In particular, as Kidman and Cooper (1996b) found, students have difficulty with the process of obtaining shapes' measurements, determining which dimensions to consider, and how to integrate these dimensions when calculating either area or perimeter.

The Information Integration Theory (IIT) method Anderson and Cuneo (1978) offer an excellent opportunity to explain the process of area concept development. IIT has been widely used to identify the intuitive rules applied by students to integrate dimension information. In particular, recent studies have employed IIT to investigate students' perceptual judgement of area (Kidman, 1999; Kidman and Cooper, 1996b; Lautrey, Mullet & Paques, 1989; Silverman & Paskewitz, 1988; Schottman & Anderson, 1994; Wolf, 1995); while functional measurement, the methodological counterpart of IIT, has allowed the diagnosis, in simple algebraic terms, "... of the rules which govern integration of information about perceived stimuli."(Wolf, 1995, p. 49-50).

In these studies, students have been provided with different rectangular shapes and asked to rate their area on a linear scale. The general consensus of these studies has been that students' judgements of area obeyed two-dimensional rules. They have also shown a transition from additive to multiplicative judgement rules. The expectation is that children will make the transition from an additive integration rule to the normative multiplicative integration rule at some stage between the ages of 5 and 12.
This paper describes and reports on an investigation to determine the link between students’ intuitive judgement rules and their progress on common classroom area tasks. The investigation was based on the body of literature and the functional measurement methodology stemming from the work of Anderson and Cuneo (1978).

METHOD

The investigation used a multi-method design. The quantitative methodology of functional measurement was combined with the qualitative methodology of semi-structured interview. (A comprehensive outline of the methodology of the study, including how IIT determines area judgement rules, is provided in Kidman, 1997, and Kidman & Cooper, 1996b). The sample consisted of 36 students aged 9 to 13 years with an equal number of boys and girls and a range of mathematical abilities, one third each of above average, average and below average.

The instruments used were three experiments and an interview. The first experiment contained 16 rectangular wooden pieces painted to represent chocolate and with dimensions corresponding to the factorial combinations of 3, 6, 9, and 12 cm. The pieces were presented to students who were asked to judge the area of the rectangular pieces in relation to two end anchors. To obtain measures of the students’ area judgements, the students were provided with a 19 point scale with two end anchors, two ‘special’ pieces of dimensions 2.7 x 2.7 cm and 15.8 x 15.8 cm. The second experiment used 16 rectangular pieces identical in dimensions to the first experiment, but with a rectangular corner ‘bitten’ off producing a figure of equal perimeter, but less area. The dimensions of the ‘bitten’ off corner were all one third of the width and one third of the height of the rectangular pieces. The third experiment again used 16 rectangular pieces identical to the first experiment, with the exception that they had a semi-circular ‘bite’ out of one side producing a figure with less area but greater perimeter. The ‘bite’ was centred along one dimension with the radius of the ‘bite’ one third of the length of the shortest dimension. Throughout the three experiments, each student was quizzed as to the method they were using to rate each piece, they were asked as to whether they were aware of any changes they made to their method over the course of the three experiments, and diagrams were sought.

At the conclusion of the three experiments, the students were interviewed. Initially, the students’ understanding of both area and perimeter were discussed. The students were asked to identify if they had employed either or both of these concepts to rate the chocolate pieces. To conclude the interview, the students were asked to complete the 5 classroom tasks shown in Figure 1.

The tasks were designed to cover a range of ability and instructional levels. All students were expected to be able to complete the task involving the congruent subregions as this should be among initial area activities presented to students 7 and 8 years of age. The task involving the diagram of a rectangle marked with 3 cm and 5 cm was designed to investigate the student’s computational knowledge. The youngest students in the study were expected to be able to subdivide the region into a grid, while the older students were expected to be able to calculate the area using a formulae.
Find the area of a rectangular piece of carpet which has sides of 3 m and 5 m.

Find the area of this shape

A rectangle has a width of 3 cm and its area is 12 cm.

What is the length of the rectangle?

Find the area of this shape

Figure 1. The 5 classroom tasks

The real-world word task was designed to determine if the “draw a sketch” technique (Department of Education, 1988, p. 196) would be utilised. All but the youngest of the students should have been familiar with this technique. Both the “draw a sketch” and knowledge of the area formulae were investigated in the other word problem. The remaining task of the L-shaped figure investigated the student’s principled conceptual knowledge (Baturo and Nason, 1996) and problem solving approach.

RESULTS AND DISCUSSION

The functional measurement technique of the IIT method (Anderson & Cuneo, 1978) revealed both additive and multiplicative intuitive judgement rules were present in the sample of students (Kidman, 1997). It was found that a student could be categorised as being either predominantly additive (that is, the student intuitively had a perception of area where doubling the lengths of the sides of a rectangular region can be seen as doubling the area) or predominantly multiplicative (that is, the student intuitively had a perception of area where doubling the lengths of the sides of a rectangular region more than doubles the area) by noting the three judgement rules used by the student over the three experiments. Codes existed which were used to create the two categories. This is summarised in Table 1.

It can be seen that the predominantly additive category was composed of 16 students, from five different codes. It was not possible to determine a judgement rule for one student, in Experiment 1, due to intersecting locations on the factorial plot. The 20 students in the predominantly multiplicative category were less variant in their codes. 60% of the students experienced ‘infra-individual’ rule changes (for example, the removal of a corner in Experiment 2 caused the student to alter their judgement rule from additive to multiplicative.

It is interesting to note that for the students in this study, the proportions perceiving area as either predominantly additive or predominantly multiplicative is consistent.
across the age range (Kidman, 1997). Thus the differences between the ages was not as obvious as could be expected.

KEY A = additive judgement rule M = Multiplicative judgement rule
? = unknown judgement rule

The older students had had increased levels of instruction, but do not seem to have advanced much beyond the younger students. It is clear that many students, irrespective of age, are experiencing confusion between area and perimeter.

The two categories, predominantly additive and predominantly multiplicative, were linked with the strategies that emerged throughout the three experiments (a comprehensive description of the strategies is provided in Kidman, 1999), and from the completion of the five classroom tasks. These links are shown in Figure 2.

**Predominantly additive thinkers.** These thinkers perceive area to double when the lengths of the sides of rectangular regions double. Additive thinkers tend to think in terms of units of one (Steffe, 1992). 16 students displayed this thinking style. The actions and statements of these students throughout the three experiments revealed 4 strategies and 1 descriptor clearly linked to their additive thinking.

The *test piece rotation* strategy was particularly robust across the three experiments. In this strategy, the student would measure the outside edge of the rectangular region, by rotating the test piece so each edge was compared, around the end anchors.

The *index finger* strategy was also very robust across the three experiments. Initially the student placed an index finger adjacent and parallel to one side of the test piece. This is then repeated by moving the finger along to the next adjacent parallel position. The student repeated this procedure along the edge of the rectangular piece to the opposite side.

The *vertical alignment* strategy involved a rotation of the test piece prior to a rating being made. Each of the wooden pieces were presented to the students in a uniform manner, but some pieces were presented in a horizontal alignment (lying flat \(\equiv\)), while others had a vertical alignment (standing tall \(\perp\)). During Experiments 1 and 2, many additive thinkers rotated the test pieces when presented with a horizontal alignment so that it became vertical. One student indicated the need for the pieces to
be presented “like chocolate on shop shelves ... like the way the wrapper would go” (Rhea, 10 yrs).

The *request a ruler* strategy occurred among additive thinkers in Experiment 1. Students commented prior to starting the experiment: “I need a ruler to do this” (Jack, 9 Yrs); “This can't be done properly without a ruler” (Jodie, 11 Yrs). Jodie insisted that “we always use rulers to measure. You see, without one you can't measure something”. Jack (9 Yrs) explained that he needed to “measure the chocolate pieces to see if one was bigger or not”. He wanted to measure the longest sides of each piece.

The *extra piece* descriptor of the Experiment 2 test pieces was quite prevalent among students employing predominantly additive thinking styles. Such students perceived the near rectangular region as being basically rectangular with an ‘extra piece’ added onto it, despite having been introduced to the second set of test pieces as being “identical to the first set of pieces except they have a rectangular corner 'bitten' off”. It is possible that this view originates from the students’ perception that the area has additive properties, and therefore the ‘extra bit’ is also added.

**Predominantly multiplicative thinkers.** These thinkers have the perception where doubling the lengths of the sides of a rectangular region more than doubles the area. 20 students displayed this thinking style. Such multiplicative thinkers have the ability to think of units of one, and about units of more than one, simultaneously (Steffe, 1992). The actions and statements of these students throughout the three experiments also revealed 4 strategies and 1 descriptor clearly linked to their multiplicative thinking.
The test piece overlay strategy was particularly robust across the three experiments. It involved overlaying the test pieces onto the large end anchor in a series of flip and slide transformations.

The end anchor overlay strategy involved the small end anchor being overlaid onto the test pieces using a series of randomised flip and slide transformations also. It was also particularly robust across the three experiments. Jenny (11 Yrs) claimed she “... counted how many squares, see these little squares [indicating the small end anchor], I want to see how many of them cover this bit [holding up the test piece]”. Jay (9 Yrs) explained “it has to be the small square that you use because it doesn’t change each time like the bigger ones do”.

The partitioning strategy also occurred among multiplicative thinkers across the three experiments. These students were familiar with the method of partitioning both the length and width of a rectangular shape, and integrating these values using multiplicative reasoning. One of the students made imaginary marks along the two salient dimensions with her finger. She partitioned the width of the test piece into what appeared to be 1cm lengths, maintaining a mental count of the partitions. Upon completion of the width, her attention focused on the length of the test piece and she repeated the partitioning process, again with 1cm partitions, maintaining a mental count as she progressed. Other partitioning students explained that they imagined the chocolate pieces already divided into squares, counted the squares on two dimensions, and multiplied “…them together, like you do for area sums” (Phillip, 13 Yrs).

The remove effected ‘bit’ strategy emerged, through drawings, during Experiment 2 and maintained its presence through Experiment 3. Students using this strategy mentally removed the “effected bit”. Phillip (13 Yrs) explained that when he worked with “the boards with nails in and rubber bands ... and if my shape was wonky, the teacher told me to get rid of the crooked bit and work with the rest of it”. As a result of his classroom geo board lessons, Phillip mentally removed the altered sections of the test pieces.

The piece removed descriptor existed for students who thought multiplicatively, where they perceived the basic shape as rectangular, but with a piece removed. Such students either remembered being told a piece had been removed, or they have a more wholistic view of the shape, than the additive thinkers.

Performance on classroom area tasks. Table 1 indicated that five students are truly additive thinkers as they only employed additive integration rules across all three experiments. For these students, their performance on the five classroom area tasks was characterised by 2 strategies - failure to even attempt a task, and if attempted, the student would concentrate on some form of boundary counting. The failure to attempt a task was partially characterised by students who simply said “pass” (Ben, 9 Yrs) presumably because they were tired or bored. Students who read a task a number of times but did not actually attempt the task were also included in this category. They were not able or prepared to offer a solution even when told a solution was possible; for example, “This doesn’t have all the numbers, so I can’t do it” and, after being told it was possible, “Next” (Anne, 12 years). Boundary
counting included either grid line counting around the four sides of the figure, or a count of the spaces around the four sides of the figure.

Nine students were truly multiplicative thinkers as they only employed multiplicative integration rules across all three experiments. For these students, their performance on the five classroom area tasks was characterised by four strategies — drawing diagrams, creating subdivisions, skip counting, and performing area calculations. Two tasks were word problems. While both could have been solved without diagrams, six of the nine students successfully used diagrams. Two students (aged 11 Yrs) attempted to use diagrams for the carpet task but had difficulty deciding which measurements belonged on which dimension. Steven (11 Yrs) finally decided "it doesn't matter anyway, 3 times 5 is 5 times 3". The creating of subdivisions could be seen as an extension to the draw a diagram strategy. The majority of truly multiplicative thinkers automatically drew subdivisions on the L-shaped figure, however only a minority successfully found the solution. Computational errors caused two of the 9-year-old students to obtain an incorrect area. Skip counting in the task involving congruent subregions was also evident only among the truly multiplicative thinkers. The only students to obtain correct solutions for the classroom tasks, using multiplicative processes were the truly multiplicative thinkers.

The remaining 22 students (11 additive thinkers and 11 multiplicative thinkers) experienced 'intra-individual' rule changes. In the case of the additive thinkers, for one of the three experiments they thought multiplicatively. Similarly, for the multiplicative thinkers, for one of the three experiments they thought additively. This rule change may be the result of the students’ having the ability to think of units of one, and of units of more than one, but not both simultaneously. The classroom strategies for the additive thinkers and the multiplicative thinkers in this group were the same. They attempted all tasks, and these attempts included calculations of perimeter, ½ perimeter as well as calculations of area through 1 to 1 counting of the congruent subregions. Computational error also prevented these students from obtaining a correct area solution. For this group there was a lot of confusion between area and perimeter. The younger students particularly would calculate a ½ perimeter by simply adding the given dimensions.

CONCLUSION

This experiment extends the body of literature stemming from the work of Anderson and Cuneo (1978) by using non-rectangular regions. The findings confirm that two area judgement rules do exist, that an individual can alter their judgement rule, and that there is confusion between area and perimeter, possibly resulting from the student’s inability to think multiplicatively.

The misconception of area of rectangles being dependent on the sum of the dimensions is fairly constant across the age range especially for students who experience inter-individual rule changes. Such students may have the ability to think of units of one, and of units of more than one, but not both simultaneously. Students making rule changes experience difficulties with classroom area tasks in that they confused area with perimeter. It may be beyond the student’s ability to think multiplicatively for area tasks, irrespective of their academic backgound.
Students using additive thinking need to measure regions with a ruler or index finger and prefer a vertical alignment. Truly additive students tend not to attempt classroom area tasks. It is possible that such students do not have a workable method for some area problems, and as a result they choose not to attempt them.

Students using multiplicative thinking tended to use overlay strategies as well as partitioning, and some are capable of interpreting word problems and drawing diagrams to solve classroom area tasks.

REFERENCES

By applying symbolic computation and graphics, we tried to enhance students' ability to go from visual interpretation of the limit concept to formal reasoning. While being taught the topic “approximations of functions by Taylor polynomials”, the students analyzed the remainder and performed animations that illustrated its convergence. They used the Mathematica software for manipulating algebraic expressions and for generating a wide variety of dynamic graphics. We observed that the graphics produced by the animations were in a sense present in the students' minds even when the computer was turned off. Here we describe a situation in which the interaction with computer graphics helped the students overcome confusion caused by misleading images of the limit concept.

Introduction

This paper deals with the conceptual understanding of the convergence process obtained by approximating a function by means of Taylor polynomials. Central concepts in analysis such as limit and infinite sum are very much related to approximation theory. Therefore, by means of polynomial approximations, we tried to clarify the limit concept. We analyzed students’ perceptions of the limit concept in the context of a computer-based mathematics laboratory program. For this purpose, we used Mathematica software (Wolfram Research), which permits symbolic computation, graphics, and animation. Special attention was given to using animation in order to visualize and analyze the dynamic process of convergence. Our research focused on the question to what extent did the use of symbolic computation and dynamic graphics actually help the students in the transition from their visual intuitive interpretation of the limit concept to formal reasoning.

This paper describes some research that examined an approach to teaching analysis at the high school level. The main topics taught were Approximation and Interpolation, from which we explored the issue of Approximation theory in connection to the limit concept. High school students learning at the highest level (Age 16-17, N=84) were involved in the research.

Theoretical Background

In studying students’ perceptions of the limit concept, it is important to take into consideration the intuition of infinity. Our logical schemes are naturally adapted to finite realities. As Fischbein, Tirosch, and Hess (1979) observed, the natural concept of infinity is the concept of potential infinity. Openhaim (1986) noticed students’
difficulties in grasping that the behavior of a sequence with regard to convergence is unaltered if we omit a finite number of the terms. Davis & Vinner (1986) noticed some unavoidable misconception stages in understanding the limit concept. In trying to understand the difficulties in learning the limit concept, Cornu (1981) described "spontaneous models" that pre-exist before learning the limit notion. Moreover, the definition of limit is formulated in terms of an unencapsulated process (given $e$, an $N$ can be found such that...) rather than being described explicitly as an object (Cornu, 1991).

In attempting to overcome such difficulties, Dubinsky & Tall (1991) proposed using computers in order to enable the students to make constructions on the computer screen leading to corresponding constructions in their minds. Li & Tall (1993) discussed three approaches to teach the limit concept: (1) a (formula-bound) dynamic limit approach, (2) a functional/numeric computer approach, and (3) the formal $e-N$ approach. Monaghan et al. (1994) added a key stroke computer algebra approach. We suggest an additional approach: the use of animation to visualize the processes of convergence and to interact with the dynamic graphics. The "Calculus & Mathematica" course (Brown et al., 1991) and Devitt's "Calculus with Maple" course (1993) helped us in preparing the chapters on approximation by expansions. The reference to Euler analysis (Brown et al., 1990) was especially helpful. We used Mathematica for animating the remainder. For analyzing the results we were aided by Verillon & Rabarbel's article (1995) on cognition and artifacts. Assuming that cognition evolves through interaction with the environment, the authors studied the effect of accommodating to artifacts on cognitive development, knowledge construction and processing, and on the nature of the knowledge generated. They stressed the difference between the artifact, as a man-made material object, and the instrument, as a psychological construct.

The Teaching Experiment

The first author taught the students mathematics six hours a week, two of the six hours in the PC lab. The laboratory consists of 20 PCs, each equipped with Mathematica and a hardware system (called classnet) that permits transmitting the content of the screen of each computer to all the computers in the classroom. A pedagogical strategy in the experiment was to use the technology to follow great mathematicians' thought processes. For example, two different approaches were used to approximate a given function by polynomials: analytical and algebraic. In the analytical approach the notion of order of contact was introduced, and as an application the students were required to find the polynomials of degree 2, 3, 4,.... that have the highest possible order of contact with a given function at $x=0$. Mathematica helped the students to solve the relevant systems of equations. In the algebraic approach Taylor polynomials were introduced by using the intuitive idea of Euler: to express non-polynomial functions as polynomials with "an infinite number of terms". The students used Mathematica to follow the original text of Euler described in Euler (1988). Following Euler's "experimentalist" thinking, the students
used his algebraic approach to represent infinite sums: they used Mathematica syntax in order to expand functions as power series, applying the method of undetermined coefficients exactly as Euler did. Both approaches converged to the coefficients of the Taylor series but each one has its own characteristics: the analytical approach describes the process of the different polynomials approaching a given function; the algebraic approach represents the polynomials with "an infinite number of terms" as an object. The students made a graphical representation of the results. By means of animation (Kidron, 2000 - Example 1), they were asked to “encapsulate” the process into an object. For example, Figure 1 shows a “dynamic” plot that illustrates the fact that in a given interval, the higher the degree of the approximating polynomials, the function \( f(x) = \sin(x) \) and the approximating polynomial are closer.

![Figure 1](image1.png)

Figure 1 a "dynamic" plot of \( \sin(x) \) and the approximating polynomials for \(-\pi \leq x \leq \pi\)

The animation permitted the students to see the dynamic process in one picture: they were also requested to stop the animation and observe the different steps of the dynamic picture. In the laboratory, the teacher demonstrated a full process, by means of animation, followed by a group discussion using the classnet. The students noticed that for \( x \) values nearer to 0, the function \( f(x) \) and the approximating polynomial \( P_n(x) \) are closer. In order to clarify the meaning of “closer”, the teacher had the students analyze the remainder. The students were given the proof of Taylor's theorem at \( x = 0 \) and they computed the expansion of \( \sin(x) \) around \( x = 0 \) up to exponent 5. The error \( (f(x) - P_n(x)) \) - the remainder of Lagrange - is \( \frac{f^{(6)}(c) x^6}{6!} \) for some \( c \) value between 0 and the current \( x \) value. The absolute value of the error as a function of \( x \) and \( c \) with \(-\pi \leq x \leq \pi , \ -\pi \leq c \leq \pi \) was plotted. Because the \( c \) value in \(-\pi \leq c \leq \pi \) that corresponds to the exact error is an unknown number, the students were requested to look at all pairs \((x, c)\) such that \(-\pi \leq x \leq \pi , \ -\pi \leq c \leq \pi \).

The following 3-dimension graphics (see Figure 2) represents the error (in fact, an upper estimate on the error) as a function of the two variables \( x \) and \( c \).

![Figure 2](image2.png)

Figure 2 the error as a function of \( x \) and \( c \)
In this plot the upper estimate of the error is obtained, for example for \( x = \pi \) and \( c = \frac{\pi}{2} \). In the laboratory, the teacher demonstrated that in the example \( f(x) = \sin(x) \):

\[
\lim_{n \to \infty} R_n(x) = 0, \quad R_n(x) = f(x) - (a_0 + a_1 x + a_2 x^2 + \ldots + a_n x^n).
\]

Using animations of 3-dimensional plots in a fixed domain, the students saw with \( f(x) = \sin(x) \), how the upper estimate of the error gets smaller when the degree of the approximating polynomial is increased (Kidron, 2000 - Example 2). One student raised an interesting question: Suppose that the degree of the approximating polynomial is fixed; could we obtain the animation with the domain as a variable? At this stage of the course the students could use Mathematica as a programming language to obtain the dynamic graphical output. The teacher encouraged them to construct a visual representation of \( \lim_{n \to \infty} R_n(x) = 0 \) by animation, where the domain of \( R_n(x) \) is variable (Kidron, 2000 - Example 3).

**Research methodology and data analysis**

The methodology adopted for evaluating the students' work and for research purposes was as follows: the teacher demonstrated an idea in the PC lab. The students were then asked to explore the idea by applying their examples with Mathematica. The teacher collected three types of data: (1) students' questions and remarks during the sessions, (2) the Mathematica files of the students' examples, and (3) written tests without the use of Mathematica. We present here a class discussion and some findings from a written test. The following class discussion demonstrates the way the students used Mathematica to interact with the dynamic graphics produced, in order to re-construct their knowledge of the limit concept.

*The class discussion* The task given to the students in the lab was as follows: Select a function \( f(x) \) and illustrate \( R_n(x) \to 0 \). Most of the students dealt with functions similar to the example given in the class. Here we describe the class discussion that followed the presentation of an example by one of the students, Matan. His example was: \( f(x) = \cos(2x) \) for \(-\pi \leq x \leq \pi \)(see Figure 3). He animated (Kidron, 2000 - Example 4) the plots of the absolute value of the error \( f^{(n+1)}(c) \frac{x^{n+1}}{(n+1)!} \) as a function of two variables \( x \) and \( c \),

\[-\pi \leq x \leq \pi, \quad -\pi \leq c \leq \pi\]

where \( n \) grows from 3 to 13 with step = +2

![Figure 3 "animation" illustrating \( R_n(x) \to 0 \) for \( f(x) = \cos(2x) \)](image)
In the example that was demonstrated in the laboratory, \((f(x)=\sin(x))\), when \(n\) was increasing, the upper estimate of the error was steadily decreasing for every \(n\). This was not the case in Matan’s example, \((f(x)=\cos(2x))\), as is seen for \(n = 5\). We quote students' reactions:

Nimrod: *When the degree \(n\) of the approximating polynomial is increasing, the approximation must be better.*

Nimrod tried to explain what he meant by "the approximation must be better".

Nimrod: *In some place in the infinite they will be the same. I mean by "better" that when \(n\) is increasing the error is decreasing. It could not be that the error is getting bigger! Maybe the error is not getting smaller. I mean that maybe we cannot see it in the graph but the error is getting smaller all the time when \(n\) is increasing.*

We noticed some confusion in Nimrod’s reactions. He did not expect that the error would suddenly increase for \(n=5\). He attributed the surprising effect to some limitations of the graphics.

Matan: \((f(x) = \cos(2x))\) is an even function. An even function is expanded in a power series with even exponents. I should have given values to \(n\) that go from 2 to 14 with step +2 instead of taking \(n\) from 3 to 13.

Matan connected this surprising effect to an irrelevant fact. He used Mathematica to check his conjecture. He chose even values for \(n\) but the surprising effect remained unchanged.

Hannah: *Let us look at the different graphs that produced the animation. They do fill the requirement that \(R_n(x)\) approach 0 as \(n \to \infty\). The problem is with the degree \(n = 3\) and not with \(n = 5\). From the fifth degree and all the degrees onwards we got exactly what we expected: the error becomes smaller as \(n\) increases. We say \(R_n(x) \to 0\) if \(R_n(x) > R_{n+1}(x)\) and this happened from a certain value of \(n\) onward. In Matan’s example \(n>3\).*

Tomer: How could we know from which \(n=N\) the process begins?

Nili: *Could it be that from a certain \(N\) the error will get smaller for a few steps and afterwards the error will get bigger? We could not find the \(N\) graphically. How could we know from which \(N\) the error becomes smaller all the time?*

Hannah: *Something disturbs me - if the accuracy (\(c\)) is 0.8, for example, and you find \(N\), for example, \(N=10\) such that for all \(n \geq N\), \(|R_n(x)| < 0.8\), then you will not see the phenomenon we described for \(n = 3\). This means that for every \(\varepsilon\) there will be the \(N\) that belongs to it. Maybe we will find \(N\) if we will compare \(\frac{f^{(n+1)}(c) \times n!}{(n+1)!}\) with \(\varepsilon\) and we will look for the first \(n\) for which this expression is smaller than \(\varepsilon\).*

The students gave other examples that demonstrated that \(|R_n(x)|\) was not always decreasing. Motivated by these examples, the students searched for the \(N\) from which onwards, the absolute value of the remainder decreased.
The written test We were interested in two aspects:

1. The students' ability to visualize the process described by the formal definition of limit, and
2. their ability to express the formal definition correctly.

One of the written tests dealt with the notion of the limit, \( \lim_{x \to 0} R_n(x) = 0 \).

The test checked the students' ability to connect the visual and the analytical aspects of the limit concept. The students (N=84) worked on the test without using Mathematica. We identified different ability levels of connecting the visual and analytical aspects of the limit concept.

Most of the students (81%) were able to visualize the process described by the formal definition of the limit and to translate visual pictures to analytical language: "We are given \( \varepsilon_1, \varepsilon_2, \varepsilon_3, \ldots \) find the appropriate \( \delta_1, \delta_2, \delta_3, \ldots \)". They had no difficulty in proceeding step by step through a discrete sequence of \( \varepsilon_1, \varepsilon_2, \varepsilon_3, \ldots \) finding the appropriate \( \delta_1, \delta_2, \delta_3, \ldots \) and were aware that this process is infinite, probably in the sense of "potential infinity". "You can always find a number which is smaller than the previous one, and so on infinitely".... "To every \( \varepsilon_n \) there is \( \delta_n \)."

A smaller number of the students (68%) were able to express the formal definition: "to every positive number \( \varepsilon \), there is a positive number \( \delta \) such that...". Some of the students who failed to express the formal definition wrote: "\( \delta \) is not dependent on \( \varepsilon \); \( \varepsilon \) is dependent on \( \delta \)". "\( \delta \) is not dependent on the error, since \( \delta \) is fixing the error: the nearer we approach the point \( x=0 \) about which the function was expanded, the smaller is the error".

These students remembered the order in which they worked in the laboratory - beginning with domain and finding the error. The Cauchy's definition begins with \( \varepsilon \)... It was difficult for them to reverse the order!

Discussion and Conclusions

The class discussion around Matan's example related to the concept of the limit, \( \lim_{x \to 0} R_n(x) = 0 \). The surprising effect of the dynamic graphical feedback that Mathematica provided was very important for the students' learning experience. The students expected, as in the example demonstrated in the lab, that \( R_n(x) \) will approach 0, steadily decreasing for every \( n \). The unexpected effect of the little jump back when \( n=5 \) in Matan's example, \( f(x) = \cos(2x) \), was stronger while observing the animation than in the static plots (Kidron, 2000 - Example 4). The contribution of such feedback to the learning process is particularly effective if it is surprising (Dreyfus & Hillel, 1998). The result could be a re-construction of the meaning of some mathematical notions. Mathematica helped the students to identify "that something is not going as they expected". They had to understand by themselves the cause of the confusion. The way the students used the dynamic graphical feedback enabled them to realize that the behavior of the sequence with regard to convergence is unaltered if we omit a finite number of the terms \( R_n \).
The students used Mathematica to follow Euler's reasoning. In Euler's approach (Euler, 1988) infinite sums were represented as an object: the polynomials with an "infinite number of terms". The students used Mathematica also as a symbolic language to generate dynamic graphics, which enabled illustrating the convergence process. Using animation only to visualize the process of convergence was not enough in order for the process to become a concept, the concept of limit. In addition, the students had to interact with the dynamic graphics, to have control over the dynamic representations. Actions on the dynamic representations aided the students in developing their own reasoning. We could clearly see that the students' use of the artifact influenced the nature of the generated knowledge. In order to overcome their pre-conceptions of limit, the students were encouraged to further construct and re-construct their knowledge using the dynamic graphics approach to handle the limit concept explicitly.

We were interested in determining to what extent this re-construction of their knowledge helped the students in their transition from visual intuitive interpretation of the limit concept to formal reasoning. The class discussion around Matan's example enabled the students to modify the misleading idea that they could observe the approach $R_n(x) \to 0$ as $n$ is increasing in the sense that $R_n(x)$ steadily decreases for every $n$. The class discussion paved the way to the formal definition of $\lim_{n \to \infty} R_n(x) = 0$ (beginning by $\varepsilon$, then finding $N$ such that...). However, in the written test, only $2/3$ of the students were able to write correctly the formal definition of $\lim_{n \to \infty} R_n(x) = 0$. The dynamic graphics produced by the animations were present in the students' minds even when the computer was turned off. Some even remembered the order in which they worked in the lab (beginning with domain and finding the error) and had difficulties in reversing the order. To overcome this difficulty, additional tasks are being prepared for use in further applications of the program.

Abstract: In this paper, the first results of a comparative study on proof and proving in geometry teaching are represented. Twelve eighth grade classes (approximately 14 year-old students) were observed in France and Germany, in order to analyse the impact of culturally embedded classroom practices on the teaching and learning of proof. Also, the differences in functions of proofs based on the observed French and German teaching practices are presented here. In particular two ideal types of mathematical cultures in classroom practice have been singled out.

Results of international studies which compare mathematics teaching in different countries suggest that cultural diversity in mathematics education goes far beyond instructional methods. This research has outlined qualitative differences between the topics that were the focus of lessons and what students were expected to do as they studied these (Cogan and Schmidt 1999). Hitherto there have not been carried out any comparative studies concerning the teaching of proof, one main topic of mathematics teaching. However, Balacheff has been reflecting upon the idea that "ethnomathematical" questioning on the proof is just as necessary as its commonly accepted epistemological inquiry (Balacheff 1999).

In my comparative case study on proof and proving in French and German geometry lessons, differences in classroom practice and their implications for the learning and teaching of proof will be analysed. This study questions: How do culturally embedded classroom practices influence the teaching and learning of proof? For this I focus on the differences within proof forms and functions. The hope is that this will enrich the research in the proof and proving field from an inter-cultural as well as a classroom-cultural perspective.

Research in the Field of Proof and its Teaching

One main problem of the teaching of proofs is that students, once convinced of a statement's validity, experience so much difficulty understanding the importance of the statement's proving. In the following different approaches to this problem will be briefly represented and discussed.

On the one hand a series of learning situations, including proving exercises, have been created in order to stimulate among students processes of formulating conjectures and refutations (Balacheff 1987). Therefore, problems were designed to lead to controversy among students which should involve them into a process of proving (see further Boero, Garuti, and Mariotti 1996). In these approaches the social dimension of proof and proving is seen as essential for didactical concerns.
Moreover teaching practices of proof and forms of proofs being taught have been analysed from an epistemological perspective. Hanna and others criticised the over emphasis of formal proofs in everyday teaching (Hanna 1989; Wittmann and Müller 1990), which does not give students an adequate understanding of the meaning and function of proofs. Research in this field has made it clear that proofs have a variety of functions (de Villiers 1990), for example an epistemic function that is to understand why; a systematic function which is to relate different mathematical concepts already studied in class.

Further, proof conceptions of teachers and students as well as students' aptitudes in proving have been examined in several empirical studies (Healy and Hoyles 1998; Reiss and Heinze 2000). The latter having a focus rather on cognitive than on social aspects, even though including proving processes. These studies have given interesting insights into implicit proof conceptions of students, but they give little evidence in how far these conceptions are caused by the teaching of proof in mathematics lessons.

Research on argumentation processes gives a clue of argumentation formats in classroom situations, but is limited at the same time to the level of primary school (Krummheuer 1993; Schwarzkopf 2000). It might be interesting to see how argumentation formats in class might be linked to proving processes; analyses which have not been done yet.

All in all, in proof research few empirical studies exist on proofs and proving in everyday classroom situations (Herbst 1998). This means that we have little evidence showing in how far students’ difficulties are due to everyday mathematics teaching practice.

Theoretical framework and methodological considerations

The present study refers to sociological and didactical research theorising everyday practices. These practices can be characterised as mostly determined by pragmatic aims and a general concern of effectiveness in action (Krummheuer and Naujok 1999). In these situations interacting partners typically presume common understanding and references, which allows to structure learning processes on the basis of habitual practices. Discourses are further marked by a high degree of implicity and indexicality, which means that statements often can be understood only within the context they have been stated. From a sociological perspective this has been described as a "pragmatic cognitive style" of everyday practices (Soeffner 1989).

Focussing on everyday classroom practices from this theoretical approach helps to analyse from students’ and teachers’ point of view what we might consider as learning or teaching obstacles. A focus on their prospect is inevitable as didactic research not only aims at offering alternatives to habitual practices but hopes
changing misleading practices.

In order to analyse everyday classroom practices comparing these becomes an insightful tool. A comparative approach allows to single out characteristics of teaching practices in different contexts which could not have been reconstructed from single cases (Kelle 1994).

The methodological frame of the present study refers to the concept of "ideal types" developed by Max Weber (Webersche Idealtypen), and describes idealised types of mathematics teaching reconstructed from classroom observations in France and Germany (Weber 1904 /1988). This means that typical aspects of teaching practices are reconstructed on the basis of the whole qualitative studies rather than on an existing empirical case.

Methodical design and data analysis

The study uses methods of qualitative social sciences mainly participating classroom observation – about 30 lessons were seen at 6 different classes of eighth grade students (14 year olds) in France, compared to 30 lessons at 6 German schools (same age group). Within the observed classes, two were from a French-German college, the others from ordinary classes of collèges in Paris and German Gymnasium and higher level classes of comprehensive schools in Hamburg.

With respect to proving on the one hand and variation of contents on the other, six teaching units concerning Pythagoras' Theorem and six further units dealing with similarity and special lines in triangles were chosen. Each lesson has been recorded, so that analyses of transcripts and blackboard drawings and writings could be possible later. Classroom observations have further been expanded by protocols. As a tool to support the data analyses the software Atlas-ti is used.

Analyses of the observed proofs are done from two perspectives which are supposed as complementary: firstly, content related analyses, secondly reconstruction of argumentations. This means that forms and functions of proofs are analysed with respect to their mathematical substance and not separate from it. For I suppose as Granger that form and content of proofs cannot be separated (Granger 1994).

Research on Pythagoras' Theorem by Fraedrich and on geometrical settings by Parzysz and Douady is referred to as a theoretical framework for the content related analyses (Douady and Parzysz 1998; Fraedrich 1995). Analyses of the structures of argumentation are guided by the theoretical work of Duval and Toulmin (Duval 1995; Toulmin 1958). Duval's theoretical analyses allow for a distinction between argumentation and proof by formal aspects, whereas Toulmins' scheme helps to work out different argumentation structures. Results of the latter analyses will be published elsewhere.
First results of content related analyses

Sorting proofs of Pythagoras' Theorem which have been observed in classroom situations in France and Germany showed four different forms of proofs: 1) Proofs based on comparisons of areas 2) Proofs based on calculations of areas 3) Proofs where applying theorems on similarities, 4) Proofs using visualisations of the theorem of Euclid, meaning \( a^2 = pc \) and \( b^2 = qc \). Analysing these proofs makes evident two different interpretations of Pythagoras' Theorem: a statement about comparing areas as well as an assertion about relations of lengths, which is evidently not the same.

Taking into account that every type of proof favours one or the other interpretation of the theorem, it is surprising that in our observations tackling the meaning of Pythagoras' Theorem is not necessarily coherent with the proof done in class. When comparing French and German teaching, one has to notice that no differences concerning such inconsistencies of teaching could be found. Whereas there had been differences in the meaning, which has been assigned to Pythagoras' theorem, both interpretations – about areas and about relations of lengths - have been found in German mathematics lessons, but not in French classes. Further in German mathematics teaching all different types of proofs as systemised above could be found, while in French mathematics lessons only proofs of type one and two have been identified which correspond with proofs in curricula and in textbooks used in class.

By analysing the role of proofs within teaching it became apparent that introductory phases are essential for the teaching of proof in the observed German lessons, whereas phases of exercises play an important role for French teaching of proofs.

All observed German classes start with two or three lessons where students and teachers are engaged in a process of discovery of the theorem before proving it. In contrast to this in French teaching Pythagoras' Theorem is directly introduced to the students in the very first lesson of the teaching unit and proved with guidance of the teacher.

Having proven the theorem in French lessons, complex and sophisticated problems have to be solved by students at home as well as in class. These exercises require an application of different theorems and concepts, which have been studied in former teaching units, including Pythagoras' Theorem. Whereas in German lessons all exercises have been analysed as typical routine tasks which request simple application of Pythagoras' Theorem.

Two cases of German (the case of Nissen) and French (the case of Pascal) teaching have been chosen and shall be presented in the following, in order to illustrate typical characteristics of different teaching patterns.
The Role of discovery of theorems - the case of Nissen

Teacher Nissen starts her teaching unit on Pythagoras’ Theorem with a calculation problem: the length of the rafter of a rectangular saddle roof is to be figured out, the width of the house given. At this time Pythagoras’ Theorem has not yet been introduced, so that the students have to find a way of solving the given problem. Completing the figure by squares on the sides of the triangle and calculating the areas of these squares leads to a relation between the sides of the given triangle: $2a^2 = c^2$.

The study of the special case of a right-angled isosceles triangle is used to introduce the central idea of Pythagoras’ Theorem in two lessons. This approach allows for consideration of the theorem from two different points of view: the aspect of areas and the relation of length of the triangle’s sides. At the same time one of the most important applications of Pythagoras’ Theorem, the calculation of length, is already treated in the foregoing lessons. Throughout in the course of the teaching unit, the insights gained in the special case are prolonged to the general idea of Pythagoras’ Theorem. In contrast, the proof strategy used in the special case is not taken up any more. This might be easily explained from a mathematical perspective for the proof in the special case cannot be generalised.

In the teaching the first two or three lessons do have a special role, they lead students to discover the theorem itself and to understand the theorem in a double way, as a theorem about areas and as a theorem on the relation of lengths of the triangle’s sides. Further the special case makes it possible for the students to figure out a proof on their own, or with little help from the teacher, for the central idea of the proof is as simple that the students can do so as well.

Proofs and problems initiating justifications - the case of Pascal

Having prepared the technical part of the proof by working on the binomial in the preceding lesson, teacher Pascal works out Pythagoras’ Theorem together with the students by its proof: the area of a square with lengths a+b is calculated in two different ways: first by using the binomial, then calculating the sum of the inner square’s area, that is $c^2$, and the areas of four right triangles $4 \cdot \frac{a^2 + b^2}{2}$. This takes about half of the lesson and is completed by exercises applying Pythagoras’ Theorem.

The problems given to the students in Pascal’s class after the theorem has been introduced can be divided into two types of problems: routine versus complex exercises. Whereas in the routine tasks Pythagoras’ Theorem only has to be simply applied for calculating length, for example the length of a triangle’s side, the complex problems cannot be solved without analysing the geometrical configurations and the use of other theorems and concepts, as properties of the circumscribed circle or similarities. Further, analyses of these problems have shown that different ways of solutions are possible, among those very elementary ones, these are solutions which are based on concepts and properties that have already been introduced at grade 6.
year olds).

The teacher insists on complete justifications, why the way a student worked out a solution and her or his use of theorems and concepts is legitimate. The proof of Pythagoras' Theorem, which has been produced in collaboration between students and the teacher, offers in a way a model how justifications should be structured and marks the level of rigour which is expected by the teacher. Problems and proofs of theorems are functioning as an amalgam where the responsibility of truth is given from teacher to students and back. Everyone is asked to justify by good reasons the validity of mathematical statements she or he has claimed.

Teaching styles and functions of proofs

In the observed German lessons it seems typical that the discovery of theorems is based on special cases and applied problems, where proof and different interpretations of the theorem are merging into one another. In this pattern of teaching proofs gain the function of assigning meaning to the theorem. For meaning is here that students understand applications and different interpretations of a theorem. This explains why no problems occur when the central idea of the proof used in the special case is given up for a general proof for the same interpretation of the theorem is prolonged.

Whereas different interpretations and applications seem to be essential for German ways of teaching proof, successful defence of claims of validity of mathematical assertions can be described as typical for the observed French teaching.

Proving in French teaching is seen as an activity which characterises the whole teaching and not just phases when theorems as Pythagoras' Theorem are proven. Every exercise, even those where students are not explicitly asked to prove something, has to be edited so that the given solution is justified. It has to be made clear what is considered as assumptions, which theorems, concepts and properties are applied. For meaning is here to state the conditions of a statement's or solution's validity. The proof of Pythagoras' Theorem, which has been done in collaboration but strongly guided by the teacher, serves as an exemplary scheme on how to organise one's thoughts. This pattern of argumentation, which is acquired through edited justifications for solutions of problems as well as through proofs of theorems, gives proofs the function of defining conditions of validity. The responsibility of justifying which of the already in class studied theorems and concepts are to be used and why shifts from teacher to students and back.

Conclusion

Comparing the role of proof in German and French teaching contexts has made aware of different teaching patterns and different functions of proofs. These functions of proof can hardly be interpreted as different levels of proofs, such as more formal and
less formal proof types. It is the function of proofs which is different. In the observed
German teaching the function of proof is to "understand why", whereas in French
teaching it is important to "defend why" a statement is true.

Differences in proof functions might explain why a plurality of proof forms could be
found in German teaching. Different types of proofs can be beneficially used for
working out distinct interpretations of theorems' meanings. This might be regarded as
a loss of time when proofs' functions are to give a model as to how results should be
legitimated. In mathematics instruction where processes of "defending why" are
typical for teaching and learning in general it is more important to allow time for
students' own argumentation and proving activity. We may presume that this
characterises distinct relations to knowledge and rationality as ingrained in culture.

It seems very interesting to see in how far these differences have an impact on the
structures of argumentation in class. The argumentation analyses done so far point
out that in general assumptions are made explicit in French discourse, whereas in
German classes there might be more lenience for assumptions that rest implicit in
argumentation. Formats of argumentation might remain implicit in German practices
for sharing of meaning is more important than argumentation types.

Analysing "mathematics classroom cultures" from a comparative perspective gives a
way to single out different teaching practices of proof. These differences might help
to understand student's difficulties with proof from new perspectives. What effects do
classroom discourses have on the learning of proof? Which functions do proofs gain
through teaching and what impact does this have on students' conceptions of the
proof and their aptitudes for proving?

INVESTIGATING FACTORS THAT INFLUENCE STUDENTS' MATHEMATICAL REASONING

Dietmar Küchemann and Celia Hoyles
Institute of Education, University of London

We report on the responses of high attaining groups of fourteen-year-old students to one written algebra item and two written geometry items that formed part of a nationwide survey designed to test mathematical reasoning. Preliminary findings suggest that responses are influenced by topic (algebra or geometry), gender and familiarity, as well as by general mathematical attainment. Additionally responses to familiar (algebra) items appear to be subject more to the influence of textbook than of general mathematical attainment, while responses to unfamiliar (geometry) questions are more subject to variation between classes.

In this paper we report some preliminary findings from a written survey conducted in the first year of a three-year longitudinal study of mathematical reasoning. The aim of this research is to advance understanding of how students learn to reason mathematically by analysing their progress over time, and specifically to identify through large-scale longitudinal study, individual, school and teacher factors that are predictors of secondary school students' competence in mathematical reasoning.

A 50 minute survey was administered in June 2000 to 2797 high attaining fourteen-year-old students from 63 randomly selected schools within nine geographical areas that spanned England. The items were iteratively designed and tested over a period of three months. The starting point for the construction of each item was an issue concerned with proving, followed by a trawl of the literature around this issue and a search for relevant tasks in the curriculum. We report here on students' answers to one open-response algebra item (A1), one open-response geometry item (G2a), and one multiple-choice geometry question (G3).

Frequencies for the sample as a whole are given as well as for four groups of students (P1, P2, Q and R) in order to illustrate some trends in the data. Groups P1 (N = 30) and P2 (N = 28) are parallel top mathematics sets from a non-selective suburban school, Q is a group of 25 of the best students selected from four mixed ability classes in a highly selective school, and R (N = 31) is the top set from an urban comprehensive school.

Students were given a Baseline Mathematics Test a few weeks before taking the proof survey, to provide a measure of their general mathematical attainment. This test consisted of 22 multiple-choice items selected from the Third International Mathematics and Science Survey (IEA, 1996). There were no questions on mathematical reasoning. The mean scores on the test, for the total sample and for groups P1, P2, Q and R were 15.3, 16.4, 16.2, 20.0 and 15.2 respectively. Thus the mean scores for P1, P2 and R were roughly similar to the mean for the (high attaining) sample as a whole, while the mean for Q was substantially higher.
Pattern spotting responses to a question about generalising a structure

Question A1 (shown in Figure 1) is concerned with generalisation in a setting (tile patterns) familiar to English students. (There is extensive work on a generalisation perspective to introducing algebra; see Mason, 1996).

As well as providing a numerical answer, students were asked to show how they had obtained their answer. Responses were coded into 5 broad categories (Table 1, below). We discuss just one category here, which we name pattern spotting. In this students obtained the incorrect answer 180 by applying a number pattern without recognition of the structure of the question (see Hoyles and Küchemann, 2000, for a description of the other categories). The diagram in question A1 shows 6 white tiles surrounded by 18 grey tiles. Students were asked for the number of grey tiles needed to surround a row of 60 white tiles. The incorrect answer of 180 grey tiles was found by deriving a (false) relationship, either between the given and required number of white tiles (there are 10 times as many, so there will be 10 times 18 grey tiles) or, less frequently, between the number of white and grey tiles (there are 3 times as many, so there will be 3 times 60 grey tiles).

Table 1: Response codes for question A1

It was not unexpected that some students would resort to using number patterns and thereby attempt to make an empirical, as opposed to a structural, generalisation (Bills and Rowland, 1999). Despite the drawbacks of such an approach (see Hewitt, 1992), the use of number patterns has been widely advocated in UK curriculum materials for many years, even in such stimulating materials as the DIME project (Giles, 1984). However, in such materials students are asked to produce a systematic...
list of numerical data from which to induce a rule. Here, for reasons as yet unclear, many students were attempting to generalise from a single numerical instance; that is, not only were they ignoring the spatial structure of the situation, but they were not testing their rule on other numerical data.

Figure 2 shows the frequency of the pattern spotting response for question A1. The solid black column shows that over one third of all the students gave this response (total sample, \(N = 2797\)). This is far larger than we had anticipated, and almost as large as the proportion of students who answered the question correctly (43 %).

Figure 2 also shows the responses for groups P1, P2, Q and R. We draw attention to two noteworthy features. One is the difference between classes P1 and P2. These are parallel classes from the same school, so the finding strongly points to the operation of teacher influences, though at this stage we do not know what these might be. A second interesting feature is the relatively high pattern spotting frequency (48 %) for group Q. The students in this group were selected for their high mathematical attainment within an already selective school. Many of those who gave this pattern spotting response to question A1 gave high level responses to other items on the proof survey (including the geometry item to be discussed below); many also scored highly on the Baseline Maths Test. Again, the reasons for the high frequency of the pattern spotting response for group Q are not yet known, though the textbook used in the school might provide a clue.

Responses to an item to distinguish perceptual from logical reasoning

Question G2a (Figure 3) is based on an item by John Gardiner (personal communication). We used it to investigate whether students use perception or logical reasoning in explaining their answers to a simple (but unfamiliar) figural question (see Lehrer and Chazan, 1998; Harel and Sowder, 1998).

Students are presented
with identical overlapping squares and are asked whether the two non-overlapping regions have the same area, and why.

Responses were coded into 3 broad categories, which are shown below (Table 2). For code 1 responses, students gave no reason or only mentioned the non-overlapping areas and deemed them to be the same (or not the same) because they looked to be the same (or not). Code 3 responses focussed on the overlap, with an argument along the lines: ‘The squares overlap the same amount (and have the same area), so the non-overlapping regions have the same area’. The code 2 responses were similar but with the area of the overlap treated in a specific rather than a general way; for example, students might state that if one third of each square overlaps, then the same amount, two thirds, of each square does not overlap.

<table>
<thead>

<td>3</td>
<td>Correct answer (Yes); logical argument</td>
</tr>
<tr>
<td>9</td>
<td>Miscellaneous incorrect answers (including no response)</td>
</tr>
</tbody>
</table>

Table 2: Response codes for question G2a

Figure 4 shows the frequencies for each code, for the total sample (the solid black columns) and groups P1, P2, Q and R. Perhaps the greatest surprise was that over half the total sample gave a code 1 (perceptual) response. The relatively poor response of class R is also of interest. It matches that class's performance on another geometry item (question G1) where the students made an incorrect response based on perception rather than mobilising a simple geometric argument (see Hoyles and Küchemann, 2000). On the other hand, there is less difference between classes P1 and P2 than on question A1, and the performance of group Q is much as one might expect from their general mathematical attainment, with relatively few code 1 responses and relatively many code 3 responses.
Choices of argument to explain a geometrical conjecture

In question G3 (Figure 5, below), students were presented with a mathematical conjecture and a range of arguments in support of it (options A, B, C and D). They were asked to make two selections from these arguments—the argument that would

G3 In the diagram, A and B are two fixed points on a straight line m. Point P can move, but stays connected to A and B (the straight lines PA and PB can stretch or shrink).

Avril, Bruno, Chandra and Don are discussing whether this statement is true:

\[ x° + y° \text{ is equal to } 180° + z°. \]

Avril's answer
I measured the angles in the diagram and found that angle x is 110°, angle y is 125° and angle z is 55°.

\[ 110° + 125° = 235°, \]
and \[ 180° + 55° = 235°. \]

So Avril says it's true

Bruno's answer
I can move P so that the triangle is equilateral, and its angles are 60°.

So x is 120° and y is 120°.

120° + 120° is the same as 180° + 60°.

So Bruno says it's true

Chandra's answer
I drew three parallel lines. The two angles marked with a ● are the same and the two marked with a ○ are the same.

Angle x is 90° + ● and angle y is 90° + ○.

So x plus y is 180° + ● + ○, which is 180° + z.

So Chandra says it's true

Don's answer
I thought of a diagram where the angles x, y and z are all 170°.

So in my diagram x + y is not equal to 180 + z.

So Don says it's not true

a) Whose answer is closest to what you would do? ........................................

b) Whose answer would get the best mark from your teacher? ..........................

Figure 5: Question G3 parts a) and b)

PME25  2001
be nearest to their own approach and the argument they believed would receive the best mark from their teacher. The question was deliberately couched in dynamic terms ("Point P can move ...") to invite students to adopt a dynamic approach to the question. Fischbein (1982) suggests that such an approach can be an effective way of accessing generality and of gaining insight, and option C (Chandra's answer) is similar to an approach that he recommends for tackling the angle sum of a triangle. Frant and Rabello (2000) also suggest that a dynamic approach can be useful at an intuitive level and for forming conjectures, (though they seem to argue that a static approach is needed for a formal proof).

Two aspects of the students' responses are of particular interest. One is the marked difference between the choices for 'own approach' and for 'best mark'; the other is the difference in choice between girls and boys, particularly for 'own approach'.

Table 3 shows the distribution of choices for the total sample. It indicates that by far the most popular choices for 'own approach' were A (40 %) and B (35 %), both of which are empirical arguments, with only 10 percent choosing the general argument, C. On the other hand, 50 percent chose C for 'best mark'. This response pattern also occurred with a parallel numerical question (A3) and it echoes, the findings of Healy and Hoyles (2000) in their survey with 16-year-old students. (Not surprisingly, given the large number of students involved, the difference between the choices for 'own approach' and 'best mark' was highly significant: $\chi^2 = 1759.5$, df = 16, p < 0.0001)

Figure 6 shows the frequency of choices for 'own approach' for girls and boys in the total sample. It can be seen that the girls show a clear bias towards choice A with the boys showing a lesser bias towards C and D. These differences were also significant ($\chi^2 = 63.8$, df = 4, p < 0.0001). At this stage the reasons for the differences are

Figure 6: Question G3 - frequency of choices of 'own approach' for girls and boys in total sample
not clear, but they would seem to be worth investigating further. Similar differences occurred in question A3 and with some other items in the survey.

Discussion

These simple statistics suggest that: first, type of response to a familiar algebra item about generalisation may be related to general mathematics attainment but may also be influenced by teaching and textbook: second, that since geometry is given rather little emphasis as a context for reasoning in the English curriculum, 'better' responses in geometry (that is, introducing a logical as opposed to a perceptual explanation) may be more strongly related to general mathematics attainment than in algebra and also geometry responses may be subject to more variation (as in class R) due perhaps to teacher belief and interest: third, that even students who have had rather little introduction to proving have already developed two different conceptions of mathematical reasoning, in that arguments that they assess would receive the best mark differ from arguments they would adopt for themselves: and fourth, gender might also be a factor influencing response. Many of these results are similar to those reported following the analysis of a survey conducted in 1998 of older (16-year-old) students' conceptions of proof (see Healy and Hoyles, 2000). These suggestive findings will be investigated further: statistically using multilevel modelling (Goldstein, 1995) and qualitatively through interviews with students and teachers selected on the basis of the profile of individual or class response.

Acknowledgement

We gratefully acknowledge the support of the Economic and Social Research Council (ESRC), Project number R000237777.

Notes

1. Information about the study can be found on the project's website at www.ioe.ac.uk/proof.
2. The Year 8 book devotes several pages to number sequences, and these are presented in a fairly open way; however, the setting is nearly always purely numerical, rather than involving spatial patterns as in A1.
3. In a fourth category, not listed in the table, students obtained the correct answer by measuring, for example by imposing a square grid on the diagram and counting squares. Such responses were given by only 0.5 % of the total sample and by none of the students in the four groups under discussion here.
4. Code 3 responses were subdivided into those that did and did not make explicit reference to the fact that the squares A and B had the same area.

Abstract: Rapid advances in the global information infrastructure herald a new era of computer-assisted instruction based on multimedia capabilities and online access. One of the most promising developments lies in virtual reality (VR), which allows for an immersed learning experience in simulated environments spanning 3 dimensions. VR can be used to merge images, video, animation, and text to provide a rich sensory environment. This capability can be deployed to support instruction in spatial visualization and geometric reasoning. The multimedia presentation in concert with the active involvement of the user can make the learning experience more comprehensible, enjoyable, and memorable. This paper explores some background issues relating to the use of VR on the Internet, and demonstrates the promise of the novel technology in the context of spatial visualization.

Introduction

In recent years, the rapid development of the Internet and multimedia capabilities has led to rapid innovations in the fields of science, education, business, and other domains. One of the most promising applications of the infobahn lies in education. A widely recognized strength of the Internet lies in its vast arsenal of data and documents (Pea and Gomez, 1992).

The potential of computer networks to revolutionize education has been widely acclaimed. Unfortunately, much like the earlier technologies of television and film, the envisioned promise of computer networks has remained largely unfulfilled (Solis, 1997).

Since the mid-1990s, a promising new technology has appeared in the form of virtual reality (VR) on the Internet. The technology allows for the simulation of 3-dimensional worlds on a 2-dimensional computer screen. Through a simulated control panel known as a dashboard, the user can explore the virtual environment in any direction: moving forward, backward, up, down, and sideways or spinning on the spot. Moreover, the interaction occurs in real time.

In the literature, several studies have reported on training materials to enhance spatial visualization abilities in general and spatial visualization in particular. To date, most of the programs have focused on the manipulation of physical objects. However, the use of tangible objects is subject to drawbacks such as procurement cost, storage
space, restricted access, and mechanical failure. These limitations underscore the need for materials which transcend the constraints of temporal access and physical space. To this end, VR on the Internet represents a promising vehicle to enhance the learning environment.

The next section presents the background behind spatial visualization as well as VR on the Web. The material is followed by a case study in the form of an educational program to enhance spatial visualization. The concluding section presents some final remarks and directions for the future.

**Theoretical Background**

Spatial visualization represents a subset of spatial skills. The former has been described by McGee (1979) as "the ability to mentally manipulate, rotate, twist, or invert a pictorially presented stimulus object." (McGee, 1979, p. 893). According to one school of thought, mental manipulation is the primary task in spatial visualization (Ben-Chaim et al., 1988).

The importance of spatial visualization springs its relationship to most technical and artistic occupations including mathematics, science, art, and engineering. However, spatial visualization is not one of the standard components of the school curriculum. Rather, spatial reasoning is acquired informally through informal channels.

Even so, several studies of training programs to improve spatial visualization have been reported in the literature, in concert with various theoretical analyses and hypotheses regarding spatial visualization ability (Ben-Chaim et al., 1988; Battista, 1990; Battista & Clements, 1996; Lean & Clements, 1981).

Virtual reality on the Internet is a technology which allows for the fusion of multimedia files ranging from text to video. In addition, the technology offers a novel capability through its ability to present simulated 3-dimensional worlds.

VR on the Internet has been implemented through various formats. Perhaps the most versatile among these standards lies in the Virtual Reality Modeling Language (VRML). The language provides a relatively compact description of 3-D worlds which can be rendered or depicted using appropriate software.

VRML is a complement to the HyperText Markup Language (HTML), which specifies how information should be presented in a 2-D format on a computer screen. The complementary nature of HTML and VRML is illustrated by a program in which HTML is used to specify a window on a computer monitor. For this application, HTML could be used to partition the window into several frames, one of which might present a 3-D world specified through VRML; another frame might provide explanatory material for the VRML world through text and 2-D images specified in
A third complementary standard lies in the Java programming language. Java is a general-purpose language which can be used to depict objects in HTML or control a VRML world. For instance, an applet is a small program written in Java which may be used for, say, providing an animation of a dog running across a 2-D scene whose overall structure is specified in HTML. In an analogous way, Java can be used to process information or specify complex relationships among objects in a 3-D world whose overall organization is specified in VRML.

The technologies of HTML, VRML, and Java provide a versatile vehicle for presenting information to students in multiple media formats. HTML can be used to lay out the 2-D presentation on the screen, while VRML provides a 3-D multisensory experience, and Java is used to control behaviors within and between the following interfaces: the 2-D screen, the 3-D world, and complex interactions with the user.

The present study involves the creation of software using VR to enhance spatial visualization skills, followed by an analysis of its efficacy. Differences in the performance among the students on a spatial visualization test were investigated, both before and after instruction using the software. More specifically, the study was designed to address the following questions:

- Does Web-based instruction in spatial visualization affect the attendant capabilities among students?
- Do the effects differ for spatial visualization instruction through virtual reality in comparison to simple text and graphics?
- Which sub-factors of spatial visualization are affected the most by the use of virtual reality on the Web?

**Methodology**

The study was conducted in fall 1999 at two girls’ high schools in neighboring districts in southern Korea. The schools were the most prestigious in their respective districts, and were of equal caliber as measured by scores on a nation-wide entrance exam. Each of the two schools featured about 50 PC’s in its computer laboratory, all of them with full Internet connectivity.

All students in the sample were members of tenth-grade computer classes taught by mathematics teachers. The two teachers, both male, had recently become digital enthusiasts and wished to introduce their students to the potential of the Internet.

Before embarking on the instruction, all the students were administered the MGMP Spatial Visualization Test to obtain a baseline and background information on their
skills. The Test was developed by the Middle Grade Mathematics Project (MGMP) funded by the National Science Foundation (Ben-Chaim et al., 1988). Thirty-two multiple-choice items, each with five options, comprise the test. The test is an untimed test with 10 different types of items. The types of representations used are as follows: two-dimensional flat views, three-dimensional corner views, and a "map plan," which depicts the base of a building using numbers within squares to indicate the number of cubes to be placed on each spot. The test includes tasks such as finding either flat or corner views of "buildings," adding and removing cubes, combining two solids, or applying the notion of a "map plan".

After the pretest was given, all the students studied the software on the Web. The material required an average of about 2 hours of study, spaced over a period of approximately 2 weeks in December 1999. Then the posttest was administered immediately after the end of this period.

**Case Study**

A vital aspect of effective learning is the engagement of the student as an active participant. The use of virtual reality as a vehicle for education offers the following advantages.

- **Student interest.** VR offers a lively medium with a richer sensory texture than 2-D platforms such as books or television. The medium naturally attracts the student's attention. A motivated student is more likely to absorb and retain the material presented. In addition to the inherent attractiveness of VR, our case study elicits interest by presenting the target material in the form of a game.

- **Multiple media.** An amalgam of visual media helps to capture the student's attention and to develop a mental model of the material at hand. The technology of VR offers multiple visual formats such as imagery, animation, and video. Moreover, VR provides an integrated platform for sound and text as well as visual modes. These sensory models can be combined in synergistic fashion to convey concepts in a compelling way.

- **Learning by doing.** Many courses in the curriculum involve laboratory exercises in order to provide an immersive experience for the student. However, experimental facilities can be expensive to maintain, cumbersome to handle, time-consuming to run, and sometimes hazardous for the users. All these limitations can be reduced or even eliminated through computer simulations, while at the same time providing a realistic experience. These same factors have been prompting organizations around the world to rely on computer simulations to an increasing extent, ranging from business games to military training.

Our case study involved the development of an educational software to enhance
spatial visualization ability. The software itself was implemented in VRML code. A snapshot of the primary module in VRML is shown in the left pane of the screenshot in Figure 1. By using the mouse, a student could rotate the virtual building along any axis, or “move around” to see any side of the building at will.

As shown in the figure, the VRML module was displayed in one of two key frames in the window. The overall format of the window was specified through HTML.

### Data Analysis and Results

An analysis of the pretest data was first conducted in order to determine whether the group difference in spatial visualization was statistically significant. A summary of the analysis of variance on the pretest scores for the treatment and control groups is reported in Table 1. As anticipated, the intergroup difference was not statistically significant at the .05 level. The result indicated that the two groups were relatively homogeneous in their spatial visualization skills prior to instruction.

<table>

<tbody>
<tr>
<td>Control Group</td>
<td>31</td>
<td>24.09</td>
<td>5.66</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

An analysis of variance for the gain scores (posttest minus pretest) for the treatment and control groups separately is reported in Table 2. For each group, there was a significant overall gain on the MGMP Spatial Test. According to the t-test for two dependent samples, the t-value was -6.69 with p < .000 for the treatment group; and -3.36 with p < .002 for control group. Therefore, for each of the two groups, the difference between the pretest and posttest was statistically significant. One
interesting outcome was that the standard deviation for the treatment group declined dramatically after the experiment. The result of this investigation showed that spatial visualization ability for each group improved significantly after the Web-based instruction.

Table 2. Comparison of the gain scores for the two groups.

**p<.001

Table 3 presents an analysis the posttest results for the treatment and control groups. This comparison indicates the differential impact between software using virtual reality versus that without. The t-value using the t-test for two independent samples was 2.95 with p< .005. This result indicated that the instructional effect of the program using virtual reality was higher than that employing only text and images.

</tr>
</tbody>
</table>

*p<.01

Table 4 presents the results of the pretest and posttest by item type for both the treatment and control groups. Item type 10 yielded a surprise: the difference between the treatment and control groups on the pretest was statistically significant at the .01 level. On the whole, however, spatial ability between the two groups did not differ significantly prior to the Web-based instruction intervention.

On the other hand, a significant difference in improvement due to the treatment was observed for item types 1, 2, 4, 8, and 10. There five item types dealt with the rotation factor, one of the sub-factors of spatial visualization. We may infer that the spatial visualization program using virtual reality was more effective than the one without. Moreover, VR software was most effective for enhancing the rotation factor in the spatial visualization task.

Conclusion

The study investigated a number of issues relating to spatial visualization. The results were follows. First, Web-based instruction for spatial visualization was capable of improving the target skills. Second, the spatial visualization program using virtual reality was more effective than its counterpart composed solely of text and images. Finally, the Web-based program using virtual reality for spatial visualization was particularly effective for enhancing skills in three dimensional rotation.

The results indicate that certain materials which are difficult to teach in the mathematics curriculum can be taught effectively through suitable Web-based instruction. In particular, virtual reality is a versatile vehicle for enhancing spatial visualization, presumably due to its interactivity and dynamic display for the user.

The efficacy of Web-based instruction has been demonstrated through an educational program encoded in VRML. Virtual reality on the Internet provides an integrated environment for accessing the wealth of information being digitized all over the globe. Not only is access possible, but VR offers a multisensory vehicle for
presenting information in a compelling way. The active role of the user in navigating a virtual 3-D space and the instant response of the system provide an immersive experience.

One promising direction for the future lies in autonomous learning capabilities. The maturation of machine learning techniques offers a means of developing intelligent tutoring systems which can tailor a presentation not only to the basic level of expertise for a particular student, but also to his or her changing level of knowledge. The learning capabilities may be implemented using techniques such as case based reasoning, neural networks, and induction.

Such intelligence may be implemented as a kernel of a smart system for multimedia presentations. A framework for such intelligent systems has already been developed (Bordegoni et al., 1997). The framework for intelligent presentations has been adapted to software agents and their embodiment as icons (Andre, 1997). The framework may also be tailored readily to the educational environment. We plan to investigate these and related topics in the years to come.

CHILDREN'S INTUITIVE KNOWLEDGE OF THE SHAPE AND STRUCTURE OF THREE DIMENSIONAL CONTAINERS

Erna Lampen and Hanlie Murray
University of Stellenbosch, South Africa

Abstract.
Research about children's knowledge of the shape and structure of 3-dimensional containers or boxes was conducted with 137 boys and girls in grades 1, 2, 3 and 7. The children had to build cardboard boxes from into which an empirical referent object had to fit. The problem solving processes were videotaped and analysed together with the children's spatial products. Grounded theory procedure was used to develop the following categories to describe the problem solving processes: spatial strategies, assignment of meaning, focus on influencing factors, measurement and planning and evaluation methods. The results showed age as well as gender differences and differences in the assignment of meaning which indicated that shape perception, as in contrast to object perception, is a minimum requirement for horizontal geometrisation of everyday 3-dimensional objects. Moreover, idiosyncratic representations of spatial aspects in children's drawings that were previously ascribed to lack of knowledge of conventions are suspected to have deeper conceptual roots.

Theoretical background
Liben (1981) proposed a model for the study of spatial development that distinguishes between three types of spatial representations, namely spatial storage (implicit spatial knowledge of which a person is largely unaware), spatial thought (spatial knowledge and processes such as imagery that one can reflect on and manipulate during problem solving) and spatial products (external products, 2-dimensional or 3-dimensional, that represent space in some way). These representations can be made of specific spaces (as in geographical or environmental cognition) or of abstract spatial properties (such as understanding of projective relationships). This study took children's spatial storage of boxes as the starting point and endeavoured to deduce aspects of spatial thought about abstract spatial properties by studying their spatial products such as their overt actions, verbalisations and the 3-dimensional boxes they built from cardboard.

Freudenthal suggested that geometry for young children should start in their living space and viewed the study of boxes as a sensible starting point for the geometrisation of 3-dimensional objects. Children should handle and study boxes through practical problem solving activities so that boxes can become mental objects for them, carrying properties of shape and structure that can be revisited on different levels (Freudenthal, 1983:228). However, Olson and Bialystok (1983:37) showed that children initially perceive objects without necessarily being aware of their spatial properties like shape and structure. In
addition, Cassirer (1955) discussed the development of spatial thought and reasoned that the meaning given to spatial situations determines what is observed and represented. He suggested that spatial meaning and thought develop through three levels: from personal mythical meaning and thought, to representational meaning and thought, to scientific meaning and thought. Spatial representations in mythical space reflect the individual’s imagination and personal interpretation (a box is a house in a play situation). In representational space greater objectivity is possible through the use of language to negotiate common understanding (a box can be used as a house, but is a box) of representations in different media. Understanding in scientific space requires the development of concepts that often contradict experience, for example that a point has no dimension and a line has no thickness. In order to develop scientific spatial thought, or geometric thought, many primary intuitions must be challenged. Van Hiele’s theory of geometric thought emphasizes development from a basic level ability to observe and identify geometric figures as a whole based on visual appearance (Van Hiele, 1960). His theory does not deal with the meaning (mythical/representational/scientific) children assign to the (geometric) objects they work with. Recently, a more basic level of geometric thought than Van Hiele’s first level was proposed, based on research indicating that young children do not attend visually to a figure as a whole but rather to some salient aspects of a whole figure (Clements & Battista, 1992:429). However, revisiting Van Hiele’s earlier description of levels (1959:8) confirms that he did view thought on the visual level or Level 0 as pre-geometric thought. Where geometric thought is concerned with qualitative and quantitative aspects of shape and structure of spatial objects and situations, the pre-geometric spatial thought of young children in particular has not yet been described adequately with regard to factors like intent and assigned meaning (see also Clements & Battista, 1992:430). This study was designed to research children’s primary spatial/geometric intuitions of and meanings assigned to the concept of a box.

**Research design**

Elements of a revised clinical interview (Ginsburg et al, 1983) were combined with the observation of small groups of children who were free to interact while they solved the problem. A revised clinical interview allows the provision of an empirical referent to the subjects to help focus their thinking. Their overt actions on the referent object are recorded as data and analysed.

**The task.** The task had to be difficult enough to elicit a series of spatial thought processes. For this purpose, a box had to be built on the basis of an image of a box, in the absence of an example. The task was compared to Watanawaha’s DIPT classification (Clements, 1983:16) and assigned a (3,2,2,1) level of difficulty, which is the most difficult level described. In addition, the task was designed to be independent of the need for knowledge of conventions for drawing 3-dimensional objects, and conducive to self-evaluation by the children during the process of construction.
Each child received an A2 sheet of cardboard, a 30 cm ruler, a pair of scissors and a roll of cellotape. The children could choose an object (empirical referent) from a selection of articles small enough to hold comfortably in their hands. The children were requested to build a box into which the object that they had chosen could fit. They discussed their understanding of the word box and used hand movements and language to describe the shapes and structural properties of boxes they imaged. During the task giving phase it was stressed that simply wrapping the empirical referent object was not allowed. After a pilot study involving 31 children in different grades, the task was given to altogether 106 children in grade 1 (average age: 7 years), grade 2, grade 3, and grade 7. These children were used to tackling problems for which standard answers and procedures are not available. The children were videotaped while they solved the problem. Video data made possible the use of grounded theory development as analytic process, because the researcher could return repeatedly to the original data as the research question was refined.

Categories for describing the problem-solving processes

The children constructed boxes from cardboard according to two predominant strategies that can be described as a whole to parts strategy and a parts to whole strategy. Both strategies showed developmental variance in the degree of analysis and synthesis of the structural properties of a box. The most primitive whole to parts strategy that was identified was that of cutting a single piece of cardboard and folding it in half to produce a flat envelope. An equivalent parts to whole strategy was the cutting of two similarly shaped pieces of cardboard and cellotaping them together on top of each other to produce a flat envelope. Midway along a possible continuum of progressive analysis of parts and synthesis into a structured 3-dimensional whole, were the following variation of strategies: A whole to parts strategy that comprised of folding a strip of cardboard into three parts, one of which formed the base of the intended box and the other two forming vertical faces on the left and right sides of the base. The equivalent parts to whole strategy entailed the cutting of three similar pieces (typically rectangles) and cellotaping them next to each other to be folded as in the whole to parts strategy. In both cases the resulting holes (vertical faces) were covered with custom made pieces of cardboard that fitted the direct shape of the missing vertical faces. The most sophisticated strategies incorporated pencil and paper design processes and can be described as follows: The whole to parts strategy entailed the folding of four vertical faces, creating a base in the process (at this stage the box looks like a flat tray). Then measurement and drawing were used to determine the exact position and size of a vertical face at the back of an envisaged closed box. Cuts or incisions were made at the correct places to allow the one half of the flat tray to fold over the other half. These cuts created a new vertical face separating top and bottom, so that a typical box used by confectioners or take-away food providers for cakes, pies, pizzas, etc., was formed. The equivalent parts to whole strategy entailed the design of a standard net for a rectangular prism, which in most cases
approached the shape of a cube. The most typical primitive box that the children constructed was a flat tray (fig. 1).

Factors that influenced the construction process. Three factors were identified.

1. The children's focus was either predominantly on the properties of the empirical referent object for which they had to build a box, or on the properties of the construction materials, or on a mental image of the box they wanted to make. The children who were able to integrate the demands of the referent object, the material and the image of the intended box, were successful and reached integrated focus. Some children's focus varied between object, material and image during the construction process. The children who focused on the object made boxes that were too small, and lacked structural synthesis of the parts into a 3-dimensional whole. Children who focused on the demands of the rigidity of the cardboard and difficulties with cutting and taping made boxes that were far too large and often diverged from their intended box. For example, triangular prisms were constructed non-intentionally, because gravity caused vertical faces to drop towards each other and the child would stick the top edges together in the position they came to rest. Children who focused predominantly on their image of a box made boxes that were far too large, but showed varied degrees of structural analysis and synthesis.

2. Measurement or the lack of measurement influenced the construction process. For the purpose of this research, measurement was defined as any intentional action to ensure fitting between parts of the box and between the empirical referent object and the box. Measurement strategies predominantly took the form of manipulate and estimate actions, where children handled the empirical object or the parts they constructed from cardboard to ensure fitting of various degrees of accuracy. Some children made no effort to fit parts intentionally while other children used their rulers to measure objectively with a standard unit.

3. Planning and evaluation methods. All children made use of kinesthetic imagery involving hand movements or manipulation of the parts of the box or the empirical referent object to plan and evaluate during construction. Excessive 3-dimensional modeling of parts of the box around the object was observed among children with object focus. They typically had to model the
position of each face in 3 dimensions to determine lengths of sides, orientation of faces and relative position of faces. Excessive 3-dimensional modeling usually vitiated the planning and evaluation process, since these children were unable to retain the structural relationships between the faces in 3 dimensions when they tried to tape the faces together in 2 dimensions. Excessive 3-dimensional modeling indicated ineffective imaging of the structural properties of the box.

**Success.** A successful box was defined as a container that provides a useful and appropriate (suitable) volume, has clearly visible faces that are integrated to a 3-dimensional whole and exists separately from the object for which it was made, retaining its 3-dimensional structure when the object is removed. Measured accuracy and closedness were not taken as criteria for success, since these aspects were not specified during task giving and lent themselves to estimation and interpretation. The boxes were classified according to shape and structure and the following variations were found: rectangular prisms (fig.1), triangular prisms, cylinders, envelopes (fig.2) and wrappings (fig.3). Clearly envelopes and wrappings were not successful boxes according to the criteria described above. In addition prisms and cylinders were judged unsuccessful when the faces were not differentiated clearly (whole to part strategies where fold lines were not intentionally constructed) or integrated properly (part to whole strategies where the edges of the faces were not joined intentionally).

**Factors that caused failure.** The following factors were identified.

1. Limiting effects of 2-dimensional thinking. Some children had difficulty in representing a third, vertical dimension. After 40 minutes of trying various methods, their boxes were flat envelopes. The following examples of acute limitations were found: Children who believed that a (perspective) drawing of a box or of the empirical referent object would produce a box when cut out (Daniel and Dale, gr 2); children who handled the cardboard as if it was a sheet of rubber and did not produce fold lines, resulting in the inability to form vertical faces (Elizabeth, gr 3); children who drew unfoldings (nets), but were unable to visualise the effect of folding these drawings into a 3-dimensional box (Adam and Lara, gr 1).

2. Limiting constructions in 3 dimensions. As already indicated in the discussion of criteria for successful containers, some children had difficulty in integrating the faces they constructed into 3-dimensional boxes. Three types of difficulties were identified. Children who lost the orientation of faces in relation to the whole when they had to tape the faces together in 2 dimensions (Yolande, gr 7); children who did not produce clear fold lines to separate the faces of the box (Hlubi, gr 7) and children who did not integrate the sides of the faces to form edges of a box. The lack of integration of sides was also evident while the children made the polygonal faces for their intended boxes from the cardboard. They would draw a rectangle with one side almost on the edge of the sheet of cardboard, yet would not use the edge of the cardboard as a side of the rectangle. In another case a child...
(Shane, gr 3) used one rectangle as a template to cut two more rectangles side by side, the edge of the hole where the previous rectangle was cut out forming one side of the next rectangle. As he cut out the second rectangle, he taped the two rectangles together side by side and fitted them into the hole created by cutting them from the sheet of cardboard. He repeated the process with the third rectangle and ended with three rectangles taped together as if they had never been separate, fitting exactly into the hole they left in the sheet of cardboard.

3. Mythical meaning. Some children who had difficulty constructing their intended boxes regressed in terms of the meaning they had given to the task during discussion and made fancy objects instead of boxes. Examples of such objects, which the children themselves judged as not being boxes, were houses (complete with chimneys, doors and windows), mushrooms and bags. These terms were used by the children themselves when they talked about their products.

Discussion of the results
The results will be discussed according to age and gender variants.
Strategy. The choice of strategy shifted from whole to parts in grade 1 to parts to whole in grade 7, with the exception of grade 2 where whole to parts strategies (producing flat trays) dominated. In general boys used more parts to whole strategies and girls more whole to parts strategies. The girls in grade 7 that used whole to parts strategies used very primitive strategies, merely wrapping the empirical referent object or at most pressing in tentative fold lines after wrapping the object. The only boy in grade 7 that used a whole to parts strategy succeeded in fully explicating and representing the shape and structural properties of a box, producing a cake or pie box as described earlier. Most grade 7 boys used a parts to whole strategy that entailed the design of a net, while most grade 7 girls used a parts to whole strategy by which they assembled a net from cut out faces in a step by step fashion. This indicates that although the girls were able to fully analyse the shape and structural properties, they did not yet have a complete understanding of the synthesis of these aspects into a whole.
Focus. Children who followed parts to whole strategies showed predominantly image focus, while children who followed whole to parts strategies showed predominantly varying focus. Integrated focus occurred only among children who followed parts to whole strategies. Of grade 1 children, 50% showed varying focus, while the rest showed predominantly material focus, indicating a lack in skill with cutting and taping activities. Although 40% of the grade 2 children showed varying focus, image focus occurred most among the rest of the children. In grade 7, image focus and integrated focus occurred most and with the same frequency, indicating that skill in imaging has developed. The greatest difference between boys and girls was the degree to which they reached integrated focus. Only 9% of the girls compared to 28% of the boys reached integrated focus. On the other hand 19% of the girls compared to 9% of the boys showed object focus. As discussed earlier, integrated focus was a
sure indicator of success, while object focus leads to too small and often unintegrated boxes.

**Measurement.** Most of the children who followed *whole to parts* strategies did no measuring. *Parts to whole* strategies were characterized by manipulate and estimate measurement methods. Objective measurement (with a standard unit) was only used by grade 3 and grade 7 children. More girls than boys in grade 7 made use of objective measurement, which may be an indication that accuracy becomes more important for girls than for boys in grade 7. On the other hand Piaget, Inhelder and Szeminska (1960:33) showed that visual estimates become more accurate once children are able to measure objectively, which may indicate that the boys trusted their estimated measurements and did not experience a need for more accuracy. Piaget et al mention the intuition that children have of vanishing volume between a 3-dimensional object and its 2-dimensional net, which results in nets that are too small to be folded into a copy of the referent object. A related intuition was noticed in this study, namely that children intuitively produced 3-dimensional boxes from 2-dimensional material that were far too large for their empirical referent objects, possibly in anticipation of extra volume needed in 3 dimensions.

**Success.** *Parts to whole* strategies were more successful than *whole to parts* strategies (84% compared to 45%). As can be expected, the success rate increased with age as the choice of strategies shifted towards *parts to whole* strategies. Across ages, with the exception of grade 2, the boys were more successful than the girls (see table 1).

In 57% of the cases failure was caused by the inability to produce vertical faces. This was also the reason for the dip in performance among grade 2 boys.

**Meaning.** As indicated before, some children (in grades 1 and 2) assigned personal mythical meaning to their boxes and constructed houses and other objects. It seems that the standard image of a box for most children was that of an open rectangular prism. From the strategies children used, two deeper representational meanings of the concept box can be deduced. On the one hand children assigned the meaning *a box covers an object.* This was evident from strategies that involved wrapping actions and favoured closure above structure. These children often constructed the vertical lateral faces of the box first and attached a base and a lid later. On the other hand children assigned the meaning *a box can receive an object* as was evident from the large number of flat trays and other open boxes that were constructed. These children constructed the base of the box first. The base served as a stable point of reference and therefore these children were better able to represent the structural properties of a box. Children who integrated the two meanings produced boxes with vertical sides high enough to cover the object and clearly visible structure in 3 dimensions.
Conclusion
This study showed that young children do not necessarily view boxes as geometric objects in the sense that they are aware of the shape and structural properties of such boxes. Moreover, they may be able to represent certain properties, noticeably properties of shape, in media like language, kinesthetic images and even plane drawings and yet they may not be able to construct a 3-dimensional model from 2-dimensional material. The development from object perception and the assignment of personal, mythical meaning to the perception and representation of abstract spatial/geometrical properties and relationships seems to require a transitional phase of shape perception and representation based on the assignment of representational meaning. This implies that the assignment of representational meaning and the accompanying perception of the shape of objects may be a pre-requisite for young children to start with geometry at an entry level. This study also showed that aspects of representation that are judged to be based on lack of knowledge of conventions in a medium such as drawing, may have deeper intuitive and conceptual roots. One notable example is the lack of integration of the edges of 3-dimensional objects and even the sides of 2-dimensional figures.

References
This paper presents a case study of two 7th-grade students during their explorations in the computer-based microworld Geoboard. In their explorations of the connections between geometrical shapes and the corresponding computer instructions, the students needed to use elementary number theory concepts. The study uses inductive and discourse analyses to trace the development of the mathematical discourse between the students. It demonstrates how the computerized environment supports the construction of concepts which are tightly related both to the characteristics of the learning environment and to the relevant number theory content.

Introduction

Understanding elementary number theory concepts is fundamental for many branches of mathematics, yet it has received only minor attention in the research literature. Existing studies fall into three main categories: one, studies in which elementary number theory concepts are used to investigate other mathematical issues (Martin & Harel, 1989; Leron, 1985; Lester & Mau, 1993; Movshovitz-Hadar & Hadass, 1990); two, studies that explore the multiplicative structure of numbers through problem solving (Ball, 1990; Graeber, Tirosh & Glover, 1989; Greer, 1992); and three, studies that explore understanding of elementary number theory concepts by pre-service teachers (Zazkis and Campbell, 1996a; Zazkis and Campbell, 1996b; Zazkis, 1998; Zazkis, 1999).

In this study we use the qualitative methods of inductive analysis and discourse analysis to trace the construction of elementary number theory concepts by seventh grade students, engaged in computerized explorations of number theory concepts such as prime number, divisor, and greatest common divisor (gcd). Under the present space limitations we can only sketch the theoretical framework and hint at some of the results. For full details, see Lavy (1999).

Methodology

The computerized environment under study consisted of MicroWorlds Project Builder (MWPB) – "a Logo-based construction environment which, in addition to retaining the expressive capacity of the Logo programming language, has a number of useful object-oriented features
and facilities for direct manipulation which can be used to promote links between action- and conceptionally-based ideas.” (Hoyle & Healy, 1997)

The geoboard is a mathematical package implemented on top of the basic MWPB environment. It consists of a simulated round board with pegs at constant intervals on its perimeter. The students can change the number of pegs by using the logo instruction: newboard $n$.

For example, newboard 8 will create a 8-peg Geoboard.

A class of ten 7th-grade students met several times after school hours in the computer lab, and explored the effects of the instruction repeat $n$ [jump $k$] on geoboards of varying number of pegs. The command jump $k$ results in a line segment being drawn from the “current” peg to the $k$-th peg counting clockwise, which now becomes the new current peg. The statement repeat $n$ [command list] results in the list being executed $n$ times in succession. Each choice of specific values for $n$ and $k$ resulted in a screen display of a regular polygon or a star with varying number of vertices (Fig. 1). The students were encouraged to look for mathematical patterns connecting the input numbers and the shapes and the number of vertices of the resulting polygons or stars. These investigations led to the emergence in the students’ discourse of concepts such as prime number, divisor and greatest common divisor (gcd).

![A 7-peg polygon (jump size: 1 or 6)](image2)

**Figure 1:** Shapes obtained by the command repeat $n$ [jump $k$]

We have chosen to concentrate on one couple, Noam and Jacob, whose actions and screen productions were captured by a Video camera. These students were selected because, more than all the other students, they tended to “think aloud” during their work.

The major part of the research data is the verbalized discourse, which took part between the students during the activities. The research data included in addition to the verbalized discourse, the screen pictures at
every stage of the inquiry, the students’ body language and every piece of written paper they produced.

The data were analyzed by two kind of qualitative methods: inductive analysis and discourse tools. Inductive analysis (Goetz & Lecompte, 1984) is a method which integrates between scanning the data looking for phenomenological categories, and successive refinement of them when confronted with the new events and interpretations. According to this approach, the investigator is the primary instrument of data collection and analysis. In keeping with this approach, there were no predetermined criteria or categories made.

To get a better understanding of the learning process, two discourse tools were applied: interaction analysis and focal analysis. These tools derive from the premise that in order to understand how students learn, we cannot separate cognition from socio-cultural influences: the way we express ourselves may throw light on how we understand. The research object is the discourse through which the pair under study interpret each other’s ideas, thus gradually co-constructing their shared reality.

The first discourse tool is interaction analysis (Sfard & Kieran, 1997) through which we examined the interactions between discourse participants, with the help of a diagram constructed from the data according to a set of simple principles (ibid). The second discourse tool is focal analysis (Sfard, 1998), which is concerned with the discourse content and highlights additional aspects of the discourse between the students. Here the researcher interpreting students’ utterances is trying to understand what students actually see\(^{1}\) when they express their ideas.

Analyzing the mathematical discourse of the two students enabled us to get a better description of their personal learning profile, and to characterize more succinctly their individual contribution to the mathematical discourse. Triangulation of the three methods enabled us to obtain a comprehensive point of view of Noam and Jacob’s learning process.

**Results and discussion**

Through a detailed analysis of the data scripts, we came up with four categories which were then refined in each iteration of the data review. We called the emerging categories utterance types, number theory concepts, argumentation and rules.

We used utterance types to categorize the different kinds of mathematical utterances Noam and Jacob used through the inquiry. These included general utterances like, “we need one [number] which has many divisors.

---

\(^{1}\) a real or imaginative action.
You understand why" (Noam); specific utterances like, "fifteen. It has a common divisor with twenty" (Jacob); and general utterances masked as specific: "twenty four less the jump". Noam phrased this utterance when they were investigating the equivalence of \texttt{repeat n [jump k]} and \texttt{repeat n [jump n-k]}. He used the number 24 even though they were working with a 15-peg board, hence our conclusion that 24 (the "canonical" number of pegs in these investigations) stood for a general number of pegs.

There were two types of 	extit{number theory concepts}: the first type involved explicit geoboard notions: "With such primes, there will be only one simple polygon and all the rest will be stars". In the second type the number theory concepts appeared in a purely mathematical context: "Is twenty seven prime?"

\textit{Argumentation} included the instances in which one student phrased an argument and tried to convince his colleague of its validity.

\textit{Rules} included all the instances in the discourse in which the students tried to formulate mathematical rules.

The process of categorization helped us to characterize the learning profile of Noam and Jacob, to describe the concept development during the inquiry, and to understand the contribution of each of the students to the shared learning process.

During two sessions of inquiry, the students phrased 46 tentative mathematical "rules", most of which being related to two main concepts. Adopting the students' own terminology we called the first concept \textit{n-star} and the second concept \textit{common denominators}. In what follows we will describe the concept of \textit{n-star}.

\textit{n-star} is a star polygon with the same number of vertices as the number of pegs on the geoboard. The actual name used by Noam during the investigation was in fact \textit{24-star}, but since he used this name for all kind of geoboards, regardless of their number of pegs, we thought the name \textit{n-star} was appropriate.

After Noam and Jacob had been exploring the Logo instruction \texttt{repeat n [jump k]} on a 24-peg geoboard, Noam noticed that certain values of \textit{k} yielded a 24-star. He said to Jacob, "Wait, let me try again, I want to see something here". He could not quite formulate yet what he saw, and he needed to check a few more values of \textit{k}, and then he said: "I want to check something, ok? I think I reached some pattern in 24-stars of all the vertices." Jacob tried to formulate his interpretation to Noam's discovery but he seemed unaware of what was special about this star: "look, if you put a prime number, it will give you a star". At this point Noam made a correction: "no, not just a star, a 24-star". Jacob then rephrased Noam's idea by saying "star of all [vertices]", and Noam repeated, "yes, star of
all, this is the pattern I reached”. From this point on both students continue to use the new concept naturally in their discourse.

The development of the concept n-star reveals a process of concept refinement. At first the students use the utterance “a jump of prime number makes a star”; later they use the utterance “a jump of prime number creates an n-star”; then they refine their utterance further by saying, “a jump of a number that is disjoint to n [the number of pegs] makes an n-star”; finally, they use the utterance, “a jump of a prime number which is not a divisor of n, makes an n-star”.

The construction and the refinement of the concept n-star has been achieved via a mutual effort of Jacob and Noam, and we will now follow this construction by identifying the specific contribution of each student to the process (Figure 2).

In a geoboard with an even number of pegs

We will get a: for a jump of:

- n-star
- Prime (4.9)
- Prime (4.10)
- Odd (4.11)
- Relative prime number to n (4.13)
- Prime number that does not divide n (4.14)

Figure 2: Schematic description of shared construction of the concept n-star

Fig. 2 describes the construction of the n-star concept as a joint endeavor of Noam and Jacob. The broken lines refer to Jacob’s part and the solid lines refer to Noam’s part. In the rectangles on the right appears the size of jump and the in the rectangles on the left appears the geometric
outcome – a star or an n-star. (The numbers in parentheses refer to the utterance number in the original data).

The first rectangle in Figure 2 refers to Jacob’s utterance (4.9), that in an even geoboard (this is our own shorthand for a geoboard with an even number of pegs) a jump by a prime number will create a star. Few minutes later Jacob phrases utterance 4.11, that it takes an odd number of jumps to get a star. (It looks as though Jacob has regressed in his understanding at this stage of the inquiry: analyzing the rest of the verbalized discourse reveals that Jacob confuses between odd and prime numbers.) The second rectangle refers to Noam’s utterance (4.10) in which he characterizes the star as a special case of n-star. This is Noam’s discovery and he is the one who first coined the concept n-star. This utterance is a refinement of Jacob’s previous utterance (4.9), in which he was not yet aware that this was not just any star, but actually an n-star. The fourth rectangle refers to Noam’s utterance (4.13) in which he emphasizes the fact that the size of jump is a number that does not divide n. Although Noam used the word "star" in this utterance, looking at the preceding and following transcript, it is clear that he meant an "n-star" (hence the broken arrow in Figure 2).

The fifth rectangle refers to Noam’s utterance (4.14) in which he connects 4.13 with 4.9 and arrives at the conclusion that in an even geoboard, a jump by a prime number that does not divide n creates an n-star.

We have used interaction analysis to characterize the learning profile each student brought to the discourse, and how it helped them to construct a shared meaning of the learned concepts and how it contributed to each one’s individual learning. Applying interaction analysis to the discourse concerning the development of the concept n-star, reveals that Noam has a rich private channel which he uses in the inquiry process. Jacob, on the other hand, makes an effort to follow Noam’s actions and tries to communicate with him. Noam’s utterances are mainly concerned with mathematical interpretations that he makes for himself during the investigation, while Jacob tries to penetrate Noam’s private discourse in an effort to take part in Noam’s hidden processes. Significantly, most of the time Noam is the one who types the Logo instruction at the keyboard. When we pointed this out to Jacob he said, “he [Noam] is good at it”. Most of Noam’s utterance were completed or explained with certain screen images and came as reactions to Jacob’s questions. Noam was busy with his personal discourse while he was trying to figure out the connections between the polygons or stars appearing on the screen and the Logo instruction he was typing. Jacob, on the other hand, helped Noam to work systematically and to run a more systematic investigation. Noam uses an “examples language” even when
he talks about patterns. Jacob, on the other hand, tries to generalize even when his generalizations are sometimes incorrect. Many times during the discourse Noam’s utterances are corrections to those of Jacob, for example, when Jacob says to Noam, “look, if you take a prime number it will give you a star”, Noam answers, “no, not just a star, a 24-star”. Since Noam find it difficult to express himself verbally, he relies on Jacob’s utterances, and by using them as a basis and rephrasing them, they finally arrive at the correct conclusion. In fact, each student functions as an “expert”, promoting his partner further within his zone of proximal development (ZPD). Noam, who is adept at handling the computer, helps Jacob understand the mathematical regularity of the geoboard. Jacob, on the other hand, pushes Noam into a more systematic investigation, which in turn leads Noam towards new directions to explore. The way Jacob formulates his ideas helps Noam articulate his own more clearly.

The n-star concept emerged from a synthesis of the geoboard learning environment (stars and polygons, the number of pegs n and the jump k) and the related number theory notions (primes, divisors, gcd, etc.) The construction of the n-star concept was the result of a process in which the students learned how to generalize from examples, create and refine hypotheses, and see mathematical patterns through the screen images.

UNDERSTANDING TEACHERS' CHANGING APPROACHES TO SCHOOL ALGEBRA:
CONTRIBUTIONS OF CONCEPT MAPS AS PART OF CLINICAL INTERVIEWS
Roza Leikin, Daniel Chazan*, and Michal Yerushalmy

Haifa University, Haifa, Israel; *Michigan State University, East Lansing, MI, USA

In this paper, we present a part of a larger study that examines changes in teachers' conceptualizations of school algebra. From a larger corpus of data, this paper examines data from two interviews with two teachers. Among other mathematical tasks the teachers were asked to draw a concept map for the concept "equation." Our hope was that these concept maps would help us identify teachers' conceptions of equation and how those conceptions fit inside a larger approach to school algebra.

Objectives/purpose
Within mathematics education, there is a strong assumption that teachers' "amount" of mathematical knowledge is a key component of their capacity to teach mathematics successfully. Quantitative attempts to support this assumption have used crude measures of prospective teachers' content knowledge and of the mathematical resources that they bring to teaching tasks and have not shown a positive correlation between the number of mathematics courses taken by teachers and their students' achievement (Begle, 1979). Thus, in order to examine this assumption more carefully in the future, it seems useful to develop better tools for describing and assessing teachers' mathematical understandings of the subjects they teach.

In science education, concept maps -- defined as a two-dimensional representation of relationships between selected concepts -- have been used extensively with a wide range of students, both as an instructional tool and as a mechanism for assessing the understandings of individuals (e.g., Novak, 1998). More recently, concept maps have been used in mathematics classrooms (e.g., Wilcox & Sahloff, 1998) and in research on student learning (e.g., Doerr & Bowers, 1999; Schmittau, 1991; Williams, 1998).

In this study, we will examine the strengths and weaknesses of concept maps as a tool for examining teachers' understandings of the mathematics that they teach. Are there reasons that concept maps might be especially useful in understanding how teachers conceptualize their approach to a topic? Or are concept maps limited in some principled ways when used to explore teachers' understandings?

In particular, we are interested in teachers' understandings of equations and the solving of equations. With the presence of new technologies, the algebra curriculum is in a state of flux; an extremely visible impact of the use of technology in school algebra involves using numerical and graphical representations of functions to identify solutions of equations. As a result, there is disequilibrium in the mathematics education community's views on relationships between algebra and functions (see, for example, Lee, 1996; Bednarz et al., 1996; or Lacampagne et al.
Therefore, it seems especially useful to have tools to assess teachers’ understandings in this area, as shared understandings of relationships between algebra and functions change.

**Perspective or theoretical framework**

Utilizing concepts from research on the psychology of student learning (Vinner, 1991), researchers interested in the understandings of high school teachers have studied their conception of function (see Cooney & Lloyd, 1993, for a review). As school algebra curricula have changed, some studies explore the conjecture that teachers’ implementation of curricular topics related to functions are influences by the teachers’ definitions of function. If that conjecture were true, teachers’ definitions of function would shed light on their willingness and capacity to implement function-based curricula approaches to algebra. For example, Lloyd and Wilson (1998) focus on relationships between a teacher’s implementation of the Core Plus curriculum and this teacher’s conceptions of function. They suggest:

"... because Mr. Allen was able to reconcile the Core-Plus approach to functions with the prominent features of his own conceptions of functions, the Core-Plus materials furnished a way for him to translate his understandings into new, but comfortable, pedagogical strategies" (p. 271).

We in addition suggest that it might be fruitful to create a construct “approach to school algebra” that indicates a teacher’s overall orientation and to find tools to elicit and analyze such views.

**Methods of inquiry**

**Sample:** This research report describes a small piece of data from a larger study (Yerushalmy, Leikin, & Chazan, in press). We will focus on two in-service, high school mathematics teachers from a larger of sample of nine teachers. All of the interviewees in the larger study come from one U.S. school district. The district in which the interviews took place adopted a district-developed introductory algebra curriculum. This curriculum is built around the assumption of technological support, primarily in the form of graphing calculators. According to the criteria in Chazan and Yerushalmy (in press), this course takes a functions-based approach.

"[It] initially emphasize[s] the interpretation of: letters as variables, rather than unknowns; expressions as the correspondence rules for functions; the Cartesian coordinate system as a space for displaying the results of calculation procedures, rather than the points in a solution set; and the equal sign as the assignment of a name to a particular computational process (f(x)=...) and as the indication of identity between two computational processes."

**Interviews:** Each interviewee was interviewed twice, once at the beginning and once at the end of the school year (1999-2000). Between the two interviews, the interviewees taught the district’s curriculum and met five times during the year to discuss issues in algebra curriculum reform.

In the fall, interviewees were asked to compare and contrast different equations and to solve equations of different types. In the spring, the teachers were asked to discuss a set of statements about relationships between equations and functions and
then relate these to their thoughts about teaching students what the solution to an equation is and how to recognize equivalent equations.

Besides these mathematical tasks, both in fall and in spring interviews, the teachers were given a table of concepts (e.g., variables, unknowns, statements about numbers, functions, ...) and asked to draw a concept map of an equation. Of course, interviewees also added their own terms. In the fall, if an interviewee did not know what a concept map was, the interviewer provided an example of a concept map for the notion of quadrilateral. In spring interviews, the teachers were asked to compare new maps they had drawn in preparation for the interview with their fall maps.

Throughout the interviews, the teachers were asked to talk aloud. All the interviews were videotaped and any written work done during the interview was collected.

**Data presentation and analysis:** We will analyze the fall and spring interviews to identify the teachers’ conceptions of “equation” and whether they hold a functions-based or an equations-based approach to school algebra (Kieran, 1997; Chazan & Yerushalmy, in press). The discussion section will reflect on contributions of the concept maps to our understanding of the teachers’ views.

**Results**

**Peter:** In the fall, Peter was just starting to teach the introductory algebra curriculum. He consistently connected the concept of equation with a concept of function when performing tasks and discussing his performance. But, different tasks highlighted two different kinds of connections. For example, Peter viewed the equation $2z = x^2$ as a comparison of two functions.

> Basically the way I would think about it first anyway is that I would think about what this problem means is where does the output of this function $2z$ the same as the output of this function $x^2$.

In contrast, when solving the equation $x^2/4 + y^2/9 = 1$ he said:

> ... That one has they in there and it doesn’t look like we are comparing it to another function it seems like all those points in one relationship ... So I would say I could think of this one as a function just $y$ equals [by isolating $y$]...

More generally, whenever $y$ was explicitly a second variable, in an equation in two variables, or in a system of two equations in two variables, he continued to think about functions, by turning equations of two variables into functions of a single variable.

Overall, Peter’s fall concept map suggests that he is thinking about a function-based approach to school algebra. Almost all of the terms used for construction of this map and connections between the terms can be associated with function based approach (e.g., letters as variables, inputs as candidates for solution sets, ...). Peter, for example, explained:

> ... When I thought of an equation ... the first thing that I saw was ... a function. What I really thought of when I meant function was I kind of think of that is relationship between variables. ... And from there spread out into the idea of variables, things that
are changing that include the input and output ... The input was restricted by the domain, and ... part of the inputs can be a solution set.

One link seems not to fit with this interpretation, viewing an equation as a function. However in his discussion of the map, he connected it back to his two views of the connections between equation and function:

I wasn’t sure ... if equation and function were exactly the same. ... You could think of an equation as a function. ... Equation I [also see] kind of built of function obviously kind relate to that. ... I thought also that graph went of an equation as you can think of equation as the function itself.

![Fall and Spring Concept Maps]

**Figure 1: Peter's concept maps**

While Peter’s fall map was not organized hierarchically, his spring map is more tightly organized and has hierarchical components. In his spring map, equations were defined as an equality of functions (as opposed to inequality). He also connected equations directly with tables, graphs in the Cartesian plane, and symbols “because equation can be thought of as a graph; ..., or can be illustrated by table.”

In contrast to the fall interview, in the spring, Peter thought of equations in two variables as constructed out of two functions of two variables. For example he expressed his reasoning about the equation $x^2/9 + y^2/4 = 1$ as follows:

> We are trying to find where that output matches up with this different relationship between x and y. So here [in the right side] x and y are not written here because it is a constant function of 12 ... To make more sense I will write that I am just thinking of these as $f(x,y) = g(x,y)$, that’s how I am, interpreting those.

Peter felt that his ideas had not changed much from fall to spring.

> My thinking hasn’t changed much... I [am] actually pretty surprised how this [spring map, which] is done after a lot of thinking about teaching similar to this [fall map, which presents] just some random thoughts I had 6 month ago...

Interestingly, he suggested that his teaching effected his spring concept map and even seemed to say that it was organized according to “how it [solving of equations?] was taught in my class in the last ... three months or so...” However, his spring map was more complicated than that. In his words, it
represented both how he thinks, how the introductory course is organized, and "normal" approaches as well.

This [spring map] is kind of a combination of the way I think about algebra and the way that school curriculum thinks about algebra and how that probably different from the traditional view about algebra or what you see in normal Algebra-1 book.

He continued and clarified why he placed "unknowns" in the branch of "Symbols," something that could be taken as in tension with the rest of his map. Variables were related to equations that are built of functions; unknowns were associated with either equations as they are presented in standard textbooks or points of intersection of the functions corresponding to equations’ solutions.

I put unknown here, which is a little bit different... I could have put variable here too [under symbols] but traditionally when you are talking about symbolic manipulation which is usually the algebraic manipulation, which is traditionally taught, variable can be thought as unknowns. Which is different than how I think about it.... The reason I think the unknown fits under equations is because we are looking for the point now....

Bob: Bob was a second year teacher in the fall of 1999. In 1998-99, he taught at junior high school. For the new year, he was transferred to the high school. At the junior high school, Bob taught the introductory algebra curriculum. This curriculum seemed different to him than the way he had thought about algebra in the past.

Throughout the fall interview, Bob consistently compared two approaches to school algebra. He discussed solving each one of the tasks in the interview according to two different approaches. He provided explanations from two perspectives, continually referring to what he had thought "before" and what he thought "now:"

Before it [solving equations] was, ... much more of trying to manipulate and do operations to each side... Now I think of that more like this is one function this is another function they got to be equal somewhere.

However, when he solved equations, he seemed more comfortable operating in the "before" mode. For Bob $x^2/9 + y^2/4=1$ was an equation because it had an equal sign in it, an observation that fits his "before" mode. Then, shifting to his "now" mode, he discussed this equation in two variables as a comparison of two functions in two variables. At the same time, in discussing the graph of the solution set to this equation, he described the ellipse as "not necessarily a functional relationship." He concluded his reasoning about the similarities between this equation and an equation in one variable:

Ah...it's still an equality um...this is in this has only one this $[2^x=x^2]$ is really showing you only one variable this $[x^2/y^2/4=1]$ is showing you two variables ...It's $[x^2/y^2/4=1]$ not necessarily a functional relationship except for again if we make that z it is in three dimensions.

But, ah...similarly that their solutions would be values that if I'm solving this $(2^x=x^2)$ I'm looking for the values and that makes this true. Solving this I'm looking for the values x and y that makes that true. So that will be similarity. So this [equation in two variables] is a curve and those $[2^x=x^2]$ are curves.

Bob’s fall concept map provides indications of two ways of thinking. First, an equation has unknowns that may be variables and it has an equal sign. But, it is not
so easy to label his fall map as indicating an equations-based approach. For example, in discussing the map, he said:

> Both algebraic and transcendental [equations] can be solved by algebraic and symbolic manipulation, [by] looking at the Cartesian plane and [by] the graph and the intersection or tables of inputs and outputs... Solution set for either would be determine by domain and equivalent equations or [by] the intersection of the graph or where the tables ... have the same output.

Like his fall map, Bob’s spring map includes both hierarchical and web-like components. In contrast, to the fall map, the definition that it provides for equations is less clear. Equation is under functions, along with graphs and tables. On the other hand, if one has “more than one function,” it connects with “two sides of an equation.” For him “An equation can frequently be made up of two functions then we can start talking about intersection points and solution set”.

In the spring, Bob feels that both the organization and the content of his map have changed. Even with the ambiguity about the relationship between equations and functions, he spring map seems to reflect more explicitly Bob’s “now” mode of thinking: “Here [in the spring], I started with relationships and functions, with equation as a part of function.”

The rest of the spring interview supports these observations drawn from the concept map. When choosing a proposition that expresses a relationship between an equation and functions he, for example, said:

Figure 2: Bob’s concept maps
I wouldn’t agree with number 2: A function is a way to represent an equation. ... Because I think of an equation as a subset of functions, as opposed to a function being a subset of equation... The function can be represented can be written out as an equation.

His interview comments revealed that he was referring to two views of equations. An equation can represent a function: “This \[ y=3x-5 \] is talking about a relationship: for any \( x \) value you are getting \( y \) values.” This contrasts with his view of equations in one variable.

I am trying to think, here \[ x+2=3(x-1) \] we will be talking about two linear functions and we are looking at two linear functions and when does those two lines cross.

Equation in two variables bring forth a mixture of ideas:

I can see that \[ 5: x^2+xy+y^2=12 \] as ... three variables three dimensions and then this is the value that you want I guess [if not in 3D] then I would have to refer back to what I said about \( 3 \) \[ y+2=3(x-1) \] and \( 5 \) \[ x^2+xy+y^2=12 \] that this still representation a nonfunctional relationship. If \( x \) is supposed to be the independent and \( y \) the dependent or switch it around either way it is not a ...function.

Discussion

Are there reasons that concept maps might be especially useful in understanding teachers’ knowledge? One strength of concept maps is that they can indicate a conception of a concept as well as how this concept fits into a larger web, potentially revealing tensions in a teacher’s thinking. For example, Bob’s fall map suggests a definition of equation from his “before” mode and a web that has elements of his “now” mode.

Are concept maps limited in some principled ways when used to explore teachers’ understandings? School algebra is a complicated domain to conceptualize. The teachers we interviewed knew different views (Bob’s “before” and “now,” Peter’s own views and what appears in texts). There also is the question of how teaching appears in the maps. Does the way that teachers teach fit with how they think themselves? Which of these is being represented in the concept map?

As a result, we would certainly advocate the importance of discussion of maps with interviewees, as well as the combination of concept maps with other interview tasks. Without such supports, it seems very difficult to assess what one sees and to determine whether repeated use of concept maps over time reveals changes in perspective or representations of different aspects of a teacher’s thinking.

Abstract: In this report, we present an on-going research about the professional development of pre-service secondary mathematics teachers. This professional development is analysed through their relationship with algebra. After presenting our theoretical frame and methodology, we describe the multidimensional grid of professional competencies in algebra that we have developed in order to analyse the professional relationships with algebra and their evolution. We face then our research hypothesis with the first results obtained through the analysis of questionnaires and interviews.

I. INTRODUCTION

Various research studies have recently addressed the issue of teachers’ professional development (see e.g. (Cooney, 2001) for a synthesis). Our on-going research belongs to this category. It focuses on the professional development of pre-service teachers (called PLC2) who, in France, have just passed the national competition called CAPES in order to become secondary mathematics teachers and are given one year of professional training in an IUFM (Institut Universitaire de Formation des Maîtres). Note that during this year of professional training, they also have one class in full responsibility, 6 hours per week. Research also focuses on one particular mathematical domain: algebra, as we hypothesise that reconceptualising mathematics in an important part of professional development, which includes changes in general epistemological views and changes in the perception of specific mathematical domains. The choice of algebra is motivated by the following reasons:

- algebra is a domain which poses severe learning difficulties and is the first step towards mathematics rejection for many students,
- algebra is a domain, all our PLC are concerned with as they have to teach algebra or pre-algebra in their full responsibility class,
- algebra is a domain which, a priori, they feel easy to teach. Algebraic thinking is for them a natural thinking mode and they have a great familiarity with the algebraic techniques they have to teach. Understanding pupils’ difficulties requires thus from them a lot of efforts,
- algebra is a domain where naïve epistemological views are strongly inadequate,
- and, finally, this is a domain which has been extensively investigated by research. We have now a fairly good knowledge of the main difficulties pupils meet with elementary algebra, and research also provides engineering designs whose aim is...
to tackle these difficulties more efficiently. These research results strongly inspire the short professional training they receive at the IUFM.

Through this research work, we want to better understand how the PLC’s relationships with algebra change when they move from a student position to a teacher position, thanks both to the training they receive at the IUFM and their practical experience as teachers. We hypothesise that the different professional competencies which can be attached to algebra are not equally accessible, for reasons which have also to be understood and that a better knowledge of such differences could help to design more efficient pre-service training strategies. Conceiving efficient training strategies in the context of the IUFM is not an easy task, due to severe institutional constraints. For French secondary teachers, pre-service professional training is concentrated during the two years they spend at the IUFM. During the first year, they essentially prepare the very difficult national competition whose professional component reduces to the choice and presentation of a selection of exercises on a given mathematical theme, during the oral part of the competition. During the second year, the part of training officially devoted to the didactics of mathematics, different from one IUFM to another one, rarely exceeds 120h.

II. THEORETICAL FRAMES AND METHODOLOGY

Theoretical frames:

For this research, we rely on different theoretical frames. At a global level, we rely on the anthropological theory developed by Chevallard (1997, 1999) in order to analyse “mathematical and didactical organisations”, the associated “mathematics praxeologies” (in terms of tasks, techniques, technologies and theories), and also the mathematical professional work of the teacher via its different “gestures”. As regards the analysis of the teacher, we also refer to the frame developed by Robert (1999), relying on research in ergonomy in order to give account of the functioning of the teacher, seen as an actor in a “dynamical open environment”. These theoretical frames lead us to hypothesise that professional development is a very complex process, that its understanding requires a multidimensional analysis taking into account and connecting the different professional gestures of the teacher, both in and out of the classroom. Of course, we also rely on educational research in algebra and especially on synthesis such as those produced by Bednarz, Kieran and Lee (1996) or Grugeon (1995). We hypothesise that professional expertise in algebra is a complex mixture of competencies specific to this domain and more transversal competencies which strongly intertwine in professional practices.

Methodology:

Taking into account our “problématique” and the nature of our hypothesis, we have chosen a qualitative methodology based on the triangulation on multiple sources of data and analysis which allow to take into account the multidimensionality of professional competencies and professional development as a process. It includes:
- questionnaires and interviews with students just before they take the CAPES competition, that is to say at the end of the first year at the IUFM,
- observation of the training process organised by the IUFM for the PLC2 as regards algebra,
- questionnaires taken by the complete cohort of PLC2 at the beginning and at the end of the academic year,
- and, most important, the following up of a group of PLC2 (6 in 1998-99 and 6 in 1999-2000), selected among volunteers, through regular interviews, videotaped classroom observations, collection of teaching material (personal teachers notes, assessment tasks, selected students' copy-books excerpts and productions).

Moreover, in order to analyse the whole data, we have built a methodological tool: a multidimensional grid of professional competence in elementary algebra (MGPCA), thanks to the results and categories coming from the research work used as a theoretical or experimental reference. We briefly introduce this grid in the next paragraph.

III The multidimensional grid of professional competence in elementary algebra

As stressed above, we consider that professional competence has to be analysed in multidimensional terms. It can be modelled as a multivariate function which shapes the decisions the teacher takes in his (her) different professional gestures, the way (s)he faces unforeseen situations, the discourse and analysis (s)he develops at a more reflective level. This professional competence, as regards algebra, relies both on transversal and specific competencies. The MGPCA focuses on the specific competencies and tries to describe potential underlying knowledge. We hypothesise that such knowledge influences the different professional gestures in a non-uniform way and that it cannot necessarily be made explicit. One ambition of the research is to explore the complexity of relationships between knowledge and competencies, to try to find the real influence professional algebraic knowledge plays with respect to other determinants of PLC2’s behaviour, and to evidence some regularities which could help to better understand teacher’s behaviour and improve training strategies.

The grid is structured around three non-independent dimensions: the epistemological, the cognitive and the didactic ones. In the following, we synthesise the contents of knowledge which structure the grid according to each dimension.

The epistemological dimension:

Epistemological knowledge in the grid, is structured around, on the one hand, some important features of the historical development of algebra, on the other hand, the distinction between the “tool and object” dimensions of algebra (Douady, 1984).

As regards the first point, one essential epistemological characteristics is the complexity of the algebraic symbolic system and the difficulties of its historical development. Such knowledge can help to understand the difficulties met by present pupils. Another important point which arise from historical development is the
extension and diversity of the algebraic domain. Such knowledge can support the change of epistemological views about algebra, allow to better understand the rationale for the progression in algebraic knowledge organised by the curriculum and eventually discuss this. We conjecture that, at the beginning of the academic year, our PLC2 are unaware of this complexity and tend to reduce algebra to the algebraic structures and theories they have been taught at university.

As regards the second point, the distinction between the tool and object facets of algebra allows to structure algebraic knowledge around two perspectives: a tool perspective where algebra is considered as a set of tools allowing to solve different kind of problems internal or external to the mathematics field, an object perspective where algebra is considered as a structured set of objects with specific properties, semiotic representations, treatment modes, which are studied for themselves (Grugeon, 1995).

We conjecture that PLC2, at the beginning of the academic year, mainly see algebra as a tool for solving problems which can be modelled in terms of equations and that, as teachers, they will tend to over-emphasise the work on algebraic techniques.

The cognitive dimension:

This component deals with potential professional knowledge about learning processes in algebra. We have organised this part of the grid around three main points linked to resistant learning difficulties evidenced by didactic research: the relationships between arithmetic and algebra, the symbolic system of algebra and the relationships between different semiotic representations used in algebra, the role algebra can play in the development of mathematical rationality. For this part of the grid, we especially rely on the synthesis made by Grugeon (1995) in her attempt to define a multidimensional grid of analysis of pupils’ competencies in elementary algebra.

Algebraic knowledge builds on arithmetic knowledge but also against it. Algebra, when introduced, shares with arithmetic many objects and symbols but these have to take new meanings: for instance, equality has to become an equivalence sign in order to allow algebraic manipulations, letters have to take several different new meanings. Beyond that, arithmetic and algebraic thinking modes are of a very different nature, the first one belonging to the synthetic mode and the second one to the analytic mode. Understanding algebraic thinking modes also imposes semantic changes. Algebraic work contrarily to arithmetic work cannot only rely on external semantics, semantics has to take also an internal dimension proper to algebraic expressions. Other kind of knowledge deals with the specificity of the symbolic system of algebra, already evoked in the epistemological part, and the resistant difficulties it induces (for instance those resulting from the lack of closure). Learning difficulties can also be linked to the necessary interaction in algebraic work, as in any mathematical work, between different semiotic registers, especially here: the symbolic register, the natural language register, the numerical register and the graphical register, and the difficulties of conversion between non-congruent semiotic representations. Finally,
we integrate in this cognitive part, knowledge about the role algebra can play in the construction of students' mathematics rationality.

As regards this cognitive dimension, we conjecture that, at the beginning of the academic year, PLC2 are not aware of the learning difficulties evoked above, but that, through their practice and discussions with pairs, they soon become sensitive to most of these, even if they are not able to interpret them in coherent and analytic ways as research allows to do, and thus react efficiently. As regards rationality, we conjecture that, due to the general educational French culture which over-emphasises the links between rationality and geometry at the expense of any other one, integrating this pole of knowledge will result more difficult.

The didactic dimension :

Knowledge relevant to these two first dimensions certainly influences the didactic and mathematical organisations, the teachers develop. But these are also shaped by what we will call here more specific didactic knowledge: knowledge of the curriculum, of the specific goals of algebraic teaching at a given grade, of possible progressions and activities for the teaching of algebra compatible with these and well adapted assessment tasks, knowledge of educational resources: textbooks but also publications from the IREM (Instituts de Recherche sur l'Enseignement des Mathématiques), websites (especially as regards the use of computer tools such as spreadsheets for the teaching of algebra), etc.

IV. SOME PRELIMINARY RESULTS

The first results we present here result from the analysis of questionnaires and interviews. In the near future, we will face them with the detailed analysis of the different elements of the PLC2's following up. This will allow us, we hope, to better understand the possible relationships between systems of knowledge and competencies. We summarise these results according to the three dimensions of knowledge structuring the MGPCA.

The epistemological dimension :

The first analysis tend to confirm the conjectures made about the initial PLC2s' state. Nevertheless, the training at the IUFM seems to easily destabilise the vision of algebra as a domain reduced to the field of algebraic structures and theories. For most students, boarders of algebra tend to blur or to become questionable, for some others a duality seems to install between two points of view: the mathematical and the educational, resulting in two distinct conceptions of algebra which coexist. As regards the diverse facets of algebra and the tool/object dimensions, the object dimension strongly predominates and this priority tends to resist to the training. Their initial vision of the different tool facets of algebra is limited and integrating a functionality of proof for numerical properties seems specially difficult. The strength of the cultural obstacle is especially visible here.

The cognitive dimension :

PME25 2001
As conjectured, initially, the PLC2 are not aware of the difficulties of the transition between arithmetic and algebra. The short training they have (6h) seems to make them aware of the differences between the arithmetic and the algebraic processes for solving numerical problems. But they tend to see the algebraic method as the "right method" safer, simpler and more rigorous, which has to take the place of arithmetic methods, more intuitive and, at the same time, requiring more astuteness. As one of them expresses at the end of the year: "An arithmetic approach is more a reasoning out of standard ways. It is less framed. One cannot really say that there exists a method". PLC2 teaching grade 8, where the solving of problems which can be modelled by first grade equations is an important point in the syllabus, seem specially sensitive to this difference. Nevertheless, even at the end of the academic year, deeper interpretations of the arithmetic / algebraic cut are not spontaneously evoked by students, at the exception for some of them of situations where they are asked to interpret students’ errors.

As regards the symbolic system of algebra, students are very soon aware that they have to face resistant learning difficulties. Some of these are helped by previous experience of giving private remedial courses. But we notice evident differences in the way the PLC2 interpret these difficulties and in the way they tackle these. Once more, the grade they teach in full responsibility seems to have an evident influence on their perception. Knowledge related to the internal semantics of algebraic expressions and the role this knowledge plays for piloting and controlling algebraic work seems the most difficult to internalise. What predominates in algebra for them is the existence of formal rules for transforming expressions and equations, and the algorithmic character of most elementary algebraic practices. This doesn’t help them to pay the necessary attention to what becomes crucial in more complex algebraic computations. Once more, we see here the strength of a cultural obstacle equalling algebraic computation to computation without intelligence. As regards the connections between different semiotic registers, they identify difficulties in the mutual conversions between the symbolic register and the natural language but are not necessarily able to analyse these in more technical terms.

The didactic dimension:

As regards the building of a progression, textbooks and the local advisor the PLC2 have in the high school where they teach in full responsibility have a predominant influence. Generally, the PLC2 don’t meet difficulties when deciding the different points they want to address, but they have more difficulties at identifying the real aims of the teaching of pre-algebra or algebra, at the grade level corresponding to their class or at foreseeing the time they will have to spend on such or such chapter. As expressed by one of them in the final interview: “At the beginning of the year, I tried to build a progression but... I don’t succeed in knowing how many time I will stay on one notion. So, now I mainly try to see in what order and with what spirit I want to approach the notion”.

3 - 302

PME25 2001
The PLC2 also have some difficulties at taking into account the initial state of knowledge of their students when they come to teach algebra. Such a difficulty is stronger, as can be easily foreseen, at the beginning of the academic year. As expressed by one PLC2 in the first interview: “I have to say that I didn’t give a lot of exercises on this topic because I thought that it was well known. At the beginning of the year, I wanted to arrive very quickly to algebraic developments and factorisations. The remainder was only matter of recall. I realised too late that it didn’t work. I didn’t choose to go back, but it was perhaps a wrong decision. My problem is that for some of these students, I can explain one thousand times, that doesn’t change anything. I don’t know how to do”. This excerpt shows the PLC2 becoming aware of the problem, doubting about the adequacy of his initial strategy and, at the same time, we can understand up to what point he is deprived from means in order to tackle the problem. Visibly, spontaneously, he remains in a state of global approach, insufficient to analyse real students’ difficulties and needs, and conceive appropriate educational strategies, beyond the explanatory strategy which is the sole to be evoked.

As regards the mathematical and didactical organisations, at a more local level, textbooks once more play an essential role, but most PLC2 don’t only use the textbook selected by the high school for their class. Visibly, the work they did the year before, when preparing the CAPES, which obliged them to search and select exercises on specific mathematical themes by looking at different textbooks has created some “habitus”. Two great tendencies emerge: in the first one, the PLC2 tries to cover extensively the diversity of types of tasks proposed by the textbook, this result in very few examples for each type ; in the second one, the PLC2 focuses on some selected tasks and one can see, through the progression along the exercises of the same type, a progressive attempt to play on specific didactic variables, even if this expertise mainly remains implicit. The same diversity occurs as regards the relationships between techniques and technologies (this word being taken here with the Chevallard’s acception of discourse explaining or justifying a technique). Some PLC2 mainly stay at the technical level (including of course the description of the technique), other give real importance to the technological dimension. But, even at the end of the academic year, the elaboration of technological discourse seems to remain under their sole responsibility. The different data coming from the questionnaires and interviews show that there is a sensible evolution during the academic year: the lesson conception evolves, the relationship to assessment evolve, but each evolution seems to have its idiosyncrasy. As expressed by one PLC2: “Let us say that, every time, I have tried to ask myself more questions before introducing something new. A sort of a priori analysis. I ask myself what will be the students’ difficulties. But it is difficult to foresee. And also, how to introduce that new thing. At the beginning of the year, I delivered the course more directly, now I always try to do some activity which prepares the notion”. The interviews show the difficulties they have at analysing classroom situations, but we notice a great difference between the analysis they are able to produce personally and the analysis they are able to
produce when working in small groups on the same activity designed for students or on classroom videotapes.

V. DISCUSSION

In this research project, we try to better understand the change in the relationships with algebra of French pre-service teachers, moving from a student position to a teacher position, and the development of an initial professional expertise in that area. We consider this development as a multidimensional and complex process, involving epistemological, cognitive and didactic changes. We are perfectly aware that what can be reached through this first year of professional training is necessarily very limited. These evident limitations make all the more important to detect possible germs for priming professional development. The results we have obtained up to now are certainly very partial but they clearly tend to show that some interesting and subtle evolutions can take place. All of these don’t directly affect the design and management of classroom situations. At a first level, they seem more able to express in a priori and a posteriori analysis of classroom sessions, and more in a collective way than in an individual way. Results also show important differences in the accessibility of the respective parts of what can be considered today as professional expertise in algebra. We would like to add that the influence of the short didactic training offered by the IUFM will remain anecdotal if it is not properly echoed by a reflective analysis of PLC2’s practices in the class they have in full responsibility. This is, both from an experiential and affective point of views, the fundamental object in the transition they live. There is no doubt that for the PLC2 who have been selected for the following up, we are in some sense in the optimistic conditions, taking into account the strong institutional constraints of this pre-service training.

REFERENCES

Problems that require examination of repeating patterns were presented to a group of 106 preservice elementary school teachers. A theoretical framework of reasoning by analogy was used to analyze students' responses. It was found that not only relational structure of problems but also their relative computational complexity influence students' ability to successfully map between familiar and unfamiliar tasks. Consideration of multiples and division with remainder were the main mathematical tools utilized in students' solutions, but in many cases students didn't demonstrate their awareness of the relationship between these tools. It is suggested that pedagogical approach should help students connect their understanding of multiples with their understanding of division with remainder and contribute to a more complete understanding of repeating patterns.

Patterns are the heart of mathematics. Students' ability to recognize or develop patterns is related to their ability to reason mathematically in general and to develop reasoning by analogy in specific (White, Alexander & Daugherty, 1998). In this study we examine students' strategies as they engage in tasks that invite exploration of repeating patterns in familiar and unfamiliar situations. What mathematical tools are utilized? Is there consistency in students' approaches? What influences their choice of a strategy? -- These questions are of interest in this investigation.

THEORETICAL FRAMEWORK: REASONING BY ANALOGY.

Analogical reasoning was explored generally in the context of science and cognitive science. Despite apparent relationship between analogical reasoning and mathematical learning (White, Alexander & Daugherty, 1998), only recently researchers in mathematics education became interested in reasoning by analogy in specific mathematical contexts. Reasoning by analogy in mathematics was explored mostly in considering word-problems in arithmetic and beginning algebra (Novick, 1995, English, 1998).

According to English (1998) reasoning by analogy in problem solving involves mapping the relational structure of a known problem (that has been solved previously, referred to as "source") onto a new problem (referred to as "target") and using this known structure to help solve the new problem. Analogy can be recognized in isomorphic or "almost isomorphic" problems. In our
interpretation, isomorphic problems, also denoted by English as “completely isomorphic”, are those possessing the same structure not only from a mathematical, but also from a linguistic perspective. They can be presented in (i) the same situational setting, or in (ii) different situational settings. We refer to problems as “almost isomorphic” when they have similar components, but are not “completely isomorphic”, that is, (i) they possess the same mathematical, but different linguistic structure, or (ii) a source problem can be seen as isomorphic to a part of a target problem or vice versa.

Mapping the structure of the source problem to the target problem is the key aspect of reasoning by analogy. In order for a mapping to take place a relational structure of the source problem must be identified, as well as similar relational structure of the target problem. English (1997) suggests that failure to identify the relational structure of the source problem is a significant cause of children's impaired mathematical reasoning. Furthermore, successful solution of a target problem is not an immediate and natural consequence of a successful mapping (Novick, 1995). The solution procedure may need to be adapted or extended, especially in case of problems that are not completely isomorphic. Successful mapping is essential for recognizing the need for such adaptation. In summary, solution by analogy requires recognition/identification of a similar relational structure, mapping between source and target, and adaptation or extension. Each step presents its own challenges.

METHOD

Tasks

The participants were presented with three problems and in each case they were asked to explain and justify their solution.

1. What is the 177th digit to the right of the decimal point in the decimal representation of 0.76543?

2. A toy train has 100 cars. The first car is red, the second is blue, the third is yellow, the fourth is red, the fifth is blue and sixth is yellow and so on.

   (a) What is the color of the 80th car?

   (b) What is the number of the last blue car?

3. Imagine a toy train with 1000 cars, following the 7 colour repeating pattern 1- red, 2 - orange, 3 - yellow, 4 - green, 5 - blue, 6 - purple 7 - white

   (a) What is the color of the 800th car?

   (b) What is the number of the last blue car?

Each of these problems presents, either explicitly or implicitly, a repeating pattern (of length 5, 3 and 7 respectively) and asks to determine the attribute (digit or color) of this repeating pattern that corresponds to a particular place. A possible approach to the solution of these problems is to identify the remainder in division of “place” by “length” and assign the attribute that corresponds to the place of this remainder.
remainder. For example, in question 1, the remainder in division of 177 by 5 is 2, and therefore the attribute corresponding to the 177th place is the same as the attribute corresponding to the second place, in this case digit 6. Another approach is to notice that every 5th digit is 3, therefore digit 3 appears in every place that is a multiple of 5; 175 in particular. Then the attribute of the 177th place is determined by counting up from a multiple. Mathematically, the two approaches described above are equivalent, however, as suggested by our data, they present a different cognitive difficulty and have a different explanatory power.

Participants and Procedure

Written responses were collected from a group of 106 preservice elementary school teachers, enrolled in a core mathematics course. It should also be noted that tasks similar to question 1, that is, consideration of digits in a repeating decimal pattern were discussed in class. Consideration of the remainder was among the possible solutions presented and examined by the participants. Therefore, question 1 presented a familiar situations, while questions 2 and 3 presented situations that can be describe as unfamiliar. Strategies used by participants to solve each problem were identified and recorded. The partial data analysis presented below focuses on inconsistencies in students' approaches when dealing with analogous situations. In analyzing students' solutions the researchers were interested in students' mapping between isomorphic problems as well as mapping and adaptation in cases that were not completely isomorphic.

RESULTS AND ANALYSIS

Isomorphic Mapping

(i) Same situational setting.

This mapping is represented within our instrument in the structural relationship between questions 2a and 3a (or 2b and 3b), where the only differences are in the numbers. Both the target attribute and the pattern length are larger in problem 3 than in problem 2. Most participants were successful in this isomorphic mapping. In most cases (79 of our of 106) the strategies presented by participants in problem 2 were exactly the same as the strategies chosen in problem 3. However, simply varying the magnitude of the numbers in the situation was enough to prompt 27 of the participants to change their strategies when going from one problem to the next. Carlo, for example, in dealing with problem 2a chose to attend to the remainder in division by 3 (the pattern length).

Q2a. When 80 is divided by 3 the remainder is 2 that means the 80th car will be blue because that is the colour of the 2nd car.

However, when faced with the same situation in 3a he changed his strategy and counted up from a multiple of 7, the pattern length.
Q3a. Every 7th car is white, so car 798 is white because 7\times114=798. Then 799 is red and 800 is orange.

Why wasn’t his strategy in 2a successfully mapped to 3a? A possible explanation is in the relative computational complexity of the task. While the remainder in division by numbers 3 can be easily identified mentally considering divisibility tests, the case of division by 7 is different. Therefore, Carlo’s work can be seen as an attempt to relate the problem to pieces of easily identified components of prior knowledge, considering multiples of 7 as a point of reference and counting up from that point.

It is interesting to note that although division of whole numbers results in quotient and remainder, only the remainder provides useful information for these questions. Although many students felt comfortable discussing the remainder in division without pointing to the quotient, there were 12 participants who changed from this very consistent strategy. They felt compelled to explicitly state both outcomes of the division statement only when dealing with the larger numbers in question 3. This is further evidence supporting the claim that computational complexity of isomorphic problems is enough to prompt students to change their strategies.

(ii) Different situational setting.

Although question 1, and 2a have identical mathematical and linguistic structure, they present the student with a different situation. The variation of the problem from finding the 177th digit to finding the colour of the 80th car was enough to cause 21 of our students to change their strategy for dealing with the new situation.

Amanda displayed good use of the counting up from a multiple in question 1, but opts for remainder in division in problem 2a.

Q1. Since the repeating portion is 5 digits long, then every 5th digit will be a 3. So, 175 [digit] will be 3 and 177 [digit] will be a 6.

Q2a. 80/3 = 26r2. Since the remainder is 2 then it will be the same colour as the second car... blue.

Both of these strategies are equally effective. So effective, in fact, that it is surprising that Amanda would change from her initial one. Perhaps this is due to a refinement of her strategy as she maps from one problem to the next, as remainder in division can be seen as an improvement of the strategy of counting up from a multiple. Of the 21 participants that showed an inconsistent mapping in the face of a situational change, only six could be attributed to a refining of strategies. The other 15 produced glaring inconsistencies in their failure to map their procedures from one situation to the next. This is demonstrated in Jason’s solution.
Q1. 177/5 has a remainder of 2. Therefore, the 177th digit will be 6.

Q2a. 80 is divisible by 2, and since the 2nd car is blue, the 80th car is blue.

Jason's strategy in 2a referred to as multiple of the initial position, will be discussed in a later section.

Almost Isomorphic Mapping
(i) Different linguistic structure.

Our instrument did not provide data representative of this type of mapping.

(ii) Target and source are partially isomorphic.

Problems 2b and 3b, are isomorphic to each other, but present a slight variation on 2a and 3a respectively. Problems 2a and 3a ask for an attribute that corresponds to a given place, while 2b and 3b ask to determine the largest place that has a given attribute. We consider the pairs 2a and 2b, 3a and 3b as almost isomorphic. An attempt to map a new problem (3b) to a familiar one (3a), is demonstrated in Cindy's work.

Q3a. 800/7 = 114 with a remainder of 2. So, the 800th car will have the same colour as the 2nd car. Orange.

Q3b. 1000/7 = 142 with a remainder of 6. Blue cars have a remainder of 5, so it must be car 999.

We consider this refinement to be an adaptation consistent with the remainder in division by the pattern length mentioned earlier. Alternately, the strategy of counting up from a multiple can be adapted to target a specific attribute (in this case colour) rather than a specific position, as exemplified by Bill.

Q3a. 798 is a multiple of 7, so it will be white. 799 is red and 800 is orange.

Q3b. 994 is a multiple of 7 (994 = 142 x 7). So 995 is red, 996 is orange, 997 is yellow, 998 is green, 999 is blue.

Of our 106 participants, 29 of them didn't rely on the “almost isomorphic” structure of the two problems and thus did not map their strategies from problem 2a to problem 2b (or 3a to 3b). In 21 of these cases this involved going from a remainder in division process in 2a to a counting up/down from a multiple in 2b; an inconsistency that can be viewed as a hierarchical regression in the development of students' schemes (Zazkis & Liljedahl, 2000).

Errors in mapping

In this section we mention several errors, that were more than single occurrences and therefore require attention.
Recognition of a repeating pattern involves recognition of its length as well as its attributes. Five students consistently identified incorrect length of these patterns. In each case the identified length was one more than the actual length. It appeared that they considered the place where the digit (or the color) repeated for the first time, and this served as a reference. Writing out the repeating pattern several times may help clarify this confusion.

Another error was caused by incorrect correspondence when considering multiples. In question 1, for example, searching for the 177th digit to the right of the decimal point in the decimal representation of 0.76543, Sally correctly recorded that

\[ Q1. \] Every fifth place had the same digit, and therefore a digit in a place that is a multiple of 5 is always the same.

However, this digit was identified as 7, which is the first digit in the repeating pattern, rather than the last one. So her reasoning continued as follows:

\[ Q1. \] So 175th digit is 7 and 177th digit is 5.

Sally, as well as three of her classmates consistently applied this incorrect mapping between the place and the attribute. Requiring students to list the correspondence between digits/colors and places explicitly should help in identifying the correct correspondence.

While the above mentioned “bugs” appear not difficult to “debug”, the reasoning Jason used (discussed earlier) hints at a more profound misunderstanding.

\[ Q2a. \] 80 is divisible by 2, and since the 2\textsuperscript{nd} car is blue, the 80\textsuperscript{th} car is blue.

In this reasoning, Jason is assuming that every multiple of the initial position of the blue car shares that attribute. Monica, expressed the same reasoning even more explicitly.

\[ Q3b. \] Since the blue car is in the 5\textsuperscript{th} position all multiples of 5 will be blue.

This logic remains a mystery to us. At first occurrence we were ready to dismiss such reasoning suggesting that these students memorized the ingredients that played a role in solving similar problems - multiples and remainders - and then mis-assembled them in their responses. It could be that students incorrectly generalized the observation that “every seventh car is white” (a statement which is true for our repeating pattern of length seven) to “every fifth car is blue” in the same repeating pattern. However, the fact that consideration of a multiple of the initial position occurred in responses of 15 different students, requires further investigation of this line of reasoning in future research.
CONCLUSION AND PEDAGOGICAL IMPLICATIONS

Reasoning by analogy follows the sequence of recognition-mapping-adaptation. We suggest that isomorphic mapping of a problem does not necessarily imply isomorphic mapping of a solution. Solution depends on computational complexity and often patterns with small and compatible numbers are not easily generalized. Therefore, adaptation may be required not only for problems that are not completely isomorphic, as suggested by English (1998) and Novik (1995), but also for completely isomorphic problems of different degree of computational complexity.

Although the claim that, for example, 996 leaves a remainder of 2 in division by 7 and the claim that 996 is larger by 2 than a multiple of 7 communicate the same mathematical relationship, these claims are not equivalent in terms of their explanatory power for learners. Consideration of remainder in division presents a unifying scheme that enables a student to deal with a large class of problems, including all of the problems in our instrument. However, students’ ability to generalize this strategy and apply it for various questions is not well developed. When faced with unfamiliar situations students often prefer to invoke counting up from a multiple strategy. We found in these data, as well as in-class interactions among students, that a distance from a multiple is a reasoning that is applied by participants in a more spontaneous and natural way. This slip back towards the familiarity of multiples is an indicator of the lack of recognition of the invariant multiplicative structure inherent in division with remainder statements.

Our recommendation is that pedagogical approach to division with remainder should build on what appears as a natural tendency of students - consideration of multiples. Capitalizing on multiples, remainders can be considered as “adjustment” or “translation” along the number line. This approach would enforce the view of a remainder as indicator of partition of whole numbers, rather than simply an outcome of an operation, and empower the understanding of repeating patterns as well as the relationship between additive and multiplicative structures.

THE DECA-BASED APPROACH: A MATHEMATICAL PROGRAM TO LEARN AND APPLY TWO-DIGIT NUMBERS

Eng Leong Lim, Kathryn C. Irwin & Dennis W. Moore
University of Auckland

This study examines the effects of an instructional program designed to promote students' understanding of two-digit numbers. The program enables students to identify the tens and ones in two-digit numbers and to add two-digit numbers of different levels of difficulty. One student was taught, using a multiple baseline experimental design to track the learning associated with teaching procedures during the process of schema acquisition. Results show marked gains in both the understanding and addition of two-digit numbers, generalization and expansion of these concepts in the classroom and at home, and a more positive attitude.

Introduction

This study, which is part of larger investigation, concerns one child, Jim, who at age 10 had still not learned to identify tens and ones or to add two-digit numbers. It uses a methodology rarely seen in mathematics education, although common in applied behavior analysis. This methodology tracks a student's learning with precision, so that the effects of teaching are clear.

The study is based on the theory, proposed by Fuson (1990), that children use particular schemas in developing whole number concepts, especially for multidigit numbers. She suggested that children begin with a unitary conceptual structure that links cardinal meanings of spoken and written numerals (five, 5) to perceived objects (5 dots). They extend this unitary conception to numbers over 10, in which the separate numerals (e.g. 15) have no quantitative referents in themselves. They then move on to develop further conceptual structures to accommodate the meaning of a decade with extra ones, a decade-ones conception. This is followed by two further conceptions, a sequence-tens and a separate-tens-and-ones conception. In a sequence-tens conception, single units of ten are formed within the decade part of the quantity. This is an extension of the unitary counting except that the sequence is now counted in units of tens (e.g. 10, 20, 30). The separate-tens-and-ones conception is built through experiences in which a child comes to think of a two-digit quantity as comprising two separate kinds of units -
units of ten and units of ones. Both kinds of units are counted by ones (e.g. fifty three is 53 - 1,2,3,4,5 tens and 1,2,3 ones) but the units of ten means that each digit in that position comprises a “ten-uniteness”. With this conception, the child understands that each ten is made up of 10 ones and can then switch to the unitary thinking of ten ones if that approach is required. This last conceptual level is required for additive decomposition as used by Gravemeijer, McClain and Stephan (1998).

A child’s construction of the sequence-tens and separate-tens conception depends heavily on their learning environments, including that of linguistic structures (e.g. Fuson & Kwon, 1992; Miura & Stigler, 1987). Some languages are seen as having direct and systematic structures for labeling multi-digit numbers. For example, the Chinese number word for 51 is “five ten one”. The direct correspondence of the spoken number word to the written numeral makes it easier to match the two forms of the number. This linguistic structure moves the learner directly into the separate-tens-and-ones conception. Combined with other cultural factors and experiences such as being taught with a strong emphasis on rote counting, this schema is constantly being reinforced for the learner. English has a much less regular structure, particularly from 11 to 19.

Fuson and colleagues trialed a teaching program to facilitate the separate-tens-and-ones conception with two groups of six-year-olds in a lower economic district (Fuson, Smith & Cicero, 1997). Results suggested that the program helped raise the performance of the participants to be substantially above that reported in other studies of children of higher SES and for older children. Their responses were reported to look more like those of East Asian children than of U.S children in other studies. The theoretical basis of this study was expanded for use with two-digit numbers (Fuson, Wearne, et al., 1997).

This case study builds on the theoretical framework of Fuson and colleagues. It follows the learning of one boy who started with a unitary understanding of two-digit numbers and follows his progress through to the addition of two-digit numbers using a separate-tens-and-ones conception. The question behind this
research was whether or not an intervention program based on this theoretical framework could be shown to help a slow learner develop these conceptual structures for use in two-digit addition.

**Methodology**

Jim was a ten-year-old boy enrolled in a suburban primary school. He was referred by the school’s special needs coordinator because of difficulties with his learning. The class teacher reported that he was unable to identify the tens and ones in a two-digit number even after an intensive year of remedial mathematics with a teacher aide. In a pre-intervention assessment with the, he gained a score on the Basic Skills portion of the Key Math Diagnostic Test (Revised) of 5 years 10 months. An assessment with the WISC-III placed him on the 5th percentile with an overall score of 70-82.

The initial focus of the instruction was identifying the tens and ones in a two-digit-number (Fuson’s decade-ones structure) as the boy had serious difficulties in this area. To accomplish this, teaching emphasized the use of the “deca-language” as well as the tens and ones value in a given two-digit number. In the created deca-language, numbers are named as in Chinese, so that 11 is called “ten one”, and 71 is “seven ten one”. Instructional charts associated with the deca-language program were prepared to provide him with an understanding of the separation-tens-and-ones concept. These are similar to standard 100s charts except that the single digits are at the bottom, so that it read, in part:

A multiple baseline across behaviors design (Barlow & Hersen, 1984) was used to examine the effects of the intervention on different areas of mathematical performance. This design clarifies the relationship between instruction and performance on measures that are not directly part of the instruction: in this case on 13 dependent variables used to assess this learning. The first set of three of these
measured Jim's ability to identify two-digit numbers, the second set of six measured competence in horizontal addition, and the third set of four measured generalization in a different setting as well as vertical addition.

The researcher conducted all sessions during class time, three times a week for 8 weeks, in a quiet room within the school compound. Each session lasted about 30 minutes including the testing which followed the individual teaching.

**Intervention**

There were six phases in the intervention. These were a baseline phase, when initial measures of his performance were found through tests were administered during the session, four instructional or treatment programs and a maintenance phase when his performance was assessed but he received no special teaching. Treatment 1 (T1) used the deca-language to reinforce the separation-tens-and-ones conception. The theory was taught using different sets of charts as the basis of discussion. As Jim had demonstrated the ability to read and write two-digit numbers in English during baseline, the instruction focused on the ability to differentiate the tens and ones in a given two-digit number, using deca language. Treatment 2 (T2) focused on the addition component of the program. Again, the treatment was streamlined to meet Jim's needs as identified from baseline data. Therefore, there was particular emphasis on the addition of numbers 6-9 and of multiples of ten as the second addend. Treatment 3 (T3) focused on the addition of two-digit numbers as the second addend, both with and without regrouping. Treatment 4 (T4) focused on adding by visualizing a chart without it being present. Each treatment included a practice phase with a number of different questions that involved the use of the theory that had been discussed.

Figure 1 shows the number of test items that Jim completed successfully in each of these phases. The introduction of T1 was associated with an increased performance in reading and writing two-digit numbers in the deca-language. Results for the ability to read a given number in the deca-language (Deca read) show that he moved from a mean of 20% correct during baseline to 80% with the introduction of treatment. Similarly, Jim moved to 93.3% for writing a given
Figure 1. Percent correct of test scores for different measures across experimental phases.
number said in the deca-language (Deca write). These scores improved further to 100% for both skills during maintenance and were still evident 4 weeks later.

With the introduction of T1, similar improvement in test results was obtained for the ability to state the tens and ones of a given two-digit number. During T1 Jim moved from a mean of 4% to 86.7% for the ability to state the tens and ones of a given two-digit number. These scores improved further to 100%.

For the next set of six measures, baseline data on addition suggest that Jim was able to add numbers 1-5 with reasonable accuracy. This performance was maintained throughout the treatments and maintenance. There was an improvement in performance for adding numbers 6-9 with the introduction of T2, from a mean baseline of 60% to 100%. This level of performance (100%) also occurred during maintenance. Although addition was not targeted in T1 the test scores suggest that T1 has had an impact on the adding skills of single digit numbers. This was also true for addition of multiples of ten, where addition moved from a mean of 25% (Sessions 1-5) to 66.7% (Sessions 7-9).

Treatment 2 also brought about a further improvement of test performance for the addition of single digit numbers with regrouping. Scores improved from a baseline of 42.8% to 100% during treatment, with a score of 93.3% during maintenance. For the addition of multiples of ten, the introduction of T2 was associated with an increase in performance from a mean of 25.7% during baseline to 53.3% during treatment and 100% during maintenance.

Treatment 3 focused on two-digit addition. This brought about a change from a baseline mean of 14% to 100% during intervention. This score remained high (90% mean) during the next phase without the use of the 0-100 charts. A similar improvement was evident at the onset of Treatment 3 with two-digit addition with regrouping. Test scores improved from a mean of 14% during baseline to a mean of 86.7% during intervention. However, test scores dropped to 0% on this during the next phase of return to baseline without the use of the charts.

During Treatment 4, charts were no longer available and Jim was asked to visualize them. This was done through an emphasis on mental mathematics. He was
encouraged to visualize the previously learnt process of movement across the 0-100 chart. The visualization process was reinforced through a return to the tens-and-ones structure learnt during T1. Test scores in two-digit addition with regrouping improved from a mean baseline (B2) of 0% to a mean of 60% with the introduction of Treatment 4. This further improved to a score of 100% during maintenance.

Generalization was assessed through his ability to use these skills in the classroom. This is seen by his ability to state the tens and ones in a two-digit number, to demonstrate them with place value blocks for tens and ones and to add in horizontal and vertical formats. Initially he was correct only for single digit adding (31%). At the end of the 8th week he was correct on 87.5% of the items. Least progress was made in problems in a vertical framework. Therefore the last session (session 21) was used to apply his adding skills to the vertical format. This involved pointing out to the participant that the addends given in a vertical format consisted of two-digit numbers and had tens and ones that could be added in the same way as for addends in the horizontal format. A score for the test items in the vertical format after that session suggests that this knowledge was sufficient for the participant to then apply the adding skills to the questions.

Evaluation

In a meeting held 7 weeks after the conclusion of the program, the class teacher reported that Jim had further improved on the skills acquired during intervention. He was able to solve two-digit addition questions given in a vertical form as class work. She also reported that he was able to identify and write three-digit numbers. He was said to be much more confident in mathematics and was more involved in the class discussion. He was also more willing to take risks and attempt questions that were previously difficult. His parents reported a change in attitude towards numbers, so that he was more willing to attempt homework questions in mathematics and demonstrated confidence that his answers would be correct. Jim himself reported that he now felt that he could do more mathematics and did not struggle as much as in the past. He recognized that he was learning more and had made much progress since the beginning of the program.
These results support the hypothesis that the deca-based number system as introduced in Treatment 1 provided a scaffolding structure in enabling the student to separate the tens and ones in a given two-digit number. Using the skills that he had already acquired in adding single digit numbers (1-5), this number structure was then applied to areas in addition where he had previously struggled. With this knowledge, and further instruction (T2, T3 and T4) using the same number system in the addition of two-digit numbers, his results suggests a greater mastery of skills in addition, generalization into the classroom and an increase in confidence towards mathematics. These results support the hypothesis that the mastery of the separation tens-and-ones conception in the two-digit number will facilitate the learning of operational mathematics.

Can interaction between inferior strategies lead to a superior one? 
The case of proportional thinking 
Liora Linchevski and Baruch Schwarz, The Hebrew University of Jerusalem 

Abstract 
The idea that interaction among peers leads to cognitive development is not new. However, this study focuses on an issue hardly been studied so far: this is the case when two children who do not succeed at solving a task by themselves, succeed to solve it when working in collaboration. A study by Schwarz, Neuman, and Biezuner (2000) showed that this phenomenon (we refer to as – “the two-wrongs-make-a-right phenomenon”) is possible. It depends on the kinds of tasks and of interaction between students, though. In this paper we report on a research-study that investigated “the two-wrongs-make-a-right phenomenon” in the domain of proportional reasoning. We focus on: a) the cognitive gains of couples in which both students are “wrongs” in comparison to the gains of couples in which one is an “expert” and the other is “wrong”; b) The effect of hypothesis testing on the cognitive gains of the individual. 

Scientific background 
The role of a child’s interactions with her/his age peers in the development of his/her cognition, has long been discussed both from a Piagetian and a socio-historical perspective (e.g., Hartup, 1970; Vygotski, 1986). This study is in line with these efforts. However, it focuses on a phenomenon that has not been systematically investigated, the cognitive gains of two "wrongs" interacting to solve a task they are unable to solve individually. 

A priori, it seems dubious that when two wrongs interact, at least one of them reaches cognitive gains. At any rate, it seems obvious that in two other kinds of interaction, the wrong should gain more: In modeling studies (in which one child observes a more competent child) and in active interaction studies in which the "wrong" interacts with a more competent child (e.g., Botvin and Murray, 1975; Murray, 1974; Kuhn, 1972). 

In this section we argue that a cognitive gain from interaction between two wrongs is theoretically possible. For this purpose, we analyze the factors suggested by researchers to be responsible for the cognitive development of peers in active interaction and in modeling studies. Two factors have been recognized, disagreement and being strategic (also designated as being able to give reasons/arguments for a specific solution or offering an operational solution e.g. Miller & Brownell, 1975). It was suggested that when two interacting solvers disagree, their cognitive gains originate not only from a pragmatic component, the disagreement, but also from the contradicting solution itself. This suggestion was confirmed by a study conducted by Doise, Mugny and Perret-Clermont (1975) in which students gained from being presented a contradicting solution by an adult, whether the solution was correct or
not. In another study, Doise and Mugny (1979) showed that interaction with a less capable child proposing a contradicting solution led even the more capable child to progress. In the same study, Doise and Mugny showed that when interacting students used different strategies, they progressed, whereas when they used the same strategies, they could not. A key result obtained by Doise and Mugny in their study of interactions between children with different levels of competence is that if the difference of level between the two students is too big, low-level students did not progress. As for modeling studies, Botvin and Murray (1975) showed that observing peers expressing and defending different (counter)-arguments is responsible for cognitive gains. Also Kuhn (1972) showed that in modeling studies, the observer who disagrees with the modeler is in a situation of mismatch, and he actually converses with the modeler in a kind of "tacit interaction".

In addition to disagreement and to being strategic Doise (1978) has showed that hypothesis testing, that is, the manipulation of materials available in the task to check whether the solution found is correct, also leads to cognitive gains. However, Doise (1978) showed that the more competent student is often too dominant when undertaking manipulations, preventing the less competent student from making gains on the task.

Glachan and Light (1982), on the basis of their review of modeling and active interaction studies, hypothesize that "interaction between inferior strategies can lead to superior strategies or, in other words, two wrongs can make a right" (p. 258). Glachan and Light grounded their hypothesis on the analysis of the very conditions that peer interaction studies have found as affording cognitive gains: disagreement, being strategic, and hypothesis testing. Such conditions do not depend on whether the peers are right or wrong. It ensues then that the active interaction among two wrongs can lead to cognitive gains when such conditions are fulfilled. The researchers suggest that such an interaction can be beneficial because the differing strategies being pursued by the two children lead to the making of moves inconsistent with those strategies. "The child is thus led to (jointly) make moves which he would never otherwise had made, so that established inefficient strategies are disrupted. As a consequence of this disruption one or both of the children may see possibilities for better strategies. Interaction is thus envisaged as a destabilizing influence" (ibid.). In sum, Glachan and Light hypothesized that two wrongs can make a right if they have different strategies and have opportunities to resolve their conflict.

The "destabilizing influence" alluded to by Glachan and Light has, without any doubt, Piagetian roots. It relates to stages of development. But what about the process that turns wrongs to rights? The analysis of the studies on adequate conditions for cognitive development through peer interaction shows that cognitive gains are intermingled with the utterance of arguments and counter-arguments. For example, Miller and Brownell (1985) showed that non-conservers are more likely to yield to conservers because conservers
produce counter-arguments (see also, Doise et al., 1975). Botvin and Murray (1975) have shown that in modeling studies, the cognitive gains of observing peers originated from listening at solvers expressing and defending different (counter)-arguments leads to cognitive gains (see also Kuhn, 1972). And indeed in subsequent studies (Murray, Ames & Botvin, 1977), it was shown that cognitive dissonance taking place in argumentation or in observing conservers giving reasons for their points of view was the main source for significant gains.

The studies on peer interaction and cognitive development we just reviewed are to be related to studies directly focusing on argumentation. For example, Kuhn, Shaw and Felton (1997) and Schwarz, Neuman, Gil and Ilya (in press) showed that peer interaction fosters argumentative reasoning. In these studies, the researchers observed the arguments as outcomes of dyadic interaction and showed that their quality increased as a result of the dyadic interaction. The researchers did not analyze the conditions under which peer interaction occurs, but it seems that at least the two first conditions, disagreement and being strategists were fulfilled.

In a recent study Schwarz and colleagues (Schwarz, Neuman & Biezuner, 2000) have experimentally identified the “two wrongs make a write phenomenon” in the domain of decimal numbers. In this experiment, weak high-school students with conceptual bugs regarding comparison of decimal numbers were invited to collaboratively solve problems. They had a calculator at their disposal. It was shown that in pairs of “wrong” students having different bug, at least one of the “wrongs” turned to be “right”. In contrast, this effect was not identified for wrongs in pairs in which one was wrong and one was right. Analysis of several case-studies in this experiment showed that the calculator was used to test hypotheses and was important in the argumentative process that led to change. However, the conditions that led to change were not systematically manipulated. The object of the current research is to deepen the study of the “two wrongs make a right phenomenon”. This phenomenon needs to be examined in new domains and under new conditions in order to lead to general principles concerning gains in peer interaction. In the present study we aimed at empirically checking the “two wrongs make a right” phenomenon, in a new mathematical domain – proportional reasoning. In light of the research-review on peer interaction, we studied the "two-wrongs-make-a-right phenomenon", under three working assumptions: (a) the two wrongs disagree, (b) they have different strategies, and (c) active hypothesis testing is made possible. We aimed at evidencing this phenomenon by studying the effectiveness of the interaction between two-wrongs and comparing it with the effectiveness of the interaction between one wrong and one right (expert).

Research Design

The choice of the mathematical domain and the specific tasks within this domain, has been made according to the following criteria: (1) there exist a diagnostic task measuring students’
competence in the domain; (2) the number of strategies used to solve the task is limited; (3) The strategies are hierarchical; (4) The students are consistent in using the strategies. The topic of proportional reasoning and the "blocks task" (Harel, Behr, Post, & Lesh, 1992) fulfill these criteria. A detailed theoretical analysis of the blocks task appears in Harel et al. (1992). A short description of the task is given here.

Description of the blocks task: In Harel et al. the student was given a drawing representing two pairs of blocks (A, B) and (C, D). A and C are "built" of big cubes while B and D are "built" of small cubes. The tasks appear in nine configurations (a configuration is a set of two pairs of blocks). In A there are always less cubes than in C. The variables are the number of cubes in B and D. There are three possibilities: the number of cubes in B (resp. in D) differs from the number of cubes in A (resp. in C) by 1, 0 or -1. The students were informed about the relative weight of A and B. The three alternatives are A>B (A heavier than B), A=B and A<B. The students are then asked to decide about the relative weight of C and D (4 possible answers are always displayed: C>D; C<D; C=D; "It is impossible to decide").

Harel et al. gave the 9 configurations of the blocks task to 18 Grade 7 students. Three types of strategies were uncovered. Harel et al. showed that the match representation-strategy was not random and only six such pairs (called solution process) could be identified. From these findings, it appears that the blocks task lead students to adopt solution processes that attest their level of proportional reasoning. However, it appears that for none of the nine configurations proposed by Harel and al. it is necessary to adopt a solution process attesting explicit considerations concerning the comparison of two ratios.

For our study we have made some modifications: (a) in Harel et al. the cubes in the structures A, B, C, and D had different magnitudes, and sometimes students needed to infer that a small cube weighted more than a big one, a fact creating a physical "disturbance" regarding proportional reasoning. In our case all cubes had the same size. The different weights were represented by different colors; (b) the concrete models of the blocks were presented in addition to the drawing of the blocks; (c) Harel's configurations led students to opt for additive solution processes (yielding correct answers); in our configurations the difference between the number of cubes in the different blocks were various; (d) the students were provided with a balance to check their hypotheses.

Procedure
32 lower-level Grade 10 and 11 students participated in the study. The study had three phases: individual pre-test, pair-interaction, and individual post-test.

Pre-test: The students were given the 9 configurations, one at a time, and were asked to justify their answers. Five levels of strategies were expected:
S0: Guessing [included in SP1 in Harel et al.]. The student totally ignores configurations A and B and does not provide any justification.
S1: Visual Shape level [included in SP 1 in Harel et al.] The student ignores A and B, however he/she refers to the difference between C and D.

S2: Additive proportional level [corresponds to SP2, SP3 and SP4 in Harel et al.] The student takes into consideration A and B. The explanations, however, are based only on the difference in the numbers of blocks among the 4 structures.

S3: Quasi-multiplicative proportional level [includes SP5 and SP6 in Harel et al.] The student's considerations are based on the proportional weight of a single block. However, he/she does not use it for a complete proportional reasoning.

S4: Multiplicative proportional level [new solution process] A full multiplicative proportional reasoning. S4 was not found in the students' responses to the 9 tasks.

After the pre-test, tasks 1, 2 and 6 were excluded. Tasks 1 and 2 were found to be trivial and task 6 was identical to task 8. Tasks 5, 7, and 9 were chosen for the interaction phase, and tasks 3, 4, and 8 were used as the post-test.

The students' answers were scored according to two scales: (1) Competence: right – R=1, wrong – W=0; (2) Strategies 0 to 3: S0=0, S1=1, S2=4, S3=7. Since in each phase of the research 3 configurations were involved, the jump of three in the scores between S1 and S2 ensured that a student that used S2 once will score higher than a student who used S1 three times. It was found that students might use a high strategy and give a wrong answer or vice versa. The decision was to score strategies higher than competence.

Conflict Scale: The “conflict” between two students was defined as the difference between them in competence and strategy on tasks 5, 7, and 9 in the pre-test. From competence perspective there were 3 possibilities: R&R (the two students are right on the task); W&R (one wrong one right); W&W (the two are wrong). In the framework of this research theoretical focus, the following scores were assigned: R&R = 0; W&R = 1; W&W = 2, the highest score (2) was assigned to two wrongs. For each task the possible range was 0-2 and for three tasks it was 0-6. From strategy perspective the range between the students' strategies (S0-S3) was 0-7 and for the three tasks it was 0-21. The final conflict-score between two students was calculated as the sum of these two components.

Cognitive Gain: Each student was given a cognitive score for each task. The score was defined as the sum of competence (0,1) and strategy (0,1,4,7). The cognitive gain was defined as the difference between the average of a student’s cognitive-scores in the post-test (tasks 3, 4, 8) and the pre-test (on the same tasks). We calculated also the cognitive gain on the basis of the interaction tasks (tasks 5, 7, 9) and the post-test (tasks 3, 4, 8).

The interaction phase: The students were randomly arranged in couples. The conflict-score of each couple was calculated. A minimum conflict-score of 1 was required. The couples that did not meet this requirement were placed again in the list and reallocated. All together we
had 16 pairs. In the interaction phase each couple solved together 3 tasks – tasks 5,7,9. The interaction phase was done under two conditions, with and without balance, that concretize the possibility or the impossibility to check hypotheses. The students were encouraged by the interviewers to verbalize and explain their considerations and decisions. In each task, immediately after the couple had reached an agreement or agreed not to agree they were given the opportunity to check their solution by the balance. After the weighting process they could change their solution/s and explanations. All the sessions were videotaped. Each student got for every task two cognitive-scores, for performance before and after the weighting process. The sum of the three singles cognitive-scores served as the student’s cognitive-scores.

Post-test: The students solved individually tasks 3, 4 and 8. The cognitive-score for each task and a total score for the post-test were calculated.

Results and Discussion

I. Students’ performance in the 3 phases of the research are displayed in Table 1.

The difference between the students’ average cognitive-score in the post-test and the pre-test was statistically significant ($t(32)=3.37$, $p=.002$). The difference between the students’ average cognitive-score in the interaction phase II and the post-test phase was significant ($t(32)=4.09$, $p=.000$). The difference between interaction phase II and interaction phase I was significant ($t(32)=6.27$, $p=.000$). These results show that interaction advances students’ cognitive gains, it also shows that their performance during interaction phase II is higher than their performance in the post-test. However, analysis of the individual scores shows that in interaction phase II the jump in the cognitive-scores was due more to the competence component of the score than to strategy. Analysis of the individual scores shows that students who scored lower than their partners while working in pairs regressed more in the post-test than students who scored the same or higher than their partners.

II. The research main theoretical focus was “the two-wrongs-make-a-right phenomenon”. Our assumption was that a couple of two “wrongs” would gain more than a couple of “wrong” and “right” (expert). The definition of a couple was done in the following way: An expert was defined as someone whose average cognitive-score in the pre-test was higher or
equal to 6, and a “wrong” as someone whose score was lower than 6. The data showed that we had eight couples of two "wrongs", six couples of an expert and wrong and two couples of two experts. For the analysis the 2 couples of experts were excluded because of a possible roof effect. The difference between the pre- and post-test was statistically insignificant (t(28)=0.72, ns). However, the results indicated a tendency of a higher gain for couples of two "wrongs" (average of 1.313) in comparison to couples of expert and wrong (0.931). These results, albeit not statistically significant, support our theoretical assumption that when two wrongs interact the possibility for at least one of the wrongs to progress is real. Although the “wrong” student is exposed to incorrect arguments, the quality of the cognitive process is not inferior to the one that takes place when one of the interacting students is right. On the contrary, the results support our theoretical framework that indicates the possible benefits of such an interaction and the potential limitations of the other one. For example, expert students tend to dominant the interaction and thus to suppress counter-arguments to be raised.

III. Students’ cognitive-gain as a factor of the conflict-score between the interacting couple is shown in Table 2.

<tr>
<td>7-15</td>
<td>0.2</td>
<td>6</td>
</tr>
</tbody>
</table>

The results show that the maximal gain was obtained in the second level of conflict and the minimal one in the fourth level. These results support the theoretical assumption that a high level of conflict is not always beneficial. It may implies domination of one of the partners that prevents the interacting students from gaining while a moderate conflict, even between two “wrongs”, may lead to significant cognitive-gains. However, these results should be re-checked in the light of a possible roof effect.

Summary

The paper reported on a study aimed at examining the “two-wrongs-make-a-right phenomenon” - where the terms “wrong” and "right" imply hierarchy of competence in a well-defined mathematical domain - in an empirical research. The mathematical domain in which this study took place was proportional reasoning. We argued that when certain theoretical conditions are fulfilled – disagreement, being strategic, and hypothesis testing – the quality of an interaction between two “wrongs” is not inferior to the one that takes place when one of the interacting students is right. The findings of the study support our assumptions. The first finding of the study is not surprising - interaction between peers yields
cognitive gains. The second finding support our assumption that interaction between two “wrongs” generates cognitive gains. Moreover, the results suggest that interaction between two wrongs is cognitively more productive than interaction between wrong and right. The results also show that hypothesis testing effects the cognitive gain of the interacting couple. It was also interesting to see that the students’ cognitive-gains reached their highest level immediately after the process of hypothesis testing and dropped in the post-test. However, this study is only the first step in the investigation and leaves many research-questions open. For example: What are the interaction processes between the two “wrongs” that lead to the cognitive changes of the individual? How wrongs turn to be right? What is the optimum level of cognitive heterogeneity? Will a student working on his own, while having the opportunity the check his hypotheses gain the same? These questions are the focus of our current research.

Abstract
This study investigated the relationship between children's strategies, their accuracy and speed measures in a numerosity judgement task. Based upon a rational analysis of the task at hand, several strategies were specified in terms of their course of response times and accuracy. Several significant relations were found between pupils' accuracy data and the distinct strategies that were derived from their response-time patterns. These results support our rational task analysis and validate previous findings concerning numerosity judgement strategies.

1. Theoretical and empirical background
Many studies (for an overview see Siegler, 1996) have shown that children of a particular age use several strategies to solve the same cognitive task. This multiple strategy use allows them to adapt their strategies to inherent task characteristics such as problem difficulty as well as to situational demands such as the need to answer quickly or accurately. The larger the repertoire of strategies, the better one can adapt one's strategy choice in function of the task requirements.

In a series of studies (Luwel, Verschaffel, Onghena, & De Corte, 2000; Luwel, Verschaffel, Onghena, & De Corte, in press; Verschaffel, De Corte, Lamote & Dhert, 1998), we investigated the development of children's strategy use in a numerosity judgement task from the perspective of "strategic change" (Lemaire and Siegler, 1995). This theoretical framework distinguishes between four dimensions of strategic competence. Changes in any of those dimensions can yield overall improvements in speed and accuracy of performance: (a) acquisition of new strategies and abandonment of old ones, (b) shift towards greater use of more efficient available strategies, (c) improvement in the fluency and efficiency with with strategies are executed, and (d) increase of the adaptive nature of the choice among available strategies.

In all of our studies participants were asked to determine numerosities of blocks that were presented in a square grid structure (see Figure 1).
Based on a rational task analysis and on the results of Verschaffel et al. (1998), three major strategies for solving this task were hypothesized. Application of each of these strategies depended on the ratio of blocks to empty squares in the grid. When there were few blocks but many empty squares in the grid the use of an *addition strategy* by means of which (groups of) blocks are counted (and added) was hypothesized. When there were many blocks but few empty squares, we hypothesized that participants would use a *subtraction strategy* in which the number of empty squares is subtracted from the (estimated or computed) total number of blocks in the grid (i.e., the anchor). When the number of blocks and empty squares is too large to be counted within the given time constraint participants will fall back on a rough *estimation strategy*, whereby the number of blocks is determined in a quick but imprecise way.

It was assumed that the addition and subtraction strategy were relative accurate strategies leading to, respectively, linearly increasing and decreasing response times with an increasing number of blocks. Due to its nature, the estimation strategy will elicit less accurate responses with relatively quick response times that lie within the same range. The assumed connection between the use of a particular strategy on a particular numerosity judgement item and the time needed to solve that item, led to four hypothetical response-time patterns (see Figure 2).

2. Method

One hundred and nine children participated in the study: 59 second graders (aged 7-8 years) and 50 sixth graders (aged 11-12 years). All participants were asked to judge different numerosities of blocks that were presented in square grids of three different sizes (7 x 7, 8 x 8, and 9 x 9) as accurately as possible within the given time constraint of 20 s. All pupils ran three sessions and in each session all possible numerosities of blocks in one grid size (i.e., 49, 64, and 81) were presented randomly. Children's responses and response times were recorded by the computer.
Half of the pupils was given information about the total amount of squares in that particular grid at the beginning of each trial. For instance, in the case of the 7 x 7 grid, children in the information condition were shown the number 49 at the beginning of each trial. We included this manipulation to investigate the effect of information on children's strategy use

![Graphs showing patterns of response times](image)

*Figure 2.* Hypothetical response-time patterns with (a) application of the addition strategy, (b) use of the addition and estimation strategy, (c) execution of the addition and subtraction strategy, and (d) application of the addition, estimation, and subtraction strategy.

3. Research questions and hypotheses

The results with respect to the effect of different task and subject variables are already reported elsewhere (see Luwel, Verschaffel, Onghena, & De Corte, in press). In the present paper we focus on several hypotheses about the relationship between the process data (i.e., the applied strategies) and the product data (i.e., response times and error rates).

**Hypothesis 1:** The accuracy of the addition and subtraction strategy will be considerably greater than the accuracy of the estimation strategy. Furthermore, there will be no significant difference in accuracy between the addition and the subtraction strategy.

**Hypothesis 2:** There will be a negative relationship between the number of trials on which the estimation strategy is used, on the one hand, and the accuracy of the pupil on the task as a whole, on the other hand. The more the less accurate estimation strategy is used, the lower the overall accuracy will be.
Hypothesis 3: The overall accuracy of children fitting Pattern 3 will be higher than the accuracy of pupils who fit Pattern 4, and both will be higher than the accuracy of participants with a type 1 or 2 response-time pattern. Using only the more accurate addition and subtraction strategies (Pattern 3) will result in more accurate responses than when the less accurate estimation strategy is used in addition to the other two strategies (Pattern 4). Moreover, because of the use of the subtraction strategy for the largest numerosities, both strategy repertoires will lead to a higher overall accuracy than the combined use of the addition and estimation strategy (Pattern 2) or merely applying the addition strategy (Pattern 1).

4. Results

Before we discuss the results with respect to each of the four hypotheses, we will shortly describe how we identified children's strategies. For this purpose we compared the individual response-time patterns with the four hypothetical response-time patterns in Figure 2 by means of two- and three-phase segmented linear regression models (Beem, 1993, 1999). These models look, respectively, for one or two change points in the data pattern and describe the relationship between the independent and dependent variable by means of, respectively, two or three regression equations. After having determined the number of segments in a data pattern by statistically testing for the presence of one or two change points, we looked for a possible fit with one of these hypothetical patterns by comparing the b-parameters in the different equations under two hypotheses. For a detailed description of this procedure we refer to Luwel, Beem, Onghena, and Verschaffel (2000). This method resulted in 77% of the second graders and 83% of the sixth graders fitting one of the four hypothetical data patterns. For reasons of clarity the data in all analyses were aggregated over grid size and type of information condition.

Hypothesis 1 was tested for each type of pattern separately. Due to an unequal division of the pupils over the different patterns (see Luwel et al., in press), we were only able to test this hypothesis for the second graders fitting Pattern 2, for the sixth graders fitting Pattern 3, and in both age groups for Pattern 4. Accuracy was measured in terms of the absolute deviation from the given response to the actual numerosity (i.e., the error rate). The error-rate patterns of the subjects included in the analysis were divided into two or three segments by means of the change points computed in the individual response-time patterns and for each segment the mean error rate was computed.

For Pattern 2, the mean error rates of the different segments were compared by means of a t-test for dependent samples. This test showed that the mean error rates of Segment 1 (addition strategy) ($M = 1.38$) were significantly smaller than the mean error rates of Segment 2 (estimation strategy) ($M = 11.78$), $t(24) = 2.67$, $p = .01$. 

For Pattern 3, the same test did not show a significant difference in mean error rates between Segment 1 (addition strategy) and Segment 2 (subtraction strategy).

For Pattern 4, we conducted an analysis of variance with age as independent between-subjects variable and segment as independent within-subjects variable. This analysis revealed a significant main effect of age, $F(1, 94) = 7.06, p = .009$, and of segment, $F(2, 188) = 177.00, p < .0001$. Both variables were involved in a significant interaction effect, $F(2, 188) = 5.12, p = .007$. A posteriori Tukey tests revealed that in both age groups, Segment 2 showed significantly larger mean error rates than Segment 1 and 3 ($M$s: 6.05, 0.80 and 1.58 for the second graders and $M$s: 4.42, 0.72 and 1.21 for the sixth graders), all $p$'s < .0001. The mean error rates in Segment 1 and 3 did not differ significantly in both age groups. Furthermore, the mean error rates of the second graders in Segment 2 ($M = 6.05$) were significantly larger compared to the mean error rates of the sixth graders in that segment ($M = 4.42$), $p = .0001$, whereas we did not observe an age difference for Segment 1 and 3.

These findings confirm our first hypothesis: for Pattern 3 and 4 there was no significant difference in mean error rates produced by the addition strategy, on the one hand, and the subtraction strategy, on the other hand. Moreover, for Pattern 2 and 4 the mean error rates resulting from the use of the estimation strategy were significantly larger than the mean error rates produced by the addition strategy (and the subtraction strategy in the case of Pattern 4).

To test Hypothesis 2, we computed the correlation between the number of trials on which the estimation strategy was applied and the mean error rate of the pupil on the task as a whole. For both age groups this correlation was computed for pupils fitting Pattern 4.

This analysis revealed a significant positive correlation for the second graders, $r(41) = .60$, as well as for the sixth graders, $r(53) = .41$, all $p$'s < .05, suggesting a negative effect of the use of the estimation strategy on the global accuracy.

For Hypothesis 3, we compared the mean error rate on the whole task for the different types of patterns by means of a $t$-test for dependent samples. For the second graders we could only compare Pattern 2 with Pattern 4. The $t$-test revealed that the mean error rates for Pattern 2 ($M = 4.64$) were significantly larger than the mean error rates in Pattern 4 ($M = 2.49$), $t(24) = 3.45, p = .002$. For the sixth graders, the only comparison was between Pattern 3 and Pattern 4. Results showed that the mean error rates in Pattern 4 ($M = 2.09$) were significantly larger than the mean error rates of Pattern 3 ($M = 1.01$), $t(44) = 4.42, p < .0001$.

5. Discussion

The present results confirmed our hypotheses in which we predicted a number of relationships between the strategies that were identified on the basis of the
individual response-time patterns, on the one hand, and their accuracy data, on the other hand. These findings support our rational task analysis in which we specified the different types of strategies in terms of their expected course of response times and their degree of accuracy. It was shown that the addition and subtraction strategy were relatively accurate strategies, whereas the estimation strategy was a less accurate strategy. Moreover, this study also validated previous findings concerning numerosity judgement strategies.

1 A pilot study revealed that some children made large numerosity judgement errors due to an incorrect determination of the anchor. We wanted to investigate whether the provision of information about the anchor could prevent this kind of errors.
THE FORMULATION OF A CONJECTURE: THE ROLE OF DRAWINGS

Mirko Maracci

Department of Mathematics - University of Pisa, Italy

Abstract. The study presented in this paper arises from a research project dealing with the process of solving open-ended problems in a geometrical context. The specific moment of conjecture formulating is taken into consideration and namely a particular behaviour concerning the process of drawing producing is analysed. The theoretical framework of figural concepts provides us with the starting point from which developing our considerations.

Introduction

Many investigations on the role drawings play within geometrical activity have been carried out from different points of view. Duval (1995) focuses on the “traitements spécifiques au registre des figures et à celui d’un discours théorique en langue naturelle” (p.173) and highlights the differences between them. Other studies point out and inquire into the intimate relation that exists among drawings, figures and concepts (Fischbein 1993, Laborde – Capponi 1994).

Notwithstanding many questions remain to be answered and in particular the role drawings play in solving geometrical problems has to be deepened.

In this paper we present a study developed from a research project, still in progress, which intends to investigate on the solving strategies of open-ended problems (Maracci 1998). With reference to the theoretical framework of figural concepts (Fischbein 1993) we focus on the role that producing drawings plays in solving construction-problems.

Figural concepts and satisfactory drawings

According to Fischbein’s theory of figural concepts (1993) when dealing with geometrical activity we are concerned with a mental construct which simultaneously and intrinsically possesses both figural and conceptual properties.

The perfect fusion between the two components of a figural concept seems to be only an ideal and extreme situation, indeed “what happens is that the conceptual and the figural properties remain under the influence of the respective systems, the conceptual and figural ones” (ibidem, p.150).

According to this theory a drawing is the material concrete representation of a figural concept, reflecting the tension between the figural and the conceptual component.

In previous studies (Maracci 2001) the hypothesis has been formulated that when producing a geometrical drawing students try to harmonize figural and conceptual aspects. The search for such harmony does not seem to be conscious, one could speak of a generic feeling of satisfaction from students’ point of view. Three factors have been pointed out which might characterize this generic feeling and make a drawing satisfactory:

- a drawing should correctly represent the geometrical situation into consideration, students’ interpretation of the given situation and of the produced drawing should be consistent;
• a drawing should be recognized as sufficiently generic;
• a drawing should possess a good gestalt, it should satisfy the fundamental laws which control the basic processes of perception.

These conditions may appear and combine in many different ways.

**Our research**

As mentioned above our study derives from a more extensive research concerning the processes of solving open-ended problems in a geometrical context (Maracci 1998). Seventeen students (11th and 12th grades) selected from different scientific high school were involved, all of them evaluated by their teachers as medium-high achievers. These students were presented with 4 open-ended problems to be solved in individual videotaped interviews during which they were asked to think aloud. The study presented in this report focuses on the specific moment of the formulation of a conjecture. The analysis of the transcripts of the interviews shows some different behaviours on students’ part. In this report we will focus on the following one:

• after a period of investigation conducted with the aid of drawings, students get the correct conjecture and face the task of formulating it precisely;
• the conjecture is achieved with clear and explicit reference to one or more specific drawings;
• students verbally formulate their conjecture producing at the same time a new drawing very similar to those which they previously referred to.

With respect to such a behaviour the following question may be posed:
when they seem to have elaborated the correct conjecture with reference to a satisfactory drawing, why do some students feel the need of producing a new drawing so similar, if not identical, to the previous one?

A first answer has been proposed by formulating the hypothesis that students may interpret drawings diachronically, i.e. they may consider each drawing with its history as representing a specific process of the problem solving session (Maracci, 2001).

Here we will concentrate on the particular case of construction-problems and try to face the question from a different point of view.

The only problem we will refer to in the following is:

**Problem:** Given two equal segments, construct two equal triangles with a common vertex and having the two given segments as homologous sides.

This problem presents some difficulties in the identification of a solution. In order to solve it one could reformulate the problem shifting her attention from the construction of the two equal triangles to the construction of the common vertex.

**Conjecture formulating and drawing producing in construction-problems**

A strategy to successfully approach a construction-problem may be assuming the required objects as given and then proceeding backward in the search for some characterizing properties from which getting the needed construction. In this case when formulating her conjecture one needs, first of all, to restore the correct logical order of the relations.
As far as construction-problems are concerned students are required to explicitly give a procedure, a list of operations to perform in order to actually carry out the construction. The conjecture students have to elaborate and formulate consists indeed of a series of instructions which may hardly be put in the form “if... then...” or in any case in a more concise form. Correctly describing a construction is a really demanding activity: it requires both to control the global organization of the procedure and to assure that each step may be actually performed. Performing it on the paper might provide a very useful support and in fact many students actually carry out their construction. Thus students are engaged both in the verbal description of the construction and in the production of a new drawing.

On the other hand the production of a drawing is a demanding activity too. In previous researches students’ difficulties in producing and managing drawings in solving geometrical problems have been highlighted (Maracci 1998, Maracci 2001). When producing a drawing students try to reach a harmony between figural and conceptual aspects. Even if it is not consciously stated, the need of balancing correctness, generality and good gestalt permeates the whole process of production of a drawing.

Thus students are involved in at least two really demanding processes: the verbal formulation of the construction itself and the production of a new drawing.

Silver (1987) pointed out that the “overwhelming number of processes to control” is one common difficulty students face in solving mathematics problems. In order to overcome such difficulty students might try to activate some form of control over the processes to be carried out.

**Production of drawings as a means of control**

We remarked that when verbally describing their construction some students produce a new drawing establishing a, more or less explicit, correspondence with those to which they referred in the search for the construction itself.

**Our main hypothesis** is that the production of a drawing similar to previous ones is an attempt to activate a form of control over the processes of description of a construction and of production of a drawing.

According to our hypothesis establishing such correspondence might provide a control at least at two different levels:

- in order to be a satisfactory representation a drawing has to combine and balance needs for correctness, generality and good gestalt. When producing a new drawing, making reference to an already made satisfactory one may assure students that they are really producing a satisfactory drawing.
- Moreover, with concern to construction-problems, producing a new drawing similar to previous ones may play a more specific role. The drawing, with respect to which the correct construction has been grasped, might represent the final configuration, the outcome itself of the construction.
Establishing a connection, a correspondence between that drawing and the new one might allow students to interpret the former as a preview of the result of the construction they are performing and describing.

If the construction is correct and it is correctly performed the established correspondence has to persist up to the end of the construction itself and the resulting drawing has to be consistent.

Extracts from problem solving sessions
In the following we present some excerpts from two protocols relative to the activity of formulation of a construction. We shall analyse the excerpts in the light of the previous considerations.

Barbara (12th grade, scientific high school)
What follows is the exact moment in which Barbara gets the properties characterizing the common vertex of the two unknown triangles. Drawing 4 is that with respect to which she has conducted the core of her exploration and it is that to which she is referring when grasping the correct construction (item 128)

128. Bar: there! I have to consider the perpendicular bisector of the segment... oh, there... I found it [...].
So I have to trace, to consider the segment AD - she indicates the segment AD in drawing 4 - and to find... wait, - she indicates segments AO and DO in drawing 4 - then segment AD, I found the perpendicular bisector of the segment by cutting it in two equal parts and tracing the perpendicular, then I know that point O has necessarily to belong to the perpendicular bisector of AD, wait - she looks at drawing 3/1 and renames the endpoints of the two segments (drawing 3/2) - I trace, - she traces AD - I trace... I consider the midpoint and trough it I trace - she traces the perpendicular bisector of AD - then, now I know that point O has necessarily to belong to the perpendicular bisector of this segment, but it has to belong to the perpendicular bisector of segment BC - she indicates BC in drawing 4 - isn't it?... I trace BC and - in drawing 3 she traces BC and its perpendicular bisector - there ...

130. Bar: no, it does not work [...]

134. Bar: not, since... in this drawing - she is referring to drawing 4 - I assumed these two segments equals - she marks BO and CO - but in this drawing - she refers to drawing 3/2 - I'd actually get this one
equal to this one - she indicates (drawing 3/2) the segments AO and CO.

136. Bar: point O should be here theoretically - she labels by O the intersection point of AD and BC - but it is here actually - she indicates the intersection point between the perpendicular bisectors of AD and BC.

140. Bar: no, since... I'm really fool! - she marks the correct point O and traces AO, BO, CO and DO (drawing 3/3)

After having caught the correct construction, Barbara does not formulate it referring directly to drawing 4. She chooses to refer to another one. Her choice is indeed quite unusual: Barbara does not produce a new drawing from the beginning, she prefers to refer to an already made one (drawing 3/1). Drawing 3/1 provides her with a satisfactory representation of the initial configuration (i.e. the two equal segments); the presence of the triangle, related to previous investigations, seems not to influence the formulation of the conjecture.

Because of the mutual position of the two segments, drawing 3/1 seems suitable to be put in correspondence with drawing 4 and Barbara makes this correspondence complete by renaming the endpoints of the segments so as to conform them with drawing 4 (item 128).

While formulating her conjecture Barbara actually performs the construction (drawing 3/2), but suddenly she stops (item 130). At this point no one could tell what is wrong. In the following minutes Barbara continually shifts her attention from one drawing to the other.

In items 134 and 136 Barbara finally explains what causes her uncertainty. Trying to mentally anticipate the result of her construction, Barbara failed in positioning point O in her mind (it is only in item 136 that she labels point O in her drawing). Because of this mistake, the correspondence between the two drawing does not seem to be suitable any longer (item 130).

As it clearly appears (item 134), Barbara expected to get the equality between the sides BO and CO as a result of her construction. But what she gets, or better she thinks she is getting is the equality between AO and CO. Barbara's expectation derives from the fact that she is performing her construction making explicit
reference to drawing 4. This allows her to interpret that drawing as a prevue of the outcome of the construction itself.

As soon as Barbara thinks that the established correspondence fails, she has no doubt that some mistake occurred, even if she is not immediately able to specifies which one.

It takes some minutes before Barbara realizes what really happened (item 140) and can, so, successfully conclude her problem solving session.

This protocol gives an interesting example how establishing a correspondence among drawings might provide one with a means of control over both the production of a new drawing and the correctness of the construction itself.

Let us remark a further aspect, at the end of the construction the resulting drawing (drawing 3/3) is quite similar to drawing 4: they share characteristics as the mutual position of the triangles and their shape. One might wonder whether such perceptive similarity plays the fondamental role in the correspondence between the two drawings. We could better discuss this question after having considered the next protocol.

**Davide (12th grade, scientific high school)**

Davide conducted his search for a conjecture mainly with the aid of two drawings (drawing 4 and drawing 7), and it is exactly with respect to drawing 7 that he grasped it. As Barbara did, he chooses not to refer to that drawing; he decides to produce a new one.

80. Dav: *he draws two equal segments (drawing 8) - I know that these two angles... these two sides are equal – he marks VD and AV in drawing 7 – in the same way these two ones – he marks BV and CV – so here, one can... however, I'm constructing it below – he labels the endpoints of the previously drawing segments in conformity with drawing 7 - I mark the midpoint of the segments AD and BC – he constructs the midpoints of the two segments – these are... – he indicates the perpendicular bisector of AD – the geometrical locus of the points with equal distance from the endpoints A and D, [...]
I construct another straight line which is... the geometrical locus of point with the same distance from the endpoints B and C – he constructs the perpendicular bisector of BC and labels the intersection point by V.

We can notice that drawing 8 shares the same initial configuration with drawings 4 and 7, that is the mutual position of the segment AB. The core of the search for the construction has been conducted with reference to such configuration, it is evidently satisfactory to Davide, so that he decides to use it as the starting point for his new drawing. Moreover he makes the correspondence between drawing 8 and drawing 7 stronger by naming the endpoints of the two initial segments in the same way (we observed the same behaviour on Barbara’s part (item 128)).

While verbally making his conjecture explicit Davide constructs the vertex V. As we can see, the final configuration appears completely different from previous ones, notwithstanding this does not affect Davide’s confidence about the correctness of his conjecture nor of his drawing.

We want to point out that despite the undeniable perceptive differences, the correspondence between drawings 8 and 7 persists in a deeper sense. Drawing 8 represents the segment BV equal to CV and the segment AV equal to DV, as they were represented in drawing 7. Even if they are “globally” different the two drawings represent the same “analytic” relations among the same elements.

On the other hand if we look back at Barbara’s protocol we can observe that she never refers to how drawings appear globally. She explicitly refers to analytic relations among the drawn elements.

Consistently with the theory of figural concepts (Fischbein, 1993), students interpret drawings as reflecting figural and conceptual aspects, the correspondence students establish among drawings is not limited to perceptive aspects, it deeply involves analytic relations too.

Conclusions
Solving a construction-problem requires one to explicitly give a procedure, a list of constructing operations. Producing a drawing might provide a useful support for the verbal description of the construction. But verbally formulating a construction and contemporary producing a new drawing are two really demanding activities, in order to successfully manage them some means of control may be needed.

The analysis of the experimental data suggests that such a control may be found in relating the new drawing to that with reference to which the construction has been caught.

Establishing such a correspondence might assure that one is really producing a satisfactory drawing.

Furthermore previously produced might be interpreted as a models of the outcome of the construction itself.

Many key points remain to be clarified. Far from being exahustive, our research poses new questions to be answered. We should like to point out the followings ones:

• when problems different from construction ones are involved, is any
correspondence among different drawings established? Which eventually is its role?

- might establishing correspondences among drawing play roles of control over other activities in the process of problem solving?

Students' difficulties in managing drawings have been highlighted in previous researches (Maracci 1998, Maracci 2001). We think that deepening which role drawings play in the process of solving geometrical problems might contribute to clarify such difficulties. In order to be able to plan specific didactical activities a further development of this research is anyway needed.

Notes

1. The original drawings were scanned and processed by means of a computer in order to obtain, on the basis of the analysis of the videotapes, the way they appeared at each moment of the problem solving sessions. Numbers which designate drawings refer to the whole session. One of the drawings relative to the protocol of Barbara (drawing 3) was processed in order to be allowed to follow its production step by step.

2. Let us remark that at this point Barbara has not still labeled point O on her drawing (cfr item 136)

Abstract. In the theoretical framework of Vygotskij's Theory this report discusses the mediating function of particular tools available in a microworld. Following the analysis carried out by one of the authors, in the case of Cabri a new microworld has been set up and a teaching experiment carried out. Some results are reported and the theoretical notion of semiotic mediation discussed.

Introduction
A long-term experiment concerning pupils' introduction to theoretical thinking in the algebra domain has been carried out over the last two years. Activities were accomplished in the field of experience (Boero, 1995) of "symbolic manipulation within a microworld": "L'Algebrista" (Cerulli & Mariotti, 2000). As in previous experiences, (Mariotti, forthcoming b), in this experiment the evolution of the field of experience is realized over time through social practices; in particular, classroom verbal interaction is made possible by means of 'mathematical discussion' (Bartolini Bussi, 1998).

The didactic problem concerns the ways of realizing a theoretical approach to symbolic manipulation. A key-point is that of stating the "system of manipulation rules" as a system of axioms of a theory. The nature of the particular environment may foster the evolution of the theoretical meaning of symbolic manipulation. This is not really the approach pupils are accustomed to, on the contrary, Algebra, and in particular symbolic manipulation, are conceived as sets of unrelated "computing rules", to be memorized and applied.

In this report we shall limit ourselves to the discussion of some elements of the external context (Boero et al., 1995) and their functioning in the concrete realization of classroom activity. These elements may function as instruments of semiotic mediation (Vygotskij, 1978). The general basic hypothesis is that

\[ \text{meanings are rooted in the phenomenological experience, but their evolution is achieved by means of social construction in the classroom, under the guidance of the teacher.} \]

Our research project is aimed at studying the functioning of an artefact, when it is conceived as a potential instrument of semiotic mediation (Vygotskij, 1930-1978). In particular, we focus on a specific type of artefact: a microworld.
Semiotic mediation

Vygotskij distinguishes between the function of mediation of technical tools and that of psychological tools (or signs or tools of semiotic mediation) (Vygotskij, 1978: 53). The use of the term psychological tools, referred to signs as internally oriented, is based on the analogy between tools and signs, but also on the relationship which links specific tools and their externally oriented (for the mastering of nature) use to their internal counterpart (for the mastering of oneself) (ibid.: 55).

Through the complex process of internalisation (Vygotskij, ibid.), a tool becomes a "psychological tool" and will shape new meanings; in this respect a tool may function as a semiotic mediator.

The following sections will be devoted to illustrating this theoretical hypothesis in the case of a set of particular tools (the microworld L’Algebrista) and the theoretical meaning of algebraic statements, that we shall briefly recall as 'Algebra as a Theory' (in the following AT).

Semiotic mediation in a microworld

A new research project was set up, along the same line and according to the same general hypothesis of a previous research project involving the Cabri microworld (Mariotti et al., 1997; Mariotti & Bartolini, 1998; Mariotti, in press). As far as Cabri is concerned, previous studies have focussed on the analysis of the specific elements of the microworld (dragging facility, commands available, macro ...) as an instrument of semiotic mediation that the teacher can use in order to introduce pupils to a theoretical perspective. Taking into account the main results obtained from these studies, a new microworld (L’Algebrista) was designed, incorporating the basic theory of algebraic expressions. Similarly to what happens in Cabri in relation to Geometry, AT, as far as it is imbedded in the microworld, is evoked by the expressions and the commands available in L’Algebrista. As a matter of fact, L’Algebrista is a symbolic manipulator which is totally under the user's control: the user can transform expressions on the basis of the commands available; these commands correspond to the fundamental properties of operations, which stand for the axioms of a local theory. As a consequence, the activities in the microworld which produce a chain of transformations of one expression into another, correspond to a proof of the equivalence of two expressions in that Theory.

According to the Vygotskian framework, expressions and commands can be thought as external signs of AT and, as such, they may become tools of semiotic mediation (Vygotsky, 1978).

The main elements offered by L’Algebrista as instruments of semiotic mediation related to the theoretic aspects of algebra, are the following:

• expressions in L’Algebrista are signs of algebraic expressions; their intrinsic structure and their logic within the microworld refer to algebraic expressions as theoretical objects;
- commands (buttons) are signs of axioms and definitions of an Algebra Theory;
- transforming an expression into another using the buttons corresponds to proving that the two expressions are equivalent, the produced chain of justified steps corresponds to a proof;
- new buttons may be introduced using a specific command (Il Teorematore – i.e. Theorem Maker); such new commands become signs of theorems;
- adding new buttons to those already available is a sign of the meta-theoretical operation of adding new theorems to a theory.

Classroom activities develop constructing a parallel between the activities within the microworld and the evolution of AT. Transformations within L'Algebrista, via the use of the "buttons" available, correspond to proving equivalencies by using axioms in AT. Furthermore, as soon as a new equivalence is derived, i.e. it is proved, it can be introduced as a Theorem, and using the "Theorem Maker" it can become a new "button". The introduction of a new "button" is discussed collectively: thus the evolution of the theory occurs as a social enterprise.

In the following section we shall discuss a number of examples showing some aspects of the internalisation process related to the particular tools offered by the microworld, contributing to the evolution of the theoretical meaning of symbolic transformations.

**Making conjectures and proving**

The classroom activities consisted in alternated sessions in which the pupils were asked to solve problems inside and outside the microworld. Articulation between these two modalities constitutes one of the main characteristics of the activity design. As far as the analysis of the internalisation process is concerned, activities "without the computer" may highlight some interesting aspects. Let us consider the following problem, to be solved in the paper and pencil environment. Pupils are asked to compare three expressions and to find out which ones are equivalent; they are then requested to prove their conjectures.

Consider the following expressions:

\[
\begin{align*}
    a\ast(a-b) & \quad (a-b)\ast(a+b) \\
    a\ast(a-b) & \quad a\ast(a-b) \\
\end{align*}
\]

a) Which of them do you think are equivalent? Which do you think are not? Why? Can you prove this?

b) Analyse your proof and specify, for each step, whether you have used a theorem or an axiom.

Silvio (Fig. 1) starts to reduce the second and third expression into a form that makes it easier to compare them with the first. This part of the protocol looks like typical productions provided by the pupils when asked to compute (Italian: “calcolare”). In
this case Silvio, although not requested to do so, uses his computing skills to produce a conjecture; nevertheless, his explanation shows that the properties of the operations, i.e. the axioms previously introduced, were used in the heuristic phase as tools to predict the equivalence.

Figure 1. Silvio writes:
I think the 1st and the 3rd are equivalent, but not the 2nd, because applying the properties they become equal, while the 2nd does not.
I applied the distributive property.
I applied the distributive property on these two pieces.
I summed the two equal terms $-a^*b$ and $-a^*b$ and I cancelled the result with its opposite obtaining 0 for the 1st theorem.
I cancelled also $+b^*b$ with its opposite and I obtained $-b^*b$ because it was $-2b^*b$.
At this point the 3rd expression is equal to the 1st expression.

Figure 2. Marta writes:
The first and the third expressions are equivalent, whilst the second is not because giving the same numerical numbers to a and b the result is not the same of the other two.

Distributive property of multiplication (axiom).
Commute property of multiplication (axiom).
According to our theorem this is 0.
Unlike Silvio, Marta (Fig. 2) does not use the properties of the operations to produce her conjecture: nevertheless, she produces a correct proof, specifying (as required), at each step, the axiom or the theorem she is applying. According to our hypothesis it looks as though the distinction, clearly defined within the microworld, has been internalised: axioms are represented by given buttons, theorems, once proved are introduced by pupils in the microworld, as new buttons. It is interesting to remark that, consistently with this history of the class community, Marta refers to the theorem, that she is applying, as "our theorem".

**Signs derived from L’Algebrista**

The basic point of symbolic manipulation concerns the use of operation properties as rules of transformation, which preserve the equivalence between expressions. Although perceived globally, manipulating an expression consists of successively transforming one single chunk at a time; consequently, identifying and treating the structure of an expression becomes fundamental, so as to foresee the effect of single transformations towards a specific global goal.

The representation of an expression within the L’Algebrista incorporates its mathematical tree structure, and this structure becomes explicit, thanks to the *selection function*. As a matter of fact, in order to act on an expression, one first has to select a sub-expression and then to click on a button: the corresponding command will be activated only if the selection is 'correct', i.e. compatible with the property to be applied. The selection function represents an external sign that in the actual interaction with the machine can be used as an external control on one's actions. Internalisation of this control seems to constitute a basic point in the construction of the theoretical meaning of symbolic manipulation.

![Mathematical expressions](image)

Figure 3. In the case of a comparison task, performed in the paper and pencil environment, the protocol (Fig. 1) shows that pupils use signs clearly derived from L’Algebrista, in particular the *selection function*, or the iconography of the buttons.
Lia's protocol is an example of an interesting phenomenon which can be interpreted as testifying an important phase in the internalisation process. Pupils may use the *selection function* as an external sign controlling the algebraic structure of an expression: Lia tries to prove that the two expressions are equivalent. At each step she underlines (*selects*) a sub-expression and transforms it using an axiom that applies. This behaviour, not explicitly required by the task, refers directly to the interaction between the user and L’Algebrista: Lia refers clearly to the buttons of L’Algebrista using the word *button* (It.: *bottone*) and reproducing the iconography (for instance, in the case of the *buttons of neutral elements* (It.: *elementi neutri*). At the same time, however, she refers to the properties using the expression commutative, distributive, etc.

**Discussion**

The instrumental function characteristic of the microworld, functioning as a control on the activity of transformation, is internalised, and contributes to the evolution of the theoretical meaning of symbolic manipulation.

A button provides the external control on the operations accomplished by the machine; the use of the button is interpsychological: it occurs externally, it concerns the interaction between the pupil and the machine; similarly to a personal interchange between human beings, the machine reacts to the subject's action, autonomously from the subject's intention. This reaction may or may not be consistent with the goal of the subject but in any case it directs the activity towards the goal.

The button evolves into a sign and its functioning starts to be oriented internally, so that the button evolves into an intellectual tool regulating the symbolic transformation consistently with the goal of the task. In this respect Silvio's protocol is illuminating. Let us compare the two sequences of computation: according to the Vygotskian explanation, in the activities in the microworld the external sign, i.e. the button to be activated, has realized a break between the steps of automatic computing, allowing the pupil to become aware of the theoretical relationship between two expressions in the chain of computation. The written sign used by Lia and also used by Silvio and Marta is a temporary support control which testifies this

---

1 $0+A \rightarrow A$: this button transforms an expression of the kind “0+A” into the expression “A”, where “A” can be any expression. This button corresponds to the axiom defining the neutral element of the sum operator.

2 Similarity with the case of human interaction should not hide differences, which cannot be ignored. On the contrary, what we are interested in is to study the specificity of a machine, and in particular of computer devices, in the functioning of social construction of meanings. The limits of this paper prevent a full discussion which we are obliged to omit.
evolution. (Similar phenomena of creating temporary sings have been described in Bartolini Bussi et al.1999; Mariotti, forthcoming b)).

A final remark: as already said, our analysis does not take into account a basic point: the role of the teacher in the process of evolution of meanings.

The role of the teacher develops at the meta level, when guiding the evolution of meanings: it becomes determinant in a process of decontestulization required in order to redefine the role of "buttons", and "new buttons", outside the microworld. In fact, commands must be detached from their context and explicitly referred to mathematical theory.

Further investigations into the delicate role played be the teacher are required for a better and clearer description.

ATTITUDE TOWARD MATHEMATICS: SOME THEORETICAL ISSUES
Pietro Di Martino and Rosetta Zan
Dipartimento di Matematica
Università di Pisa, ITALY

Abstract
Research on affect has produced many meaningful results in the context of mathematics education. Nevertheless, the theoretical framework needs further development, in order to grant effective tools for observing, interpreting, and possibly modifying students' decisions in the context of mathematics activity. In particular the construct of attitude toward mathematics appears to be an ambiguous one. After a brief survey of some theoretical issues that are still open, we propose further questions involving the definition itself of attitude.

Attitude toward mathematics: an ambiguous construct
The attitude construct finds its origin in the context of social psychology (Allport, 1935), in connection with the question of foreseeing individual's choices in contexts like voting, buying goods, etc. The construct appears ambiguous from the beginning, but the research develops more toward the formulation of measuring instruments than toward the theoretical definition of the construct. Furthermore in these times the quantification is considered a warrant of the discipline's scientific nature. The instruments that have been produced have given theoretical and methodological contributes of great importance (such as those of Thurstone and Likert), but the attitude's "measurement" soon found itself facing the problem of identifying the possible variables.

In the field of mathematics education the construct gains renewed popularity with the reevaluation of affect in the learning of mathematics. This reevaluation, according to us, has two reasons, which are both very important:

- The needs to explain the failure in the problem solving context of individuals who possess the necessary cognitive resources. The studies in this field underline the role of metacognitive abilities (Schoenfeld, 1985; Zan, 2000) but also the influence of the emotional factors on the control processes (Borkosky, Carr, Rellinger & Pressley, 1990; De Bellis & Goldin, 1999).

- The mathematical activity itself, as described by important mathematicians, such as Hardy, Hadamard, Poincarè, is marked out by a strong interaction between cognitive and emotional aspects.

In the field of mathematics education there is a general agreement in seeing the affective domain as divided into emotions, attitudes and beliefs (McLeod, 1992). The
agreement is not as unanimous in the definition of these constructs (Hart, 1989), and the studies on attitude, in mathematics education also, privilege measurement problems more than definition problems. With the development of research in this field, and especially with the increase of awareness of the affect’s role in mathematics learning, the necessity of a theoretical framework has grown too. Attitude research in mathematics education has been criticized in several respects:

1. The construct of attitude appears to be vague and ambiguous. Moreover mathematics educators often do not clearly describe the definition used in their own research (Hart, 1989).

2. The first attempts to measure attitudes seem “exceptionally primitive” (Leder, 1987), and “the driving force in much of this research seems to be the statistical methodology rather than the theory” (McLeod, 1987, p. 134). Kulm (1980) points out that: “The measurement of mathematics attitudes in the future should make use of many approaches, and researchers should not believe that scales with proper names attached to them are the only acceptable way to measure attitudes” (p. 365).

According to Hart (1989): “Beliefs, attitudes and emotions have been examined via scores on paper-and-pencil instruments and occasionally via individual student interviews. This view of beliefs, attitudes, and emotions might be called a black-box approach (...) The time and effort required to collect and analyze the data obtained from the think-aloud interview are much greater than the time and effort required for the paper-and-pencil instrument, but the information gained is a richer reflection of the student.” (pp. 43-44)

3. Despite the fact that research lately has shifted from quantitative methods toward a multidimensional approach, including qualitative methods, like interviews, classroom observations, and essays, several problems have not been solved yet. One of these problems is linked with the relationship between beliefs and attitudes. Silver (1985) points out that: “(...) we need to investigate the relationship between beliefs and attitudes. Are all attitudes also beliefs; if not, then how do we distinguish those that are from those that are not?” (p. 256)

Independently from the chosen definition of attitude (whether implicit or explicit), the attitude observation instruments always include beliefs observation instruments. Thus the attitude research has to deal with problems that the beliefs research has highlighted, especially the mismatch between exposed beliefs and beliefs-in-practice: the beliefs that students declare are in the end definitely different from those that guide their solving processes and their behavior in general. A way of interpreting this mismatch is to distinguish the beliefs toward school mathematics from those toward abstract mathematics (Schoenfeld, 1989). If the measurement of attitude includes the observation of beliefs, this beliefs differentiation implies a similar distinction of attitudes.

4. More in general, some researchers think that the term “attitude toward mathematics” should be divided in several components. Kulm (1980) delineates the
objects and situations on which attention is focused for mathematics attitudes: mathematics content, mathematics characteristics, teaching practices, mathematics classroom activities, and mathematics teacher. Tirosh (1993) suggests the opportunity to describe students' beliefs, attitudes, and emotions toward mathematics in terms of "specific affects", namely their reaction and feelings toward specific mathematical topics, specific tasks and specific activities.

In conclusion, the problem of 'measuring' attitudes is often faced without an appropriate theoretical framework (McLeod, 1992).

Further theoretical questions

A deep analysis of the construct 'attitude' requires first of all a definition of the term itself. In the variety of definitions of attitude toward mathematics used in the different studies, we can identify two important typologies:

1. A 'simple' definition of attitude describes it as the positive or negative degree of affect associated to a certain subject. According to this point of view the attitude toward mathematics is just a positive or negative emotional disposition toward mathematics (McLeod, 1992; Haladyna, Shaughnessy J. & Shaughnessy M., 1983).

2. A more 'articulated' one recognizes three components in the attitude: an emotional response, the beliefs regarding the subject, the behavior toward the subject. From this point of view an individual's attitude toward mathematics is defined in a more articulated way by the emotions that he/she associates to mathematics (which, however, have a positive or negative value), by the beliefs that the individual has regarding mathematics, and by how he/she behaves (Hart, 1989).

According to us the acceptance of either definition brings up several and distinct problems.

Remarks on the 'simple' definition

- Apparently the absence of a connection with the cognitive aspects could be criticized in this definition. As a matter of fact many studies, explicitly or implicitly based on this definition, follow models (Mandler, 1984, 1989; Ortony, Clore & Collins, 1988) which emphasize the cognitive source of emotions: "Mandler's view is that most affective factors arise out of the emotional responses to the interruptions of plans or planned behavior. In Mandler's term, plans arise from the activation of a schema. The schema produces an action sequence, and if the anticipated sequence of actions cannot be completed as planned, the blockage or discrepancy is followed by a physiological response (...) at the same time the arousal occurs, the individual attempts to evaluate the meaning of this unexpected or otherwise troublesome blockage. (...) The cognitive evaluation of the interruption provides the meaning to the arousal." (McLeod, 1992, page 578)
- Even those who accept this definition, when measuring attitudes use questionnaires based on beliefs. In this way it is implicitly assumed that certain beliefs imply a positive emotional disposition.

For example a widely used item is "mathematics is useful". This belief is considered positive, assuming implicitly that it gives place to a positive emotion. As a matter of fact this implication is not natural at all, as the opinions and reported feelings of important mathematicians demonstrate (see for example Hardy, 1940).

Furthermore we agree with Gal and Ginsburg’s remark (1994), about the attitude toward statistics: “Thus, a student’s responses to items assessing usefulness-of-statistics issues might have little to do with feelings or attitudes towards statistics as a subject; instead they may only reflect on the student’s vocational development (...) or knowledge about requirements or content of certain jobs.”

- Accepting this definition, it is quite clear that ‘positive attitude’ means ‘positive’ emotional disposition. It is thus important to question why a positive emotional attitude is meaningful in the context of mathematics education.

The goal of promoting a positive attitude may have two reasons:

i) The attitude’s influences on an individual’s choices about mathematics courses to take. As Hart says (1989): “It is relatively clear that decisions about how many and which mathematics courses to take in middle school, high school, and college can be influenced by affective characteristics of the student (...)” (p. 38)

However it seems to us that to promote a general positive emotional disposition toward mathematics is not very significant, if this disposition is not linked with an epistemologically correct view of the discipline. In other words an affective goal of mathematics education is to promote a “view of mathematics as vibrant, challenging, creative, interesting, and constructive” (Silver, 1987, p. 57).

ii) The idea that a positive attitude is connected to success. As a matter of fact this connection is far from being clear. McLeod (1992) refers data from the Second International Mathematics Study, that indicate that Japanese students had a greater dislike for mathematics than students in other countries, even though Japanese achievement was very high. Ma & Kishor (1997), after analyzing the correlation attitude / achievement in 113 studies, underline that this correlation is not statistically significant: they explain this as caused by the inappropriateness of the observing instruments that had been used. According to us, on the contrary, this limitation is a natural consequence of the ‘simple’ definition of attitude. In fact it is not enough that the mathematical experience is generally associated with positive feelings: it is also important for such an experience to be meaningful. For example a distinction is needed between a child that likes mathematics because of the calculation involved and another one that likes it because of problem solving. Furthermore also negative emotions play an important role in mathematical activity.
McLeod, Metzger and Craviotto (1989) found that experts and novices have the same emotional reactions in problem solving situations, but differ in that experts are better able to control their reactions than novices. In particular a minimum degree of anxiety seems to be necessary to invest adequate resources in the task.

Remarks on the ‘articulated’ definition

-In this case both the emotional and cognitive dimensions are explicitly underlined. But too often the interaction between these dimensions is not properly considered. In particular it is important to consider beliefs together with the emotions that they elicit. For example the belief "In mathematics there is always a reason for every rule" is to be considered differently whether it elicits a positive emotion ("and I like this") or a negative one ("and I don’t like this").

Similarly it is essential to distinguish emotions according to their cognitive source (Ortony et al., 1988). This suggests the opportunity to differentiate ‘simple’ emotions (associated with an individual’s tastes) and ‘complex’ ones (associated with an individual’s beliefs).

-According to the ‘articulated’ definition the attitude construct is multidimensional, so it can not be quantified with a single score. The possible alternatives are:

(i) Give a score for each dimension (beliefs, emotions and behavior). This is close to the original idea that Thurstone & Chave (1929) suggested. They pointed out that even if attitude is a complex construct (that can not be measured with a single numerical index) it can be measured using several indices. They underline the fact that the same process is followed in measuring physical objects (like a table). We find interesting their remark that the choice of the characteristics to be measured depends on the context.

(ii) Give up ‘measuring’ attitude, and describe it qualitatively with the pattern beliefs / emotions / behavior and the connections between them (it may be interesting to notice that in an article written recently by Ruffell, Mason & Allen (1998) the term ‘probing’ is used instead of ‘measuring’).

Regarding the dimension “beliefs”, in our opinion a questionable aspect is the observation of single beliefs rather than of belief systems. For example the belief “Only those who are intuitive are successful in mathematics” does not give significant information about the individual, unless we know the belief that the individual has about his own intuition. Cooney, Shealy & Arvold (1998) underline this aspect regarding research on teachers’ beliefs: “It is important to understand not only what teachers believe but also how their beliefs are structured and held” (p. 306). Grigutsch and Törner (1998) tried to carry on a research similarly focused on this aspect, analyzing the beliefs of expert mathematicians.

-In this case what a ‘positive’ attitude should mean is not clear: but referring only to the emotional dimension seems lessening to us. We think that two other possibilities are preferable. The first is to find out whether a typical pattern beliefs / emotions /
behavior of students who are successful in mathematics exists, and to define this pattern as positive. The second one is to define as positive the attitude typical of experts, which obviously brings up the problem of the existence of such attitude (Grigutsch & Törner, 1998). This rises other questions: recognizing if these two possibilities lead to two different definitions of positive attitude, and, if that is the case, deciding which is more useful.

Conclusions

Research in mathematics education has already accepted the importance of affective factors to interpret behavior of individuals who are involved in problem solving in the mathematics context. The research in this field has produced a substantial amount of knowledge. But for affect to be a real powerful theoretical instrument, a further analysis of the affective constructs is necessary. In each discipline, after a first period when the introduction of new concepts plays an important role in building up the theory and in the production of results (without considering how clearly and rigorously these concepts are used), a second period follows when the researchers feel the necessity of clarifying the nature of the concepts that have been used. The analysis of such concepts may create 'monsters' (i.e. ideas that apparently undermine the knowledge produced up to that moment), but this crisis is extremely fruitful for the further development of the discipline. This is what happened with concepts like those of function or continuity in mathematics history: monsters created by Dirichlet, Cantor, Weierstrass (i.e. discontinuous functions at every point) have, as a matter of fact, opened up new horizons in the field of mathematics. There is still another reason for this analysis. Because of its nature, mathematics education deals with constructs, theories and methods that are taken from other disciplinary contexts, like psychology, sociology, anthropology, etc. (Sierpinska & Kilpatrick 1998). The problems that researchers have to face, nevertheless, are exactly what pushes them to use such theories and constructs, and these problems are specific of mathematics education. As regard to the construct 'attitude', the research in mathematics education deals with problems that are different from those typical of social psychology, where the construct originated. Mathematics educators are interested not only in foreseeing the choices of the students, but in observing, interpreting and possibly modifying their decisions in the context of mathematical activity. In our opinion this difference is important, and is another reason that forces us to a deep reflection, and in particular to re-think the meaning and the sense of the terms involved.

Our aim with this paper is to contribute to this type of reflection.

Encapsulation of a Process in Geometry
Hartwig Meissner
Westf. Wilhelms-Univ. Muenster, Germany

Abstract: The theory of encapsulating a process concentrates on "procepts" in arithmetic, algebra, and calculus (Davis, SFARD, Tall & Gray et al, Dubinsky et al). In this paper we will discuss the existence of procepts in geometry and we will give examples.

1. Encapsulation of a Process

Vinner (in Tall 1991, p. 65ff) discussed the role of definitions in learning mathematics and how children may overcome the "conflict between the structure of mathematics, as conceived by professional mathematicians, and the cognitive processes of concept acquisition". Mathematical definitions mainly describe objects or a static view while the process of acquiring new insight often runs in parallel with activities or procedures or mental processes in time. Thus there are divergent roots to develop individual mathematical concepts and Tall & Vinner (1981) use the term "evoked concept image" to describe the part of the memory evoked in a given context.

These inconsistent views, an object on the one hand and procedures on the other, must grow together to form an appropriate mathematical concept (or rich and powerful "concept image" with the words of Vinner). Piaget (1985, p. 49) has already pointed out that "actions and operations become thematized objects of thought or assimilation". This idea has become very powerful today to understand the development of certain concept images in mathematics education as a process of "interiorization" or "reification" or "encapsulation".

"When a procedure is first being learned, one experiences it almost one step at time, the overall patterns and continuity and flow of the entire activity are not perceived. But as the procedure is practiced, the procedure itself becomes an entity - it becomes a thing. It, itself, is an input or object of scrutiny. All of the full range of perception, analysis, pattern recognition and other information processing capabilities that can be used on any input data can be brought to bear on this particular procedure. Its similarities to some other procedure can be noted, and also its key points of difference. The procedure, formerly only a thing to be done - a verb - has now become an object of scrutiny and analysis; it is now, in this sense, a noun" (Davis 1984, p.29f).

Especially guess-and-test procedures - we think - are a valuable tool to develop such a "full range of perception", a rich "concept image", an efficient "relational understanding" (Skemp 1978, Meissner 1979, 1983). In our case studies using the One-Way-Principle with calculators or computers we observed exactly that mental development as described by Davis. The children first learnt to press the correct sequence of buttons to solve the given problem. Then, when the problems change, the input must be guessed now to use the meanwhile familiar sequence of buttons to get a given output. An intuitive feeling developed how to select better inputs (Meissner 1987). By the use of the One-Way-Principle the children developed a relational understanding for multiplicative structures, for percentages, for growth and decay, and for the concept of function.

SFARD (1987) distinguishes also two kinds of mathematical definition, referring to abstract concepts as if they were real objects or speaking about processes and actions. "The structural descriptions seem to be more abstract. ... To speak about mathematical objects, we must be able to deal with products of some processes without bothering about the processes themselves." She claims (1987, p. 168) that the operational conceptions develop at an early stage of learning even if they are not deliberately fostered at school. In SFARD (1992, p. 64f) she identified a constant three-step pattern

1Mueller-Philipp describes in her doctoral dissertation (1994) how the dynamic view (y = f(x)) and the static view (graph) grow together by guess-and-test and how children become able to switch from one view to the other.

in the successive transitions from operational to structural conceptions: "First there must be a process performed on the already familiar objects, then the idea of turning this process into a more compact, self-contained whole should emerge, and finally an ability to view this new entity as a permanent object in its own right must be acquired."

SFARD calls these three components of concept development "interiorization", "condensation", and "reification", respectively. "Condensation means a rather technical change of approach, which expresses itself in an ability to deal with a given process in terms of input/output without necessarily considering its component steps. Reification is the next step: in the mind of the learner, it converts the already condensed process into an object-like entity."

Since 1986 DUBINSKY and his colleagues (see TALL 1991, COTTRILL et al 1996) also studied the encapsulation phenomenon and they developed the APOS theory. They see three steps (A - P - O) to get mental objects (which then become part of a Schema S):
A Actions - usually step-by-step activities - are necessary at the beginning,
P By controlling and reflecting the action step-by-step consciously (interiorizing) the action becomes a Process.
O The process becomes an Object when "the individual becomes aware of the totality of the process, realizes that transformations can act on it, and is able to construct such transformations".

GRAY & TALL analyzed the duality between process and concept and came to a similar view. They consider (1991, p. 72ff) "the duality between process and concept in mathematics, in particular using the same symbolism to present both a process (such as the addition of two numbers 3+2) and the product of that process (the sum 3+2). The ambiguity of notation allows the successful thinker the flexibility in thought to move between the process to carry out a mathematical task and the concept to be mentally manipulated as part of a wider mental schema." They hypothesized that the successful mathematician uses a mental structure "which is an amalgam of process and concept". TALL (1991, p. 251ff), reflecting the dual roles of several symbols and notations: "Given the importance of a concept which is both process and product, I find it somewhat amazing that it has no name. So I coined the portmanteau term "procept". In 1994 GRAY & TALL proposed the following definitions: "An elementary procept is the amalgam of three components: a process which produces a mathematical object, and a symbol which is used to represent either process or object. A procept consists of a collection of elementary procepts which have the same object." In TALL et al (2000a) we find a table of examples for symbols as process and concept.

Especially when discussing advanced mathematical thinking we can discover a lot of "procepts". DUBINSKY (2000, p. 43) lists such concepts, that have been treated on the use of APOS theory: "functions, binary operations, groups, subgroups, cosets, normality, quotient groups, induction, permutations, symmetries, existential and universal quantifiers, limits, chain rule, derivatives, infinite sequences, mean, standard deviation, central limit theorem, place value, base conversion and fractions".

2. Procepts in Geometry?

Studying the above mentioned references we miss geometry, at least "concrete", visual geometry. Are there no procepts in geometry? Is the process of learning geometry that much different from the process of learning arithmetic and algebra and calculus? Are there no procedures or processes in geometry to become objects on a procept level? Most of the work on the "encapsulation of a process to an object" concentrates on examples in arithmetic, algebra, and calculus. We do not know papers on examples in geometry.

One of the reasons might be that in many countries geometry is not in the center of teaching mathematics and therefore there is not much research on how children learn geometry. In German

---

2 For more details see [http://www.cs.gsu.edu/~runec/index.htm](http://www.cs.gsu.edu/~runec/index.htm)
primary school books for example we have only about 5% of the pages with geometry topics. (And even less than 5% of the time spent on mathematics education in German primary school classes then really are used for teaching geometry).

Another reason might be that there still is a method of teaching and learning geometry which is similar to an axiomatic approach: We start with "definitions" and properties (line, point, circle, square, ...), discover relations and prove statements. Of course, it will be difficult then to discover (like in arithmetic) "processes which may produce a mental mathematical object". Then there also is no necessity in geometry for getting symbols which are used to represent either a process or an object.

TALL et al (2000b) formulate the hypothesis that there are three types of mathematics (space & shape, symbolic mathematics, axiomatic mathematics) and that each of them is accompanied by a different type of cognitive development. They consider - before focusing on the growth of symbolic thinking - "briefly ... the very different cognitive development in geometry". There are perceptions of real objects initially recognized as whole gestalts and classifications of prototypes. Reconstructions are necessary to give hierarchies of shapes and to see a shape not as a physical object, but as a mental object.

STRUVE (1987) also analyses how concept images in geometry develop. He summarizes, that children in primary and lower secondary classes learn geometry like a natural science, they describe, explain, and generalize phenomena. Thus, for them, geometry becomes an empirical theory.

For the author of this paper it is a miracle that we in physics can use mathematical formulae and even complex mathematical theories to predict future events. We trust - but we cannot prove like in mathematics - that events will occur tomorrow in the same mode as yesterday when there will be the same conditions. There are big similarities between physics and empirical geometry: Given certain assumptions we can predict events - by the use of mathematical theories.

What does that mean for the theory of procepts? When we analyze in "3+2" possible step-by-step procedures of the children we also observe "empirical mathematics" with real objects. And like in geometry the children generalize and learn to predict future events. We trust, but we cannot prove, that "3+2" always "will be the same", but we (as mathematics educators or researchers) avoid speaking of a miracle by introducing "counting principles" (like axioms in geometry). In this view an elementary procept in the meaning of TALL et al (2000a) just is the shift from the empirical stage to the theoretical stage. Consequently, following these ideas there should be no fundamental obstacle to find procepts in geometry, too.

3. Pivotal: Tagging

When we look for procepts in geometry we first need activities or procedures. At the beginning they may be "experienced one step at a time". After practicing them for a while the user perceives "the overall patterns and continuity and flow of the entire activity, the procedure itself becomes an entity - it becomes a thing" (DAVIS).

TALL et al (2000a) distinguish procedure and process. For them procedure is like a specific algorithm. Using the example "4+2" there are lengthy procedures (as "count-all"), compressed into shorter procedures (like "count-on" or first "count-both" or "count-on-from-larger") or other techniques (i.e. "remembering known facts" or "derived facts"). These different procedures all are used "to carry out essentially the same process in increasingly sophisticated ways".

We see the symbols used (4+2, 2+4, 6, etc.) like a tag to describe (or to evoke!) the according processes or objects mentioned. In general we think the symbols or tags play the same role as key words, they are tools to name or to recall a process or an object. They are used to abbreviate or to condense or to summarize the "evoked concept image" to get one single "sign" (for communication).
Symbols and tags serve like key words. In arithmetic/algebra/calculus we use letters a, b, c, d, ... and other symbols like +, %, dy/dx, ... to evoke concept images. But other key words like "six", "field", "parallel", ... or "□", "Θ", ... or "Ω", "®", ... or "∟" ... might do the same. Only important for mathematics education is the concept image evoked by that tag or symbol or key word.

TALL et al (2000b) point out that "symbols occupy a pivotal position between processes to be carried out and concepts to be thought about. They allow us both to do mathematical problems and to think about mathematical relationships". Important, there is only one symbol with a dual meaning. And we like to add, it is not important what type of symbol or tag or key word it is.

Thus we add explicitly the process of tagging or naming, that means communication is an essential part of developing procept images:

(a) carry out accurately the given one procedure/technique
(b) several procedures/techniques are possible, select one
(c) several procedures/techniques are possible, make an efficient choice and explain
(d) carry out the process flexibly and efficiently, i.e. determine and select an appropriate procedure/technique and discuss possible alternatives
(e) use an abbreviation (tags, symbols, key words) when discussing, arguing
   (the same "name" for both, the procedural and the conceptual aspect)

Table 1. Development of an (elementary) procept image

4. The Spatial Procept "Net"

We will give an example from our classroom research (MEISSNER & PINKERNELL 2000):

A teacher showed a model of a three sided pyramid (Fig. 1) and asked the class: "What did the cardboard paper look like before I folded it to make this pyramid?" Friederike (age 8:2) drew a square and added three triangles to its sides (Fig. 2). She then showed with her hands how to fold the pyramid, pointed to the side of the square where there is no triangle, and said: "Then there's a hole, isn't there?"

Let us discuss and analyse this case in more detail. First, Friederike gets, probably without realising it, two contradictory stimuli at the same time. The key word "pyramid" leads to a square because all pyramids Friederike has known so far had a square as their base. However the given solid says that Friederike only needs three triangles. She compromises and gets the hole. Obviously she is familiar with a mental folding-up procedure, but she has not enough experiences to bridge the gap immediately.

But is it necessary at all to fold mentally before deciding if this drawing is a net of a pyramid? By looking at Fig. 2 experienced geometricians see that it does not represent the development of a solid. They can tell without actually folding the net. In their reasoning, the process of folding has been encapsulated to the static concept "development". Friederike, however, has some notion of "development" in which she still needs to carry out the process of folding explicitly, as her hands indicate. Thus we consider "development" as a procept in spatial reasoning.

This episode was observed before we systematically introduced activities in the classroom to draw developments for solids (pyramids, rectangular solids, houses): The children learned to make the net of a pyramid by placing a wooden model onto a sheet of paper and then repeatedly tilting it
from its base onto one side and back to the base again, each side being encircled with a pencil. The resulting figure would be a star shaped net. Next, we have asked them to make the net of a rectangular solid. What we have experienced many times is that in strictly following the learned procedure they forget the solid's upper side and produce a net that would fold to an open box.

We then pointed onto the missing side of the given solid asking where this was drawn. Very often there was a laughter in the classroom and immediately the drawing was completed correctly. The procedure “development” they had acquired so far was based on an activity of what could be called “tilting from and back to the base”. With the rectangular solid this procedure of “tilting” had to be revised by extending it. This mental change is typical for the development of procepts. Proceptual thinking also includes the ability to revise an encapsulated procedure to meet new demands (GRAY 1994, p.2). We saw a similar expanding of the procedures when we used solids with concave sides.

To draw the developments the children got a card board and a wooden solid. Some of the children just started tilting and drawing. Others first took the solid to find an appropriate starting position on the card board (by tilting without drawing) to make sure that their drawing will fit on the paper. Here the activity already becomes a flexible and efficient process.

The last lesson of that teaching unit (details see MEISSNER & MUELLER-PHILLIP 1997) started with an exhibition of about 20 different (plane) developments of buildings fixed with tape on the black board. There were only lines drawn where to fold later on (but not distinguishing if to fold inside or outside). The children (grade 3, age about 8 - 9) had to describe which net might become what type of building before they could choose one of the developments to verify their guesses. We are sure some of the children just identified simple nets without any mental folding. They just saw "that is a tower" (Fig. 3) or "that is a garage" (Fig. 4) or "that is a house" (Fig. 5). We think that, for them, a simple net had become an elementary procept.

But where is the symbol, one of the characteristics of a procept? We think the net itself is the symbol. The one interpretation of that symbol is a procedural one, "folding up". The other view is static, "this is ..." (an object).

Symbols of procepts follow syntactical rules. Also from this point of view there are reasons to take (at least simple nets) as a symbol. In the following we will demonstrate this view by comparing procepts from arithmetic or algebra with the procept "net".

A process is a set of procedures:
We can describe “6” by “4+2” or “5+1” or “3+3” or ... And we can describe “cube” by

\[
\begin{align*}
\text{Fig. 3} & \\
\text{Fig. 4} & \\
\text{Fig. 5} & 
\end{align*}
\]

Each symbol belongs to a specific process:
This is true for “6” or “3²” or “1/2” as well as for nets shown in figure 3, 4, or 5.
There are "syntactical rules" to transform symbols:
Replace "3+4" by "4+3" (3+4 = 4+3) or replace "2×8" by "8×2" (2×8 = 8×2) or replace "3×(4+2)" by "3×4 + 3×2" or ... We also can replace

```
  |    |    |    |
  |    |    |    |
  |    |    |    |
```

by
```
  |    |    |    |
  |    |    |    |
  |    |    |    |
```
or
```
  |    |    |    |
  |    |    |    |
  |    |    |    |
```
or ...

There are "syntax errors":
The notation of power does not allow symbols like "2^n" or "2×n" or "2×n" or "2^n" or "2×m". Or the notation of addition does not allow "+2,4+" or "2,4+" or ... The notation "net" does not allow

```
  (missing side)
```

or
```
  (neighbored lengths)
```

or
```
  (number of side surfaces)
```

**Procepts can be extended:**
"3×4" (multiplication of integers) gets expanded to "3.5×6.9" (multiplication of decimals).

```
  "tilting"
```

gets expanded to a

```
  "conscious tilting"
```

**Symbols can be variables:**
We use letters for variables in arithmetic or algebra. A "net" also may have the meaning only of a variable, i.e. by giving the spatial shape, but no geometric proportion of the specific solid:

```
  "a" pyramid
```

```
  "a" rectangular solid
```

```
  "a" house
```

**Symbols can be manipulated:**

```
  "shifting the base"
```

```
  "rotation"
```

```
  "reflecting"
```

5. Other Procepts in Geometry
One main theorem in geometry is, what we call in German the *Strahlensätze*. (At the PME conference in Hiroshima I was told that there is no key word for this theorem in English). A figure of
four lines, where two intersecting lines cross two parallel lines, leads to three or four basic statements about the ratio of according lengths:

We think the symbol or tag of the Strahlensätze is one of the given figures. A proceptual thinking of "Strahlensätze" is only possible when we are able to regard the above figures as an entity (of related procedures). Then the procept "Strahlensätze" is encapsulated in each of these figures. The different types of figures can also be seen as manipulations of symbols according to syntactical rules. Some more manipulations may be the following:

The last figures even indicate an extension of the original concept. Of course all these symbols also implicitly include variables: It is not important where the intersection point is in relation to the two parallels nor is the size of the angle of the intersecting lines nor the width of the parallels.

Another example is Pythagoras' Theorem. There are several types of tags:

Often our students do not achieve a proceptual "pythagorean" thinking. They ignore or they do not see the property "perpendicular" or they have fixed mental images of how to name the sides of a triangle:

Also simple geometrical objects may lead to a procept. A keyword or a roughly drawn figure (of a triangle or a circle or a polygon) may provoke concept images of how to construct these figures, or of properties of these figures or of solids which these figures are part of. The roughly drawn figure might be the symbol to tag that procept with all possibilities of symbol manipulations or modifications as mentioned above. In this sense geometric drawings have a pivotal meaning. They may evoke a concept image of a single static geometric physical figure as well as of a complex procept.

PROTOTYPICAL USES OF FUNCTION PRESENT IN SEVENTH- AND EIGHT- GRADE TEXTBOOKS FROM FIFTEEN COUNTRIES

Vilma María Mesa
University of Michigan

Conceptions of function at stake in problems and exercises in mathematics textbooks for early secondary students were investigated using Biehler’s prototypical uses of function. Following a constant comparative analysis method that involved 2304 exercises and problems, five main categories were identified: rule, set-of-ordered-pairs, social, physical, and figural. Decontextualized uses—rule and set of ordered pairs—were by far the most frequent uses given to functions with contextualized uses receiving less attention. Such trend invites reflection about current practices associated with the introduction of functions in the early secondary school grades.

The evolution of the concept of function in mathematics as a discipline has followed an interesting path, changing how people understand mathematics (Buck, 1970, p. 237). The rapid changes that occurred in mathematics once the set-theoretical definition of the concept was introduced were echoed in school mathematics, generating difficult problems for the mathematics education community, problems that stimulated new lines of research (Eisenberg, 1991, p. 141). Research has provided descriptions of students’, teachers’, and prospective teachers’ understanding of function, illustrating that their views are shaped by teaching practices, mathematical discoveries, and people’s cognitive capabilities (Cooney & Wilson, 1993; Harel & Dubinsky, 1992; Sfard, 1991). The research has also suggested approaches in which less formal presentations are fostered, with technology playing an important role (NCTM, 1989, 2000; Tall, 1991). Textbook is an object that has received little attention from researchers on functions. Textbooks synthesize what is known about a concept from multiple perspectives: historical, pedagogical, and mathematical. As documents, they provide valuable information about the potential learning that could occur in a classroom. An investigation of textbook content is relevant not only to complement the set of views of function but also to help explain its relation to the difficulty of learning the concept. Obviously, what students learn from textbooks and the practicality of that learning are mediated by the school context, including teacher, peers, instruction, and assignments (Stodolsky, 1989). The textbook, as a source of potential learning, expresses what has been called the intended curriculum (the goals and objectives for mathematics intended for learning at a national or regional level; Travers & Westbury, 1989, p. 6), which implies that an analysis of textbook content becomes in some ways a hypothetical enterprise: What would happen if…? becomes the beginning of the inquiry. What would students learn if their mathematics classes were to cover all the textbook sections about functions in the order given? What would students learn if they had to solve all the exercises in the textbook? Would they learn what a function is? Would that learning work well in characterizing function? Such hypothetical questions leave open the space for different things to happen in reality: as said before, teachers mediate (and sometimes dismiss) textbook content. The answers to the
questions, however, act as an *a priori* analysis, which help to determine the plausibility of different alternatives that could occur in classrooms.

Because practices within a country are usually quite similar, looking at more than one country offers the possibility of making contrasts to highlight aspects of the concept that are taken for granted within a culture. In this study I selected lower secondary school textbooks assuming that in grades 7 to 9 function would begin to appear explicitly in school mathematics. My interest in the findings of the Third International Mathematics and Science Study (TIMSS), and the availability of the textbooks used in TIMSS led me to choose those textbooks from participating countries written in a language that I could read. In the larger study I explored the *conceptions* (Balacheff, in press) of function suggested by the seventh- and eighth-grade mathematics textbooks of selected countries participating in TIMSS. In this paper I present the process by which the set of problems that put a conception at stake was operationalized and some associated results.

**Theoretical Framework**

Different situations generate different interactions between the subject (a person's cognitive dimension) and the milieu (those features of the environment that relate to mathematics), and in consequence lead to different meanings. The different interactions explain the coexistence of multiple knowings by a subject. Contradictory knowings can coexist, either at different times in a subject's history or because different situations enact different knowings. In both cases, what is isomorphic for the observer—probably the teacher—is not for the learner (Balacheff, in press). Balacheff has characterized conceptions as a quadruplet consisting of problems, representations, operations needed to solve the problems, and verification and validation activities needed to determine that an answer has been obtained and to establish its correctness. Different sets of problems require different representations, operations, and verification and validation activities that would correspond to different conceptions as described by an observer. The analysis of a conception as a 4-tuple of different but interconnected elements allows for a description of subtle differences in conceptions that otherwise could not be distinguished. However, the problems are at the core of the issue, once they are chosen, an observer can associate to them particular conceptions. I used Biehler's (in press) *prototypical domains of application*, to assist in characterizing the set of problems.

For Biehler a concept may have different meanings in different disciplines, and those meanings are determined by the differences in practices in each discipline. Three elements are constitutive of the meaning of a mathematical concept: the domains of application of the concept (its use inside and outside mathematics), its relation to other concepts and its role within a conceptual structure (a theory), and the tools and representations available for working with the concept. Using as an example the concept of function, he identifies the "prototypical ways of interpreting functions (prototypical domains of application) which summarize essential aspects of the meaning(s) of functions."

These are *natural law* (e.g., a parabola as a representation of the curve of a cannon ball), *constructed relations* (e.g., to express a price depending on a quantity), *descriptive* (e.g., functions involving time-dependent processes), and *data reduction* (e.g., functions in
statistics). He notes that the concept of causal relation has been abandoned in mathematics in favor of a "functional relation" between two quantities (Sierpinska, 1992)... due to philosophical reasons [and] to pragmatic ones: If we have a 1-1 correspondence, we can invert the cause-effect functional relation to infer the 'causes' from the effects." The decision to invert the relation is rooted in the academic practice of mathematics; in disciplines such as physics, it might not make sense. Biehler's characterization of prototypical domains of application of function, that is, its uses, was instrumental for me in initiating a characterization of the problems in a textbook that eventually can be solved by the student. These different uses gave me a stepping stone to use in characterizing the problems needed to define the conceptions that could be elicited by textbook exercises. With these tools, I looked for answering the following question: What are the prototypical uses of function present in the seventh- and eighth-grade mathematics textbooks of selected countries participating in TIMSS?¹

Method

The original sample for the study consisted of 35 textbooks from 18 countries chosen from the TIMSS data base according to the following criteria: the textbook was intended for 7th, 8th, or 9th grade; the textbook was written in English, Spanish, German, French, or Portuguese; and the textbook contained references to functions, linear functions, graphing in two coordinates, graphing in the Cartesian plane, tables, patterns, or relations. All the exercises, hereafter tasks, from such sections (for a total of 2304 tasks) constituted the corpus of data for the study. Each task received a 4-tuple code. The first code, P, identified the prototypical use of function present in the task. The second, O, contained all the operations that were needed to solve the task. The third, R, contained all the representations that were needed to solve the task. Finally, E contained all the activities available for the student to verify that a solution was obtained and that it was correct.

The development of the categories for coding each element of the quadruplet was accomplished in four steps. First, I selected one task from the first section of each textbook to analyze in depth (35 tasks). I worked each one, following as much as possible the textbook presentation that preceded the exercise section and developing categories for each element of the quadruplet. Second, I used the resulting categories to code the remaining tasks in all the first sections of each textbook, looking for new categories and refining the properties of each. I used the constant comparative method (Glaser & Strauss, 1967) in which I described the salient features of the categories for an element and at the same time looked for possible breaks or mismatches that could lead to the creation of a new category. This second step involved 518 tasks and resulted in 133 categories. Because there were so many categories, the third step consisted in merging categories within common groups, thus yielding a smaller, more manageable number of categories for each element. The final step was to test the coding system by having other

¹ The larger study from which this paper is derived tackled the issue of conceptions suggested by textbooks (see Mesa, 2000).
raters use it to code tasks, which helped to further refine and validate the categories of the coding system. The final system consisted of 10 codes for uses of function, 36 codes for operations, 9 for representations, and 9 for controls. I report the results associated with the first element of the conception, the prototypical uses of function present in the tasks.

Results

When working with the first set of 35 tasks, I found that Biehler’s initial classification (natural law, constructed relations, descriptive, and data reduction) did not include tasks lacking a real context: namely, when the function was treated as a set of ordered pairs (e.g., “Represent in the Cartesian plane the relationship whose solution is given by the set \( R = (x, y) \mid x, y > 0 \land x, y \in \mathbb{R} \)”), when it was treated as a rule, when a pattern with numbers or figures was sought, or when there was a proportion involved. Biehler’s categorization was not accounting for phenomena that are particular to mathematics (Puig, 1997). In addition, in some tasks that suggested relations that could be classified as constructed using Biehler’s characterization, the content used geometrical definitions or principles (e.g., similarity), that suggested an additional category. The following task is an illustration of such cases:

The slide projector puts a picture on the screen. The size of the picture changes as you move the projector. The picture gets bigger and bigger as you move the projector further away. When the projector is 300 cm from the screen, the picture is 120 cm high. Here are figures for other distances [a table with six values for distance and height is given].

Draw two axes on graph paper. Mark the across axis from 0 to 500 and the up axis from 0 to 200. Label the across axis ‘Distance from screen in cm’. Label the other axis correctly. Use the figures in the table [given] to plot points.

(a) What do you notice about the points you have plotted? (b) Use your ruler to draw the graph through the points. (c) Use the graph to find the height of the picture when the projector is 350 cm from the screen. (d) How far is the projector from the screen when the picture is 50 cm high?

Such uses of function were labeled, set of ordered-pairs, rule, pattern, proportion, and geometrical respectively. Biehler’s “descriptive relation” was renamed cause and effect and was used to characterize the cases in which the task dealt with physical phenomena not dependent on time. After the final coding step, a new category appeared, graph, which was used to characterize those tasks in which the relation was given by a graph in a Cartesian plane that did not have any marks (e.g., a graph of a function \( f(x) \) is given; the student has to identify the graph that corresponds to \( f^1(x) \)). I kept a record of all the different instances of uses within each category. These examples of uses were crucial in fully characterizing the categories for uses of function (see Appendix).

To simplify the presentation, the uses that referred to physical phenomena, cause-and-effect relations, and time relations were grouped into a new category called physical to capture the character of these relations. Because they relate to human activity, data-reduction relations and constructed relations were grouped into a new category called social. Geometrical relations, graph-defined relations, and pattern relations were
grouped into a new category called figural, to highlight the crucial role of images and patterns for defining functions in these relations. Rule and direct proportion/proportion relation were grouped together into the category rule. Set of ordered pairs was left as a separate category. Table 1 presents the frequencies and percentage of occurrence of these categories. The results refer only to grades 7 and 8, yielding a sample of 1319 tasks, in 24 textbooks from fifteen countries.

As the table shows, the most frequent uses were rule and set of ordered pairs. Only one third of the uses corresponded to those involving concrete contexts: namely, social, physical, and figural. Social uses were almost twice as frequent as physical uses, which suggests that at these grade levels physical phenomena in which functions can be defined do not play a very important role. Almost 25% of the tasks had a set-of-ordered-pairs use of function, which implies that such definition still plays an important role for introducing the notion. In contrast, the figural use of function accounted for only 6% of the tasks which implies that at these grade levels it is not a common practice to present functions based solely on mathematical phenomena. Six textbooks showed important differences from this pattern: in three textbooks (from two countries, about 5% of the tasks) there were no tasks with a set-of-ordered-pair or rule use (one textbook had only social uses and the other two had mainly physical uses). The other three textbooks (from three countries, about 8% of the tasks) had more than 40% of social and physical uses.

Discussion and Conclusion

One possible reason for the high frequency of rule uses in textbooks might be didactical: Because the idea of correspondence is so fundamental to the (modern) notion of function, and because the seventh and eighth grades mark the transition period from arithmetic to algebra, transformations of numbers by means of basic operations seem to fit the double purpose of defining valid functions—with a notion of correspondence as transformation or constrained variation—while at the same time linking known operations with the new idea of correspondence. In this way the burden of considering unrealistic situations in which the correspondence can be arbitrary (as is the case with the Set-of-ordered-pairs use) is overcome. In other words, such uses of function are actually serving the didactical purposes of smoothing the transition from arithmetic to algebra and of introducing the idea of correspondence. The somewhat large proportion of tasks that

---

2 The reorganization is not only a practical one; I wanted to highlight particular characteristics of the use of function, which make several categories look as equivalent. Different criteria would produce a different reorganization.
with a set-of-ordered-pairs use of function may be due to authors’ interest in keeping the textbooks updated mathematically; also, because textbooks change slowly (Farrell & Heyneman, 1994), the influence of the new math movement was still operating in this set of textbooks (with one exception, textbooks with copyrights in the 70s and early 80s contained more of such uses). The modest contribution of tasks with social or physical uses seem to be a consequence of reform movements that suggest the use of applications in presenting mathematical concepts. The difference between social and physical uses might be related to the complexities that the latter bring to the problems (Monk, 1992).

One possible reason for the few instances of Figural use might be linked to the separation between geometry, arithmetic, and algebra in school mathematics curricula. The textbooks tended to contain separate chapters for geometry, and it seems likely that within those chapters, functions did not get much attention. The low frequency of geometrical uses could be also a consequence of the new math movement, which almost eliminated geometry from school mathematics in several countries (Ruiz & Barrantes, 1993).

Vinner (1992), Norman (1992), and Even (1989) have documented that students, teachers, and prospective teachers view functions as defined by an algebraic expression that involves numerical variables only or as black-box machines (a rule use), with meanings that are contradictory with the formal Dirichlet-Bourbaki notion (a set-of-ordered-pair use). The results of this study suggest that these groups’ understandings of function could have been expected, given the uses given to functions in textbook tasks. The characterization of problems and exercises of textbooks in this sample indicate that when functions are initially introduced to students, textbook authors tend to prefer situations in which the relation is defined through transformation of an input to obtain an output. There is also a tendency to present a formal view of function as a set of ordered pairs in which the notion of arbitrary assignment is presented. Contextual uses of function do not seem to play a significant role in the majority of the countries. Such trend poses questions to us as researchers and as curriculum developers: is the same tendency observed in classrooms? Is this an appropriate strategy to follow for students’ first encounters with the notion of function? To what extent is a more contextualized approach, as promoted by reform movements, more appropriate? How do we establish that appropriateness? As uses of function are just one of the constitutive elements of a conception, one can expect that these uses would not necessarily dictate what operations, representations, and control activities are enacted in a task. That is not the case, however (see Mesa, 2000).

Tasks with rule uses tended to be associated with a very limited (in number and in requirements) sets of operations, representations, and controls. In contrast tasks with physical and figural uses offered the most variation, thus creating possibilities of enacting different meanings for functions but also illustrating that textbooks may promote the existence of several apparently contradictory views of function. Even though there are not clear answers to these questions, the actual situation should invite reflection on an intermediate strategy to follow if a variety of (uncontradictory!) meanings are to be promoted in the introduction of functions in early secondary school.

ARGUMENTATIVE PROCESSES IN PROBLEM SOLVING SITUATIONS: THE MEDIATION OF TOOLS

Catia Mogetta
Graduate School of Education
University of Bristol

Abstract
Argumentative processes enacted in problem solving situations involve both concrete and discursive operations. An analysis of the processes of solution needs to take into account three main components: the problem, the agent and the context of solution (including all the tools available, other individuals and the situation for the devolution of the problem). When the context incorporates a dynamic geometry software, additional aspects related to the availability of dynamic tools need to be considered. The paper illustrates and analyses the role of heterogeneous tools, such as concrete tools and conceptual and theoretical tools in the process of elaborating a conjecture and proving it. Possible conflicts due to the static nature of the theory and the dynamic nature of the tools for exploration are discussed.

Introduction
Solving a mathematical problem requiring the elaboration and proof of a conjecture is a complex activity, made up of a number of phases and involving discursive, concrete and mental operations. The literature accounts for a number of studies focusing on the proving process and especially on the possible relationship between the production of the conjecture and the construction of a proof for it (Duval, 1992-93, Mariotti et al. 1997). Despite the undoubted differences between the argumentative and the proving discourse, a cognitive continuity between them seems possible, under specific constraints on the problem situation. An Italian research group (Boero et al. 1996, Mariotti et al. 1997, Garuti et al. 1998) has elaborated the theoretical construct of cognitive unity, that attempts to describe and analyse such continuity:

CU: during the production of a conjecture, the student progressively works out his/her statement through an intensive argumentative activity, functionally intermingled with the justification of the plausibility of his/her choices. During the subsequent statement-proving stage, the student links up with this process in a coherent way, organising some of the previously produced arguments according to a logical chain. (Garuti et al, 1998)

For the purposes of the present paper, the cognitive unity (CU) construct will be considered as an analytical tool to interpret and explain some of the processes students engage in when striving to organise the informal arguments produced during the solution process, into a logical chain that corresponds to accepted mathematical rules. Concrete and discursive operations involved in the production and enchaining of arguments have a cognitive counterpart in mental operations for which they are the external signs. In order to trace the evolution of arguments toward a deductive discourse within the solution of a problem, I will set the issue in the mediated activity framework. From this perspective, in any problem solving situation three main components may be identified: the problem, the agent, i.e. the individual-acting-with-
mediational-means (Wertsch, 1991) and the context of solution (including all the tools available, other individuals, be they peers or teachers, and the situation for the devolution of the problem). The study reported in this paper focuses on geometrical, open problems tackled by 11th and 12th grade students in a context including the dynamic geometry software Cabri-Géomètre (Baulac et al., 1988).

The mediation of tools: the notion of toolkit.

Within the context outlined in the previous section, the word ‘tool’ incorporates many different meanings and refers to both concrete and psychological tools. Drawing on the seminal work of Vygotsky, tools and signs (i.e. psychological tools) may be distinguished according to their function:

The tool’s function is to serve as the conductor of human influence on the object of activity; it is externally oriented; it must lead to changes in objects. [...] The sign, on the other hand, changes nothing in the object of a psychological operation. [...] the sign is internally oriented. (Vygotsky, 1978, p. 55)

In some cases the distinction cannot be neatly drawn: within a certain activity, since some of the externally oriented tools may be internalised and function as psychological tools. The internalisation process, as well as the relationships among the tools used within a certain context, are complex and manifold. In order to describe them I have introduced the notion of toolkit (Mogetta, to appear) as an organised set of (both externally and internally oriented) tools that each individual develops and uses in a particular context. The idea of toolkit is meant to account for:

- the diverse and manifold nature of its components. Verbal or written signs, symbolic systems of notation, drawings, constructions and changes of configuration, dynamic manipulation through dragging, measurement and gestures may all be subsumed under the category of externally oriented tools, since the actions they mediate aim at changing the external, phenomenological world. Language, strategies of solution, theorems and definitions and all sorts of conceptual tools belong to the category of internally oriented tools, which shape and influence the mental processes enacted along the solution;

- the relationships among the components, that may change and evolve continuously. Mutual relationships among tools that are heterogeneous in nature may be developed, along the solution of a problem, either through a process of internalisation of externally oriented tools or through a joint use of different tools, that are necessarily re-interpreted (and, in some cases, re-conceptualised1) in a new context, as they may acquire a new functionality.

---

1 For instance, a student might use a theorem as an exploration tool in an initial phase of the solution, seeking possible properties of the configuration at hand, and later reuse the same theorem in order to justify the conjecture. In this case the same conceptual tool ‘theorem’ is functionally related to the phase of solution and assumes the value of argument when a proof is constructed.
The individual has a crucial role in the management of his/her personal toolkit: the evolution that occurs within the context of a problem situation is basically subjective and does not follow general rules. Wertsch (1991) refers to ‘privileging’ as a dynamic strategy to select one mediational means as more appropriate or efficacious in a particular socio-cultural setting. For example, in the context of the solution of a geometrical problem the choice of a theoretical tool, like a theorem, may be influenced by the exploration of the figure by means of the dragging tool (in Cabri): a particular configuration may be visualised and recall the mental image associated to a particular theorem. Nevertheless, in order for that theorem to function as a tool, the agent must have developed a modality of use for it. The basic idea is that any object or concept need to undergo a process of instrumental genesis (Rabardel, 1995, Verillon & Rabardel, 1995) in order to be fruitfully used for a certain purpose. Such process is described as turning an artefact, i.e. “the particular object with its intrinsic characteristics, designed and realised for purpose of accomplishing a particular task” into an “instrument, that is the artefact and the modalities of its use, as are elaborated by a particular user” (Mariotti, to appear). Schemes of use are individually developed and shape and organise the actions performed by an agent within any mediated activity.

**Heterogeneous tools: is a harmonisation possible?**

The re-organisation of tools within the specific context of the solution of a problem brings about a re-interpretation of previously acquired tools and the development of (possibly new) appropriate modalities of use for them. The process of re-interpretation is not necessarily successful, since there might be conflicts between the phenomenological and the theoretical worlds (Balacheff & Sutherland 1994), which coexist in the context where the problem is tackled. If the internal relationships among the elements constituting the toolkit mainly involve tools of the same type, and if the concrete and psychological tools are not related to an organised system of theoretical knowings, the world of theory and that of phenomenology can stay separated. Cabri is a microworld that incorporates the basics of Euclidean geometry as well as tools that allow a dynamic exploration and that give visual and conceptual feedback to the agent (Laborde, 1998). It may offer a good ground for the construction of a link between operations related to the phenomenological world and concepts and operations within the (Euclidean geometry) theory. Once they have been internalised, tools like dragging or even a generalised use of measurement, may control behaviour and shape the process of solution. As a consequence, two possibly conflicting situations might occur at the same time. On the one hand the mental processes based on an empirical approach and on visual evidence, that are spontaneously used by the agent, may be related to more rigorous and deductive processes and, consequently, the argumentative phase can end up in a proof. On the

---

2 The term knowing has been introduced by N. Balacheff to account for the distinction between the French savoir and connaissance, which is not possible in English. So knowledge is the English for savoir and knowing is the English for connaissance.
other hand, the co-existence of informal/empirical elements and formal/theoretical elements, can bring about cognitive conflicts that cannot be overcome spontaneously. The changes and evolution of the internal organisation of each individual toolkit during the solution of a problem are important for the argumentative process. When the concrete (externally oriented) tools are used in harmony with the theoretical (internally oriented) tools, the elements and information gathered along the conjecturing phase may be linked systematically within a structured argumentation that fits with the rules of the theory (Mogetta, to appear), according to the CU hypothesis. Things are not so linear in the actual solution of a problem: the intermingled use of tools of different nature requires a continuous re-organisation of the toolkit and an internal re-negotiation of the meanings previously attached to some of the tools.

The case of Andrea: when tools of different nature are not harmonised

The data analysis carried out for the study reported in the paper attempts to show how the personal toolkit of an individual agent may change along the solution of a problem and how the relationships among the tools can evolve. Such changes might head toward a harmonisation of empirical/perceptual and theoretical aspects, or rather cause (and show) a cognitive rupture between the argumentative process and the actual production of a proof for the conjecture. This section illustrates the case of a student who does not manage to harmonise tools of a different nature, thus staying at an empirical and perceptual level in the production and enchaining of arguments. Andrea (12th grade, Liceo Scientifico), had been asked to solve the following problem in the Cabri environment:

Two intersecting circles C1 and C2 have a chord AB in common. Let C be a variable point on circle C1. Extend segments CA and CB to intersect the circle C2 at E and F respectively. What can you say about the chord EF as C varies on circle C1? Which is the geometric locus of the midpoint of EF as C varies on the circle? Justify the answers you provide.

and talk aloud along the whole process, the interview being video-taped. Andrea starts off with a dynamic exploration of the problem, dragging point C around the first circle in order to observe the behaviour of chord EF. The conjecture of the constant length of EF is formulated on the basis of the visual evidence from the Cabri screen and a first attempt of explanation involving the fixedness of A and B is provided:

A: Yes, because ... EF always has to stay in the circle, the lines [CA and CB] have a certain freedom of movement and not more than that and they have to go through those points necessarily. Hence when C is shifted in one direction [he moves his hands showing the gap

---

3 The study has been conducted within a PhD project, carried out at the Graduate School of Education, University of Bristol and funded by the ESRC.
between the two lines as a rotating angle that does not change in width] I don't know how to explain... hold on, I'll think about it.

The rigid rotation of the lines through A and C and through B and C is perceived as the reason of the invariance of chord EF. The dragging of point C around the circle simply confirms that the intuition is correct and does not provide any other hint on the underlying geometrical reasons. The initial, purely exploratory, use of the dragging tool is partially modified when A. focuses on the quadrilateral in order to identify variable and invariant elements. It is the beginning of a dialectic between static and dynamic elements, respectively identified in constant angles and segments and in rotating triangles or lines, or a variable quadrilateral. Nevertheless, the basis of the actions is still empirical and the invariance is still sought at the perceptual level, with no reference to the possible geometrical reasons:

A: ... I was thinking about this quadrilateral EFAB ... to see it as many triangles and then ... I don't know... I try that [he is constructing segments to form a quadrilateral split into triangles with vertex at the centre of circle] and all the triangles then are constant ... well ... they are all isosceles triangles.

The fact that the conjecture is not refined in correspondence with the operations carried out on the figure, makes Andrea stick to the empirical approach. The lack of a phase of unpacking for the perceptually based conjecture in terms of geometrical relationships with other elements of the figure brings about a persistence in a random exploration by means of the dragging tool, with a slow and continuous movement of point C around the circle. The multiple changes in the strategies adopted to explore the conjecture involve different conceptual and concrete tools, spanning from dragging to additional constructions, to the search for invariants within sub-figures. The idea of looking at segments and angles that stay constant as C is dragged around the circle, seems to suggest the possibility of using Carnot's theorem (known in the English mathematical tradition as the cosine rule):

A: ... a cyclic quadrilateral, because as this angle here varies this other angle varies as well ... hence for Carnot's theorem ...[applied to triangle EOF] ... two sides and the angle in between ... a relationship for this one ... then a relationship for this other one with the angle ... this one is constant, this one is constant ... I can do it with Carnot's theorem!
C: How?
A: To prove that EF is constant ... because it is enough to have two sides and the angle in between in order to find the length of EF ... the two sides are both r and the angle is always the same...

Andrea's use of the theorem is nearly circular: in order to find the length of EF and show that it is constant Andrea wants to use the fact that angle EOF is constant, which has not been proved, and which is strictly linked to the invariance of EF.
Although the theorem seems to have been conceptualised correctly, its use in this specific context is not recalling other theoretical results or making a link between the perceptual and the conceptual aspects of the problem. Andrea seems to "let" the theorem take up the cognitive burden in the phase of justification: the elements involved in the theorem's hypothesis are assumed to have the properties required simply on the basis of the perceptual judgement coming from the dragging test. The dragging function of Cabri might potentially be the tool linking concrete and conceptual elements of the toolkit: but the use Andrea makes of it, even when he uses dragging in combination with theorems, is not successful in this respect. Dragging is mainly used at the perceptual level and invariance is sought and conceived of as a visual property of the figure, which has some obvious underlying reason in the rotation of the lines under the constraints of the fixed points A and B. Theorems are kind of "imposed" upon the dynamic figure, but they are not linked up with the preceding argumentative discourse based on the dynamic exploration carried out by means of externally oriented tools, such as dragging and measurement:

A: ... constant... it is 360° ... I put x this one does not move ... but with Cabri I can measure them...

C: You can measure ... do whatever ...

A: [he measures the angles with vertex at O] and I see that when C is dragged the angle stays constant

Tools of different types come to interact and to be used jointly, but the lack of theoretical control by Andrea does not lead to a fruitful interaction. The argumentation produced as a justification for the invariance of angle EOF, used as a given in the application of Carnot's theorem, is empirical and draws heavily on the exploration through dragging, as a tool ensuring the general validity of a property observed in the continuous motion:

A: I know for Carnot's theorem that instead of finding ... AB, I may find the angle and then in a triangle the angle... this one is a still triangle, it does not move and therefore angles cannot transform with no reason, since it stays fixed ... [...] and there was the chord theorem... I do not remember how it goes ... the angle at the circumference ...

Along the whole solution process Andrea tries to use a number of theorems to justify his conjecture, without expressing it in relational terms: the invariance of chord EF is not related to the invariance of any other element of the figure. Although a theorem about chords is recalled, following the development of the previous reasoning around angles and segments, and, later similar triangles are sought, A. does not abandon his conviction based on the visual evidence. The conjecture, elaborated and formulated in terms of dynamic causality, remains linked to the phenomenological aspects of the problem; any attempt to justify it by means of theorems ends up in a list of results that do not correspond to the interplay of variable and invariant elements in the problems. The cognitive unity of conjecture and proof is thus broken, possibly due to the conflict between dynamic causality, pertaining to the phenomenological world, and static theory.

Discussion and concluding remarks

The analysis of the protocol presented in the previous section shows that the heterogeneity of tools within the context of solution of a problem may bring about difficulties in the elaboration of an argumentation and its possible evolution toward a proof. Andrea’s personal toolkit includes externally oriented tools, such as dragging, measurement and additional constructions, as well as a number of theoretical knowings, exemplified by the use of Carnot’s theorem, or the recalling of theorems about chords. The problem is that such heterogeneous tools are not harmonised: the joint use of dragging and theorems, for instance, is not fruitful because the dynamic, visual evidence of the (perceptual) invariance of elements under dragging is not interpreted in terms of the geometrical reason that would justify it within the theory.

Two main issues need consideration, also in view of future research: (i) the identification of possible reasons for the lack of harmonisation of heterogeneous tools and (ii) a deeper analysis of the features of dynamic geometry environments, with a particular focus on the issue of internalisation of the dragging tool.

As for the former issue, this paper suggests that a scarce theoretical control of the (concrete and mental) operations performed during the solution of a problem may end up in an unsystematic and nearly random use of theorems. The individual organisation of theoretical knowings may account for their status within the theory (hypothesis, premise, conclusion, derivation, postulate and so forth) as it has been conceptualised by the individual agent. Modalities of use of such tools necessarily reflect such organisation and require the explicit formulation of relationships among geometrical objects in terms of their status within the problem. When theoretical knowings are used in combination with tools of a different nature, they might be re-interpreted in the new context. On the other side, concrete tools might be used to refine the conjecture in relational terms and this might require the development of new modalities of use for them. In actual fact, when a conjecture is formulated in a compact form, on the basis of the dynamic, visual evidence of a property (e.g. the rigid movement of two lines seen as the cause of the invariance of a chord), a process of refinement is necessary in order to make explicit the (static) relationships among the involved objects. Often, the strength of the dynamic causality interrupts the refining process, thus provoking a cognitive rupture in the solution process. Results of the ongoing main study suggest a conjecture/hypothesis (Mogetta, to appear), with possibly strong educational implications. The dynamic nature of the explorations carried out in the Cabri environment by means of the dragging tool, may conflict with the static nature of the theory (Euclidean geometry). Such conflict may bring about difficulties in linking the arguments elaborated during the conjecturing phase with those needed to construct a proof.

Further studies are needed in order to test the hypothesis and to better characterise some of the features of dynamic geometry environments, in terms of the nature of the tools they make available to the individual-acting-with-mediational-means. One of the most important aspects to be analysed is the issue of the internalisation of the
dragging tool. As suggested in this paper, the dragging tool has the potentiality to link up phenomenological and theoretical world. The point is to internalise it and use the dynamic variation of the figure in order to make a link between perceptual and geometrical invariance of objects.

Finally, more evidence is needed in order to establish whether and how an appropriate management of the individual toolkit each individual develops and uses in particular contexts, is linked to the idea of cognitive unity. My hypothesis, still to be tested is that there is a tendency to establish, or re-establish CU once it is broken. In correspondence with possible different causes for the rupture to occur an appropriate management and organisation of the toolkit may help the agent overcome the rupture. Further research is necessary to illuminate the issue and evaluate the actual impact of possible ruptures of the CU on the construction of a meaning of proving.

TEACHERS' CLASSROOM INTERACTIONS IN ICT-BASED MATHEMATICS LESSONS

John Monaghan

University of Leeds

Abstract

Do teachers' classroom interactions in ICT-based secondary school mathematics lessons differ from those in non-ICT-based lessons? This paper reports on data obtained from classroom observations of teachers who attempted to incorporate ICT into their lessons over the course of a school year. The analysis of the data does not indicate significant changes in teachers' classroom interactions in ICT-based lessons other than those that have quite straightforward explanations.

Introduction

Do teachers' classroom interactions (roles, behaviours, communication) change when teaching and learning moves from 'normal' lessons to information and communications technology (ICT) based lessons? This question, while intriguing, requires clarification before an attempt at an answer can be made. The literature, however, often suggests a change in teachers' roles, e.g. Heid et al. (1990) state:

In the implementation of computer-based laboratory explorations, the teacher must become a technical assistant, a collaborator, and a facilitator. ... the teacher will need refined skills as a discussion leader and as a catalyst for self-directed student learning.

This is a particularly strong statement chosen to make the point and the authors are clearly open to the charge of confusing an 'is' with an 'ought'. Farrell (1996) represents a more guarded statement:

...evidence suggests that teachers are holding on to the managerial roles while taking on some new roles (e.g. consultant, fellow investigator) when technology is used.

This paper reports on an analysis of videotapes of ICT and non-ICT mathematics lessons of 13 teachers. The analysis was part of a wider project and I begin with a brief overview of this project.

The wider study

The Moving from Occasional to Regular Use of Technology in Secondary Mathematics Classes project explored patterns of teaching and learning, teachers' preparation and use of resources, teachers and students' attitudes and teachers' confidence, over the course of one school year. 13 teachers made a commitment to move to 'regular' use of technology in the 1998/99 school year. Most had some
experience using technology in their classes but none had made extensive use of
technology before. Whilst I recognise the difficulties, if not the impossibility, of
classifying ‘ordinary teachers’ these 13 were, in an everyday sense, ordinary
teachers in ordinary schools. Project funds provided a financial incentive for
schools/mathematics departments to be involved and ICT experts/enthusiasts who
volunteered to be involved were excluded from the project. The 13 teachers were both
the subjects of the research and teacher-researchers. Most of the teacher-researchers
wrote of their experiences in a series of articles in the UK professional journal
*Micromath* (volumes 14/3, 15/2 and 15/3, 1998/99).

‘ICT use in mathematics classes’ is a collective term for a diffuse range of software
and hardware. In an attempt to focus on something common and manageable project
work focused on using technology tools: spreadsheets, graphic packages and
calculators and algebra and geometry systems. In an attempt to keep the project work
as realistic as possible individual team members chose the tools they thought most
appropriate for use with their classes. As these tools have widest application with
classes studying algebra, upper secondary classes (14-18 year olds) were the focus of
the project work (one project class per teacher).

**Methodology**

The project made use of a wide range of data collection and analysis tools but here I
report only on aspects of data collection and analysis relevant to teachers’ observed
classroom behaviours. Apart from noting patterns in these behaviours *per se* I was
interested in possible patterns of change over the course of a school year. For each
teacher the lessons observed were with the same class, the project class. Our
resources were not sufficient to observe every lesson over the course of a year. The
maximum number of lessons it was considered feasible to observe and analyze was
estimated to be four lessons per teacher, 52 lessons in total. It was decided that each
teacher would be observed prior to starting ICT work. I refer to this as the ‘base-line’
lesson. Thereafter each teacher would be observed near the beginning, towards the
middle and towards the end of the year in ICT lessons. With the exception of one
teacher, where the last ICT lesson observation was not observed, this plan was carried
out.

Lesson observation formats were discussed in project team meetings and the tool
chosen for classroom observations was a modified version of the Systematic
Classroom Analysis Notation (SCAN) (Beeby et al., 1979). It was decided that all
lesson observations would be videotaped. A desire for consistency in records of
lessons and considerable prior experience (often problematic) in videotaping lessons
informed our practical decisions on how to videotape: the camera was stationary in a
position that was as non-obtrusive as possible but which allowed the teacher and all
the students to be seen; a remote cordless microphone was attached to the teacher; the
camera followed the teacher whenever s/he was speaking. Although we were,
subjectively, satisfied with suitability of the video recordings for SCAN analysis,
there were some problems which should be noted: the visual image was centred on
the teacher and students working away from the teacher were not recorded; the
microphone picked up the teacher’s words clearly but students’ words were
sometimes obscured; the camera did not always produce a clear image of written
work or screen images which was the focus of discussion; technical problems in three
of the 51 lessons resulted in much of the sound being unclear.

The remainder of this section describes the modified SCAN system and its
standardisation and use in this research but first it should be noted that the length
restriction on this paper prevent a full presentation the data. To avoid repeated
reference to this fact I now collect together all curtailments, mergers and omissions.

♦ SCAN descriptors focused on student activity are not presented.
♦ A number of SCAN descriptors have been omitted.
♦ The SCAN descriptors explaining and facilitating have been merged in the Results
section.
♦ SCAN data is presented for only three of the 13 teachers.
♦ Details of how the original SCAN was modified are not presented (these were not
extensive).
♦ I have not subjected SCAN to criticism.

SCAN works simultaneously on three time scales – ‘activity’, ‘episode’ and ‘event’.
Lessons are viewed as a series of activities, e.g. teacher exposition, students working,
teacher-student dialogue. Each activity is viewed as a series of episodes, e.g.
coaching, explaining. Events sub-divide the episodes into social and linguistic
categories, e.g. managerial, confirmation. I now provide a fuller description of
activities, episodes and events referred to in this paper.

Activities: C - whole class exposition. Dn - dialogue, between teacher and a group of
n pupils. D1 for one-to-one dialogue. D2/3 for teacher talking to a group of two or
three students.

Episodes were essentially about what the teachers were doing, e.g. facilitating,
explaining. We made a distinction between technological and mathematical foci in
episodes. Thus two ‘facilitatings’, Ft and Fi, and two ‘explainings’, Et and Ei were
introduced. Coaching, Co, or eliciting reasons/ideas from students was assumed to be
mathematical and not technological.

The coding of the events were ways of describing what was happening on a small
scale within an episode. It worked out that essentially each sentence or two was
coded. The linguistic descriptors of the events were based on what the teachers were
saying – an assertion, a; an instruction, i; a confirmation, cf. The questions, qi or qt,
were the questions that the teachers were asking the pupils, not what the pupils were
asking the teachers. (A confirmation, or rejection, was often the reply of a teacher to a
pupil question.)
Question qualifiers described the level of the teacher’s question, not the level of a pupil’s question nor the general dialogue.

**Nature or depth of question:**

α - question requiring recall, single fact, single act, no processing involved
β - question of straight forward nature, putting together several facts.
γ - question extending of previous work involving new ideas

**Situation or Level of guidance**

1 - highly structured, close direction, small number of steps.
2 - some guidance, requires connections rather than selection.
3 - minimum guidance, open.

Coding were written into grids as below. The numbers denote minutes. 30 second blocks of time were the basic unit of analysis. Rows one and three were used to record, respectively, teacher and student, activity. Row two was used to record episodes and their linguistic descriptors and qualifiers.

3 - 386
Table 1 shows SCAN statistics for the four videotaped lessons of three teachers. Column 1 indicates the lesson and the last column shows the length of the lesson in minutes. The codes for the other columns have been described earlier. Columns C to EFt represent percentage of lesson times. Columns α1 to γ3 denote raw numbers of occurrences, e.g. teacher 1 in lesson 1 made 15 assertions.

Comparing the 13 non-ICT lessons with the 38 ICT-based lessons seven features stand out as markedly different. The figures below represent averages.

Discussion

I address issues relating to Table 1 and Table 2 before considering claims for and against changes in mathematics teachers roles, behaviours and interactions in ICT lessons.

While the project teachers had a number of common characteristics they also had many differences shaped by their attitudes to mathematics and to ICT, the ethos of their school and of their department and by their classes. The three teachers in Table 1 were selected to show differences whilst being representative of the 13 teachers. Teacher 1’s project class were 14 to 15 year olds. The ICT lessons used a spreadsheet and a graphic package (principally for transformations). She used ICT almost every Tuesday of the project year. My own subjective reaction after her first observed ICT lesson was that she had imported her normal classroom technique to the computer room. Teacher 2’s project class was an Advanced level class of 16 to 17 year olds. The ICT work focused on using Derive but spreadsheet and a graphic package was used as well. He ‘blocked’ his ICT work with the class, i.e. there were periods of
intense use and periods of little use. He stated that he wanted to use Derive as a ‘teach yourself’ tool to break away from the norm of ‘chalk and talk’ with this class and he designed worksheets to assist him with this aim. Teacher 3’s project class were 14 to 15 year olds who had a graphic calculator each during ICT lessons (but they did not take them home). As with teacher 2, ICT lessons were ‘blocked’. ICT lessons observed were predominantly teacher led with the class imitating the teacher’s key strokes. Again my subjective impression after the first observed ICT lesson was how similar his style was to his teacher-led style in non-ICT lessons.

My subjective impressions of similar styles in the first ICT and the non-ICT lesson of teachers 1 and 3 is, to some extent, borne out by a comparison of figures in the C and D columns for these two lessons of these two teachers. Later ICT lessons, however, show less whole class teaching. Against any effect or non-effect of ICT, however, it may simply be that mathematics teachers do less exposition later in the year as they become more familiar with a class.

The α1 to γ3 columns of Table 1 are interesting but, perhaps, not surprising, because of the clustering in columns α1 and β2. SCAN is not an instrument for discourse analysis, so statements about teacher-student discourse must be guarded. However, the very few γ3 occurrences in ICT lessons must question any general claim that teachers become fellow investigators in ICT lessons. Where they do occur, however, they occur in ICT lessons and in later lessons (but again teacher-student familiarity over time could be a factor).

Table 2 shows some marked general differences between ICT and non-ICT lessons but, I believe, these can be explained in most cases in very practical ways. All 13 video-taped non-ICT lessons were of the form ‘teacher exposition followed by students working on exercises’. The significant reduction in teacher-exposition in ICT-based lessons, (1), may be viewed partially as an organisational factor in that six of the teachers prepared their classes before they moved to the computer room. The percentage increase in time that teachers talked to two or more students, (2), largely reflects the fact that the availability of computers forced students to work with two or more to a machine. It is interesting to note, however, that even when students worked in pairs in non-ICT lessons the teacher talk was largely directed to one of the pair but in ICT-based lessons the teacher talk was largely directed to all students around a computer. The significance of the coaching figures, (3), lies in the relative absence of this in ICT-based lessons. I must admit that I cannot explain this but coaching in all lessons was interpreted as the teacher pointing out mathematical features without revealing the answer and a relative absence of this in ICT-lessons does not, to me, suggest that the teachers are acting as ‘a catalyst for self-directed student learning’. The figures in (4) and (5) have obvious explanations in the ICT, or not, focus of the lesson (if you do not have ICT in your classroom, then you are not going to . The figures in (6) and (7) represent the average number of assertions and instructions teachers made. These averages conceal great variation over teachers and different lessons. One reason for the greater average in ICT-based lessons was an apparent
propensity in ICT-based lessons for six of the teachers to move quickly around the class ensuring that technical problems did not slow work down, “copy cell B3 to D3”.

There is thus a discrepancy, with many papers reporting “Clear changes in social behaviour and teaching methodologies could be seen by observation of the [computer] lessons” (Schneider, 2000) whereas, apart from changes resulting from quite straightforward reasons, this was not observed to any marked degree in the reported study.

One possible reason for the apparent discrepancy is that projects which report on changes in teachers’ roles focus on teachers who are technology enthusiasts. The teachers in this project were volunteers who wanted to use ICT in their teaching, so there is likely to be something else at work here. One thing the project teachers had little prior experience of was of using ICT in their mathematics lessons. I suspect that the time factor of experience is important (as commented above, Table 1 shows that later ICT lessons involved less whole class teaching.). In this context time is not just time learning how to use ICT tools but time to get ‘a feel’ for how lessons will run by having tried things out. As Moriera and Noss (1995) put it:

> Developing a coherent pedagogical approach for learning with computational media is a far from trivial exercise. Time is an important factor ... it is more a matter of ‘taking time to percolate’ than just to locate or create new working environments for pupils.

It must also be considered whether SCAN, or my use of it, is a reason for the discrepancy between my findings and other work. SCAN is certainly quite a clumsy tool for analyzing teacher-student discourse and I used it in quite a crude way to make frequency counts but every effort was made to ensure reliability and validity.

My final consideration in this section concerns innovation. A danger for researchers in the field of the use of ICT in mathematics classes is a tendency to believe that ICT innovation is somehow unique. Prestage (1996) made a study of teachers’ perceptions of sequencing and progression as they implemented changes introduced by the UK National Curriculum. She claimed the teachers worked in three phases over time: (i) trying to accommodate the (assumed) givens without questioning, (ii) making sense of the (assumed) givens, (iii) trying to accommodate the (now personally interpreted) givens within their own frameworks for teaching and learning. My point in introducing Prestage’s work is that there are similarities with my comments above on experience and time and that ICT innovation shares problems with other types of innovation. Cuban (1989), in a reaction to a computer symposium where claims were being made about changes in teachers’ roles, drew parallels to earlier 20th century educational technology innovations (films, radio, television) and stated that “teachers teach the way they do simply to survive the impossibilities inherent in the workplace”. Cuban may be overstating the case but all 13 project teachers saw their practice as supporting external curriculum and assessment criteria and felt a moral obligation to their students that ICT work had to support learning which would be assessed without ICT. Their innovative work had to support traditional norms.
conditions it is hardly surprising that there were no significant changes in these 13
teachers' classroom interactions in ICT-based lessons other than those that have quite
straightforward explanations.

The conditions and constraints that teachers work under point to the need for further
research in this field. Like Cuban (1989) I do not think it is enough to expect that a
machine will affect teachers' classroom interactions. Researchers and policy makers
should be looking at how the curriculum and school structures might allow for new
roles for teacher-student interaction – with and without ICT.

NOVICES' AND EXPERTS' KNOWLEDGE ON STATISTICS AND RESEARCH METHODOLOGY

Mari Murtonen & Kaarina Merenluoto
University of Turku, Finland

Abstract
Many social science students in university constantly experience difficulties with research methodology and statistics courses. In this study we compared novice students', advanced students' and experts' knowledge on these complex and difficult domains. The results of the study refer to a tendency for novices, especially when they have had problems with mathematical subjects, to place the contents to emotional or other irrelevant categories which restricts or blocks their other cognitive activities on these subjects. There was a remarkable difference in the fragmentation of concept maps and explanations between novices, advanced students and experts. The novices were also not able to use sufficient representations to understand the concepts.

Introduction
Research methodology and statistics courses are constantly experienced as difficult by many university social science students (Filinson & Niklas, 1992; Forte, 1995; Lehtinen & Rui, 1995; Murtonen, 2000). When learning research methodology and statistics, students often face the situation when they for example may have some everyday experiences of statistical phenomena and implicit conceptions or "theories" of these phenomena, but they cannot relate these experiences to their studies. Their statistical knowledge may be composed of fragmented and isolated pieces, which do function at a sufficient level in specific situations, but do not connect the phenomenon into a wider context. Students may also try to understand the concept on the basis of the surface structure of the name of the concept. It is also possible that an integrated whole of statistical concepts is not possible to attain without enough operational understanding and experiences of the methods (Sfard 1991).

According to Chi (1992), conceptual change occurs when concepts are transferred from one ontological category to another. In Chi's model, the ontological entities belong to different ontological categories. This refers to an objectivist, Aristotelian ontological assumption that the categories exist in the world. In contrast, cognitive theories suggest that categories do not exist in the world, but in the humans' minds. According to Lakoff's and Johnson's (Lakoff, 1987, Lakoff and Johnson, 1999) embodied philosophy, categories are humans' way of behaving in the environment. On the basis of this theory we assumed that there might be several categories in humans' minds, which vary from person to person. There might also be emotional categories like "difficult things" that students form on the basis of their experiences. For example, if a student has experienced difficulties with mathematics, he or she might have placed the whole subject into a category of difficult or unpleasant things. Later, they may place statistics into this same category, because
statistics reminds them of mathematics. This kind of a categorisation seems to function as an obstacle to other cognitive activities.

According to Núñez, advanced mathematical abilities are not independent of the cognitive apparatus used outside of mathematics. Rather, it appears that the cognitive structure of advanced mathematics makes use of the kind of conceptual apparatus that is the stuff of ordinary everyday thought such as image schemas, aspectual schemas, conceptual blends, and conceptual metaphor. (Núñez, 2000.) Similarly, to understand statistical phenomenon students should be able to relate them to their everyday experiences and thoughts.

The aim of this study is to compare novice students', advanced students' and experts' conceptions of research and statistical concepts in order to find the major differences between them. We hypothesise that novices, especially when they have mathematical problems, do place contents to emotional or other irrelevant categories that block other cognitive activities, while those with more positive experiences do not do so. We also assume that novices' knowledge is more fragmented than experts' knowledge, and that they lack operational understanding and experience and because of that they try to understand concepts on the basis of the surface structure, and that they are less capable of using representations and metaphors to help understanding.

Method
This study consisted of two phases. In the first phase, a questionnaire was filled in by 31 education students in the beginning of a statistics course. Two questionnaires were used. The first one was a test of statistical content knowledge measuring the understanding of e.g. mean, deviation, correlation and statistical inference. Students were also asked to estimate their certainty in each of the tasks. The other questionnaire dealt with students experienced difficulties in quantitative research methods, attitudes on research and learning orientations. On the basis of these questionnaires, four students were selected for further research. Two of the chosen students succeeded well in the statistical test, were confident in doing the tasks, did not experience difficulties in quantitative methods, had positive attitude towards the methods and their orientation was deep and task oriented. They will be called the ‘advanced students’ because of their good success in the statistics tasks. The other two students had considerable problems in the statistics tasks, had experienced difficulties in quantitative methods and they were not confident in the tasks. They will be called the ‘novice students’. They experienced problems in learning quantitative methods and they did not appreciate the methods. They were not deep oriented toward learning methodology but were more self-defensively oriented and less task oriented than the other two students.

In the second phase these four students were interviewed after the statistics course. We also interviewed two experts to be able to compare the students’ answers to an expert view. The experts were psychologists who had been working as researchers for many years. All interviewees were female. The interviews were conducted in pairs on each expertise level. Both two researchers were present all the
time. The interviews lasted from 1 to 2 hours. The reason for interviewing two
students/experts at the same time by two researchers was to encourage a discussion
between students and also between students and researchers.

The interview was about conceptions of scientific research and statistics. The
interviewees were asked to explain what scientific research is and simultaneously
to draw a concept map of scientific research. During and after drawing a concept map
the students were asked questions concerning their attitudes and conceptions of
different domains of scientific research and especially about statistics. Specific
questions about statistics were asked on what they think that happens in a t-test and
do they know what the p-value really stands for.

Results
A category of difficult things
In the questionnaires we asked the students about the difficulty of quantitative
method courses. In order to confirm that we found the students we were looking for,
we asked the students in the interviews about their experiences. We started with
novice students:

*Interviewer*: How do you experience research methodology as a subject to be learnt?
*Laura*: It feels more difficult than other courses. It might be that when one specific subject is
easy to learn, then this [methodology] is kind of a clump. It somehow frightens. It feels
somehow foggy and difficult to learn.

*Interviewer*: Does it include the whole research or just some specific domain?
*Laura*: I cannot figure out the specific domains, but as a whole. Just the research - everything
else feels detached from it.

*Emma*: Well, at least statistics feels very difficult. It would be good to have a link from it to
something more practical. It has now got a bit clearer, when I have been doing my practice
work, but at the beginning it was really hard.

Laura's notion about the research being a clump seems to be a good example of a
category of difficult things. She has no tools for managing research domain and she is
also frightened about it. She cannot even name a domain inside methodology that is
the most problematic. When Emma identifies statistics, Laura agrees with her. Laura
refers to other study subjects which are comprehensible to her as independent
domains, but methodology represents to her a domain that she cannot link to the other
study subjects and she cannot understand the subdomains of research methodology.
Emma mentions that things have become clearer when she has been working with her
practise work, which refers to the importance of practise and operational activity in
the elementary understanding of statistical concepts. The advanced students had a
very different view on methodology and statistics:

*Maria*: Well, if you think about statistics, you sure have to work on them, but I haven't had
any problems that I couldn't have overcome. Rather, I would say it's refreshing, to have
something else, something different. I have always liked mathematics, for to have something
else, too.
Jenny: And it is different from... if you think about our major subject in general, it's much about building up aggregate domains and understanding things, but here you have to learn also by heart what they mean and think how they are connected. It's not difficult. Maybe demands more work, but it's not more difficult.

In Maria's comment there is a reference to positive experiences with mathematics and she even talks about statistics as a 'refreshing' part of her studies. In Jenny's comment there is a reference to the difficulty of the subject but also a confident reassurance that she is going to work to be able to comprehend the things. She did not find the work impossible.

**Concept maps**
The concept maps of the student pairs and the experts were very different from each other. The maps are shown in Figures 1-3. The advanced students started to do the given task eagerly and they were confident about what they were doing. The experts asked if we wanted some specific kind of a map or can they just draw what they want (they were told to draw what they want). The novice students were worried about how they will do and they didn't know where to begin. They were asked to just start somewhere to write concepts on the paper. The concept map they produced was more fragmented than the others' map. It did not have as much content as advanced students' map and the concepts were just floating it the air. The map did not show much logic in the placement of the concepts. The advanced students did have a coherent structure that proceeded chronologically in the same sequence as ideal research. They drew first a small map of principles in science and then they were asked to think about practise also. They drew a different map of research in practise, but they said in the interview that these two could have been drawn in the same map.

![Concept map](image-url)
The experts' concept map had many dimensions. They constantly talked about "interaction" between the subdomains and they also drew lines and arrows to describe the interaction:

Eva: And these are, of course, constantly interacting with each other. You cannot draw a research like this. [Eva drew the pattern (a) in Figure 3]

Irma: Yes, you cannot.

Eva: Instead, it is something very complicated... [Eva drew the pattern (b) in Figure 3]

Although the advanced students did have lots of connections between the concepts in their map, they did not talk about the interaction between the domains. The experts mentioned that it is difficult to draw a figure of research, because it does not progress linearly. They ended up with a conclusion that research has to be organized somehow to be able to report it and thus it can be represented as a product. According to them,
research description is like schemata that frame the research processes. Research report also gives opportunity to replicate the study, which in turn is an important tool for assessing the validity and reliability of a research. The experts noticed that research problems can rise from many different viewpoints. They drew a researcher in the right upper corner of the concept map to point out that it depends on the researcher’s individuality how he or she does the research. The student pairs did not mention the impact of an individual researcher.

While both of the student pairs always sought for a conception that they could both agree about, the experts did not consider it a problem to have a different conception about some issues. In the end they concluded that this concept map represented only a small piece of scientific research, which is an activity of a research community and some local research groups with their own activities are just a small part of the bigger unit. They thus saw research as a very wide concept, while students only saw it as one practical research project.

Eva: And here we get to our beloved, research design
Irma: I thought it goes here with these (shows the methods)
Eva: Well, not quite... actually
Irma: Well, for me it belongs there
Eva: Ok, you could put it there if you were writing a section about research methods
Irma: Yes, then it would be it’s own section below the methods.
Eva: For me this (research design) is a very important part. This is the core of the reasoning when we are building up the research logic.

The maps and the processes that the researchers saw when the students drew the maps suggest that the novice students did not have a clear conception about how research proceeds in practise.

**Representations of statistical concepts**
The novice students were asked if they are familiar with t-test. They said it was introduced superficially, but they did not know it very well. Then the interviewer asked if they knew what the p-value stands for. The students had just finished a statistics course, where they had studied the p-value, so they should have been familiar with it. We had the following conversation:

Emma: I was just looking for the practice work, well, it (p-value) is a kind of, I mean, how it goes...
Laura: ...significant and almost significant...
Emma: Well, that how they go, all the commas and nulls and others... I asked about it in a statistics lecture and the teacher tried to explain. She wrote this awful formula on the blackboard and explained that it is based on that and there is some theoretical thing in the computer and it comes from all of these... and ... (laughing) it is not clear to me...
Interviewer: Is it somehow mystical?
Emma: No, it has been explained
Laura: Yes, it has been explained that, how it goes... But, when you should explain it in the results... It is quite easy to look it from the papers, that what is significant and so, but, strictly speaking, I don't get it at all.
Emma: Those certain numbers are in all of them, I mean that p is smaller than this and this, well, the significant is easy, but when it gives you all the numbers, then I cannot understand where these all numbers belong to.

The conversation above shows again how unconfident the novice students are about their knowledge and also how fragmented and fuzzy their knowledge is. When talking about t-test with the advanced students, Maria explains about two groups and simultaneously keeps her both hands in the air in front of her as to show two groups. The interviewer asks what the hands represent:

Maria: Well, t-test reminds me about two groups
Interviewer: Do you see some kind of distribution figures in your mind?
Maria: No, I don’t

When we asked the same question about t-test from the experts, they grasped pens eagerly and wanted to draw. They were, however, first asked to explain without paper and pencil. They showed similar hand representations as the advanced student did when she was describing the comparison groups. When allowed to draw, the experts drew two distribution lines partly overlapping each other. They had thus helpful representations about the asked test.

Discussion
The interviews showed that we succeeded to find with our questionnaires a pair of novice students, who had problems with statistics content knowledge and also attitudinal problems, and a pair of students who were good with the content knowledge and did not have attitudinal problems. The interviews about the difficulty of methodology referred to the tendency of some students to create a category of difficult things, a “clump”, where they place all things they think that are not possible for them to learn. This kind of a categorisation seems to function as an obstacle to further cognitive activities. The novice students also called for more practices, which suggests that they suffer from the lack of operational understanding and helpful representations of the concepts.

The major difference in the concept maps of the interviewees was their state of fragmentation. The map of the novices was a static picture composed of fragmented pieces of external knowledge with hardly any connections between them. The map of the advanced students had more structural elements, connections between the domains and indications of a process’ like knowledge, even some dynamics. There was, however a noticeable difference between the concept maps of the students and the one of the experts. The map of the experts formed an integrated whole of the
research, which was clearly structured but simultaneously had the dynamics of the research in action. Besides the formal knowledge of research methodology there was also a vision of the important informal knowledge reflecting the experience of the experts. The experts had also clear ways of representing the given statistical concepts, while novices had hardly any indications of representations.

The most important finding of this study was the evidence of a category of difficult things, which the novice students had, but the more advanced did not have. We suggest that this kind of mental categorisation might be one of the serious challenges to the learning of statistical methods. In order to support the learning in this kind of a complex domain, deliberate teaching arrangements are needed to help student to reassign the “difficult” things into a category of “possible for me to learn” things.

ON CONVERGENCE OF A SERIES:
THE UNBEARABLE INCONCLUSIVENESS
OF THE LIMIT-COMPARISON TEST

Elena Nardi and Paola Iannone
School of Education and School of Mathematics,
University of East Anglia, UK

Formal mathematical reasoning is often studied in terms of the students' conceptualisation of the necessity for proof, as opposed to empirical ways of reasoning; or in terms of the mechanics of the students' reasoning regarding specific proving techniques. Here, in the context of testing the convergence of a series in Calculus, we address one issue regarding the latter. In this, statements about convergence, for instance the Limit Comparison Test, are transformed by the students into statements about divergence in particularly problematic ways; in fact in ways that suggest a multiplicity of difficulties with mathematical logic and a resistance to the idea that, in certain occasions, convergence tests are inconclusive.

Transition to advanced mathematical thinking is often described as acknowledgement of and fluency with the abstract nature of mathematical objects and with formal mathematical reasoning (e.g. Tall 1991). Within upper secondary and university mathematics the latter has been studied mostly in the context of Proof: either in terms of the students' conceptualisation of a necessity for proof (as opposed, for instance, to intuitive, informal or empirical ways of reasoning (e.g. Coe and Ruthven 1994)); or it terms of the students' enactment of these conceptualisations (namely the mechanics of their reasoning, for instance regarding specific proving techniques such as Mathematical Induction (e.g. Movshovitz-Hadar 1993)). Studying the students' formal mathematical reasoning with the foci suggested in the latter studies is a particularly multi-layered, complex task as it involves a consideration of the conceptual difficulties within the specific mathematical topics, students' problem solving skills (a map of this complexity can be found in (Moore 1994)).

In this paper we wish to address one issue regarding the students' enactment of proving techniques. This is in the context of testing the convergence of a series in Calculus, a task encountered by most students in the beginning of the first year of their undergraduate studies. For this we will draw on data collected in a study of the transition from school to university mathematics currently in progress in one Mathematics Department in the UK. First however we outline the study and its methodology.
Methodology. This project is funded by the Nuffield Foundation and its initial phase (Phase 1: Calculus and Linear Algebra, October - December 2000) lasted 3 months (Phase 2: Probability will be January - March 2001). It is located within a series of projects that the first author has been involved in for several years (see Note 1) and its title is *The First-Year Mathematics Undergraduate’s Problematic Transition from Informal to Formal Mathematical Writing: Foci of Caution and Action for the Teacher of Mathematics at Undergraduate Level*. It is an Action Research project (Elliott 1991) and can be seen as a natural descendant of its predecessors (see Note 2).

The aims of the study are: identifying the major problematic aspects of the students' mathematical writing in their drafts submitted to tutors on a fortnightly basis; increasing awareness of the students' difficulties for the tutors at this University's School of Mathematics; providing a set of foci of caution, action and possibly immediate reform of practice; and, setting foundations for a further larger-scale research project.

The study is carried out as a collaboration between the School of Education (where the first author is a Lecturer) and the School of Mathematics (where the second author teaches the first-year undergraduates) at UEA. The focus of the research, examining the students' written expression, has been identified as a worthy domain of investigation in Projects 1-3: these studies examined the students' development of mathematical reasoning in the wider context of both oral and written expression - the latter merits further elaboration and refinement and has also been highlighted by teachers of mathematics at university level as an aspect of the students' learning that calls for rather urgent pedagogical action (e.g. Nardi 1999).

This is a small, exploratory data-grounded study (Glaser and Strauss 1967) of the mathematical writing of the students in Year 1 (60 students in total, 16 in the second author's tutorial class). Phase 1 was conducted in 6 cycles of Data Collection and Processing following the fortnightly submission of written work by the students during a 12-week term. Phase 2 will be conducted in two such cycles. Each 2-week cycle consists of the following stages:

- **Beginning of Week 1**: Students attend lectures and problem sheets are handed out.
- **Middle of Week 1**: Students participate in a Question Clinic, a forum for questions from the students to the lecturers.
- **End of Week 1**: Students submit written work on aforementioned problem sheets.
- **Beginning of Week 2**: Students attend tutorials in groups of six and discuss the now marked work with their tutor.
End of Week 2: Data Analysis Version 1, towards Data Analysis Version 2.

The second author, who is also a tutor and is responsible for collecting and marking the students' work, carries out an initial scrutiny of the students' scripts and composes Data Analysis Version 1 (see Note 3): this consists of a Question/Student table where each student's responses to (a selection of) the problem sheet's questions are summarised and commented upon. The focus of her comments is quite open and covers a large ground of regarding the content and format of the students' writing. In an appendix to this table she produces rough frequency tables that reflect patterns in the students' writing and informal commentary by the tutors who teach the rest of the 60 students. Following a detailed discussion of Data Analysis Version 1, the first author produces Data Analysis Version 2, a question by question table where the major issues are summarised, characteristic examples of the students' work are referred to and links with current literature are made. A large part of these discussions revolve around the exchange of ideas and expertise. Examples of this exchange include: the communication of the second author's experiences as a tutor and a mathematician as well as her observations of the lectures and the Question Clinic, her consultation of other tutors and lecturers involved with teaching the students in Year 1; also her introduction to relevant findings from mathematics education research and educational research methodology.

Version 2 is then available to the other tutors for further informal commentary (we intend to introduce more formal strategies of evaluation in subsequent projects). An outcome of the discussion on Version 2 across the cycles will be a set of Macro and Micro Points of Action - a brief reference and examples of these can be found in (Nardi and Iannone 2000).

In Phase 1, by the end of the 12th week, 6 sets of data and analytical accounts as described above were produced. On completion of Phase 2 (Easter 2001), we intend to organise a Departmental Day Workshop to disseminate and discuss our results and also cultivate opportunities for extending the project towards an implementation of our Action Points.

Formal Mathematical Reasoning in the Context of Convergence of Series. The data we wish to draw on here originate in Cycles 5 and 6 of Phase 1 and concern the students' responses to Questions 5.4(2) and 6.1c(iii) below. The students answered by using the Limit Comparison Test: Assume that for sequences \(a_n>0\) and \(b_n>0\) \(\lim_{n \to \infty} \frac{a_n}{b_n} = c \in \mathbb{R}\). Then: if \(\sum b_n\) converges then \(\sum a_n\) converges.
Question 5.4:

(4) For each of the following series, decide whether or not it converges. State carefully any tests for convergence that you use. (1) $\sum_{n=1}^{\infty} \frac{1}{n^2+1}$. (2) $\sum_{n=1}^{\infty} \frac{\sqrt{n}}{n^2}$. (3) $\sum_{n=1}^{\infty} \frac{\sin(n)}{n^2}$. (4) $\sum_{n=1}^{\infty} \frac{n}{n^2+1}$. (5) $\sum_{n=1}^{\infty} \frac{n^2}{n^3}$.

Question 6.1c:

(c) Decide whether each of the following series are convergent (justify your answers and make clear which results you are using):

(i) $\sum_{n=1}^{\infty} \frac{1}{n^2}$;

(ii) $\sum_{n=2}^{\infty} \frac{1}{n \log n}$;

(iii) $\sum_{n=1}^{\infty} \frac{n^2}{n^3 - n^2 + 1}$.

In fact both series are convergent: 5.4(2) by the Comparison Test (compare, for example, with $\frac{2}{n^2}$) and 6.1c(iii) by the Limit Comparison Test for $b_n = \frac{1}{n^2}$. In both occasions a substantial number of students used the Limit Comparison Test in particularly problematic ways. In the following we exemplify the students' responses and reflect on ensuing matters.

Regarding 5.4(2), out of 16 students only one concluded that it converges (by comparison with $\sqrt{n}/n^2$); one stated it converges but provided no justification; one stated it converges but provided an inscrutable (unintelligible scribble on the draft) justification based on the Ratio Test; and 5 did not attempt it at all. Here we are concerned with the remaining 8 responses, 4 of which involved the use of the Limit Comparison Test and 4 involved the use of the Comparison Test. In doing so we hope to illustrate one deep-seated difficulty with formal mathematical reasoning in the students' thinking.

Regarding 6.1c(iii), which was in the Problem Sheet of the following fortnight, results were better but still alarming: out of 16 students 5 did not submit any draft or did not attempt the particular question; 6 applied the Limit Comparison Test successfully and one used the Comparison Test successfully (comparison with $3/n^2$); one attempted but left incomplete and inescrutable use of the Comparison Test. Here we are concerned with the remaining three responses which involved the use of the Limit Comparison Test. As above the focus of our concern will be on the students' reasoning processes.
Here is one of the four responses to 5.4(2) that involved the use of the Limit Comparison Test, Hazel's - the other three were identical:

\[
\sum_{n=1}^\infty \frac{n+1}{n^2} \text{ by LCT, } \\
\text{let } \sum b_n = \sum \frac{1}{n} \\
\frac{a_n}{b_n} = \left(\frac{n+1}{n^2}\right) \to 0 \quad \text{does not converge.}
\]

Hazel's interpretation of the Limit Comparison Test in this case seems to be the following: if \( \Sigma b_n \) converges but \( \lim_{n\to\infty} \frac{a_n}{b_n} \neq 0 \), then \( \Sigma a_n \) diverges. In fact the test is inconclusive in this case.

Despite cautionary remarks in the Question Clinic and the following tutorial, Hazel's interpretation of the Limit Comparison Test is still problematic two weeks later. Here is her response to 6.1c(iii) - again identical to those of her peers:

\[
\sum_{n=1}^\infty \frac{n^2+2}{n^3-n^2+1} \text{ by LCT, } \\
\text{let } \sum b_n = \sum \frac{1}{n^2} \\
\frac{a_n}{b_n} = \left(\frac{n^2+2}{n^3-n^2+1}\right) \to 0 \quad \text{does not converge.}
\]

This time her choice of \( \Sigma b_n \), the harmonic series, does not converge and \( \lim_{n\to\infty} \frac{a_n}{b_n} = 0 \). As a result she concludes that \( \Sigma a_n \) diverges. Again the test is inconclusive in this case and the student ought to have pursued an answer via a different test.

What we wish to bring attention to here is the students' resistance to the idea of a test's inconclusiveness: what appears to be the case in Hazel's (and her peers') work is that, once a theorem has been selected for testing the convergence of a series, in this case the Limit Comparison Test, it must provide an answer. What escapes the students is that, for the Limit Comparison Test to provide an answer, that is the convergence of \( \Sigma b_n \) to imply the convergence of \( \Sigma a_n \), all conditions must apply: \( a_n \) and \( b_n \) must be positive AND \( \lim_{n\to\infty} \frac{a_n}{b_n} \) must be real. If either of \( a_n \) or \( b_n \) is not positive, or the limit is not real, then the convergence of \( \Sigma b_n \) cannot imply the convergence of \( \Sigma a_n \). But not implying the convergence of \( \Sigma a_n \) is not equivalent to...
implying its divergence (as Hazel's 5.4(2) response seems to suggest). Similarly, if either of \( a_n \) or \( b_n \) is not positive, or the limit is not real, then the divergence of \( \Sigma b_n \) cannot imply the divergence of \( \Sigma a_n \) (as Hazel's 6.1c(iii) response seems to suggest).

Resistance to the occasional inconclusiveness of the tests was evident in the responses to 5.4(2) of a substantial number of students who attempted to use the Comparison Test: Assume that for sequences \( a_n > 0 \) and \( b_n > 0 \) there exist positive constants \( N \) and \( c \) such that \( a_n < cb_n \) for \( n > N \). Then: if \( \Sigma b_n \) converges then \( \Sigma a_n \) converges. Here is a characteristic response, Nicolas':

\[
\begin{align*}
\sum_{n=1}^{\infty} \frac{\sqrt{n+1}}{n^2} & \leq \sum_{n=1}^{\infty} \frac{\sqrt{n+1}}{n} & \text{which does not converge.} \\
\sum_{n=1}^{\infty} \frac{\sqrt{n+1}}{n^2} & \leq \sum_{n=1}^{\infty} \frac{\sqrt{n+1}}{n} & \text{does not converge.}
\end{align*}
\]

Nicolas' interpretation of the Comparison Test in this case seems to be the following: if \( \Sigma b_n \) diverges and \( a_n < b_n \) then \( \Sigma a_n \) diverges. (Note also that in his draft it is \( \Sigma a_n < \Sigma b_n \) that he has written, not \( a_n < b_n \), but we leave this issue - dealt elsewhere (Nardi 1996) as tendency to handle series and \( \Sigma \) as finite sums - aside for the moment). The fact is that the test is inconclusive in this case. Again, what escapes the students is that, for the Comparison Test to provide an answer, that is the convergence of \( \Sigma b_n \) to imply the convergence of \( \Sigma a_n \), all conditions must apply: \( a_n \) and \( b_n \) must be positive AND \( a_n < b_n \). If either of \( a_n \) or \( b_n \) is not positive, or the inequality does not hold, then the convergence of \( \Sigma b_n \) cannot imply the convergence of \( \Sigma a_n \). Also, if the conditions hold but \( \Sigma b_n \) is divergent, then the divergence of \( \Sigma b_n \) cannot imply the divergence of \( \Sigma a_n \) (as Nicolas' 5.4(2) response seems to suggest).

Underlying the students' attitude seems to be a desire for closure and completeness: according to this, a convergence test must cover the ground of possible responses to a question; the contingency of absence of such an answer is unsettling and therefore students feel it needs to be avoided at all costs. Albeit, instead of seeking an answer via the employment of a different convergence test (lack of flexibility in switching modes of pursuing an answer is documented in the problem-solving literature, e.g. in (Schoenfeld and Hermann 1982)), they tend to 'mutate' the proposition at hand (here: the Limit Comparison Test) towards a convenient expression that serves their purpose.
Here the 'mutants' include the versions of the Limit Comparison Test from which the alleged divergence of the series in question can be deduced and are ostensible reversals/negations of the proposition in the Test (difficulties with the action of negation have been documented e.g. in (Barnard 1995)).

This desire for closure and completeness is not uncommon at all: it seems to be located neatly side by side, for example, with the students' greater fluency and gravitation towards a sense of symmetry in reasoning in general. Examples: the students' far swifter handling of 'if and only if' statements as opposed to 'if' ones - as the literature on the students' difficulties with *modus ponens* suggests (dating back in the 1970s e.g. with O'Brien's work (1973)); of equalities as opposed to inequalities. The latter is documented e.g. in (Anderson 1994) and in parts of our data, sampled elsewhere (Nardi and Iannone, in preparation), where, for example, the students' handling of a proof by Mathematical Induction was hindered by the fact that the statement-to-be-proved was in the form of an inequality (hence the proof for P(n+1) could not be constructed from the assumption that P(n) is true as straightforwardedly as in the case of an equality).

NOTES

1. These projects are:
   - **Project 1**: a doctorate (Nardi 1996) on the first-year undergraduates' learning difficulties in the encounter with the abstractions of advanced mathematics within a tutorial-based pedagogy
   - **Project 2**: a study of the tutors' responses to and interpretations of the above mentioned difficulties (e.g. Nardi 1999), and,
   - **Project 3**: UMTP, the *Undergraduate Mathematics Teaching Project* with Barbara Jaworski and Stephen Hegedus, a collaborative study between researchers and tutors on current conceptualisations of teaching as reflected in practice and their relations to mathematics as a discipline (e.g. Jaworski, Nardi and Hegedus 1999).

2. We tend to think of this study as Project 4, not only for its obvious thematic links with the previous projects but because it carries further the methodology of partnership (Wagner 1997) and materialises what was an underlying intention in Projects 2 and 3: the involvement of the mathematician as a reflective practitioner and her engagement with Action Research.

3. In the conference presentation we intend to demonstrate and discuss samples of the Problem Sheets, Versions of the Analysis (1 and 2), Extracts from the Data and the List of Micro and Macro Action Points.
REFERENCES

Research often focuses on disaffection in the mathematics classroom as evident in disruptive behaviour, absenteeism or special needs: thus it ignores a group of students whose disaffection is expressed in a tacit, non-disruptive manner, namely as disengagement and invisibility. Ignoring this often large group implies that the mathematical potential of these learners may remain defunct. We have been awarded a 12-month research grant to study quiet disaffection in secondary mathematics classrooms, to uncover the reasons for student disengagement from school mathematics (1) and suggest re-engagement strategies (2). Here we focus on (1): we review relevant literature, discuss methodological constraints and introduce a preliminary set of themes that have emerged from our initial classroom observations.

In the UK, as well as other countries, an increasingly smaller percentage of students appears to be pursuing the study of mathematics at upper secondary level and beyond (ICMI 1998). Evidently the number of students who pursue mathematical studies affects the supply of teachers for this core National Curriculum subject area. The students' choice is seriously influenced by their attitudes towards and performance in mathematics which in turn are deeply shaped by their school mathematical experiences (Johnston 1994), and, in particular, by the mathematics teaching they have experienced in school (Dick & Rallis 1991).

Since the publication of the Cockcroft Report in 1982 attitudes seem to have slightly improved (Brown 1999) but performance is at unsatisfactory levels as evident in recent international comparisons (Jaworski & Phillips 1999). In sum, given the strong links between attitude, performance and choice of further study and career, research on attitudes towards mathematics at school level, and in particular on disaffection in the mathematics classroom, is essential.

Disaffection is defined often in research as disruption or truancy (Elliott 1997) and disaffected students are often seen as a subcategory of students with special educational needs (e.g. Tattum 1986). In these studies two major theoretical perspectives seem to frame current discourse on the origins of disaffection: cultural transmission theory (e.g. Reid 1987) (disaffection as faulty socialisation into local and...
familial cultures: so, for example, regular school non attendance is accounted as parentally condoned absence) and process theory (e.g. Cooper 1993) (disaffection as a result of the experience of schooling). Research however also suggests that schooling can compensate for faulty local and familial socialisation and thus can reinforce or ameliorate culturally transmitted attitudes (Reynolds and Sullivan 1979). Therefore curriculum and pedagogy can be employed towards modifying student attitudes.

Moreover, recently emerging perspectives view disaffection as rational choice rather than deviant behaviour (e.g. Dorn 1996). These works suggest that a pathology of absence from school can be studied in terms analogous to a pathology of presence: in a world outside school which offers increasing access to knowledge that is independent of adult authority, education through schooling may seem less and less relevant (e.g. Schostak 1991). In attempting to explain what actually motivates students to attend school and conform to its conventions, Schostak and others contend that it is not curricular provision but an unthreatening environment for self discovery and development that maintains school attendance.

This new perspective implies a modified definition of disaffection beyond truancy and disruptive behaviour that includes the quietly, invisibly disaffected (Rudduck, Chaplain & Wallace 1996): those with low engagement with learning tasks, those who perceive these tasks as lacking in relevance with the world outside school and their own needs, interests and experiences, those who routinely execute but do not get substantially involved with the tasks. These students attend school but often underachieve. Re-engagement of these learners is then of strategic importance and the role of curriculum and pedagogy in this is central.

Quiet disengagement is a relatively under-researched type of disaffection. Our study aims at examining students' experiences of quiet disaffection in the mathematics classroom and at suggesting re-engagement strategies. It thus intends to highlight the needs of an often large group of learners whose mathematical potential may at the moment remain inert. This integration of cognitive and affective perspectives on mathematical learning, namely one that merges the study of students' attitudes towards and achievement in mathematics, has been highlighted in the relevant literature as a potentially fertile ground for research in an area where traditionally the distinction between cognition and affect has been dominant (McLeod 1992). Arguably this distinction has been counterproductive as studies of mathematical cognition have tended to miss important characteristics of performance as they failed to gather crucial data on students' affective responses. Furthermore studies of performance, unlike affective studies, have had a stronger influence on curriculum development and teacher education, and an integrated perspective is likely to enhance the influence of findings relating to affective issues.
Since the early 1990s there has been a growing realisation that the classical divide between cognition and affect in mathematics education, traced back in 1956 and Bloom's two volume Taxonomy of Educational Objectives, is not particularly helpful. In fact the interrelatedness of the two domains emerged as early as the 1960s (e.g. Simon 1967). Nowadays non cognitive predictors of performance (House 1995) are seen as pertinent in studies of learning: beliefs, attitudes and emotions towards mathematics are an inextricable component of general mathematical performance (Reynolds & Walberg 1992; Wong 1992; Jones & Young 1995; Ma 1997; Hensel & Stephens 1997) as well as particular mathematical skills (e.g. abstract mathematical thinking (Iben 1991); problem solving (Kloosterman & Stage 1992, McLeod 1993)). Reflecting tendencies in the general literature on disaffection, various studies address the relationship between attitude and performance as a function of the individual's self concept (Jones & Smart 1995; Maqsud & Khalique 1991; Williams 1994; Norwic & Jaeger 1989; Norwich 1994; Skaalvik 1994) as well as of the students' experience of mathematics teaching in the classroom (e.g. the role of 'interesting' class activities (Schiefele & Csikszentmihalyi 1994); the role of teachers' attitudes towards error making (Brown 1992)). In general, disinterest in mathematics generated by certain pedagogical approaches seems strongly linked with underachievement (Boaler 1997).

Non-mathematically specific research (e.g. Keys and Fernandez 1993) suggests that it is likely that, as students proceed to the later years of their schooling, they often become more disenchanted with the education process. In their work 'teaching and learning practices' ranked highly in the students' questionnaire responses to what made them positive towards school and school work. In considering implications for mathematics lessons, the students expressed a general preference for 'working with their friends', 'making' and 'discussing things'.

The above resonate with the findings in Jo Boaler's comparison of two schools with different approaches to mathematics teaching (1998): in the first school, which used a traditional text book approach, despite being 'repeatedly impressed by the motivation of the students who would work through their exercises without complaint or disruption', the students' three most frequent descriptors of mathematics lessons were 'difficult', comments related to the teacher and 'boring'. Students believed that mathematics just involved memorising and routine execution of rules. In the second school which used an open-ended project approach despite having 'very little control, order, and no apparent structure to lessons' students were expected to be responsible for their own learning and the three most frequent descriptors of mathematics lessons were 'noisy', 'a good atmosphere' and 'interesting'. Elsewhere (1997b) Boaler discusses also gender related differences on the same issues.
In the study mentioned earlier, Keys and Fernandez refer to disillusionment with and dislike of school; lack of interest and effort in class and homework; boredom with school and schoolwork; dislike of certain teachers or types of teachers; resentment of school rules; belief that school would not improve career prospect; low educational aspirations; low self-esteem and poor academic performance, as factors associated with disaffection or disengagement. They also discuss the concept of motivation as intrinsic (arising from interest in the subject being studied) or extrinsic (depending on the availability of external rewards). Norwich (1999) adds to these reasons two more categories: identified (e.g. recognition of the importance of mathematics) and introjected (e.g. parental pressure). In his work, introjected reasons were the stronger influences on satisfactory learning and behaving whilst intrinsic reasons were the stronger influences on unsatisfactory learning and behaving. This substantial reciprocal relationship between attitude towards and achievement in mathematics has been made in another recent quantitative study in the United States (Ma 1997) with the three attitudinal measures being 'Importance', 'Difficulty', and 'Enjoyment' and with 'Achievement' as the outcome. Significantly Ma contends 'making difficult content easy to learn is barely enough to improve mathematics achievement. It is more important to ensure that difficult mathematical content is presented in an interesting, attractive and enjoyable way'. And: 'It is inappropriate to assume that high achievers in mathematics have few attitudinal problems'.

Our study originates in the first author's previous involvement with a study of disaffection in secondary education and the second author's previous school-based research and teaching experience in the area. Results from the now concluding study that the first author has been involved in indicate that there is a wealth of evidence specific to mathematics to be explored with regard to this form of disaffection. Therefore research which offers an extension of this study and addresses this rarely explored, but significant, topic is timely.

Methodology. Participants of the research are mathematics teachers and students based in 3 Norwich schools, involved with the previous study (e.g. (Oakley 1999)). This previously established contact and willingness to participate (all schools were approached but our selection was based on school response, pilot lesson observations and timetable constraints). The field of the research are Year 9 mathematics lessons. This is a one-year project and is funded by the Economic and Social Research Council (Award No R000223451).

We are currently completing Phase 1 (October 2000 - January 2001). The second author observes students in mathematics lessons in which the participating mathematics teachers are involved and, also through consultation with the teachers, is now engaged with identifying a group of mathematically disengaged students.
In Phase 2 (January - April 2001), this extensive observation of the mathematically disengaged students will be supplemented with interviews of the observed students (these will be interviews of the whole class cohort in groups of approximately two to five students to avoid the implication of the observed students noticing their 'singling out' for observation): these will be semi-structured interviews in which the researcher will draw the students into an exploration of particular classroom incidents (Disengagement Incidents) as well as their general attitudes towards mathematics and its teaching. This process will be supported by occasional interviews with the teachers and supplemented quantitatively by an attitudinal survey administered to the students.

The researcher keeps fieldnotes of the lesson observations - the interviews will be audio-recorded. She then passes her fieldnotes on to the project director, the first author, who annotates them with comments of a substantive and of a methodological nature. This commented upon document is the Observation Protocol and there is one such document for each lesson. In this document there is preliminary identification of Disengagement Incidents. This process is carried out on a weekly basis so that the researcher's technique is constantly informed by these comments. Also in a weekly meeting we discuss the researcher's response to these comments. As an example, in the Appendix, we provide an Observation Protocol from one lesson (a preliminary analysis of the Disengagement Incident in this lesson is available in (Nardi and Steward 2000). Also: see Endnote for the plan regarding our conference presentation).

A note on methodological constraints. During Phase 1 and the seven weeks of classroom observation, we encountered, and partly resolved, several obstacles of a methodological nature: while engaging with identifying the 'subjects' of our study, the quietly disaffected in the mathematics classroom, or, to use another term that has grown to be of common use amongst us, the 'invisible' ones, we may have not 'seen' them; in other words they are perhaps the ones that are not present in the researcher's fieldnotes. The occasional hesitation of the researcher to approach some of these students was due to her concern that, by focusing on them she would actually render them 'visible' or her focus would actually result in re-engagement because the students would believe this is what she wants or expects to observe. We are currently resolving this by trying to foster an image of the researcher to the children that is completely dissociated from that of a teacher or that of an assessor of their work or some sort of 'authority' figure. This has been a complex task given this researcher's long-term experience as a teacher and the internal struggle between her identity as a teacher ('insider') and her identity as a researcher ('outsider') (Elliott 1991). Another methodological constraint is a certain transience in the nature of invisibility that we observed: over the seven week period we have identified episodes of 'invisibility' for some students who, in a following lesson, sought help from their teacher or peers and appeared engaged with their mathematics. Of course there have also been a number of students that are 'permanently invisible'. We intend our fieldwork to be as inclusive for
both groups as possible. Finally, there seems to be a type of invisibility as far as engagement with the mathematics is concerned that is, paradoxically, deeply embedded in extreme, disruptive behaviour; in other words disruptiveness seems to cover up feelings of inadequacy towards the mathematics. Often these loud students choose not to engage in the mathematics and the manifestations of this can take various forms - for these students it is very apparent, for 'invisible' students it is not; yet the underlying reasons for their disengagement may be the same. We feel that our observation and interviewing techniques need to allow the evidence from these 'visible' students to inform the main body of data.

Phase 1 Preliminary Themes. Within Phase 1, where examples of students’ lack of engagement in tasks they are expected to do has been observed we have sometimes been able to attribute these examples to a number of tangible reasons. We stress that this attribution is tentative. We offer this list of themes but, for want of space, the grounding of these themes to the data and the relevant literature (e.g. Norwich's extrinsic reasons for engagement have repeatedly appeared in our observations) is omitted here but is available in current (e.g. Nardi and Steward 2000) and in-preparation publications: (i) students may react positively to a change to the normal routine of their mathematics lessons especially if these are textbook based however if the format of this change is too different and students are not given enough time to adjust then, what is assumed to be a re-engagement strategy, may potentially disengage them even more or disengage a different group (this does not include puzzles but includes the often perceived as strong re-engagement activities such as 'investigations', where the otherwise welcome open-endedness of the task can be puzzling) (ii) Students can be re-engaged through using information technology and, in particular, subject specific software. However if students rarely use computers in mathematics, are unfamiliar with the software or the software is not well written this has been observed to lead to frustration and a lack of interest (iii) the impact of setting, and in particular of placing the students in a set that is beyond/below their ability, as well as the teacher's perceptions and expectations of individual students, is significant (iv) a pedantic, procedural or mechanistic approach to mathematics teaching (and/or a teacher personality with these features) has a clearly alienating impact on the students despite the teacher's aspiration for clarity and precision (v) conceptual difficulties within particular topics as well as certain uses of mathematical jargon have an immediate effect on the student's emotional response to the task and ensuing engagement. Extension and further refinement of these themes is to follow in the subsequent phases of the study.

ENDNOTE: In the conference presentation we intend to discuss samples of the Observation Protocols, the Disengagement Incidents and Associated Interview Extracts in order to exemplify the Analytical Themes that will have emerged in a more elaborate and refined manner from Phase 2.
APPENDIX: An Observation Protocol

Lesson [name of school] 1:2- 01/11/00 Wednesday, Period 4, Time: 1.25 - 2.25

Researcher 1 Field-Notes

I sat at back opposite the door. In class also (male) student teacher from university (not introduced) and support teacher for the Portuguese speaker. Students carry on work on circles. Teacher began by Recap on work on algebra in Year 8. On board: "$4 = 16$, $r = 16 / 4$ [several students called out], $r = 4$, $4 = 22$, $t = 22 / 4$, $r = 5.5$". Teacher: "If anyone has problems with that now is the time to say so". NOT SURE MOST STUDENTS WOULD OWN UP IF THIS WAS THE CASE.

On board "$x \times \text{diameter} = \text{circumference}, \text{radius} = 4.2$. Teacher asks what the diameter is. Hannah answered $8.4$, "$\pi \times 8.4 = \text{circumference}$". Students asked another question "$x \times \text{diameter} = 42". Verbally "what's the diameter?". Boy at front $+$ Zebbee $+$ Anna put up hands. On board: "diameter $= 42 / \pi$". Verbally: "You divide by $\pi$". Hannah: "I don't understand". Teacher: "I'll come and talk to you". Hannah: "I never understood". Girl on table near me asked someone else who also shook her head. Teacher on board: "a circle with circumference 72.6cm, the radius of this circle to the nearest 0.1 cm is $\pi \times \text{diam} = \text{circ}, \pi \times \text{diam} = 72.6$, diam $= 72.6 / \pi$. Teacher asks girl at back to work this out using her calculator. Teacher wanted all the digits shown on the calculator. Even though girl tried to give answer accurate to 0.1cm. "You do have to write down the whole calculator display", teacher says. "diam $= 23.12101911$, radius $= 23.12101911$ divided by $2 = 11.5605 = 11.6$ to nearest 0.1cm". Teacher asked who didn't have a calculator. A girl owned up - was asked how good her long division was. Anna who had moved to back table near me said: "I really don't understand". Teacher: "But you always say that". Teacher went to help Hannah. Teacher came back to Anna - the whole table seemed to listen.

I WASN'T SURE ANY OF THEM UNDERSTOOD WHAT TO DO. WHEN THE TEACHER WENT AWAY THEY DISCUSSED THE FIRST QUESTION - THEY WERE NOT SURE WHAT TO WRITE DOWN FROM THE QUESTION - THEY TRIED TO FOLLOW THE RULES FOR SETTING OUT ON THE BOARD. THEY HAD LOST SIGHT OF THE PROBLEM THEY WERE BOGGED DOWN WITH DETAIL - NO FLUENCY IN SOLVING THESE PROBLEMS HAD BEEN DEVELOPED.

I sat next to Jade, Charlotte and Ellie. I talked to Jade who seemed to confidently start the first question but then couldn't believe she could do it. She didn't want to sit next to her. Jade: "I'm no good at maths. I've never been any good at maths". Me: "What about last year or in Middle School?". Charlotte: "It was alright last year with Mr. J". Jade: "He didn't make you work". Jade gave up completely when she thought her two friends had a different answer to her - looked at her watch and sighed. Charlotte and Ellie were too bound up with setting out of problem - they seemed to lose sight of what they were doing. Jade approached by student teacher - body language suggested that she just wanted to be left alone. She could not believe she had done it right especially when it was pointed out that only the diameter was needed in this question. And she had worked out the radius. She started drawing margins in her book and writing down question numbers - avoid maths activities. Charlotte and Ellie started to understand what they had to do. Charlotte was more vocal than Ellie but Ellie seemed reasonably quietly confident. At 2.10 the teacher stopped the lesson to explain rounding. Charlotte and Ellie could do rounding. Charlotte (to Ellie) "Oh no she's going to explain it all". Teacher wanted all the students to go to the back of their books to write. On board: "When asked to correct to n decimal places you always look to the next digit to see whether it affects the nth decimal place. It will only matter if the value of that $n + 1$ decimal place is 5 or more in which case you add one to the nth decimal place, then e.g. 1.989898...'. Ellie and Charlotte got on with the exercise. THIS INTERRUPTED THE FLOW OF THE LESSON, LOST THE FOCUS OF CIRCLES AND WAS AN UNINTELLIGIBLE PIECE TO WRITE FOR ME LET ALONE YEAR 9 STUDENTS. Student teacher went back to Jade: "I really don't like maths". Me: "What do you when you don't understand?". Jade: "Wait till she's free and ask her". Me: "Do you put up your hand?". Jade: "Sometimes or otherwise I ask them (friends on table) - she's too scary".

Teacher gave answers at end of lesson at which point everyone gave up. IS MATHS JUST ABOUT DO YOU PUT UP YOUR HAND? Jade: "He (another subject teacher) sent me out for saying his jokes are rubbish. "If maths where she never says anything to the teacher. Jade: "I don't like any teachers".

IS THIS AN EXPRESSION OF DISENGAGEMENT OF SCHOOL IN GENERAL NOT JUST MATHS IN PARTICULAR? AT THE END OF THE LESSON I SPOKE TO THE TEACHER WHO SAID SHE HAD HAD TO ASK A GIRL'S NAME BEFORE SHE COULD GIVE HER A CREDIT AND ANOTHER STUDENT WHO SAID SHE HAD HAD TO ASK A GIRL'S NAME BEFORE SHE COULD GIVE HER A CREDIT - AN ACKNOWLEDGEMENT THAT SOME STUDENTS ARE INVISIBLE AND UNKNOWN EVEN AT THIS POINT IN THE TERM. MY IMPRESSION IS THAT TEACHER'S PEDANTIC APPROACH AND EXCESSIVE ATTENTION TO DETAIL IS INHIBITING LEARNING.

Researcher 2 'Preliminary Verdict': Disengagement Incident. Also disperse evidence.

Speculative comment about the students' response to teacher's general calls for assistance.

Evidence of disenchantment with own performance.

Evidence of teacher trying to achieve too much: learning on circles etc. AND decimal place (and how calculators deal with decimal places)? Evidence of teacher dismissing student's call for help or of teacher encouraging student to overcome usual hesitance about her performance? Anna is not an invisible child in this sense because her potential disenchantment is visible.

On Researcher 1 comment: Speculation or based on evidence?

DISENGAGEMENT INCIDENT: Distilled (after 'irrelevant' facts are removed or summarised), this episode is perhaps the first here to directly address the development of disengagement (Jade starts from a confident point but then her confidence deteriorates?) and a certain denial from the student on tackling it.

END OF INCIDENT

Teacher's assistance in identifying invisible children is invaluable. However bringing their attention to potentially invisible children their attitude towards them maybe will change. Will this affect our data?

Conjecture about the impact of teaching style on learning

Researcher 2 Comments

Speculative or based on evidence?

This paper extends previously reported research on the long-term use of an integrated learning system (SuccessMaker) that delivers mathematics activities randomly in the form of electronic worksheets and progresses students through various levels as success improves. Quantitative and qualitative changes were noted in the schools' endorsement of the ILS over a period of 3 years. However, most schools still endorsing the ILS in 2000 had predominantly transmission/absorption models of teaching and learning.

An Integrated Learning System (ILS) is basically a collection of tasks, presented as electronic worksheets, divided into a range of topics (e.g., numeration, multiplication, fractions). The manufacturers of Integrated Learning Systems endorse their products as tools to "develop and maintain mathematical skills, and to develop problem-solving skills" (Computer Curriculum Corporation, 1996, p.1) and as tools to diagnose student difficulties. In order to achieve these goals, the ILS in this study (SuccessMaker) presents "a mix of dynamically distributed exercises appropriate to a student's functional level, providing feedback and tutorial intervention when necessary and representing mathematical concepts through highly visual exercises" (Computer Curriculum Corporation, 1996, p.1). It delivers courses to each student individually, manages all student enrolment and performance data, and designates which tasks have to be completed. Its management system provides the means for teachers, laboratory managers, and administrators to organise the use of courses and to monitor student progress.

SuccessMaker is a closed system where curriculum content and learning sequences are not designed to be changed or added to by either the tutor or the learner (Underwood, Cavendish, Dowling, Fogelman, & Lawson, 1996). Each of the topics is sub-divided into collections of tasks that are sequenced in terms of performance at different levels. When students achieve high mastery at one level, the ILS automatically raises them to the next level. The random nature of the presentation ensures that task performance correctly represents level. The worksheets vary in quality, but many are generally attractive in their presentation and creative in the way they probe understanding, particularly with the use of 2-D representations of appropriate teaching materials in mathematics (e.g., Multi-base Arithmetic Blocks, Place Value Charts, fraction and decimal diagrams). SuccessMaker provides online student resources: Help (provides answers), Tutorial (directs how to do a task), Toolbox (calculators, rulers, tape measures, etc.), Reference (provides definitions), and Audio (reads text to students through earphones). The worksheets can be printed to provide off-computer activity.

The random nature of the worksheet presentation means that SuccessMaker does not provide sequences of activities that can address student misconceptions. There is also a tendency for questions to be closed and to base performance on speed (with time delays
resulting in the ILS defaulting to incorrect). The use of the Help and Tutorial icons automatically grades performance as incorrect. Because of their focus on rising through the levels as rapidly as possible, many students in this study tended to avoid using these aids.

The very nature of an ILS marginalises the teacher’s role and removes students’ initiative and autonomy (Bottino & Furinghetti, 1996). Furthermore, the one-student-at-a-time structure of the ILS discourages cooperative learning by groups of students. This is contrary to current views that learning with computers should be cooperative (Sivin-Kachala, Bialo, & Langford, 1997), particularly with respect to higher cognitive functioning (Carnine, 1993; Riel, 1994), investigations and the construction of links (Wiburg, 1995). There also appears to be insufficient task variety in SuccessMaker to prevent repetition; thus many students in this study tended to become bored. Some tasks have novel presentation and solution formats which many students found difficult to interpret. However, SuccessMaker does provide feedback to students on the correctness of their responses (desirable for effective learning according to Sivin-Kachala et al.).

**Learning and SuccessMaker.** In a re-analysis of studies into the effectiveness of SuccessMaker, Becker (1992) found very little evidence of this ILS improving student learning. He argued that the only significant improvements were found in studies supported by the manufacturers and that these had flaws. A more recent study by Underwood et al. (1996) found some statistically significant improvements from the use of the core mathematics course in primary and secondary classrooms, although the sample sizes from the primary classrooms were too low to meet Becker’s criteria for significance.

In a study comparing SuccessMaker progress in 23 schools across 6 months with changes in mathematics knowledge as measured by a standardised test, McRobbie, Baturo and Cooper (2000) found no significant improvement as measured by the test even though the ILS reported significant gains. This finding was supported by case studies of students’ progress where data from interviews indicated that children with rapid ILS improvement had acquired little mathematical knowledge. As Baturo, Cooper and McRobbie (1999) argued, the worksheet nature of the ILS makes it susceptible to the same pedagogical flaws as were found by Erlwanger (1975) in the Individually Prescribed Instructional (IPI) packages that proliferated in the US in the 70s. Nevertheless, SuccessMaker was reasonably popular in many schools in Queensland, Australia. Therefore, Baturo, Cooper, Kidman and McRobbie (2000) explored the factors that appear to influence teachers’ endorsement of the ILS. This study found that SuccessMaker was endorsed in cases where there was strong supervision, follow-up of students’ difficulties, integration with other teaching, external rewards and some novelty with respect to computers. The chance for endorsement appeared to diminish if teachers did not support it philosophically, if rotsters were inflexible and if more exciting computer options were available. All of the teachers who endorsed SuccessMaker did so because they believed it had contributed to improved levels of mathematical and affective performance in their classrooms.

This paper reports on a follow up study to the Baturo et al. (2000) study in which we investigated:
1. whether the schools’ levels of endorsement had changed over a period of three years; and
2. issues which influenced the schools’ patterns of endorsement and use.

Method

Data for this study came from two sources. The first set of data was from interviews conducted with administrators, computer coordinators, teachers, teacher aides and technical staff from the 23 low socioeconomic schools involved in the first year of the project (1997). These interviews focused on (1) logistics, management and use of the ILS, (2) teachers’ beliefs about teaching and learning and the ILS’s role in teaching and learning, (3) perceptions of students’ likes, dislikes and preferences with respect to the ILS, and (4) the schools’ levels of endorsement of the ILS (see Baturo et al., 2000). The second set of data came from a questionnaire that focused on the logistics, management, use and long term endorsement of the ILS. The questionnaire was sent in 2000 to each of the schools involved in the study; 9 primary and 8 secondary schools responded (1 school had closed and 5 schools did not respond to the questionnaire). In order to clarify their responses to the questionnaire, follow-up telephone interviews were conducted with some of the teachers at five of the schools.

Eleven of the 17 schools that responded had over 20 percent students from indigenous backgrounds. Within Australia, it has been noted that many students from indigenous backgrounds tend to experience significant difficulties in learning mathematics taught in schools (Zevenbergen, Atweh, Kanes, & Cooper, 1996). According to Kepert (1993), many indigenous students have cultural backgrounds that will not immediately allow them to access the mathematics taught in schools. This viewpoint has been supported by Frensh, Frensh, Matthews, Stephen, & Howard (1994) who claimed that too often mathematics is taught in ways that do not take into account the various learning styles of indigenous students.

The data from the interviews and the questionnaires were first tabulated in order to ascertain changes in levels of endorsement of SuccessMaker. Each school was classified in one of three categories: Full Endorsement, Partial Endorsement and Non Endorsement. If a school unconditionally endorsed SuccessMaker, it was classified in the Full Endorsement category. However, if its endorsement of SuccessMaker came with some reservations or conditions, then it was classified in the Partial Endorsement category. Those schools who did not endorse SuccessMaker were classified in the Non Endorsement category. After changes in levels of endorsement had been ascertained, the data were further analysed in order to identify factors that had impacted on the levels and the quality of the schools’ endorsement of SuccessMaker.

Results

During the three-year period in which SuccessMaker operated within the schools, levels of endorsement for the ILS decreased. Of the 6 schools that originally fully endorsed SuccessMaker in 1997, only 3 were fully endorsing it in 2000, 2 were only partially
endorsing it, whilst 1 of the schools no longer endorsed it. With respect to Partial Endorsement, of the 7 schools in this category in 1997, 2 had withdrawn their endorsement by 2000. The four schools who had not endorsed it in 1998 had not upgraded their level of endorsement.

The changes to the levels of endorsement were based on both pedagogical and logistical factors. For example, the school that changed from Full to Non Endorsement offered the following reasons: (1) extremely negative feedback about SuccessMaker from the students, (2) a realisation on the teachers' part that SuccessMaker was not an effective learning tool, and (3) the logistical problem of fitting sessions with SuccessMaker into the timetable. The two schools which changed from Partial to Non Endorsement indicated that their reasons for reducing their level of endorsement for SuccessMaker as being: (1) the transfer of the teacher who originally implemented SuccessMaker from the school; and (2) the feelings of other staff within the school that SuccessMaker was not an effective learning tool. The logistical problems of training staff, how to access reports and worksheets from SuccessMaker, and of timetabling the three regular 15 minute sessions per week (as recommended by the publishers of SuccessMaker) in the computer laboratories together with perceptions about the limited educational value of SuccessMaker were the reasons offered by the two schools that changed from Full to Partial Endorsement.

An analysis of the data revealed that all 10 schools which either partially or fully endorsed the use of SuccessMaker in 2000 made extensive use of external rewards to keep the students engaged on task. Data from the interview and follow-up telephone interviews seemed to indicate that the use of external rewards played a very important role in maintaining student activity on SuccessMaker. In contrast to this, the 7 schools who did not endorse SuccessMaker did not utilise external rewards.

When the data was subjected to more detailed analysis, it was noted that the reservations or conditions that underlay Partial Endorsement of SuccessMaker had undergone important qualitative changes during the three years. In 1997, partial endorsement was primarily based on price and logistical issues (such as timetabling computer time). By 2000, Partial Endorsement no longer was primarily based on these issues. Instead, it was based more on educational issues such as:
1. the limited roles SuccessMaker could play in a school’s mathematic education curriculum program,

2. the limited set of clientele for which SuccessMaker activities were deemed appropriate, and

3. the need for supervision.

Limited roles for Successmaker in mathematics Curriculum program

All of the schools that partially endorsed the use of SuccessMaker in 2000 clearly indicated that they did not perceive that it had general application across the whole mathematics curriculum program. This sentiment about SuccessMaker was probably best encapsulated by the comment from one of the high schools, namely, that SuccessMaker “can be a valuable component of a learning program”.

These schools identified specific niches or roles for SuccessMaker within their mathematics curriculum program. For example, most of these schools felt that SuccessMaker provided good reinforcement learning activities and was excellent for “drilling the basics in...getting kids ready for high school”. Some of the schools also felt that SuccessMaker provided effective individualised sets of learning activities for remedial mathematics students.

One of the primary school teachers indicated that she felt that SuccessMaker provided worthwhile learning activities in a few specific problematic topics such as division. She thus endorsed the use of the ILS for assisting in the teaching of these specific topics. She, however, felt that its learning activities in many topics were not pedagogically sound so she did not endorse the use of SuccessMaker in these latter topics.

Limited set of clientele

The teachers from the schools partially endorsing SuccessMaker firmly believed that it is only suited for targeted groups of students such as those in need of remediation and/or those students “who have literacy and numeracy deficits”. They were very negative about its suitability for use with the general student population. This notion that SuccessMaker should only be used for remediation and learning deficit students probably is best epitomised by a teacher from one of these schools. When she was asked during a follow-up telephone interview during 2000 whether she would endorse SuccessMaker for use with her own son, she quite unequivocally stated “no” because she felt that her son was a good learner and thus did not need SuccessMaker. However, she was most happy to endorse it, in her classroom, for those students who had learning difficulties.

Need for supervision

All of the 7 schools that partially endorsed the use of SuccessMaker in 2000 strongly emphasised the need for supervision. As one of the high schools noted, SuccessMaker could be a very effective learning tool:
providing they (the teachers) are careful about how they use it. It is not to be used as a child minding device.

An analysis of these 7 schools’ responses to the questionnaire revealed that they perceived that three types of supervision were needed in order for SuccessMaker to operate effectively:

1. supervision of the operation of SuccessMaker system
2. supervision of the students’ behaviour whilst interacting with SuccessMaker
3. supervision of the mathematical learning.

**Supervision of the operation of SuccessMaker**

All of these 7 schools had experienced on many occasions problems with the operation of SuccessMaker. For example, the ILS had a history of crashing, especially if some of the graphic capabilities of SuccessMaker were being used. Other types of operational problems that occurred included difficulties in extracting students’ scores and in extracting hard copies of worksheets. Thus, as one school said, students could not be left to work on SuccessMaker without someone (a teacher or a teacher aide) being there “to drive the wheels”.

**Supervision of student behaviour**

Although each of the 7 schools partially endorsing SuccessMaker in 2000 indicated that a teacher and/or a teacher aide was necessary in order to ensure that the ILS was functioning properly, their major reason for stressing the need for supervision of the ILS sessions by a teacher or a teacher’s aide was to ensure that the students stayed focused on the task. As one of the primary schools stated:

> the program needs human resource to supervise students to see they are on task and not just random selection.

**Supervision of mathematical learning**

Most of the schools partially endorsing SuccessMaker expressed skepticism about its publisher’s claims that it provided necessary interventions when students were experiencing difficulties with the topics being covered. These schools indicated that they had found it necessary to act upon reports of problems immediately they were identified either by SuccessMaker’s assessment mechanisms or by the teacher/teacher’s aide. Their actions generally took the form of small group tutorials away from the computer where, if necessary, recourse was made to concrete teaching materials.

One teacher in fact created a very systematised mechanism for this process. She got each child to record his or her score on assessment tasks and to print out the worksheets they were having difficulty in completing. She used this information to plan specific mathematics lessons in order to meet the needs of these students. She thus effectively integrated SuccessMaker mathematical activities into her other mathematical learning activities.
Discussion and conclusions

Over a period of three years, both quantitative and qualitative changes have been made to the schools’ endorsement of *SuccessMaker*. In 1997, 13 out of the 17 schools fully or partially endorsed *SuccessMaker*. By 2000, this number had fallen to 10 schools. However, the most important changes educationally were the qualitative changes that had occurred to the nature of partial endorsement. Whereas in 1997, the reservations/conditions that underlay Partial Endorsement were primarily based on price or logistical issues, by 2000 the reservation/conditions were primarily based on educational issues such as *SuccessMaker*’s curriculum limitations, the limited clientele for which *SuccessMaker* is appropriate, and the need for supervision.

However, it should be noted that the educational philosophy underlying the practices employed in those schools partially endorsing *SuccessMaker* in 2000 seemed to have been based on a deficit model of education. This is reflected in the schools’ comments about *how* and *with whom* they believed that *SuccessMaker* could be successfully utilised. It is also reflected in the extensive use of external rewards utilised in these schools to keep students on task whilst using the ILS. The deficit model of education assumes that underachieving students lack essential skills or orientations which allegedly hinder their academic achievement and that the major task of education for these types of students is to “fill-in” these deficits. In recent years, serious doubts have been expressed about the limitations of the deficit model. Liedke (1995), Gonzales (1993) and Hamovitch (1994), for example, have found that educational interventions based on the deficit model are not successful because they are often insensitive to the societal and cultural backgrounds of many underachieving students (particularly those from indigenous backgrounds). Because of this, many educators are arguing for educational curriculum and teaching methods that promote and build on students’ existing repertoires of knowledge and incorporate their home cultures and history. Thus, it could be argued that the use of *SuccessMaker* to overcome the deficits of underachieving students may not in the end result in significant, long term educational gains by students at these schools.

It also should be noted that the schools who still endorsed *SuccessMaker* in 2000 had instrumentalist viewpoints about the nature and discourse of mathematics. That is, they viewed mathematics as a static corpus of isolated facts, rules and procedures which students needed to learn. Because *SuccessMaker*’s random presentation of mathematical content, its structuring of mathematics closely matched that of the teachers in these schools.

Therefore, although there seemed to be a movement towards a focus on student learning amongst the teachers in the schools who partially endorsed *SuccessMaker* in 2000, methods of teaching and ways of utilising the ILS still were very transmission/absorption in nature (just as they were in 1997). Their methods of teaching mathematics were not being modified to focus on collaborative, socioconstructivist principles such as those being promoted by most current mathematics education curricula and reform documents.

Videopapers: Investigating new multimedia genres to foster the interweaving of research and teaching

Ricardo Nemirovsky, Teresa Lara-Meloy, Darrell Earnest, Branca Ribeiro
TERC. Cambridge, Massachusetts. USA

This paper reports an ongoing investigation on how mathematics teachers discuss and relate to a new genre of research publication that we call “videopapers.” Videopapers are multimedia documents that link and synchronize digitized films with subtitles, text with interpretations and transcriptions, and images or software tools associated to the content of the videopaper. We interviewed pairs of high school mathematics teachers as they encountered and discussed a videopaper based on a PME paper presented two years ago. We reflect on the different roles of the classroom video and the paper and on the process of data analysis enabled by the videopaper.

The Study

The capacity of educational research to influence teaching and learning is often questioned and dismissed (Kaestle, 1993; Sullivan et al., 2000). Educational research tends to be seen unfavorably in comparison to research in the hard sciences. In contrast to fields like medicine or engineering, the evidence generated by educational research seems to many to be inconsequential and inconclusive. This comparison is itself a product of cultural assumptions and expectations. It reflects the notion that valid research should generate evidence out of comparing different teaching and curricular approaches to improve students’ learning; accordingly, a research report would have to compare alternatives and show that one is most beneficial. Teachers would then be able to make informed decisions about their practices. This is a view endorsed and pursued by many educational researchers (Campbell & Stanley, 1963; Clifford, 1973). Others approach the role of educational research differently by stressing the need to examine and question different ways of thinking about the nature of teaching and learning. From the latter point of view, a research report is expected to articulate new perspectives on teaching and learning. By questioning assumptions and articulating new possibilities teachers might conceive of their roles differently, or see what students do in a new light. It is not so much a matter of controlled comparisons but about being generative and help to re-think what is usually taken for granted. Case studies (Stake, 1995), ethnographies (Bolster, 1983), and narratives (Carter, 1993) are some of the publishing styles preferred in these lines of work.

In this paper we report an investigation on how teachers read and talk about case studies based on the analysis of videotaped classroom episodes. The relationship between teachers and research-oriented case studies is the subject of a
small literature. Bolster (1983) and Stake (1995) propose that case studies are relevant to teachers because educational events are not governed by formal rules but by intentions and on-the-spot perceptions, which can only be conveyed by complex and detailed ethnographies. On the other hand, Kennedy (1997, 1999) argues that teachers engage with different pieces of research literature not on the basis of the paper's "genre" (quantitative comparison, case study, narrative, etc.) but to the extent to which they elaborate on issues that matter to them (e.g. classroom management, minority students, etc.). Still others stress the centrality of teachers' participation in authoring these case studies. Cochran-Smith & Lytle (1993) discuss key ideas underlying the "teacher-research" movement, one of whose main tenets is that the relevance of research is associated with teachers' shifting their professional identities, becoming actors in the work of research, and seeing teaching as intimately related to investigating questions on their own practices.

A focus of our study is to understand how the introduction of filmed classroom episodes as part of the case might generate new ways in which teachers perceive and interact with the case. The actual use of video is likely to have a deep impact on how a case is "read" or "viewed." One common observation is that educators who are shown a classroom videotape tend to immediately judge teacher's actions as being more or less good or bad, and frequently contrast his or her actions with how it "should" have been done; it is a tendency to shift the filmed episodes to a background in order to highlight one's own preconceived notions of a correct or ideal course of events. This attitude differs from one in which the observer focuses on the filmed interactions, strives to trace the inner origins of the utterances, and attempts to use the evidence to imagine how things look like to the participants in the film. We will refer to this last attitude by using the term "data analysis."

The emerging technologies of digital video are creating many new possibilities to facilitate data analysis. Digital video is simple to use in a manner that is richly connected to other forms of information (e.g. text, images, subtitles, software simulations, etc.). These possibilities are beginning to be exploited both for the development of research (Hall, 2000; Stigler & Hiebert, 1997), and for teachers' professional development (Lampert & Ball, 1998). Sabelli and Dede (1998) offer as an example research by Jacobs et al. (1997), which involves the "collaborative annotation of video-based case studies of educational practice that include ancillary information such as student products and teacher reflections" (p.9).

Together with other colleagues, we are working to develop a new genre of research publishing that we call "videopapers." Videopapers, as we conceive of them, are multimedia documents that include a text frame, a video frame, and an image frame:
Video papers can be seen with a web browser, such as Netscape. All the components are linked and synchronized. For example, buttons can be inserted in the text that will play a pre-selected interval on the video; images can be made to appear at particular times in the image frame; and the video can trigger the display of certain pages on the text frame. In order to produce a videopaper we have developed a software tool called "VideoPaper Builder" that allows authors to interconnect and synchronize the different components without having to be a programmer or even technically savvy.

In order to conduct the present study we chose a paper that had been presented at PME in Israel (Solomon & Nemirovsky, 1999), developed a videopaper out of it, and interviewed high school mathematics teachers. We conducted and filmed interviews with pairs of teachers. The teachers were asked to read the paper in advance. Then they were introduced and given access to the videopaper during the interview. The paper is based on a 16-minute classroom conversation in a high school math class taught by Solomon. The two main themes of the paper are the nature of open-ended problems and the sources for the "sense of direction" emerging in a classroom conversation. The authors argue that what makes a mathematics problem open-ended is not so much its textual definition but the classroom culture within which it is discussed and figured out. They also contend that the sense of direction of a mathematical conversation does not follow pre-planned paths and it is co-developed by the teacher and some of the students. The videopaper includes the text of the paper, the 16-minute digitized film with subtitles, and synchronized images displaying the content of the overhead transparencies being projected in front of the class.

Our approach to the analysis of the videotaped interviews shares a number of commonalities with Interaction Analysis as described by Jordan and Henderson (1995), and the interpretive approach described by Packer and Mergendoller (1989). Rather than approaching the filmed interviews with a predetermined coding scheme, we allowed the analysis to "emerge from our deepening understanding" of the events unfolding on the video-taped record (Jordan & Henderson, 1995. p. 43). We treated the participants' utterances and actions as processes accomplished over time and in interaction with others and we focused our attention on the details and meanings of these actions and utterances (Packer & Mergendoller, 1989). Our data analysis took place in a group of four researchers with varying interests and expertise who continually challenged each other's observations and required of each other the grounding of interpretations in observable events on the video record (Jordan & Henderson, 1995. p. 45).
For the purpose of presenting our analysis we will excerpt from two interviews. One interview was with June and Ron, who are beginning teachers, and another with Cara and Cher who have almost 30 years of teaching experience. All of them teach mathematics in high schools located in the Boston area.

The Interviews

We organize the selected excerpts from interview transcripts in two parts: 1) Reading the paper/watching the video, and 2) Data analysis.

Reading the paper/watching the video

Before the interview, teachers had read the paper, which included a transcription of the classroom conversation integrated with commentaries and analysis. A transcription captures some aspects of a classroom interaction but it necessarily leaves out many others. Transcribing is selecting aspects deemed to be important and making them suitable for the print medium. A large amount of "filtering" happens in transcribing classroom interactions. The reader is expected to reconstruct the events and therefore she has to assume whatever had been filtered out. In order to "picture" what went on, it is essential for the transcript's reader to project his own assumptions. Although not everything falls under the lens of the camera and the microphone picks up only part of what is being said, a video record undergoes less filtering than a written transcription. Film preserves the original tones of voice, gestures, facial expressions, etc. Another difference is that the video introduces its own time: if an utterance took 3 seconds, one has to spend 3 seconds to hear it, whereas the reading of its transcription is not constrained by the original duration. There were many examples of how these differences played out in teachers' conversation. The one that we have chosen took place in the interview with Cara and Cher. As they read the paper, they "pictured" a certain classroom interaction that resembled, in many ways, the kind of interactions they were used to in their own classrooms. Their implicit picture positioned Solomon standing at the front of the classroom next to the overhead projector. Right after viewing the videotape, Cara and Cher commented with surprise on the fact that Solomon was seated and reflected on their own perceptions on "being seated:"

Cara: I still take a negative connotation to being seated during a class. I mean, it's ingrained in me, you have to be out their performing. So that was my first observation of the film, was, gee he was seated. And it was a good thing. I mean, I took it as a supportive, he's part of the, not part of the discussion. He's letting them do it, and he's just writing down their observations.

(…)

Cara: I mean, the whole effect that he was seated.

Cher: That makes a big difference.
Cara: That physically changes the whole climate of the classroom. At least in a math classroom. I don’t think it’s so much in a history classroom, or an English classroom, where they’re reading and writing papers and all. Maybe I’m wrong. But think from your math classrooms, when you came in, didn’t you more or less expect the teacher to be up front, doing something? If you think back? (...) That role is very slowly changing in math classes. (...) because I think it speaks volumes. Rather than being Moses on the mountain, handing down the things.

The transition from reading the paper to watching the video prompted Cara and Cher to encounter their own tacit assumptions. In addition, they felt that reading the paper prior to watching the video was important in another regard: getting a sense of what to look at in the video and approaching the video with their own questions in mind. For example Cara felt puzzled by how open-endedness had been characterized in the paper. She commented on this as she was watching the video for the first time:

Mr. Solomon (in video): There’s not necessarily one correct answer.

Cara: See, that part I didn’t understand.

Later she clarified her comment:

Cara: the one thing that disturbed me when I read this (paper), and was anxious to see it in the video, is this, the concept of an open-ended question. And this is something we were kicking around a lot.

This role of “paper-reading” as a source of questions and issues with which to watch the video was made explicit at a later part of the interview:

Teresa: Was it beneficial for you to read the paper physically before you came in and watched the video?

Cara: Yes. (Cher: Definitely.) Yeah. Because I knew where it was going to head to. You know what I mean? I would have been pausing it and thinking things out myself, you know. Trying to keep at the same level as the student. And if I hadn’t been prepared, I wouldn’t have known what to be watching.

Cher: Well, yeah, and you could watch this, since you, since I knew what the, where it was going. Watch this, and focus on the watching instead of looking at what was going on and watching at the same time. So I think it was good to have, I mean for myself.

Data analysis

June came to the interview with a deep interest in figuring out why Solomon’s class had solved a problem of number sequences using successive differences. This solution was for her an unusual one, and she wondered whether it would have ever taken place in her own class. This concern of hers led her and Ron to work on data analysis in order to trace the origins of this idea within the filmed classroom conversation. Their data analysis was grounded in their non-linear examination of the
video, with important references back to the paper, and took a form that we call “narrative account.” Their narrative account for the origins of the “differences of the differences” idea integrated rich perceptions of the film, which gave them a sense of what kind of persons the students were and of their subjective experiences:

June: (referring to one of the students, Jamal) He wants to see the numbers up there. Maybe he’s a visual guy. Maybe he’s used to saying I’m seeing something here and my gut tells me that there’s something about this, and throw it out, and let’s see if somebody else in the class picks up with a fresh brain. The fact that he says put the numbers up there, I think, (...) he has a gut feeling about that.

June and Ron’s development of a narrative account prompted them to search for evidence regarding “who had said what” and “when” by going back and forth in the video and in the paper. Their emerging narrative became expressed in a typical linguistic form: “so and so said this and then someone else...”:

June: And then Nadia just keeps plugging away, and then she realizes that she did something wrong with her subtraction, and she says ok, wait I might have a different number. I forget where (in the paper) that is. (Flipping through the hard copy of the paper.) And she’s like working away there, while other people are discussing stuff. Ok. yeah. (Finds reference) Nadia says, “I didn’t stop at finding differences.” She’s the one who went to the differences between the differences. I think. And, then she got 12, and then 16 ... and then Jesse says “maybe it’s 18.” And then Nadia says ok wait, and she goes back. And she’s plugging away at the numbers while everyone else is talking, and then she comes back. And then she says 125. So, she obviously made the correction and went back out, and did the reverse of taking the differences by adding on 6 to get the next one, and then 24 to get the next one and then 125. Cause that’s not recorded in the conversation, nor in the video.

Both the sequence of the paper’s pages as well as the video’s timeline were important tools to organize ideas and to get the sense of “before and after” relating the different events that took place during the classroom conversation. Note that while their narrative account incorporates many elements visible in the film, it also reflects others that are not recorded but that were likely to have happened, such as when June said “obviously” and stated an inference about Nadia’s approach that was recorded neither in the video nor in the transcript. The following excerpt shows Ron’s development of a narrative account and June’s repeated contributions and occasional surprises.

Ron: Maria said she did the differences.
Teresa: where are you (to Ron who was controlling the movie player on the computer screen)?
Ron: She says when she went home, she did the differences. She did multiplication. Alright.
So that’s where the word differences comes up first.
June: ohhh {surprised}
Ron: Then Margaret says there’s no sequence, the only common ... but then for some reason, where does the differences {of differences} come out?
June: Jamal again.
Ron: like who says 1, 8, 27, 64 ... I mean, 7...
June: Jamal, here {points to quote in transcript}. He says ... Ron: the differences between the differences between ...
June: (Flipping through paper) He comes up with 7 and Molly quickly says the other two numbers.
Ron: It says {pointing to quote in text} "she probably had already taken the first differences."
June: Oh right, she reacted, that’s right.
Ron: But Jamal was the first that brought the differences in the discussion.
June: and I think that he sensed that there were other people that, since Molly saw it, he said yeah, yeah, he wanted {gestures forwards to imaginary board} to see them {the numbers} up there. And I think that kids sometimes do do that. They’ll say, I know there’s something in there.

Note in the last remark by June her analysis of Jamal’s actions that had introduced the differences of the differences approach, albeit in an unintended way. According to June, Jamal wanted to have his number sequence written on the overhead transparency because he felt that “there is something there” although he was uncertain about what that “something” was; and she immediately connected this observation about Jamal with a personal statement: “kids sometimes do do that.” This excerpt shows how a narrative account expresses at once: grounded evidence (e.g. “here, he says”), interpretations (“he sensed that there were other people...”), and the background of life experience (“”kids sometimes do do that.”).

Conclusions

Paper and video are both important in different ways. The classroom videotape makes possible to get a “feel” for what teachers and students say or experience, to encounter one’s own assumptions about the classroom interactions, and to formulate questions with a great degree of ownership. The paper introduces a particular interpretation, it helps to develop a sense for “what to be watching”, and its transcriptions highlight what, among the massive amount of information available in the video, appears significant to the author.

Digital video embedded in videopapers facilitates data analysis by enabling a non-linear search of utterances and events and the development of complex narrative accounts encompassing grounded evidence, interpretations, and the teachers’ background of life experience. This suggests that videopapers may be particularly suitable for teachers’ engagement with data analysis.

USING PROBLEM SOLVING TO IDENTIFY MATHEMATICALLY GIFTED STUDENTS

Kate Niederer and Kathryn C. Irwin
University of Auckland

Despite growing awareness of the characteristic behaviours of mathematically gifted students, the identification method of choice in most New Zealand schools continues to be results on standardised tests. This study looked at a range of measures for identifying mathematically gifted students in elementary school. Of the six measures identified by the literature as being useful, student’s responses to a series of difficult mathematical problems proved most useful in identifying giftedness. Two cases are discussed in which standardised test results differed from ability to solve problems.

Introduction

As the general description of a gifted individual has evolved over the years, so too has the description of the mathematically gifted. In the past, the mathematically gifted were usually identified by means of their results on achievement tests. While this practise continues to a large extent today, a number of researchers have shown that high scores on achievement tests do not necessarily imply mathematical giftedness (e.g., Span and Overtoom-Corsmit, 1986). Researchers and educators alike are looking more and more at the behaviours of students that might indicate mathematical giftedness (e.g., House, 1987). Many of these characteristic behaviours are evident when the mathematically gifted student is engaged in problem solving.

Over the last thirty years there has been an increasing awareness of the importance of problem solving in the teaching and learning of mathematics and an increasing understanding of the particular characteristics of mathematically gifted students that make them adept problem solvers. Krutetskii (1976) studied 192 students aged between six and sixteen, 34 of whom were judged as mathematically gifted.
gifted. The students were asked to work on a variety of non-standard mathematical problems. He found that mathematically gifted students differed from less able students in their problem solving behaviour in that they were able to: view the content of a problem analytically and synthetically, generalise problem content and solution method, exhibit curtailment when solving similar problems, be flexible, readjust solution techniques where necessary, look for simple, direct, elegant solutions, investigate aspects of problems before trying to solve them, remember and generalise curtailed structures of problems and their solutions, and tire less when doing mathematics than when doing other subjects.

Recent research on problem solving and problem posing has highlighted the potential within these related areas for assessment of mathematical ability. Lowrie and Whitland (2000) studied problem posing in Grade Three students and found valuable information on the students’ mathematical understanding and ability was gained by studying the problems they posed. Cifarelli (2000) describes in depth the problem solving of a college student, focussing on her methods to gain a solution as much as on the solution itself. The study revealed much about the mathematical understanding and ability of the student.

The measures that are most commonly recommended for the identification of gifted students in New Zealand are standardised tests, teacher nomination, parent nomination, self nomination and peer nomination (Dale, 1993). This study looked at these five measures and their usefulness in identifying mathematically gifted students. It also added a sixth measure, the student’s problem solving ability, because of the strong links that have been identified between problem solving ability and mathematical giftedness.

This study

Sixty-six students participated in this study. Fifty-six of the students were from two mixed ability year six classes (age 10) and ten of the students, of a similar age, were in a class for gifted students. The gifted students attended normal state schools for four days each week and the private gifted school for one day a week.
Seven of these students were already judged to be mathematically gifted and provided a benchmark for the study.

Information on each of the six measures used for identification of mathematical giftedness in this study was collected in the following manner.

1. Standardised test: Progressive Achievement Test in Mathematics (P.A.T.) (NZCER, 1998) age percentiles were obtained for each student. Students routinely sit this test in the first month of the new school year.
2. Teacher nomination of which of their students were mathematically talented.
3. Self-appraisal: students were asked to rank their own ability in mathematics.
4. Peer nomination: peers were asked whom they thought were the best mathematicians in their class.
5. Parent nomination: parents were asked whether or not they thought their child was mathematically talented.
6. Problem solving: each student sat two problem solving tests involving a total of six problems. The problems were based on those used in a study on the problem solving attributes of the mathematically gifted by Span and Overtoom-Corsmit (1986). The six problems used are shown below.

1. On a summer day a grandmother walked along the beach with her granddaughter. They saw bike tracks in the sand. They tried to work out the order in which the bike tracks were made. In which order do you think they might have been made? (A diagram followed showing a series of four intersecting tracks with some of the intersections covered by footprints)
2. If I add a father’s age to that of his son’s the total is 50 years. The father is 28 years older than the son is. How old is the father and how old is the son?
3. Sarah went to the shops and bought 4 magazines; Metro, the Listener, More and the New Zealand Woman’s Weekly. In how many different sequences can she read her magazines?
4. I have two barrels of water. One barrel contains twice as much water as the other barrel. I pour 20 litres of water out of each barrel. Now one barrel contains three times as much water as the other. How much water was there in each of the two barrels to start with?
5. Tim’s neighbours have just moved to another town. New neighbours will arrive next week. Tim has discovered that two of the new neighbours are children. He wonders what the chances are that at least one of the children will be a boy. What do you think?
6. In an office in town people are called by blinking lights. Each employee has a personal combination of one or more lights. There are exactly as many
combinations as there are workers. There are 5 different coloured lights in a straight line as shown below. How many workers are there?

Each problem was scored using a 7-point rubric. The problems chosen were expected to be difficult for the more able mathematicians in the classes to solve. This proved to be the case, with only 17 of the 66 students who attempted the problems scoring 50% or higher and only two students scoring 90% or more on the problems.

Despite the care taken in choosing the six problems, inevitably some of them proved to be more useful than others in differentiating between the more and less able problem solvers. Problems that a majority of students solved correctly, or came close to solving, were seen as too easy. Problems that very few of the students could solve, or could come close to solving, differentiated between the very able and the less able problem solvers. Problems three, five and six proved to be the most difficult problems. Two of these are permutation problems and the other is a probability problem. Of the three problems which were less successful in differentiating between the more and less able problem solvers, two could be solved using a guess and check method. Problem one proved relatively easy for students to solve for no very obvious reason.

Of the five measures tested, self-appraisal, peer nomination and parental nomination proved to be unreliable as a means for assessing mathematical giftedness and are not discussed further here.

There were strong links between teacher nomination and high standardised test results. Of the 23 students who were nominated as mathematically gifted by their teachers, 19 had test results of 90% or higher. This was largely to be expected as these test results are used in many schools to identify the mathematically gifted.
The problem solving results proved to be most interesting. Looking at the students' answers and their solution methods told us much about their mathematical ability. To illustrate this point I have chosen two students who have similar test results but very dissimilar problem solving results.

Tof and Dan scored very highly on their standardised tests, gaining 99% and 98% respectively. From their similar high test results we might expect them both to achieve well in the problem solving tests. This was not the case. While Tof gained the highest problem solving score of 95%, Dan only achieved 26%. A close look at the methods these two students used to obtain solutions to the problems yields still more interesting information.

For the second problem Dan tried to find an appropriate algorithm to help him solve this problem. He wrote:

\[
\begin{align*}
50 \\
-28 & \quad \text{Son 22} \\
22 & \quad \text{Father 38} \\
+38 \\
50
\end{align*}
\]

His addition was incorrect for the second algorithm and he reached an incorrect solution. He was not sure how to solve this problem and seems to be 'grabbing at numbers'.

In contrast, Tof wrote:

\[
\begin{align*}
50 \\
-28 & \quad 22 \div 2=11=\text{Son} \\
22 & \quad \text{Dad}=11+28=39
\end{align*}
\]

This is a very clear and appropriate way of solving the problem. Tof understood the nature of the problem and used appropriate strategies to reach a solution. His mathematical understanding is evident in his response.

A similar difference between these two boys' mathematical ability was evident in their solutions to problem six. Dan used a listing strategy but
unfortunately ignored the fact that the coloured lights could not change their position. He labelled the lights r, y, o, b, g. His first five solutions were:

- ryobg
- yobgr
- obgry
- bgryo
- gryob

He then went on to provide combinations using four lights, two lights and one light. His answer was ‘25’.

In comparison, Tof recognised the mathematical nature of this problem and set about solving it appropriately. He wrote:

\[ 2 \times 2 \times 2 \times 2 \times 2 \]
\[ 2^5 = 8 \times 2^2 = 4 \]
\[ 8 \times 4 = 32 - 1 = 31 \text{ workers} \]

He was the only student to get a correct answer on this particularly difficult problem. He recognised the nature of the problem and used appropriate mathematical tools to reach a solution. His solutions have much in common with Krutetskii’s (1976) descriptions of the work of mathematically gifted children.

The wide difference in Tof and Dan’s mathematical abilities was very apparent in their responses to the problems, yet their test results were almost identical. Teachers relying on these test results to identify giftedness would rate these two children as similarly capable and similarly entitled to any extension programme. Their different abilities, as evidenced by their problem solving solutions, would suggest otherwise.

If standardised test results were used as the primary assessment of giftedness, the top 10 students from the 66 students studied would be as shown on Table 1. Note the range of problem results, from a high of 95% percent to a low of 26%. All of the mixed class students with high test results were nominated as mathematically gifted by their teachers. In contrast, the gifted class teacher (myself) did not nominate Dan, even though he had a test result of 99%. Having worked with gifted
children for some years now I relied more on my own judgement of Dan than on his test result when deciding whether or not to nominate him as mathematically gifted. His low problem solving results supported this judgement.

Analysis of the problem solving scores for students with relatively low standardised test result yielded interesting information also. Thp and Rog, who both scored 60% on the standardised test, scored very differently on the problem solving. Thp scored a very low 14% and Rog a much higher 52%. Their solutions showed a marked degree of difference in their mathematical understanding.

Discussion

While information accrues on the characteristics of mathematically gifted students there remains no easy method for their assessment. Teachers faced with a barrage of behaviours to identify and quantify tend to defer to what is straightforward and seemingly defensible in the form of standardised tests. This study sounds a strong note of caution for this practise. Using a score of 90% or more as an identifier of giftedness failed to identify six excellent problem solvers and identified eleven students with low problem solving results. Standardised tests may not be the most appropriate means for assessing giftedness for a variety of reasons. Firstly, the tests may require students to do little more then complete algorithms. This may test a student’s memory and ability to repeat a learned procedure, rather than a student’s mathematical ability. Secondly, the more able students may experience a ceiling effect on sitting a grade level test. They may be capable of high results in tests one or more years ahead of their grade. Grade level tests may mask this. Thirdly, the test used for this study was a multi-choice test.
Whether students guessed the correct answer or whether they understood the questions and used appropriate means to solve them is unclear in such a test. The problem-solving test gave a real insight into the mathematical ability of the students who sat it.

Of the problems used in this assessment, three stood out in discrimination of the top children. Two of these questions involved permutations, including the magazine question above, and one involved probability, both of which are known to be challenging concepts.

It is apparent that standardised tests alone are a poor test of giftedness. A short additional assessment is needed to identify those children in need of extension. Problems similar to those used in this study may provide the appropriate assessment.

STUDENTS' RESPONSES TO A NEW GENERATION ILS ALGEBRA TUTOR

Stephen Norton and Tom J Cooper
Centre for Mathematics and Science Education
Queensland University of Technology, Brisbane, Australia, 4059

This study reports on the quality of discourse between pairs of students and a new generation ILS and uses this discourse to explain some of the successes of such programs. Split image video recordings were analysed to provide a rich set of data. The quality of cognitive scaffolding provided by the ILS and the social discourse that developed between pairs appeared to foster the learning of algebra by some students. The nature of the discourse between the students and the technology and among students differed. For some students the cognitive and social scaffolding was inadequate and resulted in limited time on task. The study has impacts for the role of teachers in classrooms where such technology is the primary stimulus material.

Integrated Learning Systems (ILS) have used computing technology to harness a student model that records and updates histories of individual students, an expert system that models ideal student actions, a pedagogical model that makes teaching decisions, and a graphical interface with input and output devices for interaction to implement traditional methods of teaching and learning, in particular drill and practice and similar behaviourist approaches to teaching and learning (McArthur, Lewis & Bishay, 2000). Such programs generally have well defined goals, such as factual knowledge and/or procedural skills that can be measured on standard tests. The computer-student interactions are usually controlled by the computer: it provides a stimulus, the student responds, it analyses the response and then provides appropriate feedback and further stimuli. Usually the software breaks down the content to be taught into small units, assesses progress, and then moves on to the next unit or provides remedial instruction (Maddux, Johnson, & Willis, 1997).

ILS programs tend to be clean software (Papert, 1993) in that they try to mimic quality instruction by reducing mathematics to formulas describing procedures to manipulate symbols. Because of this, the quality of scaffolding or temporary support provided to students until they can perform the intellectual tasks on their own (Ertmer & Cennamo, 1995) is very important. The software may be ineffective if it does not provide cognitive support for students as they move through their zone of proximal development (Vygotsky, 1987). As well, Salampasis (2000) noted that the additional cognitive load of studying within an electronic medium while learning new work might be beyond some students. He argued that the task of both learning the content and learning how to navigate and learn within a new medium may exceed the working memory capacity of these students and result in disorientation, the inability to cognitively process the material being learnt, and impeded learning (Cooper, 1998).
The ILS. *The Learning Equation* (ITP Nelson, 1998) is an ILS designed to be the major mathematics teaching resource for the first four years of high school. It is a complete course that extended from Years 7 to 10. It is a multimedia environment composed of voice and textual explanations, practice questions (where text cues guided students who make mistakes), summary activities, and self-tests. The software uses a cyclic approach with each of its topic units covered in each of the year levels. Generally, each unit comprises four phases. The first is an application or mathematical modelling situation where the key concept was related to an applied problem. The second is a guided explanation of the concepts and procedures with reference to a problem. That is, the students are lead through the logic behind the concepts and procedures by a series of prompts and explanations. The third phase provides practice questions, word problems and terminology activities to consolidate and extend the knowledge introduced in the initial phases. In this phase, the students can select to see the answer, see a model solution or try a problem of similar structure. The final phase provides a self-test where students are given a selection of the types of questions studied in the lesson unit. The students can see their own responses and view correct solutions with detailed working shown.

Previous studies on *The Learning Equation* indicated improved student performance on standard tests (Bracewell, Breuleux, Laferriere, Benoit & Abdous, 1998; Norton, Cooper, & McRobbie, 2000; Pfaus, 1998). This occurred for both able and less able students (Pfaus, 1998). Students were found to be more actively engaged in activities (Pfaus, 1998) and more involved in discussion (Norton et al., 2000) than in traditional classes. The importance of peer interactions in facilitating student learning when working with technology has been noted previously (Tao, 2000). The students indicated they liked being able to work at their own pace (Pfaus, 1998). Thus, it is apparent that most of the research carried out on the effectiveness of *The Learning Equation* package has endorsed its potential to enhance mathematics teaching and learning and affect.

Norton et al., (2000) put forward two explanations for the improved student cognitive outcomes from use of *The Learning Equation*. The first was that the quality of instruction and scaffolding provided by the ILS’s virtual environment might have effectively mimicked quality instruction. The second was that the classroom discourse was such that socially constructed understanding in the constructivist tradition may have been facilitated.

The aim of the study reported in this paper was to follow up Norton et al., (2000), to examine the interactions of students with the technology and with each other as they worked on the software. The focus was to determine how different students responded to the cognitive scaffolding and the social environment of *The Learning Equation*. It was hoped that examination of these variables might shed light on the apparent success of the software.
Method

Subjects and Contexts. The subjects of this study were 28 Year 9 students (about 14 years of age) in a secondary school of 650 students located in a middle class suburb in the metropolitan area of Brisbane, the capital of Queensland. Of these, a pair of capable boys, a mixed ability pair of girls and a pair of girls who were regarded as average students were purposefully selected using pre-test results for detailed study to illustrate a range of student responses to the software. The class was taught by an experienced mathematics teachers who was regarded as a quality teacher by his peers but whose normal teaching conformed to that described as the “school mathematics tradition” (Gregg, 1995, p. 443).

Data collection methods. The methods used were observation, collection of artefacts, interviews and tests. The student pairs were observed over six lessons and split-screen videotape data (combining feed from the computer with a video) was recorded for two lessons. This enabled the face reactions of the students and their discussions to be superimposed alongside The Learning Equation software screen, showing interactions between the students and the technology. The student pairs were interviewed following the observations. All students were administered pre- and post-tests with respect to algebra achievement. The results of these were reported in Norton et al., (2000). As the focus of this study was to examine students’ response to the The Learning Equation software, the data from these tests are not provided in this paper.

Analysis. A hermeneutic interpretive and naturalistic approach to data analyses was adopted (Denzin & Lincoln, 1994). Information was analysed for commonalities cumulatively across the life of the study.

Results and Analysis

In The Learning Equation class, students sat and worked in pairs at small desks upon which the networked computers were located. Typically, the lessons started with an overview of the tasks to be undertaken that day. On most occasions, the early part of the lesson was also used to model key procedures that students had been required to complete for homework. Interactions between the three pairs and the teacher were very limited. For most of each lesson, students worked almost exclusively on the computers. The classroom was quite noisy.

The three pairs of students recorded divergent responses to The Learning Equation. The capable pair (Malcolm and Brendan) and the mixed ability pair of girls (Michelle and Sarah) achieved good marks in both the operational and structural components (Sfard, 1991) of the post-test after working on the ILS. The performance of Malcolm, Brendan and Sarah was consistent with their previous grades in mathematics, while Michelle’s performance was an improvement upon her previous grades. The third pair (Candice
and Lota) performed poorly after working on *The Learning Equation*. Their results in mathematics in previous tests had been average.

When working on *The learning Equation*, Malcolm and Brendan took turns with the mouse and keyboard to input responses. They initially kept a record of procedures "so you know where you are if you make a mistake, you can go back and do that bit"; however, as the study progressed they ceased this behaviour. They increasingly used mental arithmetic; that is, most "minor" computations, which might involve two or three steps, were carried out without resorting to pencil and paper algorithms. When working with larger numbers the pair resorted to using a hand held scientific calculator, often reading the problem aloud to each other.

If, they made an error, the pair would read and re-read the given information (as evidenced by the movement of the mouse indicator over the screen) and then discuss the possible options. Most often these discussions were very brief and justification was not attempted; it was rare for a discussion to last more than 10 seconds. They would then try an option and see if the input resulted in affirmation from *The Learning Equation* that they were correct. They appeared to operate in small bites of information before trying it out and moving to the next trial. Their comments were typically of the form, "well why don't we try dividing both sides?" After several failed attempts, the pair would cease study and randomly input until the software provided hints and finally the correct answer. Sometimes, they were systematic in using a process of elimination in order to get the correct answer. They systematically tried all probable solutions without an apparent preferred sequence until the software accepted their response. Sometimes the pair discussed why the answer was correct but this was rare. They engaged in reflection only occasionally.

Malcolm and Brendan exhibited clear enjoyment when their work was rewarded with a tick. The immediate feedback seemed to motivate them. Their cognitive time on task was very high, with little off task chat noted on the videotapes. What snippets of off task chat there were seemed to act as mental breaks and did not usually last more than a few seconds. They repeated the self-checks up to three times, trying to improve upon their score. The boys explained, "We want to get that one question we always get wrong right, we kept doing it to get a past." They rarely asked for the assistance of the teacher explaining "he takes too long to get here." Instead they either worked it out themselves, used the cognitive scaffolding provided by the software, or used the feedback facility to cheat the system; they became autonomous learners. They often did not follow the prescribed sequence of activities recommended by the software, but moved about according to their own preferences.

The following is a synthesis of their comments on *The Learning Equation* environment. The paragraph is a joint construct since the boys shared their evaluation of the program.
We would have done better by working with the computers because if your get an error you can go back and re do it. In a normal class, you can not really do that because of the limited number of questions of a particular type. But we work harder in a normal class because a teacher can supervise you all the time. When you work in a pair, it is good because you can sometimes help each other work it out. The problem questions lets you see how the maths is related to the real world better than a textbook. We liked the pictures and how each question is explained. And you get sample solutions and not just the answer like you do with a textbook. We would like to work with the computers again. There is no mathematics teacher we have had that we would prefer over the computer. The teacher should just tell us what units have to be done and then let us do it.

In summary, the boys appreciated: (a) the cooperative working in pairs; (b) the practice examples, the variety of activities and the cognitive scaffolding provided by the ILS; and the medium of delivery (the computer).

Like the boys, Michelle and Sarah shared turns, reduced their quantity of note taking, enjoyed success, and gradually became largely independent of teacher assistance. However, they discussed and argued more than the boys before submitting a response. They also rationalised to each other more frequently. Comments such as the following were frequent while they worked, "How did you get that? ... Well, I just divided both sides by \(x^2\) ... Why does that make sense to you?" When one did not understand, they would try to explain it to each other and, unlike the boys, did not quickly resort to a form of guessing strategy. Comments like, "no you don’t divide you take because the other way is add," were common when they made an error. This seemed to represent a genuine attempt to understand the underlying structures. In summary, their discussions were overtly focused on algebra structure and procedures; they particularly provided a rich discourse in algebra procedures.

Unlike the boys, Michelle and Sarah generally followed the suggested sequence of the program, including most of the examples. The time discussing each question they did not understand meant that they completed fewer questions than the boys had. When the girls had the option of selecting from "try again", "see the answer" or "see a complete solution", they most often selected "see the answer" as a first option and tried to explain the result to each other. After several attempts without understanding, they would select "see a complete solution". When competing the self-checks, the girls operated as a pair and shared the workload so that it was really a learning activity rather than a testing activity.

The following comments represent a summary of their assessment of The Learning Equation.
The program is good, as we went along we got better and worked better together. With the computer you don’t get as bored because you can read the instructions rather than just listening. But when you have a teacher, they can show you to do this step and then this step and I like that kind of teaching and help. We work harder on the computer because we do it together and that helps us to work hard. We also talk a lot more, helping each other, in a normal class we focus more on our individual work. The teacher tells us to “shut up” if we talk. But sometimes on this thing, I get really frustrated because I don’t do well on the self-check. I work so hard and just die when I get poor result on the self-check (Michelle). However, if the teacher is really good at explaining then I would prefer to work in a normal class.

Overall the impression was that, like the pair of boys, the girls had formed an efficient symbiotic relationship helping each other with their learning. They placed greater emphasis on the importance of cooperative work and discussing than the boys, and they had some complaints about the cognitive scaffolding provided by the software. They felt that there was not enough information to enable them to understand the procedures. Like the boys, they appreciated the variety of work and stimulus media; but, unlike the boys, they felt that the program encouraged them to work harder than in a traditional class.

The third pair, Candice and Lota, had a poor attitude towards The Learning Equation. Initially, they were non-committed, but they gradually grew hostile toward the software and trying to learn from it. This process started in the first lesson when they had trouble logging on. Three lessons later they were still having problems. It seemed a case of “Murphy’s law”; technical “hitches” seemed to plague them. The girls quickly developed anger toward the technology and resented using it. They complained that the structure supplied “was not detailed enough and did not make it clear what had to be done”. This was particularly so when procedures required more than one step, a frequent occurrence for the ILS. They resisted using pencil and paper even when encouraged to do so.

Candice and Lota appeared to require higher teacher input and supervision than the other two pairs, both in terms of behaviour and mathematics, in order to work with the ILS. The teacher continually exhorted them to “work”. They would not use their calculators unless told to get them out, they would not begin work until told which activities to work on, and they would continue repeating old work unless told to move on to new section. In order to progress through the mathematics activities, these girls frequently typed in random letters and the answer was provided by the technology, sometimes as a first option. Often the girls did not process the data nor did they read the explanations provided, but simply progressed to the next task. The girls constantly complained that The Learning Equation was “too complicated”. Arithmetic problems, particularly
dividing and multiplying by fractions, constantly thwarted the girls and made it difficult for them to complete the algebra. The girls' response to frustration was to put their hands up for teacher help. Often this was not forthcoming, so the girls went off task, discussed social issues, and distracted other pairs of students. Their attitude was summed up simply, "we hate it, it does not explain like a teacher ... it is too much for our brains and it aggravates us!". Both girls wanted to return to a classroom where a teacher taught the mathematics. They believed they would get more encouragement and better explanations from a teacher than from The Learning Equation.

Analysis

The cognitive time on task for the successful pairs of girls and boys was high and their knowledge of the operations and structures of algebra improved. Both pairs commented that the cognitive scaffolding provided by The Learning Equation was a positive factor. They liked particularly that every question was explained, and that explanations "showed you this step then this step". They also believed that the paired interaction with the program was beneficial. As was stated, "you can sometimes help each other work it out", and "we work harder because we do it together".

The boys used a form of "immersion" in order to learn to do the problems. This included guessing and doing the self-checks repeatedly until they achieved mastery. However, while the boys progressed in their structural knowledge of algebra (as tested by word problems), their discussions did not reflect a structural orientation. Michelle and Sarah differed from Malcolm and Brendan in that the social aspect of the cooperative learning process was much more important and pronounced in their behaviour. As well, their discussions showed that they tried to understand the structures of problems.

For Malcolm, Brenda, Michelle and Sarah, the cognitive and social scaffolding provided by The Learning Equation was sufficient to foster a quality-learning environment. However, for Candice and Lota, the combination of mastering a new instructional medium and new mathematical content provided a cognitive load that was beyond them; they had cognitive overload. They found the cognitive scaffolding of the ILS inadequate; as a pair, they could not provide each other with the support they each needed. These factors together with the limited intervention of the teacher in both the cognitive and social domain resulted in them spending limited time on task and little movement within their zone of proximal development. Both girls exhibited a hostile attitude towards the ILS, technology in general, and mathematics; and they learnt very little algebra from The Learning Equation.

Implications

The study provides evidence that when well-structured ILS programs are used with pairs, the cognitive scaffolding of the ILS can combine with the social discourse that
develops between students to promote learning (in this case, learning of algebra operations and structures). However, this success is not uniform. Different pairs may adopt quite different discourses with the software and each other, and this may be gender based. Some students, particularly those with lesser mathematical background and a greater need for teacher intervention and direction, may well show limited cognitive progress and exhibit negative attitudes to the technology and mathematics. For such students, the role of the teacher remains critical.

INSIGHTS INTO CHILDREN'S RULER CONCEPTS – GRADE-2-STUDENTS’ CONCEPTIONS AND KNOWLEDGE OF LENGTH MEASUREMENT AND PATHS OF DEVELOPMENT

MARCUS NÜHRENBÖRGER, University of Münster, Germany

The paper is concerned with the qualitative investigation of pre- and postconceptual knowledge of grade-2-students with respect to their ruler concepts. The analysis of children's drawings of rulers, their supporting explanations and their ruler techniques indicates that they have already constructed ruler concepts with different ways of understanding of the key measuring aspects prior to formal instruction. Their ruler concepts frequently exceed an instrumental understanding of linear measurement. However, some children interpret measuring in a familiar arithmetical framework simply as counting even after measurement has been formally introduced.

THEORETICAL BACKGROUND

We owe the understanding of the development of children's length concepts primarily to the work of Piaget, who is widely recognized as the pioneer of research on measurement (PIAGET et al. 1974). He showed that the concept of length measurement depends on the comprehension of the construction and co-ordination of linear units. The process of linear measurement requires the ability of integrating space and number concepts in an idea of iterative, dividable and countable units. This idea is based on knowledge and conceptions of units and numbers and their integration into the process of linear measuring (BOULTON-LEWIS et al. 1996, HIEBERT 1984, NUNES et al. 1993).

Length concepts are an important part of elementary mathematics education. The introduction of length is the first formal measurement process to be taught and provides the basis for more sophisticated measurement concepts such as area or volume. Traditionally, the introduction of magnitudes such as length follows an instruction sequence (German: „didaktische Stufenfolge“). This instruction implies that children develop and use informal units, prior to the use of standard units and conventional measurement instruments. The underlying goal of this approach is that children on the one hand recognize the relationship between the one-dimensionality of length and the single countable objects and on the other hand realize the necessity of standard units (OSBORNE & WILSON 1992; RADATZ et al. 1998).

However, the iterative use of informal units requires above all the competence of counting and the accurate joining of objects. Students may not pay attention to the length of the objects nor consider them as units (HIEBERT 1984). The neglect of these aspects during formal instruction may explain why fourth and fifth graders frequently demonstrate insufficient knowledge and misconceptions of length units (CARPENTER et al. 1988; GRUND 1992). An increasing number of publications in the last decade questions the traditional sequential introduction of length (AINLEY 1991, BOULTON-LEWIS et al. 1996, BRAGG & OUTHRED 2000, NUNES et al. 1993). Recent studies indicate that students have already had experiences with culturally developed tools of length measurement in everyday life, e.g. with a ruler or a folding-rule. Even if classroom instruction is based on the use of informal units, students of all grades tend
to compare visually or use their everyday measuring skills rather than using informal units (BOULTON-LEWIS et al. 1996, NUNES et al. 1993). A ruler has not only a concrete relation to the reference context of measuring but also a theoretical relation to the representation of the measurement process. It involves mathematical figures and presents an iconic illustration of structural connections between conventional units and numbers (STEINBRING 1993). BRAGG & OUTHRED (2000) as well as HIEBERT (1984) emphasize that many students are able to use a ruler for measuring and have mechanical knowledge about reading and using the ruler scale. But most of them obviously have only a poor understanding of the measurement process. They don’t know more „than rules about rulers“ (BRAGG & OUTHRED 2000, 97).

According to the „moderate-constructivist“ view, children do not simply accept everyday practices or phenomena in a passive way but rather construct subjectively significant concepts in an active-ideoosyncratic way in interaction with their environment (GERSTENMAIER & MANDL 1995). Hence, by using a ruler children construct individual understanding of length measuring and develop ideoosyncratic concepts regarding the construction and co-ordination of marks, spaces and numbers. Therefore, students’ ruler concepts imply on the one hand their measuring and drawing skills and on the other hand their understanding of the concepts underlying these procedures, i.e. their knowledge and conception of the relationship between the measurement of length and the numberline represented on a ruler scale.

In this paper the following questions with respect to the conceptual ruler knowledge of children will be investigated: In how far do grade-2-students focus on the represented key aspects of linear measuring (the structural connections between linear units and numbers) when they use a ruler? In how far do they interpret these symbols as a representation of measuring system?

**Methodology**

The qualitative longitudinal study underlying this paper is concerned with the investigation of the development of length measurement concepts of grade-2-students. 12 children from an urban school in Münster were selected as case study children according to their performance in a pretest about their knowledge of length and their teacher’s assessment of their mathematical abilities and performances. This process led to the selection of two girls and two boys in the following three categories: low, average and high achievers. These children were interviewed shortly before the formal sequential introduction of the magnitude „length“ (pre-interview), a week as well as six months after this unit (1st and 2nd post-interview). The interview tasks were designed to include a variety of components of length measurement in different contexts. Instead of paper-pencil-tests practical tasks were chosen because of their correspondence to measuring in a real life context and to facilitate the use of conventional measurement tools and objects. The half-standardized interviews were evaluated following the „interpretative paradigm“ (BECK & MAIER 1993). The interview episodes referred to in this paper address iconic and verbal ruler representations and the techniques of ruler use.
Table 1: Questions to the ruler concepts

RESULTS AND DISCUSSION

The focus of analysis in this paper is on the ruler pictures, because they provide iconic evidences of the interpretations of the structural relations of measuring. When children draw an object or a phenomenon they consciously turn their attention to their rather vague mental images, organize their knowledge about the use and construction of the object and focus on the significant subjective structural characteristics (Biest 1991). Both, the ruler pictures, which are supported by verbal explanations, and the ruler techniques open a window in the students’ world of ruler concept.

In this paper, the paths of development of ruler pictures are described and analyzed.

Ruler pictures: All the interviewed students were able to construct ruler pictures and to emphasize significant subjective key characteristics of the ruler scale. Their ruler pictures can be assigned to one of four types of drawings which result from the construction and co-ordination of numbers and marks (Nührenbörger, in press):

Table 2: Examples of types of ruler pictures with different chief characteristics
A Number-Ruler is characterized by numbers following the counting sequence from left to right and starting with the first counting number „1“ (if children started with „0“ they showed a deeper relation to the measurement scale). Children who drew these pictures consider numbers to be a subjective dominant and significant aspect of a ruler. They interpreted the measurement scale on the basis of their arithmetical and counting skills; that means that they connected the linearly ordered numbers of a ruler with their conceptions of numbers. This seems obvious because in general, numbers are mentally internalised in an intuitive way as a numberline from left to right. Children drew pictures of Number-Ruler merely in the pre-interview.

Most of the students drew marks and numbers which indicates that they have understood the marks to be a key aspect of the measurement scale. The Number-Intermarks-Ruler only has marks between the numbers without any visible subdivision into equal units. The marks rather seem to be an insignificant element which decorates the ruler. However, marks had a characteristic signification for the children so that some subjectively important marks were counted and noted in the familiar arithmetical context. The intervals between the numbers were constantly equal because the marks were counted and noted rhythmically. But it may be possible that the students have perceived a „conventional concept of equal intervals“ (PETITTO 1990, 71). They recognized that rulers usually have equal intervals, but could not explain their structural significance in connection with conventional units.

If children drew marks together with numbers as a visible iterated unit they drew a Number-Mark-Ruler. On the one hand this ruler picture shows again an arithmetical interpretation of the ruler as a numberline. But on the other hand the role of zero and especially the spatial distribution of numbers and marks indicate an already promising anchor of the interpretation of centimetre as a dividable unit. Some students counted a certain quantity of marks (or intervals) and consequently wrote numbers in an appropriate counting sequence. Few of the pictures show individual „sense constructions“ regarding the unit subdivision presented on the scale.

Students’ drawings of Unit-Rulers contained a connection between number and space concept which led to the idea of an iterated and subdivided unit. The students showed different facets of understanding of units, both for equal intervals and for rules of subdivisions. While one student drew only a double subdivision with irregular intervals, others drew a ruler picture containing a tenfold subdivision and equal intervals. The starting point of the ruler scale was particularly important. A ruler beginning with „0“ or starting right at the edge shows that the drawer recognizes that „1“ represents the first line segment. In contrast, a ruler with the starting point „1“ indicates an orientation on the sequence of number words. But they do not automatically exclude a deeper understanding of measurement, e.g. one student called his ruler picture with starting point „1“ a „one-minus-subtraction-ruler“.

**Paths of development of the ruler pictures:** The relative small sample of 12 students already demonstrates the diversity of children’s ruler concepts with respect to their
drawings prior to formal instruction (see Table 3). It is remarkable, that four students
drew an Unit-Ruler, one of them even with a tenfold subdivision.

| Unit-Ruler with          | - tenfold subdivision  
|                         | - fivefold subdivision  
|                         | - different subdivision  
|                         | - double subdivision    
| Number-Mark-Ruler with   | - fivefold/tenfold subdivision 
|                         | - steps of two or five  
|                         | - steps of one          
| Number-Intermarks-Ruler with | - three/four/five intermarks  
|                         | - one intermark         
| Number-Ruler             |                           

Table 3: Paths of development of the ruler pictures

The development of the ruler pictures indicates a growing orientation towards the structural construction of the measurement scale. From the pre-interview to the first post-interview two different paths of development can be recognized:
- from the Number-Ruler to the Number-Intermarks-Ruler and
- from the other three ruler types to the Unit-Ruler with a fivefold subdivision.

It is remarkable that even directly after the measurement unit none of the students was able to draw a correct ruler and that three ruler pictures still referred to an arithmetical number concept. The analysis of the second post-interview shows that the majority of children developed further structural understanding of rulers in the absence of formal instruction. For example, two students show a development path from a fivefold subdivision Unit-Ruler to a tenfold one, while two other students still drew the less sophisticated Number-Intermarks-Ruler.

**Verbal explanations:** The explanations of the students about their ruler pictures contained key words according to the numbers and marks which generally describe a measurement or arithmetic context. Only a few students did not refer to any content.

The interpretation of numbers and marks as units such as metre or centimetre indicated an anchor of measurement understanding. Few students already knew at the beginning of grade-2 that a ruler represents two different, but connected units. Other students saw an interval between two numbers (or „two long marks”) as a basic iterable unit called centimetre without knowing that there is also another subdivided unit. Those children were merely able to use a unit for repeated counting. However, few of them were able to construct an explanation of the gaps between the marks that demonstrates „measurement sense“ - they interpreted the interval as a „distance-holder“ or as a unit which occasionally is also called centimetre. Some children used terms such as metre or centimetre without any unit concepts. They either interpreted marks as „number stations“ or they were unable to explain them. In a sense these terms played the role of a „number companion“ which refer to length.

Few students were not at all able to express insights („measurement sense”) with respect to the construction of the formal scale. They only explained the symbols on a ruler in a number and counting context or in a verifying-conventional way.

**Measuring and drawing with the ruler:** Nearly all students were able to use a ruler correctly for drawing centimetres. They aligned the lines with zero or back from the number to zero. Most the case study children were even able to construct a millimetre concept although millimetres are only taught in grade-3. While few students aligned millimetres correctly and utilized the references between one centimetre and ten millimetres, others interpreted the measurement scale in an idiosyncratic way - they explained e.g. a line of two millimetres as following: „Up to ten, because one millimetre is up to five“ or „up to the second longer mark“ or „up to the longer mark just before the number two“ or „up to two“. These creative „sense constructions“ indicated subjective interpretations of the relations between numbers and marks on the formal scale. But they showed on the other hand that some students have a poor understanding of subdivision - they only knew the „number-unit“ centimetre.

In contrast to the skills of drawing centimetres with a ruler, many students, even some who drew a ruler with starting point „0“, had problems with measuring an object because they were not sure about ruler alignment: „Should we align a ruler with the scale or with the other side - with the edge, with zero or with one?“
The procedure of ruler alignment was not a stable one; many students varying their procedure with regard to the situation: Although they were able to identify the length of an object as the difference between its starting and end point on the ruler, they sometimes did not pay attention to how they aligned the object with "0". Dominating for them was obviously the result of the measurement solution, because they tried to place the ruler next to an object in a way that the end of the object was marked by a number and not by an intermark. It seems that they followed an inaccurate mechanical procedure without taking into consideration what the intervals and the numbers on the ruler scale represent.

CONCLUSION

The analysis of the ruler concepts suggests that children at the beginning of grade-2 already have a subjective understanding of the measurement scale represented on a ruler. Their ruler pictures in particular demonstrate that students are able to imagine a ruler and to perceive key aspects of measuring. Their everyday experiences with measurement not only promote an intuitive approach to the technical use of rulers, but also influence the development of individual ruler concepts. These concepts vary among children and change in different paths within a schoolyear.

However, the diverse representations of characteristic features of rulers, does not necessarily indicate an elaborate understanding of the relations between linear units and the measurement scale. Although students are able to use a ruler in measurement situations, they often do not possess structured insights into the construction and coordination of units. They connect instead their imagination of measuring with their number concept and interpret some of the measuring aspects in the context of their arithmetical understanding of numbers and counting. Their use of a ruler is based on rules, which merely refer to the application and reading of numbers. Therefore children do not have problems with drawing and (partly) measuring. This differentiated perspective on ruler concepts supports and elaborates on earlier findings of HIEBERT (1984) and BRAGG & OUTHRED (2000).

The current research results suggest that the traditional formal introduction of length with non-conventional units might not help students to develop an elaborated concept of linear measuring, because it does not allow them to make connections to their previous everyday measurement experiences with conventional tools. Instead, dealing with (mainly three-dimensional) informal units obscures the linear nature of the unit of measure and the children interpret measuring with informal units in a familiar arithmetical framework simply as counting. Hence, students cannot visualize the measuring process as a composition of linear units. "Neither zero nor the iteration of line segments can be made explicit when informal units themselves are counted, thus reducing the possibility that students are able to make the important link with the underlying linear unit concept" (BRAGG & OUTHRED 2000, 103). NUNES et al. (1993, 53) emphasized that "relying on conventional units, which have already been chosen and built into an instrument, does not make measurement more difficult." This study has shown that grade-2-students have idiosyncratic anchor imagination of centimetre
and millimetre. Their everyday knowledge about the ruler scale and their skills of the ruler use should serve as a starting point for formal instruction and guide the development of an elaborated length concept. A sophisticated understanding of measurement requires both, „hands-on“ measuring activities with rulers and especially discussions and reflections about the key aspects of measuring repeatedly stimulated and encouraged by the teacher. The comparison and analysis of individual ruler pictures of the children in the classroom for example can help the teacher to identify their „pre-conceptions“ and also foster such a discussion and reflection.

RESEARCH REPORTS
Connecting Partitioning and Iterating: A Path to Improper Fractions

John Olive

The University of Georgia

In this paper I illustrate how an approach to establishing fractions based on a child's multiplicative relations among whole numbers provided one child (Joe) with both affordances and constraints for constructing meaning for both common and improper fractions. Joe established "one third" of a composite number as that number which, when multiplied by three, will give the composite number. In the computer microworld TIMA: Sticks, Joe modeled this multiplicative approach by finding a stick that he could repeat three times to equal the given "number-stick." The Sticks environment provided a venue for Joe to construct unit fractions as "repeatable connected numbers." In order to construct non-unit (common) fractions and (eventually) improper fractions, Joe had to connect this multiplicative approach to fractions with his part-of-whole view of a fraction.

Understanding fractions greater than the whole (improper fractions) has been a stumbling block for many children (Olive, 1999, Tzur, 1999). A major obstacle to their understanding stems from the over-emphasis in curricular materials on representing fractional quantities as the number of parts shaded of a partitioned figure. Interpreting 3/5 solely as "three parts shaded out of five parts total" provides no means for making sense of 7/5. A junior in college once complained to me "How can you have seven fifths of something?" when faced with the following problem (referring to a long thin rectangle on the test page): This bar is 7/5 of another bar. Draw the other bar. She was blocked by her part-in-whole interpretation of a fraction. She could not imagine the given bar as seven of five equal parts of another bar.

The research reported in this paper is part of an on-going retrospective analysis of videotaped data from a three-year constructivist teaching experiment with 12 children (Steffe & Olive, 1990; Steffe, 1998). The major hypothesis to be tested in the teaching experiment was that children could (and should) reorganize their whole number knowledge in order to build schemes for working with fractional quantities and numbers (the rational numbers of arithmetic) in meaningful ways. This reorganization hypothesis (Olive, 1999) contrasted with the prevailing assumption that whole number knowledge is a "barrier" or "interferes" with rational number knowledge (Behr et al., 1984; Streefland, 1993; Lamon, 1999).

Description of the Teaching Experiment

A team of teacher/researchers, led by Steffe and Olive, worked with the children, primarily in pairs, outside of the classroom once a week for approximately 20 weeks a year for three years. All teaching episodes were videotaped. Computer microworlds called Tools for Interactive Mathematical Activity (TIMA) (Biddlecomb, 1994; Olive & Steffe, 1994; Olive, 2000) were specifically designed for the teaching experiment. The TIMA provide young children with possibilities for enacting their mathematical operations with whole numbers and fractions. They also provide the teacher/researcher with opportunities to provoke perturbations in the children's mathematical schemes and observe the children's mathematical thinking in action.
We began working with Joe during his third grade year. Joe is an African-American student who was often in trouble with his classroom teacher. Our emphasis during the first year was on investigating the children's whole number multiplicative operations. We determined that, by the end of the first year, Joe had constructed an explicitly nested number sequence (Steffe & Cobb, 1988; Steffe, 1992). A hallmark of the explicitly nested number sequence (ENS) is the construction of composite units (units of units) that are necessary for multiplicative operations (Steffe, 1992). In a series of activities that we designed on the computer using the TIMA: Toys microworld, Joe was able to find how many (hidden) cookies would result from baking three trays of cookies, each tray having 7 hidden cookies, using his multiplication facts. He was also able to determine, however, that when he had 7 trays of cookies (a total of 49 hidden cookies), he would need to bake three more trays in order to have a total of 70 cookies. He was able to work with the difference of 70 and 49 as three units of seven because he knew that 70 was ten sevens.

The Construction of Fractions as Repeated Connected Numbers

For the first half of the second year of the project Joe worked without a student partner with a teacher/researcher, Azita (a doctoral student working with the project). The focus during this period was on using the children's whole number structures and operations in situations that we would regard as involving continuous quantities. Most of the activities took place in the computer microworld TIMA: Sticks. The manipulatives in this microworld were horizontal line segments that we called "sticks." Sticks were created by the child dragging the computer mouse across the screen. Thus the extent of a stick was the result of a deliberate motion on the part of the child. Sticks could be copied, joined together to form longer sticks (with vertical marks indicating each of the sticks that were joined), marked with vertical tick marks, partitioned into equal parts using a numeric indicator for the number of parts, and broken into separate, smaller sticks determined by the marks or parts created in the stick. Pieces could also be cut off of a stick using a mouse click. Any stick could be measured with reference to any other stick that had been designated as a measuring unit. The measure would appear as a ratio fraction or whole number. Sticks on the computer screen could be hidden from view by rectangular regions called "covers."

Through the activities with TIMA: Sticks Joe was able to use his composite units to construct what Steffe and Wiegel (1994) have called a connected number. Connected numbers are constructed by a child mentally projecting his/her concept of a whole number (e.g. eight) into an unmarked line segment to establish an "interiorized continuous but segmented unit" as a situation of the child's number sequence (p.121). This connected number 8 (say) would contain within it an implicit nesting of the number sequence from 1 to 8, and the sense of those 8 units being united into one composite unit. Connected numbers carry with them a notion of number as indicating relative size (length). Children were able to instantiate connected numbers in TIMA: Sticks by creating what we refer to as number-sticks --that is sticks created from joined repetitions (iterations) of an established unit stick. Number-sticks were referred to by
their number-name. That is, a stick created from 8 repetitions of a unit stick would be called an 8-stick.

The following protocol illustrates how Joe (J) and Azita (A) used activities with number-sticks to establish fractions as \textit{repeated connected numbers}. For instance, one third of a 24-stick is that stick, which repeated three times, will make a 24-stick. This approach to fractions of composite wholes provided Joe with the opportunity of using his whole number multiplication scheme (\textit{a composite units-coordinating scheme}) to find the appropriate stick. This teaching episode took place in the fall of Joe's fourth grade year, the second year of the Project. A set of number-sticks had been constructed at the top of the playground area of the computer screen, separated by a long thin cover that stretched across the full width of the screen (see Figure 1). Sticks created by repeating or joining copies of sticks from this set of number-sticks were also named as number-sticks (e.g. a stick created from 4 repetitions of the 6-stick was a 24-stick)

![Figure 1: A set of Number-Sticks in TIMA: Sticks](image)

**Protocol I**

While Joe has his eyes closed, Azita makes a 24-stick below the cover using repetitions of a copy of one of the sticks above the cover and erases the marks from her 24-stick.

A: \textit{The stick that I used was one third of the length of the stick I have right here} (pointing to the unmarked 24-stick).

Joe measures the stick (24 appears in the number box). He then smiles to himself and counts down the set of the number sticks ending on the 8-stick. He copies this stick and repeats it 3 times to make a stick the same length as the 24-stick.

A: \textit{That is right!}

J: \textit{You said one third, so what will be...three times eight is 24.}

Azita suggests doing more problems with the 24-stick. Joe wants to use a 21-stick but Azita asks him to do one more with the 24-stick.

A: \textit{Think of a stick you could use to make the 24-stick and tell me what fractional part of the 24-stick it would be, and I will try to tell you what size stick it is and how many times I should use it.}

J: \textit{Close your eyes.}

Joe trashes the 3-part stick and looks at the set of number sticks.

J: \textit{O.K. I didn't have to do nothing.}

J: \textit{It's umm... It's one sixth.}

A: \textit{The stick that you used is one sixth of the 24 stick?} (Joe nods his head.)

A: \textit{So, I want something, I want a stick that when I repeat it six times would give me...}

J: \textit{No!}

A: \textit{Would give me the 24..}
J: One fourth! (at the same time as Azita is speaking).
A: Oh! You used the one-fourth stick? (Joe nods yes.)
A: You used one-fourth, so I want a stick that when I repeat it 4 times will give me the 24, and I think that is the 6-stick! What do you think? (Joe nods yes.)

Azita copies the 6-stick and repeats it 4 times to make a stick the same as the 24-stick.

Joe knew to use the 8-stick for 1/3 of the 24-stick because "three times eight is 24." I regard this as a modification of Joe's composite units-coordinating scheme (a multiplication scheme) whereby Joe could coordinate the elements of one composite unit (3) with the elements of another composite unit (8) to produce the target number 24. Repeating the 8-stick three times to match the 24-stick was an enactment of this coordination. Joe's interpretation of "one third" as something that when multiplied by 3 gave the total number, was a novel application of his units-coordinating scheme. Joe's strategy supports the major hypothesis of the project: that fractions could emerge from such modifications of the children's whole number schemes (Steffe and Olive, 1990; Olive, 1999; Olive, 2000).

Joe's realization that he did not have to do anything in order to pose the problem for Azita (as the unmarked 24-stick was still visible on the screen) indicates that he was able to imagine himself acting within the microworld. According to von Glasersfeld (1981), such imagined actions are critical, as it is through re-presenting mentally their actions that children construct their numerical operations. Joe hesitated in naming the fraction when posing his problem for Azita. I suggest that he was trying to hold both the imagined stick in his head and the number of times he would have to use it. Joe ended up using the stick-size to generate a name for the fraction rather than the number of times he would have to use that stick. Joe realized his mistake as soon as Azita voiced her interpretation of 1/6. Azita's explicit use of fractional language to describe her imitation of Joe's actions in TIMA: Sticks provoked a reflection by Joe on what he had imagined, and provided scaffolding for making sense of the fractional terms. He corrected his error rather than going with it and accepting Azita's actions. This indicates that Joe could generate his result prior to action through both numerical calculation and visualized action. It is in this sense that Joe was constructing meaning for unit fractions as repeated connected numbers.

Connecting Partitioning, Segmenting and Numerical Operations

While this approach to unit fractions of composite wholes was productive for Joe, it had limitations that stemmed from its attachment to known multiplication facts. In the continuation of the teaching episode in Protocol I, Joe successfully identified the 4-stick as 1/7 of the 28-stick, but when asked by Azita what fraction of the 28-stick two 4-sticks joined together would be, Joe responded with "One fourteenth...because you add one seventh and another seventh it makes 14." Streefland (1993) refers to such errors as N-distractors (miss-application of whole-number arithmetic to a fraction situation). Unit fractions were results of numerical operations at this point for Joe; they were not yet quantities that could be united.
Joe had difficulty with making equal portions of a stick in sharing situations. His visual estimates for sharing a stick into three or four equal portions were not very accurate. Rather than making a mental partition of the stick into 4 equal parts, and indicating this partition by placing three marks on a stick, he would draw an estimate for 1/4 of the stick and repeat this estimate 4 times to see if it matched the stick. In the teaching episode following the one above, we attempted to provoke Joe's partitioning operations by asking him to make fractions of a number-stick for which there was no available number-stick (e.g. make a stick that is 1/4 of a 27-stick). Our hypothesis was that, without a known multiplication fact to solve the problem numerically, Joe would need to mentally partition the 27-stick in order to make a reasonable estimate for 1/4 of the stick.

Joe had created the 27-stick by repeating an unmarked 9-stick three times. The screen display consisted of a set of number sticks as in Figure 1 (above). The 3-part 27-stick and an unmarked copy of this 27-stick. Joe's first estimate was approximately half the length of a 9-stick. He repeated this estimate four times to create a stick approximately the same as 2/3 of the 27-stick. His next estimate was approximately the same as a 9-stick. He only repeated this stick three times and then trashed it. He adjusted these estimates, gradually getting closer to a visual approximation for 1/4 of the 27-stick. He did not use his whole number multiplication facts to help with choosing an initial estimate (e.g. a 7-stick might work as 4 times 7 is 28 -- a fact he had used in the previous episode to find 1/7 of 28). There was little indication that Joe was mentally partitioning the target stick (unmarked 27-stick) to gauge his estimates for 1/4 of the stick. He appeared to be attempting to segment the unmarked stick with his estimate and adjusting his estimate until the segmentation worked. In the continuation of this teaching episode, however, Joe did use his multiplicative relations to make an estimate for a stick that would be 1/7 of a mystery stick that had been drawn freehand on the screen. He saw that a 2-stick, repeated 7 times was approximately 2/3 of the unknown stick. He made a second guess that the 3-stick would be 1/7 of the mystery stick because "It's about 27. 21, I mean." Azita continued using the 2-stick Joe had originally chosen, creating 10 repetitions to make a stick that was about one unit stick short of the target stick. Joe confirmed that he was thinking of the mystery stick as a 21-stick when he then exclaimed "21! That's what I said!" and that the 3-stick would be 1/7 of the 21-stick because "If you use 3 seven times you might get 21."

This last task may have provoked a connection of Joe's partitioning operations with his segmenting approach to unit fractions. He could imagine seven of something being equal to the unknown stick. This relation had to be imagined as a visual partition of the unknown stick, because he had no whole number to operate with. Thus, Joe's mental partitioning operations were activated. Joe was then able to make a connection between his numerical strategy for finding a unit-fraction (find the missing factor) and his equi-partitioning scheme by estimating a numerical value for the length of the unknown stick.
Confirmation for this possible connection between Joe's numerical strategies and his partitioning operations came in the next teaching episode. Joe accurately chose a stick that was 1/5 of a target stick where no numerical values were known. Four sticks and the unknown target stick were arranged on the screen as shown in Figure 2.

![Figure 2: Which stick is 1/5 of the dark blue stick?](image)

Joe copied the second of the four upper sticks below the lower target stick and repeated it 5 times to make a stick that matched the target. In order to have quickly chosen the correct stick, I hypothesize that he made a mental partition of the target stick. Later in this episode, Joe found 1/3 of the target stick (the third upper stick). Azita asked him to make a stick twice as long as this 1/3-stick. Joe did so by repeating the 1/3-stick. When asked what fraction of the target stick this repeated 1/3-stick would be, Joe at first compared it to the longest stick in the top row of sticks. He said this last stick was a bit shorter than his stick. When pressed for a fraction name he called his stick "two thirds" of the target stick. He also called three repetitions of the 1/3-stick a "whole stick" and "three thirds." He had established the inverse relation between a part and a whole that paralleled his numerical approach: What number multiplied by 3 will give me the whole? Further along in this same episode Joe was able to link a part-in-whole view of 5/11 with his multiplicative view of a stick that was "five times as long as the 1/11-stick." He justified calling his five repetitions of the 1/11-stick "Five elevenths!" "Because its 5 and its part of 11." He was able to project the stick that was the same as 5 parts out of the 11 (a disembedded stick) back into the 11/11-stick. He was now able to combine unit fractions into composite parts of a whole through iteration. Joe was beginning to connect partitioning of a unit whole with the generation of both unit and non-unit (common) fractions. We refer to Joe's fractional scheme at this point in the teaching experiment as a partitive unit fractional scheme.

From Common Fractions to Improper Fractions through Iteration of Unit Fractions

The last teaching episode described above occurred just before the winter break in December of Joe's fourth grade year. In the next teaching episode (that took place after the winter break in February) Joe extended his fractional scheme into a partitive fractional scheme for common fractions. He was then able to generate improper fractions such as 6/5 and 9/7 through iteration of unit fractions. This was the beginning of Joe's Iterative Unit Fractional Scheme.

Protocol II begins after Joe had created 3/5 and 4/5 of a 5-part stick by drawing sticks that were the same length as 3 and 4 parts of the stick respectively. The 5-part unit stick, 3/5-stick and a unit stick with one mark 4/5 the way along the stick.
Protocol II

A: *That's really neat! Now I'm really hungry. I want you to make me another one. I want you to make me 6/5 of that candy (meaning the unit stick).*

J: *Can't!*

A: *Why not?*

J: *You only got 5 of them.*

A: *Five what?*

J: *Fifths.*

A: *You only got 5 fifths. So is there any way of making one, do you think?*

J: *Make a bigger stick.*

A: *Make a bigger stick. How much bigger do you think it should be?*

J: *One more fifth.*

A: *O.K. Do you want to show me?*

Joe pulls the end part out of the original stick that has a mark at the 4/5 position only, and joins this one piece to the original stick to make a stick one fifth larger than the original.

Joe was using his partitive fractional scheme to make 3/5 and 4/5 of the unit candy stick. What is important about the above protocol is how Joe was able to interpret Azita's request for 6/5 of the candy as being one more fifth than the whole bar. This was a possibility for Joe because his partitive fractional scheme included unit fractions as repeatable units. Thus 6/5 was six of one fifth, which was one more fifth than the whole stick. Joe was not constrained by a *part-in-whole* restricted view of fractions as were some of my college students! In Protocol III (later in the same teaching episode), Joe confirms that he can now create fractions greater than the whole through iteration of a unit fraction. Joe had successfully estimated 1/7 of a candy stick and had used his estimate to mark off all seven 7ths on the original candy stick. He had then pulled out 4/7 of the candy stick to give to Dr. Steffe.

Protocol III

A: *Can you make a stick that is...say 9 times as long as the one...seventh stick (points to the first part of the 7/7-stick)?*

Joe cuts off the first part of the 4/7-stick. He accidentally cuts this part again so he joins it back together and erases the resulting mark. He then repeats this 1/7-stick 9 times to make a 9-part stick.

A: *How long is that stick? (Joe thinks for 3 seconds.)*

J: *Nine sevenths.*

A: *Why? (Joe thinks for 15 seconds.)*

A: *You are right. It is 9/7 but why do you think it is 9/7?*

J: *Because it was...you were making these the sevenths (pointing to the parts of the 9-stick) so each of these would be one seventh.*

A: *That's really nice!*

In this last episode, Joe was able to work with a fraction as both a part of a whole (the 3/5 and the 4/7) and a unit part *out of a whole*. In repeating a 1/7-stick 9 times to make a stick 9 times as long as 1/7 of the original whole stick, Joe was able to go beyond the whole, and name the resulting stick as nine sevenths "because...you were
making the sevenths, so each of these would be one seventh”. In this sense Joe had taken the 1/7-stick as an iterable one to generate a composite unit of 9, each one of the 9 units being 1/7 of his 7/7-stick. These operations suggest that Joe had not only constructed a partitive fractional scheme (for generating common fractions) but was on his way to developing an iterative unit fractional scheme for generating improper fractions.

Conclusions

The sequence of episodes with Joe, described in this paper, indicate how powerful a child's thinking about fractions can become when it builds from his numerical schemes and operations, assisted by appropriate language scaffolding by a sensitive teacher. They also indicate the role that both partitioning and iterating operations play in constructing fractions greater than the whole. The affordances created through Joe's use of TIMA: Sticks were also important factors in Joe's construction of improper fractions. Being able to make a stick that is "9 times as long as the 1/7-stick" through repetitions of a 1/7-stick provided Joe with an instantiation of his iterable unit fraction.

MEASURES IN CABRI AS A BRIDGE BETWEEN PERCEPTION AND THEORY

Federica Olivero, Graduate School of Education, University of Bristol
Ornella Robutti, Dipartimento di Matematica, Università di Torino

Abstract

In the context of teaching geometry at secondary school level, we study students' measurement activity in solving open problems in the Cabri environment. Different uses of measures are observed in the protocols' analysis, which points out that the students' approaches are double-sided, namely perceptual and/or theoretical. A tool like measures in Cabri (in the same way as dragging) can foster the passage from perception to theory and back again. The shifts back and forth are productive in the construction of a proof, after the conjecturing phase.

Introduction

At the level of Mathematics Education research, the issue of the use of new technologies has been addressed from different points of view. Studies on how the introduction of new technologies change learning in the classroom and how they can be integrated in the classroom practice have been carried out (e.g. Artigue, 1997; Arzarello et al., 1998b; Laborde, 1998; Healy, 2000; Hoyles & Healy, 1999; Mariotti & Bartolini Bussi, 1998; Sutherland & Balacheff, 1999).

The ongoing research project we are involved in, is concerned with students' cognitive behaviour when using a dynamic geometry environment, Cabri-Geomètre (Baulac et al., 1988), in the context of the proving process in geometry (Arzarello et al., 1998a). The classroom experiments involve secondary school students, who are asked to solve open problems (Arsac et al., 1988) in Cabri, with the aim of proving their conjectures.

The problem we study is the transition from conjectures to proofs (see e.g. Boero et al., 1996), as part of a long term activity: students' transitions from the perceptual level to the theoretical one and backwards. As perceptual level, we mean the activities in which the students use perception (e.g. to see if a quadrilateral is a square, only by eye). As theoretical level, we mean activities like producing a conjecture in a conditional form and validating it with a proof. The relationships between perception and theory prove a key element in mathematics, particularly in geometry (see for example Arsac, 1992).

The different tools provided by Cabri (e.g. dragging, constructions, measures) are useful mediators (Mariotti, to appear) in helping students in the transition mentioned.

---

1By proving process we mean the process of exploring, conjecturing and proving in an open problem.
above. In a previous study, we investigated in particular the role of dragging (Arzarello et al., 1998b; Olivero, 1999) within this framework.

In this paper we analyse the role of measures in Cabri in the above transition. Our hypothesis is that measures in Cabri constitute a bridge between the perceptual level and the theoretical one and may be a support for managing productively the interaction between the two levels.

**The role of measures in Cabri: two transitions.**

Our interest in the role of measuring in the proving process comes from the fact that students activity involves the use of measures in different phases of the process and with different purposes. Certainly, the need for measures comes from the perceptual level, when the students have the intuition that, for example, one side equals the double of another one. However, when they read the measures on the screen, they are no longer at a purely perceptual level: they are working at a higher level, because they are looking for an answer: *Is my intuition true or false?*

Measures work as a tool which can provide different kinds of answer, because they foster perception but at the same time lead towards the theory:

a. a dichotomic answer of qualitative kind (yes/no, e.g. knowing if two quantities are equal or not, or if one is bigger than another one);

b. a quantitative information (a number, which tells the measure of a quantity with respect to a measurement unit);

c. a relational answer, that links the measures of two or more quantities (e.g. if one side equals the double of another one).

Therefore it is important that measurements are introduced correctly in the school curriculum, in order to avoid obstacles, misunderstandings or conflicts in the learning process. The role of the teacher proves fundamental in relation to the different uses of measures described above, in order to teach the students:

a. to manage the qualitative answer;

b. to use the quantitative information as a number within an interval of uncertainty.

---

2 A variety of dragging modalities was identified, each one showing a particular aim to be achieved in the proving process. The different modalities used by students were considered as revealing different cognitive activities.

3 Similar considerations may concern the use of measures on paper or using other tools.

4 The quantitative side of the answer linked to the use of measures usually makes students feel safe and certain about results; in particular, weak students usually rely on measures.

5 In another work (Olivero & Robutti, 2001) we point out some cognitive conflicts connected to the use of measures in Cabri.

6 An example of good management of the interval of uncertainty is in Olivero & Robutti (submitted).
c. to understand the different status of the numbers obtained by measuring a quantity and the relationships between the quantity and other ones.

The students will then be conscious that measures are useful in the proving process in order to discover, to make conjectures and, finally, to prove, but that they are not sufficient to construct a proof. Measures (and dragging too) are useful when you want to know if something is true; however, they are no longer useful if you want to prove that something is true: at this point measures need to be substituted by relations of logical consequence. Measures in Cabri (in the same way as dragging) are mediation tools between the perceptual level of students' mathematical activity and the theoretical one.

Students' measurement activity reveals two typical cognitive shifts, which were also revealed by the use of dragging (see Figure 1):

1. the transition from the perceptual level toward the theoretical level;
2. the transition from the theoretical level toward the perceptual level.

If the pupils trust measures and 'believe' measures are absolutely exact, they stay at a perceptual level. While if they use the information provided by the feedback of measures to formulate a conjecture in a conditional form ('if ... then') and to see the figure as a generic example (Balacheff, 1999), they pass to the theoretical level (Laborde, 1998).

Classroom observations have shown that the modalities of using measurements in the first transition, are for example the followings:

- when the students do not have any precise ideas about the configuration, they explore the situation randomly: they take measurements of some elements of the configuration ("mesures exploratoires", Vadcard, 1996), in the same way they as use wandering dragging (Arzarello et al., 1998b);
- when they do a guided exploration of the configuration, measurements are used to put in order a set of different cases, in order to explore them, in the same way as guided dragging (Olivero, 1999), or together with it.
- as a means of checking the validity of a perception: students see some features of the figure, but they are not sure of their perception, so they use measures on the
figure in order to validate the perception ("mesures probatoire", Vadcard, 1996),
and they remain at a spatio-graphical level (Laborde, 1998).

As far as the second transition, the students use measures for example with these modalities:

- after formulating a conjecture, sometimes measurements are used to check the conjecture within Cabri, in order to refute or to accept it.
- after constructing a proof, the students go back to Cabri in order to understand the proof and to get a better explanation: new experiments are made in Cabri and measures are used, normally, on the static figure (see, for example, Olivero & Robutti, 2001).

In the following we will present some exploratory examples which illustrate the previous ideas.

**The two transitions: some exploratory examples.**

All these examples are taken from different Italian Secondary School classrooms (15-17 years old students) which took part in our research project. The classroom sessions consisted of both group work and classroom discussions (Bartolini Bussi, 1998). Two observers took fieldnotes and video-recorded one group for each session and the discussion.

EX1. Students M & N, group work.

| 12. M: diametrically opposite points (D, E) |
| 13. N: They are on the same line (D, B, E) |
| 14. M (while N is dragging): They are on the line, right? OO' and DE are parallel. Put measures. I think it is 1/3, ...2/3, ...the double. |

The students are in the process of formulating a conjecture, so they are moving from perception to theory. At the beginning (#12-13) they formulate an observation coming from a perception. Then they use both dragging and measurements to go on with the exploration. The information M sees in the process is a relational answer: the relationship between two quantities is discovered (#14).

---

7This use is very similar to the dragging test modality (Arzarello et al., 1998b), by which students check the exactness of a construction.
8We do not present the statements of each problem because they are not important for the analysis we carry out. However, here is an example of the kind of open problems students worked with:
"Let ABCD be a quadrilateral. Consider the bisectors of its internal angles and the intersection points H, K, L, M of pairs of consecutive bisectors.
- Drag ABCD, considering different configurations. What happens to the quadrilateral HKLM? What kind of figure does it become?
- Can HKLM become a point? Which hypothesis on ABCD do you need in order to have a point? Write down your conjectures and prove them."
9 The figures represent the two transitions described above. m=measures, d=dragging, C=conjecture
EX2. Students R & M, teacher T; group work.

90. T: You need to find a different property from the one you used for the construction.
91. R: Let's try to put measures in a particular case.
93. They draw a square and then drag one of the sides.
94. R: One side gets bigger and the other one gets smaller in the same proportion.
95. T: How would you say this in mathematics?
96. M: When one gets bigger and the other one gets smaller, they are inversely proportional.
97. T: Not really. They are inversely proportional when the product of two variables is constant. Is this the case?
98. They do some calculations on the measures of the sides of the quadrilateral in different configurations.
99. R: No, the product is not constant.
100. M: Let's have a look at the sum.
101. R: The sum is constant.
102. M: So the sum of the two opposite sides is equal. The conjecture is: if a quadrilateral is circumscribed to a circle, the sum of the opposite sides is equal.

The students do not have any idea in mind. They know they have to find a property but they do not know what kind of property it can be. So they decide to start from a particular case. They put measures as a means to get ideas from. They start dragging (#93). While dragging they look at how measures change on the sides of the quadrilateral and compare them. At first a relational information is seen (#94). The teacher stimulates the students to move towards the theory (#95). Some work at a theoretical level is done (#96-97). In #98 they go back again to the Cabri measurements and do some calculations. Relationships between the measurements of the sides are observed and then transformed in a conjecture, at a theoretical level.

EX3. Students D & G, group work.

25. D: They do not coincide, because... look (she points at the 4 axes)
26. G: And this is a square, I bet it!
27. D: Wait, what does the perpendicular bisector cut...It cuts the side in a half, doesn't it? ...so this should be the midpoint...
28. G: Ah...but I want to know if it is a square
29. D: Use measurements!
30. G takes measurements of all the sides.
31. D: Maybe not... look, they are all different!

The starting point is the perceptual level: D observes a characteristic of the figure (#25). G goes on with another perception (#26). At this point D moves to a theoretical level, recollecting a property of the perpendicular bisector (#27). G goes back to the
perceptive level and wants to check her perception of the figure being a square (#28). The means D chooses to validate the perception is the use of measurements. The conclusion D gathers from the measures is a dichotomic qualitative information: the sides are all different (#31). At this point they are at an intermediate level between perception and theory.

EX4. Students L & S; group work.

110. L: UR is parallel to AB because you can see it by eye. But let's check it.
111. L marks a point on UR and a point on AB, draws the segment between these two points, marks the internal alternate angles, takes measurements.
112. S: they are equal!
113. L: yes, they are parallel.

This episode starts with a perception (#110); L explicitly says he is observing the figure by eye. However he wants to check this observation. There is a jump towards the theory when the students recollect a property of parallel lines (#111). Then there is a move back to the use of measurements. At first a qualitative information is gathered (#112). Then another move towards the theory is made (#113).

EX5. Teacher T, student F, classroom discussion.

85. T: So your conjecture is...
86. F: if a quadrilateral can be circumscribed to a circle the bisectors all meet at a same point.
87. T: when can a quadrilateral be circumscribed to a circle?
88. F: When the opposite sides...when the sum of the opposite sides is equal.
89. F calculates the sum of the opposite sides using the measurements on the Cabri figure.

The students have a conjecture (#85-86), so they are at a theoretical level. The teacher provokes them to explain the conjecture by characterising the circumscribed quadrilaterals (#87). In order to do that, after mentioning the defining property for circumscribed quadrilaterals (#88), they use measurements (#89) in order to show that this property is true. The function of measurements is to provide certainty.

Conclusions and issues for further research

From the cognitive point of view, the previous analysis shows that in the proving process there is a richness of back and forth shifts between the perceptual level and the theoretical one. This productive interaction is supported by the use of measures in
Cabri, both as a tool on its own and as a tool in addition to others, e.g. dragging. The cognitive analysis

A cognitive perspective on the use of technology seems to be particularly important if one wants to deeply understand how new technologies affect the teaching and learning process. Knowing in which way a cognitive behaviour changes when working with a software, for example, might be essential for developing suitable classroom activities in which the potential of technology is exploited together with the mathematics involved. The research results concerning dragging and measures we presented might be successfully exploited in the teaching practice, for example by showing students the different possibilities they have and 'teaching' them how to use these tools in a productive way.

And, last but not least, measures (not only in Cabri, but in general) should constitute a key topic in the school curricula as far as their epistemological role is concerned, as it is pointed out by many ongoing curricular projects that are taking place in US (AAVV, 1998), Belgium, New Zealand, and, recently, Italy.

Some possible issues for further research may be: developing a deeper second order analysis (Arzarello & Bartolini Bussi, 1998) concerning the cognitive interpretation of measurements activities, in relation to the whole proving process; analysing in details the role of the teacher in managing the introduction of technologies in the classroom, with particular respect to the different tools they embed; studying this approach from the embodied cognition perspective (Arzarello, 2000; Nunez, 2000); analysing the role of other mediators, as for example language (Arzarello, 2000; Radford, 1999), in relation to the Cabri tools.

PUTTING THEORY INTO PRACTICE

Growth of appreciating theory by student teachers

Wil Oonk, Freudenthal Institute,
Utrecht University, Utrecht, The Netherlands
email W.Oonk@fi.uu.nl

Abstract

This report presents the raw data from an ongoing study into the manner in which student teachers connect theory with actual practice. In this case, practice is primarily used to indicate the digitised teaching practices recorded in the Multimedia Interactive Learning Environment (MILE), a computer-based environment that provides an investigative representation of teaching in an actual classroom setting. A tool has been developed that incorporates 15 signals of expected theory implementation by student teachers. A prototype of the tool will be presented, as well as the considerations that underlie its design. The student teachers’ independent group work and subsequent semi-structured interviews with some of the student teachers have been taped (audio recordings). Similarly, the teacher educator’s lessons have been videoed. Furthermore, data has been obtained from the analysis of portfolio documents from the student teachers. A selection of raw empirical data is described on the basis of two observations.

Theory and practice in primary school mathematics teacher training

Primary school teachers in the Netherlands are trained at a PABO (Primary School Teacher Training College), which offer four-year programmes at the higher professional education level. Educating primary school mathematics teachers essentially involves introducing (pedagogical) content knowledge and pedagogics to pre-service teachers, and providing them with the opportunity to conduct interrelated fieldwork in primary schools.

Since the 1970s, mathematics has played a leading role in both the developments in primary education and at PABO teacher training colleges.

In the 1970s and 1980s, a programme for training primary mathematics teachers was developed (Goffree, 1979, 1982, 1983, 1984). This programme was characterised by the attention it focused on the development of student teachers who are educated to acquire— as an integrated whole —the following abilities: solve problems at their own level, learn the didactics of mathematics education and practical teaching techniques (Goffree & Oonk, 1999).

From 1990 – 1995, a team of 10 mathematics teacher educators developed national standards for primary school mathematics teacher training. In 1995, they published their work in the form of a handbook for their fellow teacher educators. In
this handbook, three pillars of teacher training are identified: construction, reflectivity and narrative knowing (Goffree & Dolk, 1995). In other words, student teachers are taught to acquire personal (practical) knowledge primarily through reflection on practical situations, which knowledge generally has a narrative character. The idea behind this is that student teachers can integrate the larger theoretical ideas with their practical knowledge by reflecting on (theory-heavy) practical situations. As such, MILE can be viewed as an extension of this new vision of teacher training education.

MILE
The goal of the Multimedia Interactive Learning Environment or MILE (Dolk, Faes, Goffree, Hermsen & Oonk, 1996) is to give student teachers a possibility to investigate teaching practice (primary school mathematics) in a specific way. The developers of MILE were inspired by the Michigan MATH project (Lampert & Ball, 1998). Seven theoretical orientations guided the development of MILE (Goffree & Oonk, 2001).

MILE is comprised of – currently 70 – recorded lessons, discussions with teachers, supervisors and other K 1 – 6 materials. From the archive, it is possible to study each lesson in its entirety or in short fragments. Key word searches of the fragment (clip) descriptions and lesson dialogue (transcripts) can be done using the search engine. Every fragment reproduces a teaching instance and, in MILE, is provided with a short description that provides further elucidation. MILE is intended as an extensive collection of situations, from which the student teachers can acquire practical knowledge (Elbaz, 1983; Verloop, 1991) as a narrative way of knowing (Gudmundsdottir, 1995). Theory can be integrated into practical knowledge by reflecting on ‘theory-heavy’ practical situations.

Experience has shown that student teachers are often not only focused on the actual teaching of mathematics when watching the fragments, but also on general didactic and educational issues. MILE thus offers the possibility to use the school subject mathematics as an arena for theoretical reflections that connect with larger pedagogical ideas.

Research subject
The research, about which is reported in this paper, attempts to answer the question: How do prospective teachers make connections between theory and actual practice when a digital representation of actual practice (MILE) is made available to them?

Considerations in the design of the research tool
How can one demonstrate that theory plays a role in the student teachers' study of practical situations? Schön (1983) has demonstrated that ‘theory in action’ is primarily implicit in nature. Only the astute observer (expert) is in a position to notice signals from suchlike theory in action. We decided to generate a list of possible signals to support our observations of student teachers at work. The signals were developed on the basis of theoretical orientation and discussion, which incorporate
the individual practical knowledge (and wisdom) of the researcher and the results from an explorative study conducted earlier (Oonk, 1999).

The tool assumed a background role during the research and evolved from a scoring list to a frame of reference. After several observations, the tool proved to be too extensive as a scoring list. The idea to use the tool to analyse the data collected came about after it had been used to only indicate the direction observations were to follow. The tool, however, appeared far too crude for this purpose and further refinements are necessary.

**The tool**

This prototype is a refined version of the first. Each signal is coupled with an example (paradigm of a theory in action) with references to sources of the theory cited.

1. While observing practical situations, student teachers can refer to the theory that comes to mind.
   Example: student teacher points to a teacher who interprets the product of 2 x 5 and, in doing so, employs the rectangle model (Treffers & De Moor, 1990, p. 75).

2. Theory is used to explain (as a means to understand) what occurred in the practical situation observed.
   Example: student teacher explains the method employed by the pupil who is using MAB (base ten) material as a working model (Gravemeijer, 1994, p. 57).

3. The student reflects the intention of the teacher or pupil(s) with the help of theory.
   Example: student teacher points out the 'mirroring technique' applied by the teacher as a means to the pupil reflect his own actions (Van Eerde, 1996, p. 143).

4. The student teacher substantiates an idea arising from observing a practical situation.
   Example: student teacher explains the process used by the teacher concerning the transition from context to model, based on an idea about the teacher's opinion of contexts (Treffers et. al., 1989, p. 16).

5. The theory generates new practical questions.
   Example: student teacher wonders at which level (phase) of learning multiplication the pupils are (Goffree, 1994, p. 280).

6. Theory generates new questions about the student teachers' individual notions, ideas and opinions.
   Example: in referring to the theory of the next zone of development, the student teacher wonders whether she is approaching her pupils (during fieldwork) at the appropriate level (Lowyck & Verloop, 1995, p. 154; Van Hiele, 1973, p. 101).

7. The student teacher can theoretically underscore her personal beliefs about an actual practice situation.
   Example: student teacher explains her opinion about a positive working environment that according to her is created by the teacher and based on classroom environment theory (Lowyck & Verloop, 1995, p. 62 Lampert & Ball, 1998, p. 123).
8. The student teacher estimates the practical knowledge of the teacher and identifies
its theoretical elements.
Example: student teacher describes the practical knowledge (of process
shortening) that, according to him, motivates the teacher to employ certain actions
(Gravemeijer, 1994, p. 58).

9. Student teacher reaches certain conclusions from his observations based on
theoretical considerations.
Example: student teacher reaches the conclusion that group work and beginning
with repeated counting better fit the foreknowledge and experience of the children

10. Making connections between practical situations in MILE and own fieldwork
experiences with the help of theory.
Example: student teacher establishes similarities between approaching a pupil in
MILE and a pupil in his/her own practical training group (Goffree, 1994, p. 211).

11. (Re)considering points of view and actions on the basis of theory.
Example: student teacher revises her opinion about a pupil's approach to
multiplication, basing it on a fellow student's reflections on the theory behind the

12. Constructive analysis (= adapting given teaching material) that is underpinned
with theory.
Example: student teacher adjusts a given course by incorporating contexts that
provoke 'didactic conflicts' (Van den Brink, 1989, p. 203).

13. The student teacher shows his appreciation of theory.
Example: student teacher expresses her appreciation of theory when she is able to
explain the solution strategy employed by a pupil (Lampert & Ball, 1998, p. 70).

14. Realising the usefulness of theory as a tool for reflecting on actual practice
('reflection on action').
Example: in a logbook, student teacher describes his modified views on theory in

15. Developing a personal theory to underpin his interpretation (creation) of a
practical situation.
Example: student teacher develops his/her own theory about open and closed

Methodology
The study involved two classes (each with 25 student teachers) at a primary school
teacher training college during the testing phase of the MILE course, 'The
Foundation'. Ten 2-hour meetings were held. For the methodology and the
development of the tool, the position was taken to conduct this section of the study in
such a manner that we could expect to optimise the results in terms of the signals of
theory use (Glaser & Strauss, 1967). The method of triangulation was then selected
(Maso & Smaling, 1998), 4 pairs of student teachers were observed and interviewed,
and a participating study of the group work with two student teachers was conducted.
In addition, the teacher educator was observed during the 10 meetings involving the entire group in order to inventory the incentives offered to stimulate the use of theory by student teachers (their theories in action). The data was recorded on audio and video tape. Furthermore, data was obtained from the analysis of portfolio documents from the student teachers.

The observations described below offer an impression of the results to date. A more detailed report will be presented at PME-25.

THEORY IN ACTION (1)
Discussing Fadoua's mistake
The MILE fragment shows a pupil, Fadoua, and her teacher, Minke, at the instruction table during a grade 2 independent working session. In a diagnostic discussion, Minke wants to attempt to identify the way of thinking behind the mistake (18-6=11) Fadoua made in her written work. It appears that Fadoua counts backwards starting from 18 ('initial error', a well known standard error) and whilst counting backwards also skips two numbers (12 and 14).

The theory that makes this practical situation more comprehensible is a result of research into subtraction strategies employed by young children, in particular the method of counting backwards. Initial errors, counting mistakes and counting too far are well-known problem areas. To avoid problems in the transition from manipulative to mental calculations when learning to shorten procedures, structural models divisible in “fives structures” can be employed to learn to subtract to twenty (Gravemeijer, 1994; Van den Heuvel-Panhuizen et. al., 1998).

After watching and analysing the video, the student teachers, Denise and Marieke, discuss the most appropriate way to assist Fadoua. Denise initially suggests solving the sum using 18 blocks (units). Marieke rejects this, however, since she believes it doesn't solve Fadoua's counting problem. She rejects the second suggestion – using the number line – for the same reasons. Marieke ultimately agrees with Denise when she suggests using the reckon rack. Denise's foremost argument is that the fives structure of the reckon rack can help Fadoua either by directly subtracting 6 or by splitting to yield 8-6 or 18-6. 'And that doesn't involve counting anymore,' she says.

After analysing another MILE fragment (involving a talk between the two grade 2 teachers, about the transfer), Marieke reaches the conclusion that Fadoua has most likely mastered splitting the numbers to ten. Based on their interpretation of the teaching method for learning to use the reckon rack (doing, seeing, working it out in your head), they list all the points for helping Fadoua.

In the previously outlined discussion between student teachers Denise and Marieke we see theory in action when they compare, face and consider, on the basis of theoretical perspectives, which material or model is (or is not) appropriate and why. A similar process occurs when they design an explanatory approach for Fadoua, partially on the basis of theoretical considerations (the reckon rack teaching method).
THEORY IN ACTION (2)

Considerations on the use of tangible material (manipulatives)

In the workshop part of the second session, the student teachers are given the task of characterising three MILE situations, A, B and C. Using that analysis, they are to attempt to select two of the three situations that bear the closest interrelationship. In fragment A, teacher Minke is teaching her pupils to memorise the five-times table. On the magnetic board, we also see two 2 by 5 and 3 by 5 tile squares Minke used before this part of the lesson. She now asks who knows a multiplication fact by heart. Kimberley knows that 5x10=50 (Minke alters this to 10x5) and Vincent knows that 8x5=40.

In fragment B, teacher Willie has the class count the five-times table by making leaps of 5 on the number line. Dwaen knows that 9x5 is just ahead of 10x5.

In fragment C, we see 20 transparent cylinders, each containing 5 balls, on the edge of the blackboard. Minke asks which multiplication table sum matches this. Clayton’s answer is 20x5.

The theoretical background in all three situations concerns the method of teaching multiplication tables and, more specifically, that of memorising the products. One possible factor could be the grid (rectangle) model in situation A, which is represented by the tile squares, which, although visible, are not in use at that point. Situation B is about repeated leaps on the number line, whereas, in the case of 9x5, the ‘one less than’ the anchor product 10x5 strategy comes into it. In situation C, theory makes an appearance in the form of visualising the multiplication structure based on the context. The structure elicits the use of strategies (Treffers & De Moor, 1990; Goffree, 1994).

To her group partner Loes, student teacher Linda speaks out in favour of the tie-in between situations A and C. The tiles and the tennis balls are ‘tangible’ (manipulatives), the number line is not (it is very likely that this terminology was borrowed from the educator during the previous plenary meeting). Using the tiles and the tennis balls, the children can assemble groups themselves. You can see the tennis balls as 20 groups of 5, but also as 10 groups of 10. The number line ‘always remains a unit’. According to Loes, you can do all that on the number line too, by adding dashes. In her view, the tiles, the number line and the tennis balls are ‘three equal aids’. When Linda speaks out for the relationship between situation A and B and the difference with situation C, she demonstrates theoretical notions about (in)tractibility and about grouping and structuring. She has a vague idea of the number line being a more abstract, ‘intangible’ construct, as opposed to Loes, who seems to see the number line as a tool or working model.

THEORY IN ACTION: SUMMARY

We see theory coming into action in situation (1) as the student teachers (re)assess their viewpoints with regard to the question which is the material or model of choice for coming to grips with a particular problem. That also happens if they substantiate their construction (help for a pupil) by using theory.
In situation (2) signals that theory is being applied become more evident when a student teacher (Linda) compares practical situations and justifies the relationship between two situations by basing her reasoning on theoretical considerations.

Conclusions

Intended to portray the connection between theory and actual practice made by student teachers, the research tool evolved into a data analysis instrument. As the study progressed, overlap was eliminated and new signal characteristics were added. Further refinement of the characteristics is considered necessary.

The interim results of this ongoing study reveal that student teachers use theory as a means to understand and explain practical situations. The frame of reference of second-year student teachers (comprised of personal experiences as pupil and trainee, supplemented with theoretical information about education and training from lectures at the PABO teacher training college) appears somewhat diffuse and fragmented. It remains difficult to draw a border line that separates practical wisdom from theory.

The mental ability to articulate observations of and reflections on practical situations in theoretical terms remains largely undeveloped. The current culture reigning at the teacher training colleges also seems to hamper the development of this. As a result, there is a real danger that student teachers will hang on to their personal (subjective) theories undesirable for professional development.

The student teachers themselves believe that working with MILE enables them to apply and further explore the knowledge that they already have. A number of them demonstrated a budding appreciation for theory. Continued study should reveal whether the signals they display actually point to integrated knowledge of theory and practice, or, in other words, practical knowledge.

PROBLEM SOLVING IN THE MATHEMATICS CLASSROOM: A SOCIO-CONSTRUCTIVIST ACCOUNT OF THE ROLE OF STUDENTS’ EMOTIONS

Peter Op ‘t Eynde, Erik De Corte, & Lieven Verschaffel
University of Leuven

Abstract. The present study aims at documenting from a socio-constructivist perspective the relations between students' mathematics-related beliefs, their emotions, and their problem-solving behavior in the mathematics classroom. To investigate these relations we did a multiple-case study of 6 students (age 14). The use of questionnaires as well as more qualitative methods like thinking aloud and interviews, allowed us to trace students' problem-solving behavior in its affective, motivational, and cognitive dimension. Results indicate that students’ beliefs as well as their task-specific perceptions determine the interpretation and appraisal processes underlying emotional experiences. These emotional experiences tend to be closely related to cognitive and metacognitive experiences and determine the problem-solving process in specific ways.

Theoretical framework

Recent theories on cognition and learning stress the situatedness of every learning activity and point to the close interaction between cognitive, conative and affective factors in students’ learning and problem solving. A socio-constructivist account of learning and problem solving (e.g., Cobb & Bowers, 1999) takes emotions and feelings to be as much a constitutive and integral part of problem solving as cognitive and metacognitive strategies. Moreover, within such a perspective emotions are not primarily characterized as typical neurological processes which, together with their corresponding expressions and feelings, can be studied independent of the individual and context. On the contrary, emotions are perceived as being fundamentally grounded in and defined by the broader social-historical context that constitutes the individual as well as by the immediate social-context wherein the problem solving activity is situated. For students this context is in the first place the instructional context. One can claim then that every emotion is situated in its instructional context by virtue of four characteristics. First, emotions are based on students' cognitive interpretations and appraisals of specific situations. Second, students construct interpretations and appraisals based on the knowledge they have and the beliefs they hold, and thus they vary by factors such as age, personal history and home culture. Third, emotions are contextualized because individuals create unique appraisals of "similar” events in different situations. Fourth, emotions are unstable because situations and also the person-in-the-situation continuously develop. One can conclude then that emotions clearly have a rationale with respect to the local social order (Cobb, Yackel, & Wood, 1989).

In the field of mathematics education, McLeod (1992) - although not specifically situating his research within a socio-constructivist perspective - already
acknowledged the relevance of studying the interactions between students’ beliefs, their emotions, and the specific context of the mathematics classroom when he argues “Since beliefs provide an important part of the context within which emotional responses to mathematics develop, we need to establish stronger connections between research in beliefs and research on emotions in the context of mathematics classrooms.” (p. 581)

Rarely scholars have addressed in their research this relation between students’ mathematics-related beliefs and emotions experienced in the classroom. More generally, the emotional reactions of students have never been major factors in research on affect in mathematics education (for the exception see e.g., DeBellis & Goldin, 1993). This lack of attention to emotion is probably due to the fact that research on affective issues has generally looked for factors that are stable and can be measured by questionnaire. Nevertheless, in the last decade several researchers in the field of mathematics education advocating a situated perspective have begun to study students’ learning and problem solving including analyses of motivational and affective processes, next to cognitive processes (e.g., Isoda & Nakagoshi, 2000; Lester, Garofalo, & Kroll, 1989; Prawatt & Anderson, 1994). They take a more socio-constructivist approach when investigating students’ emotions and focus on the dynamic interplay between student and context, using a variety of research methods (e.g., interviews, video-stimulated recall interviews, on-line heart rate measures) that should enable them to represent the student’s perspective on problem solving, rather than the researcher’s perspective. After all, research from a socio-constructivist perspective that focuses on the individual has to document how students engage in classroom practices and dynamically reorganize their ways of participating in them (Op’t Eynde, De Corte, & Verschaffel, in press). This approach stresses intentionality and emotionality, next to intellectuality, and takes activity and meaning as its basic currency. It implies a shift for researchers from an observer’s perspective to an actor’s perspective (Cobb & Bowers, 1999). What matters is not so much the classroom environment, practices, and (emotional) experiences as observed by the researcher, but the meaning students (and teachers) give to it and upon which they act.

The results from the studies mentioned above point to several important relations between the classroom context, students’ beliefs, their emotions and their problem-solving behavior. To further investigate these relationships and to advance the search for appropriate research instruments, we developed in our center a research project to study the role of emotions in students' mathematical problem solving, taking a socio-constructivist perspective and focusing on individual students as the unit of analysis. The pilot study discussed here was set up to find out if the research methods and instruments used would enable us to grasp some aspects of the dynamic interplay between the student and the class context, and in the mean while would learn us something more about the relations between students’ mathematics-related beliefs, their emotions and their problem-solving behavior.
Research design

This pilot study took place in the second year of junior high school (age 14) in three classes from different schools. The classes had basically the same curriculum for mathematics but differed in the general level of secondary education they followed.

All students of these classes were administered a self-developed questionnaire on mathematics-related beliefs [MRBQ] (Op 't Eynde, De Corte, & Verschaffel, in preparation). Two months later (after presenting the questionnaire to the classes) we made a selection of six students, one high and one low achiever out of each class as evaluated by the teacher. They were asked to solve a complex realistic mathematical problem during a regular mathematics lesson and had to fill in the first part of the “On-line Motivation Questionnaire [OMQ]” (Boekaerts, 1987) after they had skimmed the task and before they actually started to work on it. The problem consisted of a one page long story about the Balkan war between the Serbs and the people from Kosovo. A group of Kosovarian refugees tried to go to Albania through the mountains. In the mountains a women gives birth to a baby that appears to be ill and urgently needs specialized medical care. There are two possibilities, one with a delta plain of the Red Cross, another on food and by car. The students had to calculate the fastest way, given the different speeds of the respective means of transport and the distances they have to travel. Basically the problem consisted of four sub-problems that had to be solved successfully to find the correct solution, i.e. the fastest way.

Every student was asked to think aloud during the whole problem-solving process that was also videotaped. Immediately after finishing, the student accompanied the researcher to a room adjacent to the classroom where a “Video Based Stimulated Recall Interview” [VBSRI] took place (Prawatt & Anderson, 1994). The interview procedure consisted of three phases. In the first phase the student and the researcher watched the videotape and the student was asked to recall what he did, thought and felt while he was solving the problem, especially during those episodes that he was not thinking aloud. In the second phase the interviewer asked questions for clarification, more specifically ‘what and how questions’ relating to what he saw on the screen, what the student told him, what the student wrote down on the OMQ, and what he wrote on the answer form. Finally, in the third phase, the researcher tried to unravel the subjective rationale for the student’s problem-solving behavior. He looked for the interpretations the student gave to certain situations. The “why questions” that were asked, made underlying beliefs more visible and as such clarified the relation between beliefs, emotions and problem-solving behavior.

A qualitative vertical analysis of the different data resulted in six rich narratives of the way students handled and experienced the problems. These narratives were then content analyzed. After these vertical analyses of each student’s problem-solving process, a more horizontal approach was taken to look for recurrent patterns and/or fundamental differences that might deepen our understanding of what happens during problem solving and more specifically the role of emotions in this process.
Results

The results indicate that, in general, there is an individually changing flow of emotional experiences that follows from students’ interpretations and appraisals of the different events that occur during problem solving in class. We found that solving a problem in class, even the same problem, usually consists of an individually different chain of events for each student. For instance, whereas some students were confronted with a lot of obstacles when solving the problem, others encountered less difficulties they had to deal with; but all of them experience a number of different emotions in the course of solving the problem.

Frank, for example, after already having experienced some difficulties solving subtask 1 and becoming frustrated in the process of doing it, ended up relieved because he was finally able to solve subtask 1. Then, he continued with subtask 2:

Dakovica is another 14 km.

at 20 km/h

that is,...wait,...

"Wait,... that 20 km/h.... I seem to have forgotten how I had to do it, then I took a quick look, and then..."

Frank takes his calculator

"Actually, I did not really need the calculator there. I wasn't thinking properly, and then I panic, and then I immediately want to go to my calculator, and if then I stop and think for a moment, I probably know again what I have to do"

INT: "If you are searching for the solution, you have tried something, you end up at the 20 km/h, you grasp your calculator, and you don't know what to do exactly, how do you feel then?"

Frank: "A little bit, I don't know how to put it, you don't feel well because you need to go to the calculator. I always want to do as much as possible without it."

"I did not know immediately how I had to go from 20 km to 14 km."

Frank moves his hand back to the calculator but he redraws it

INT: "At such a point, yes - no, yes - no, ..., how do you feel then?"

Frank: "Then I get something like... come on what is this all about!!.... Usually I focus then on some point where there is nothing, and then I go through everything again, 20 km in one hour, how do I get to the 14 km."

\(^{1}\) Thinking aloud data are written in bold; Students' comments in the VBSRI are placed between " "; Questions of the interviewer are preceded by INT; Data from observation by the researcher are written in italics.

\(^{1}\) Thinking aloud data are written in bold; Students' comments in the VBSRI are placed between " "; Questions of the interviewer are preceded by INT; Data from observation by the researcher are written in italics.
INT: "How did you manage to find it then?"

Frank: "I just kept searching how I could get from the 20 km to 14 km. First, I thought to take some bigger numbers and that is why I was thinking of using the calculator. I don't know how I came to it, but at a certain point it worked. I was not really thinking, and then I thought, hey this is not possible, and then I start to think again and then I managed."

20 km in 1 hour
no, no, no; yes
20 km divided by 10
1 hour divided by 10
2 km times 7 is 14
6 minutes times 7 is 42 minutes

Clearly, Frank experienced different emotions when solving subtask 2 as, for example, panic, frustration, and angry. Not only do students encounter individually different obstacles when solving the same problem, but even when they are confronted with the same or comparable events these are in some cases interpreted and appraised differently according to the person (his knowledge and beliefs) and the class context.

For example, our data show that negative emotions (e.g., frustration) usually were experienced at moments that students were not able to solve the problem as fluently as they anticipated. Experiencing the inadequacy of a cognitive strategy used, is apparently as much an emotional as a (meta)cognitive process. However, the nature and the intensity of the emotion experienced, when confronted with a comparable cognitive block, can differ significantly between students. Confronted with a difficulty in an early stage of the problem-solving process, one of the students became hopeless, stating that "If I'm already not able to solve this, than I surely will not be able to solve the rest of the problem". Another student also got stuck at the same point, became a bit annoyed, but experienced this as a challenge, and tried to find a way around it. Despite the fact that they both indicated to be highly motivated and confident to solve this problem (based on the results of the OMQ), they interpreted and appraised the first difficulty they encounter in an entirely different way. Differences in their more general mathematics-related beliefs (as measured by the MRBQ), more specifically their general competence beliefs, possibly grounded in the different social contexts they function in, can account for this (see also infra).

These examples also reveal another aspect of the role of emotions in mathematical problem solving. In most of our cases, an emotional experience always triggered students to redirect their behavior looking for alternative cognitive strategies or heuristics to find a way out of the problem. However, big differences were observed in the effectiveness and/or efficiency of the cognitive strategies used.
Frank, after panicking following a first attempt, keeps focusing on subtask 2. At a certain point he thinks about working with bigger numbers (a well-known heuristic strategy), but in fact he stays with the given numbers and looks for a way to bridge the gap between 20 km and 14 km, with good result.

Steve uses another strategy getting stuck with subtask 2, crying out "Come on pal". He decides to continue with the next subtask, hoping that this will help him to find out, how he has to solve subtask 2.

None of the students in the pilot study really used coping or emotional regulation strategies to control their behavior. Some thought of it, but did not use it. Ellen, for example, persists in going on although she has not made any progress for five minutes. Asked if she would act the same way at home, she answered.

Ellen: "No, then I would take a brake and relax for a moment, so that I can try it again afterwards."

Int: "You don't do it here, why not?"

Ellen: "Because I have to keep on working. You are not allowed. You don't do that in class. You are not just going to stop and leave, telling just leave me alone for a while guys, I will continue in a few minutes"

This example also illustrates how students' behavior is determined by the beliefs they have about the practices that are or are not allowed in the mathematics class context. More generally, students' descriptions and explanations of their emotional experiences in the video based stimulated recall interviews usually refer to underlying belief-systems. Combining these data with the results on the mathematics-related beliefs questionnaire and the on-line motivation questionnaire, we found that specifically students' general and task-specific competence and value beliefs appeared to determine the interpretation and appraisal processes underlying the emotional experiences. For example, the experience of a cognitive block as challenging rather than frightening or demotivating in many cases seemed to depend a lot on students' beliefs about their competence (see supra). Of course, one might assume that their specific beliefs about the nature of solving these kinds of problems and the class teacher's acceptance of getting stuck in the process also color their interpretations and appraisals. However, these very specific beliefs nor their social correlates, i.e. the classroom norms and practices, were the focus of attention in this study.

Conclusion and discussion

This pilot study already strongly suggests that emotions are very much part of problem solving in our mathematics classrooms. Especially negative emotions as, for example, frustration and anger were frequently experienced by the six participating students. These emotions almost seem to be an integral part of problem solving. Indeed the absence of an obvious method to immediately solve a presented task as a major defining characteristic of a problem (Mayer & Wittrock, 1996) implies that
those who really want to reach the goal state, i.e. find the solution, will find themselves frustrated at some points in the process. Teaching students how to solve mathematical problems then necessarily implies that we have to learn them how to deal effectively with those feelings of frustration or sometimes anger.

The main aim of this pilot study was to test the general research approach and the quality of the methodology and instruments in function of the main study. It shows how the use of a variety of research methods and instruments in a complementary way can enable researchers to trace students’ ongoing interpretations and appraisals of events constituting their problem-solving processes. As such the analysis of students’ emotional experiences inevitably also includes an analysis of cognitive and conative processes, on the one hand, and of characteristics of the (subjective) task context (the events), on the other hand. It allows us to grasp the student’s, actor’s, perspective and the meanings underlying his activities when solving a problem, clarifying the dynamics that constitute his problem solving in class. In this way, this kind of research is a good example of how one can study the individual from a socio-constructivist perspective and what can be learned from it. Of course, a deeper and more complete understanding would have been obtained if the focus on the individual could have been complemented with an analysis of classroom interactions. This appeared to be very difficult to realize in one research project, given the available resources and the constraints implied in doing research in the classroom. However, as argued above, the absence of an explicit analysis of the classroom context does not contradict the socio-constructivist nature of this study.

Although there is a lot to gain from these kind of in-depth studies of students’ behavior, one has to stay aware of the restrictions implied in the methods and instruments used. For instance, bringing a researcher, video- and audio equipment into the classroom always interferes in some way with normal classroom life. There is sometimes a very clear influence on students’ experiences in class, as can be illustrated by the following clarification given by a student during the video stimulated recall interview “I was nervous in the beginning, because there was a camera”. However, from this study we have also learned that after a few minutes students’ behavior in the presence of the camera becomes gradually more normal, i.e. similar to their behavior when the camera is not present. Teachers’ observations in the classrooms confirm this. Nevertheless, researchers have to be aware that the research setting, even when it is situated in the classroom and stays as close as possible to authentic classroom activities, does influence students’ behavior. By explicitly allowing students to deal with these aspects in the interviews researchers might be able to trace some of these unintended influences and take them into account when interpreting the results.

SOME COGNITIVE ASPECTS OF THE RELATIONSHIP BETWEEN ARGUMENTATION AND PROOF IN MATHEMATICS.

Bettina Pedemonte
Laboratoire LEIBNIZ - Université Joseph Fourier – Grenoble I
bettyped@tin.it

Abstract

The purpose of this paper is to analyze some aspects of the relationships between argumentation and proof. Our assumption is that argumentation and proof can be compared from two points of view: content and structure. Toulmin's model (Toulmin, 1958) can be a tool to compare the two structures. The paper shows how Toulmin's model can be used to detect some structural analogies and changes between argumentation and proof during the solution of geometric problems needing the production of conjectures and related proofs.

Introduction

We will consider the solving process of geometric problems in which students interact with dynamic environments that are represented by Cabri-Geometry software. We consider a situation in which the student produces an argumentation during the production of the conjecture and then constructs a proof of this statement. The purpose of this paper is to analyse the relationships between argumentation and proof. Our research aim is to analyse similarities and differences between the structures of the two processes. In this paper we will consider situations in which the cognitive unity (Boero, Garuti, Mariotti, 1996) works.

In general, in dealing with problems asking for a conjecture, the solution is not immediate. Then the production of an argumentation during the construction of a conjecture is expected. We gave some open-ended problems to 12th-grade students in Italy and in France. The students worked in pairs on a computer running the Cabri-Geometry software. In order to favour an argumentation activity between the students, we decided to gather them in pairs. Cabri-Geometry was chosen because our hypothesis was that the software could help the students to identify the geometrical proprieties which are beneath the figure construction and which are necessary to the production of proof.

1. Cognitive unity between argumentation and proof

The relationships between the production of a conjecture and the construction of proof has been an objet of study from a cognitive perspective. Actually, research studies showed the possibility that some kinds of continuity exists between the two processes. In particular, continuity can take the following shape:

“During the production of the conjecture, the student progressively works out his/her statement through an intensive argumentative activity functionally intermingled with the justification of the plausibility of his/her choices. During the subsequent statement-proving stage, the student links up with this process in a coherent way, organizing some of previously produced arguments according to a logical chain” (Boero, Garuti, Mariotti, 1996).
This phenomenon is referred to by the authors as **cognitive unity**.

During the solving process, which leads to a theorem, we may suppose that an argumentation activity is developed in order to produce a conjecture. When the statement expressing the conjecture is made valid in a mathematical theory, we can say that a proof is produced. This proof is a particular argumentation based on a mathematical theory. We want to compare the argumentation process in producing a conjecture and proof.

2. **From the relationships between conjecture and valid statement to the relationships between argumentation and proof.**

The relationship between argumentation and proof is strictly connected to the relationship between conjecture and valid statement. We might say that argumentation is to a conjecture what a mathematical proof is to a valid statement (Balacheff, 1999).

Really, a conjecture could be provided without any argumentation. A conjecture can be a "fact", derived directly from a drawing, from an intuition and the like. In this case there is not an explicit argumentation justifying this fact. But, we are interested to the following kind of conjecture:

Let us define a **conjecture** as a statement strictly connected with an argumentation and a set of conceptions (Balacheff, 1994) where the statement is potentially true because some conceptions allow the construction of an argumentation that justifies it.

The conjecture can be transformed into a valid statement if a proof justifying it, is produced.

Let us define a **valid statement** as a statement which is provided with a proof referring to a mathematical theory. The statement is valid because a mathematical theory allow the construction of a proof that justifies it.

We are interested to compare the processes used to construct the conjecture and its validation: argumentation and proof.

The analysis of the solution process from the perspective of cognitive unity needs tools that allow the comparison between an argumentation process and a proof. Our purpose is to find these tools.

3. **Cognitive unity in content and in structure**

The previous research studies about cognitive unity considered the conditions for its existence (see Boero & al., 1996; Garuti & al., 1998). We are rather interested in its working. Our assumption is that the argumentative process in producing a conjecture and a related proof can be compared from two points of view: content and structure.

The "cognitive unity" considered by Boero & al. (1996) concerns the content. It is possible to observe whether there are analogies or differences between argumentation content and proof content. During the production of several theorems, there are many similar content elements in the argumentation and proof, therefore we can say that it is frequent to find cognitive unity (Pedemonte, 1998).

---

1 The word « argument » refers to a reason given to support or disprove something. In this paper the word « argumentation » refers to a discursive activity (cf. Grize, 1996) based on arguments.
We think that it is interesting to analyse and compare the two processes also from the structural point of view. We wish to become able to detect analogies and differences between argumentation structure and proof structure.

It is possible to compare the argumentation and proof according to relevant structural aspects like deduction, abduction and induction. In a deductive argumentation, the statement is deduced from the data by means of a principle (which permit the inference) allowing its assertion from the data. In an abductive argumentation the statement is deducted before the data is identified (Arzarello, 1998). In this case a principle allows the assertion of a statement even if all the data are not available. In an inductive argumentation the statement is deduced as a generic case after research from specific cases.

Only the deductive argumentation can be easily and directly transposed into a deductive proof. In order to transform an abductive argumentation into a proof the structure needs to be reversed. The inductive argumentation has a structure far away from the structure of a deductive proof; in this case, a link between argumentation and proof can be found only when the argumentation contains the "generic case".

According to the previous analysis we can expect that even in the case of "cognitive unity" (which concerns content) the transition from argumentation to proof may demand relevant (and sometimes difficult to perform) changes concerning structures – in particular those from abductive or inductive argumentation to deductive proof.

4. The Duval’s answer

According to Duval (1991), deductive thinking does not work like argumentation: there is a “gap” between the two processes even if they use very similar linguistic forms and proposition’s connectives. The structure of a proof may be described by a ternary diagram: data, claim, and inference rules (axioms, theorems, or definitions). Within proofs, the steps are connected by a “recycling process” (Duval, 1992–1993): the conclusion of a step serves as input condition to the next step. On the contrary, in argumentation, inferences are based on the contents of the statement. In other words the connection between two propositions is an intrinsic connection (Duval, 1992–1993): the statement is considered and re-interpreted from different points of view. For these reasons (according to Duval) the distance between proof and argumentation is not only logic but also cognitive: in a proof, the epistemic value\(^2\) depends on the theoretical status whereas in argumentation it depends on the content. Then it is easy to observe the cognitive distance between the two processes.

\(^2\) The epistemic value is the degree of certitude or conviction associated with a proposition (Duval, 1991).
According to Duval, the distance between these two processes can explain why most of the students don't understand the necessity of a mathematical proof: if there is an argumentation that justifies the statement the proof can be unnecessary.

Some doubts are currently expressed about the nature and the educational relevance of the gap between argumentation and proof, as described by Duval (in particular, see Douek, 1999). We share these doubts. We think that there are some very similar elements between argumentation and proof. In particular, assuming that a proof is a particular argumentation, both argumentation and proof structures can be described by a ternary diagram.

This is the reason why we need a tool to compare the structure of the two processes.

5. How to analyse or compare the structure of the argumentation process and the proof process?

We have built up a theoretical framework to analyse argumentation structure and proof structure. Toulmin propose a model for the argumentation structure (1958). We use this model as a tool to compare the structures relating to the two processes: argumentation and proof.

In any argumentation the first step is expressed by a standpoint (an assertion, an opinion or the like). In Toulmin's terminology the standpoint is called the claim. The second step consists of the production of data supporting it. It is important to provide the justification or warrant for using the data concerned as support for the data-claim relationships. The warrant can be expressed as a principle, a rule, and the like. The warrant acts as a bridge between the data and the claim. This is the base structure of argumentation, but auxiliary steps may be necessary to describe an argumentation. Toulmin describes three of them: the qualifier, the rebuttal and the backing. The force of the warrant would be weakened if there were exceptions to the rule, in such a case conditions of exceptions or rebuttal should be inserted. The claim must then be weakened by means of a qualifier. A backing is required if the authority of the warrant is not accepted straight away.

Therefore, Toulmin's model of argumentation contains six related elements as showed in the following figure.

\[ Q \quad \text{qualifier} \]

\[ D : \text{data} \quad \rightarrow \quad C : \text{claim} \]

\[ \text{since} \quad W : \text{warrant} \quad \text{unless} \quad R : \text{rebuttal} \]

\[ \text{on account of} \quad B : \text{backing} \]

Fig.1. The Toulmin's model of argumentation.

\[ ^3 \text{Let us illustrate this model with the same example used by Toulmin (1958). Claim : Harry is a British subject. Data : Harry was born in Bermuda. Warrant : A man born in Bermuda will generally be a British subject. Rebuttal : No, but it} \]
It is interesting to compare the idea of epistemic value (Duval, 1991) and the idea of the qualifier. The epistemic value of the claim is inherited by the epistemic value of the data. The claim’s force is inherited by the data’s force. On the contrary, the qualifier is given by the data and also by the warrant’s force. The warrant’s force is important because the warrant plays a basic role in the argumentation.

If we consider a proof as a particular argumentation, the warrant is an axiom, or a definition, or a theorem, in a specific theory.

Toulmin’s model reveals a very powerful tool to compare the process of argumentation and the proof subsequently produced. We can compare the argumentation warrant and the proof warrant. For example if the warrant in an argumentation is based on an intuitive conception, we can see whether in the proof the warrant becomes a theorem of a theory or on the contrary if it remains at the level of conception.

In the following section, we illustrate the use of this model in analysing the resolution process of an open-ended problem.

**Interview**

The experiment was carried out in four 12th-grade classes in Italy, and in one 12th-grade class in France. The students worked in pairs on a computer running the Cabri-Geometry software. We will transcribe a part of a solution protocol related to the proposed problem. This part is based on the transcriptions of the audio recordings and the written productions of the students. The experiment lasted an hour and a half.

The problem proposed was the following:

**Problem.** ABC is a triangle. Three exteriors squares are constructed on the triangle’s sides. The free points of the squares are connected defining three other triangles. Compare the areas of these triangles with the area of triangle ABC (see figure pg. 6).

According to the classification given in the previous section the following types of argumentation can be found in the students’ resolutions.

A typical deductive argumentation could be the following. Suppose the student compares the lengths of the base and the height between triangle ABC and one of the external triangles in order to compare the two areas (see figure pg. 6). It’s possible to consider the sides of the same square as bases for some triangles and compare the heights considering the small triangles constructed on the heights. The view that the small triangles have two equal angles and an equal side, allows the conclusion that the two triangles are equal under the SAA congruence criterion. Then the large triangles have equal areas.

A typical abductive argumentation could be the following. The student, who wants to compare the two areas, sees that the two bases of the triangles have the same length. It’s possible to prove that the heights have the same length in order to prove that the areas are equal. The view that the small triangles constructed on the heights generally is. If his parents are foreigners or if he has become a naturalised American, then the rule doesn’t apply. Qualifier: True: it’s only presumably so. Backing: It’s embodied in the following legislation:....
are equal can encourage the search for a theorem to prove this fact. The congruence criterions are remembered and the data to apply one of them is sought out.

A typical inductive argumentation could be the following. The student may consider some particular types of the triangles ABC: rectangle, equilateral and the like; or he may consider limit cases, for example, when the points A, B, and C are on the same line. This is an “inductive search” moving from particular to general laws. One of these examples can evolve into a particular example (exemple générique: N. Balacheff, 1988) which can lead to the proof.

**Example**

Using the model described above, we analyze an excerpt of the argumentation and the proof produced by students. Our purpose is to show how the analysis works in order to prove the efficacy of Toulmin’s model.

In order to analyse the argumentation, we select the assertions produced by students and we reconstruct the structure of the argumentative step: claim C, data D and warrant W. The indices identify each argumentative step. The student’s text is in the left column, and our comments and analyses are reported in the right column. The text has been translated from Italian into English. We start the analysis at claim C7; at this point students are comparing the area of the triangle ABC and the area of the triangle ICD. So far the students spoke about the construction of the heights of the two triangles. They decided to construct the heights in order to compare the areas of the triangles ABC and ICD.

|34. G: now, we need to do the line perpendicular to this line|33. L: ah it’s true!
|35. L: ah there’s it done but you know that it seems they are equal...|34. G: now, we need to do the line perpendicular to this line
|36. G: almost equal!|35. L: ah there’s it done but you know that it seems they are equal...
|37. L: no, more, it seems that they are perpendicular, I have observed this before|36. G: almost equal!
|44. Students together: hey, these are two triangles! |44. Students together: hey, these are two triangles!
|45. L: it’s true, ALC and ICM these are two triangles... what do they have?|45. L: it’s true, ALC and ICM these are two triangles... what do they have?
|46. G: we realized... then AC is equal to IC|46. G: we realized... then AC is equal to IC
because they are sides of the same square

47. L: wait!
48. G: AC is equal to IC because they are sides the same square, after
49. L: LC...
50. G: it's equal to CM, why ?
51. L: Then… Because it's equal to CM… in my opinion, it's better to prove… no wait this angle is right and this angle is right too.

The structure of the speech of the students is:

The triangles are equal to find sides and angles equal congruence criterion

The structure of the argumentative step is an abduction:

<table>
<thead>
<tr>
<th>D9 = ?</th>
<th>C9</th>
</tr>
</thead>
<tbody>
<tr>
<td>W: congruence criterion</td>
<td></td>
</tr>
</tbody>
</table>

The structure of the argumentation is that of an abduction. The students see that the small triangles constructed on the height are equal and they search for a theorem to prove this fact. We can observe that during the proof, students make data explicit in order to affirm that triangles ALC and ICM are equal. The abductive structure of the argumentation is transformed into a deductive structure in the proof. Once obtained, claim C9 is used to deduce that the heights of the triangles ABC and ICD are equal and consequently that their areas are equal.

The students write the proof:

I consider the triangle ABC and the triangle ICD.
At once I consider the triangles ALC et ICM and I prove that they are equal triangles for the SAA congruence criterion because we have:
• AC = IC because they are two sides of the same square
• ALC = IMC because they are right angles (angles constructed as intersection between the sides and the heights)
• ACL = ICM because they are complementary of the same right angle (-LCI)
In particular IM = AL. Then the triangles ABC and ICD have the same base lengths (as sides of the same square) and the same heights, then they have the same area.

The proof structure is a deduction:

<table>
<thead>
<tr>
<th>D9: AC = IC ALC = IMC ACL = ICM</th>
<th>C9: the triangles ALC and ICM are equal</th>
</tr>
</thead>
<tbody>
<tr>
<td>W: SAA congruence criterion</td>
<td></td>
</tr>
</tbody>
</table>

If the triangles are equal then it's possible to conclude that the heights are equal, and finally then the areas are equal because the bases are equal.

The conclusion C9 of the previous step is the date D10 to apply the inference to the second step.

<table>
<thead>
<tr>
<th>D10: C9</th>
<th>C10: the heights are equal</th>
</tr>
</thead>
<tbody>
<tr>
<td>W: inheritance</td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>D11: C10</th>
<th>C11: the areas of the triangles ABC et ICD are equal</th>
</tr>
</thead>
<tbody>
<tr>
<td>W: formula of area</td>
<td></td>
</tr>
</tbody>
</table>

The protocol is an example of cognitive unity (according to Boero, Garuti and Mariotti, 1996) Indeed, students use the “SAA congruence criterion” both in the argumentation and proof, in order to justify the statements. Words and expressions used in the two processes are often the same (“triangles ALC and ICM are equal”, “heights are equal”, and the like). But if we look more carefully, we can observe a change between the structures of the two processes: we find an abductive structure in
the argumentation (from \(D_9\) to \(C_9\)) that is transformed in a deductive structure in the proof. We cannot undervalue the importance of the structure in the comparison between argumentation and proof; it is not unusual that the student tries to transform abduction into a deduction during a resolution process (sometimes successfully, sometimes without getting an acceptable solution).

6. Conclusion

In this paper, we have analyzed some relationships between argumentation and proof; we have used Toulmin’s model as a tool in order to compare the structure of the two processes.

In the student’s protocols, it is easy to observe cognitive unity regarding the content; but even in this case, as far as structure is concerned, changes are frequently observed. The previous analysis carried out with Toulmin’s model clearly reveals the structure of both argumentation and proof facilitating the comparison between them. In particular when students use abduction during argumentation (and this seems to be natural in the production of a conjecture), a structural change is needed and can be detected in students’ protocols.

The study reported in this paper is still in progress. Further analysis will be carried out in order to clarify the nature of argumentation (particularly in the conjecturing phase) in order to find other analogies or differences with proof.

EFFICACY IN PROBLEM POSING AND TEACHING PROBLEM POSING

George Philippou, Charalambos Charalambous, and Constantinos Christou
Department of Education, University of Cyprus, edphilip@ucy.ac.cy

In this paper we examine the efficacy beliefs of prospective teachers' in posing problems and teaching problem posing in relation to their ability to construct problems. We used data from 115 questionnaires and 25 interviews to study the structure of perceived efficacy beliefs in problem posing, to examine the relationship between efficacy and actual performance in constructing problems, and efficacy to teach problem posing. The results indicated that students with high efficacy beliefs were more able to construct problems of more advanced complexity than low efficacy students. Significant differences were also found in the level of efficacy beliefs between subjects in terms of their mathematical background, prior involvement in related tasks, and gender.

AFFECT AND PROBLEM SOLVING

Despite the recently intensified interest on the affective domain, Schoenfeld (1992) argued that the arena of beliefs was under-conceptualised and stressed the need for new methodological and exploratory frames. He claimed specifically that "we are still a long way from a unified perspective that allows for a meaningful integration of cognition and affect or, if such unification is not possible, form understanding why it is not" (p. 364). In the following years research on the affective domain has resulted in notable theoretical advances, and there is now an expert consensus that affect is an essential factor in learning interacting with cognition during problem solving activities (De Bellis, 1997). Goldin (1998) proposed a five-component unified model for mathematical learning and problem solving. He considered the affective system as the most important among the five; the other four representations systems proposed were the verbal syntactic, the imagistic, the auditory, the formal notational, and the system of planning, monitoring and executive control.

Some of the questions already cleaned, to some extent, concern the structure and the development of the domain; the construct of affect, however, is still far from being well defined. The affective system includes components such as beliefs, conceptions, views, attitudes, emotions etc. related to mathematics and mathematical learning. If we define learning, as the development of one's general and specific "competencies", then affective competencies can be learned and consequently taught in the same sense as cognitive competencies can (Goldin, 1998). Regarding the teaching of affective competencies, the teacher's own belief system has a major role; it functions as a filter influencing knowledge and behaviour. Several components of the affective system have been so far investigated, including self-confidence, self-esteem, self-concept, and self-efficacy. In particular, research has shown that a teacher’s sense of efficacy is a reliable indicator of his/her teaching behaviour and effectiveness in bringing about desired learning outcomes. Teacher education programs should, therefore, enhance both the cognitive and the affective domain.

PME25 2001 4 - 41
Bandura (1997) defined self-efficacy as one's conviction that he/she is able to achieve a certain task. By analogy, teaching efficacy can be defined as one's belief in his/her capability to achieve learning outcomes. Self-efficacy is a context-specific construct in contrast to self-esteem, which is more global. That means that the study of teacher efficacy is more meaningful when carried out in terms of specific teaching tasks rather than in general. Several researchers found that the ability to construct problems and confidence in posing problems are among the most important competencies in mathematics learning, closely related to mathematics achievement. For instance, in models using path analysis the direct influences of efficacy beliefs on students' performance were estimated to range from .349 to .545 (Pajares, 1996). Furthermore, Pajares and Miller (1994) asserted that efficacy in problem solving had a causal effect on students' performance; they found that efficacy beliefs are better predictors of performance in problem solving than beliefs about the usefulness of mathematics, the involvement of students in mathematics, students' gender and experience with mathematics. In general, efficacy to perform a certain task was found to be the most reliable predictor of one's behaviour in the course of achieving this task (Bandura, 1997; Tschannen-Moran, Woolfolk-Hoy & Hoy, 1998).

Efforts to reform mathematics education had a direct impact on the philosophy of mathematics and consequently on instruction. Knowing mathematics has been widely identified as "doing mathematics" and learning mathematics as equivalent to constructing meaning for oneself and the ability to handle non-routine problems. In this context, problem posing comprises a primary factor that contributes to enhancing students' ability to solve mathematical problems (Leung, 1994). On the same line, a growing consensus that constructivism epistemology could provide the basis to prepare teachers in reform-oriented ways has led to an increased emphasis on developing teachers' ability to construct problems. One of the main responsibilities of primary teachers consists of constructing and/or selecting appropriate, pedagogically rich problem situations and orchestrates classroom activities, which facilitate students' effort to do mathematics on their own.

Problem-posing tasks may take various forms, and thus students can be involved in problem posing through a variety of situations. In this study, preservice teachers were asked to pose problems a) from a mathematical situation (Leung, 1994), b) from a given number sentence (English, 1997), and c) by modifying the structure, the data or the information given in certain problems (Gonzales, 1998). The main purpose of the study was to explore the relationship between the prospective teachers' efficacy beliefs on problem posing in each of the above-mentioned situations and their competence to complete the tasks. In this respect the present study sought for answers to the following questions: a) Is there a significant relation between students' efficacy beliefs in problem posing and their ability to construct problems? b) Is there a significant relation between students' efficacy beliefs in problem posing and their efficacy to teach problem posing? And c) are there significant differences in students' efficacy beliefs about problem posing in
terms of gender, prior involvement in problem posing, and mathematical background?

METHODOLOGY

Data collection: The data were gathered through a questionnaire consisting of 31 statements aiming at the clarification of students' involvement in problem posing and problem solving activities, and their efficacy beliefs with respect to these tasks. The questionnaire was administered to 115 preservice teachers during the final stages of their teaching practice. After a first analysis of the responses, 25 students were selected and interviewed. Six of the subjects involved in the interviews were from the low efficacy (LE) group, ten from the average efficacy (AE), and nine were from the high efficacy group (HE). The same tasks were administered to the rest of the students who did not take part in interviews.

The interviews: The interviews were semi-structured and conducted by one of the researchers. During the interviews we used tasks similar to the problems involved in the questionnaire. Each student was asked to construct problems given a mathematical situation, a number sentence, and a problem to modify. The tasks and the initial directions were as follows:

Mathematical situation (Task 1): Construct three problems based on the following story: "Michael, Nicolas, and John drove in succession on their way back from a trip. Michael drove for 80 km more than John. John drove for double the distance Nicolas did. Nicolas drove for 50 km ".

Number sentence (Task 2): "Construct three problems all of which could be solved using the equation 56: 6 = n".

Problem modification (Task 3): Read the following problem and construct up to seven different problems modifying the problem: "The students in a certain school were talking about their favourite singers. One fourth of them voted for singer A, one sixth for singer B, one eighth for singer C, and one twelfth for singer D. What is the student population of the school, if 90 students were undecided?"

The students were at first given time to construct problems on their own. Later on, whenever a student got stuck, the interviewer provided progressively clearer hints about possible ways of performing the tasks. For instance, in the case of Task 1, a common hint was "find a problem in which the answer is not fractional", in the case of Task 3, the students were advised to "insert new information", or "change the unknown", "impose new constraints", etc. If students were proposing an impossible or non-sensible problem, they were considered as failing to achieve the specified task.

RESULTS

Analysis of the questionnaires

Students' responses were factor analysed using Principal Axis factoring with varimax rotation. A five-factor solution, explaining 75% of the variance, was
identified as being the most appropriate in isolating distinct scales to identify efficacy beliefs (the loadings of all items were large and statistically significant). The first factor indicated efficacy in Task 1 and Task 2 and explained 21.4% of the variance. The second factor explained 19.71% of the variance and reflected confidence in Task 3, the third factor explained 12.58% of the variance and reflected the subjects' efficacy to teach problem posing strategies. The fourth factor explained 11.7% of the variance reflected prior involvement in problem posing activities and the fifth factor reflected students' experience in problem solving and explained 10.26% of the variance.

In exploring differences among students, we used extracted factors, which reflected efficacy beliefs, as dependent variables and the students' mathematical background (high-school strand\(^1\)), prior involvement in related tasks, and gender as independent variables. Analysis of variance showed that students from the science strand have more desirable efficacy beliefs than students in any of the other two strands (classical and the economics) in all three tasks of problem construction. The same pattern was also found on the teaching efficacy factor. There were no significant differences among the efficacy beliefs of the students from the economics strand and the students from the classical strand.

The subjects expressed significantly higher involvement with problem solving than with problem posing activities (\( \bar{X}_{ps} = 2.01, \bar{X}_{pp} = 1.66, p < .01 \)). The students' prior involvement with problem posing and problem solving was found to be related to their expressed efficacy beliefs; students with extensive experience in such tasks had a higher level of beliefs in their ability to construct problems and teach problem posing, than students with limited experience. Significant differences were also found between males and females on the factor efficacy to teach problem posing (\( \bar{X}_m = 3.11, \bar{X}_f = 2.71, p < .05 \)). These differences can partially be attributed to the male students' superior efficacy beliefs in their ability to construct problems from a given number sentence over female students (\( \bar{X}_m = 3.62, \bar{X}_f = 3.10, p < .05 \)).

Efficacy in Tasks 1, 2 and 3 was strongly correlated to the efficacy to teach problem posing (\( r = .58, r = .55, r = .52 \), respectively, \( p < .01 \)). The analysis also showed that "efficacy to construct problems" and "efficacy to teach problem posing" were significantly correlated (\( r = .62, p < .0. \) Finally, the level of students' efficacy beliefs to construct problems was significantly higher than the level of efficacy beliefs to teach problem posing (\( \bar{X}_{pp} = 3.27, \bar{X}_{tpp} = 2.81, p < .001 \)).

**Analysis of the interviews**

The interviews showed that a) all participants realized the importance of developing problem posing competencies, b) irrespective of efficacy level, they considered problem posing as harder than problem solving, and c) students valued

---

\(^1\)The students come from three high school strands: the science section (emphasis on mathematics and science), the economics section (emphasis and economics), and the classical strand (only core mathematics).
problem posing as the ultimate goal of mathematics learning. “A thorough understanding of problems and problem solving is evidenced when teachers and pupils reach the level of problem posing” (extract from interviews).

When facing a problem-posing task, 52% of the interviewed students felt uneasy (two of the LE students felt even anxious when assigned such a task). Five of the AE students said that even "hearing the term problem posing makes them feel insecure", and they consider problem posing to be "a very complicated process". The majority of the HE students felt quite comfortable with the task, though one of the students in this group mentioned that he "did not have any real experience and hence he did not like being assigned such a task". The differences among the three efficacy groups of students were more obvious, when the discussion was focused on the specific tasks of problem posing from a mathematical situation, a number sentence, or a given problem.

Concerning efficacy beliefs with respect to teaching problem posing, LE students were less confident than AE and HE students. Specifically, three LE students felt that they were "not well prepared to involve their students in problem posing activities". Explaining their position, they stated that they themselves "faced so many troubles in problem posing” and were "not confident in undertaking such a task". Two others expressed their "reservations..." and "felt more comfortable in teaching problem posing in the lower school grades". The AE subjects were more or less ready to pursue the task, though "they needed more experience with problem posing". On the contrary, five of the HE students stated that they were well prepared to integrate problem posing in their teaching, while two others held the same beliefs as the AE students, i.e., they said that they needed "additional experiences".

A student was rated as successful in a task when he or she was able to construct a good problem with little or no help. Given the initial efficacy statements of the students in each of the 13 assigned tasks, we tested the correlation coefficient between stated efficacy and performance in each of these cases. The correlations were in the range of .724 and .866 and they were significant at the .01 level.

Task 1: To rate the quality of the students’ problems we adopted the linguistic and structural criteria established by English (1997) and Silver and Cai (1996). The most important elements in a problem are (a) the type of the question, and (b) the number of important relations involved in the problem structure. The same authors classified problem questions as conditional, relational, and assignment; conditional and relational questions are more complicated than the direct assignment questions. Similarly, the number of relations involved in a problem is an indication of the complexity of the problem. Bandura (1997) asserted that efficacy beliefs could be a good predictor of the quality of peoples’ work. The average number of conditional and relational problems constructed by each efficacy group was 1.13, .92, and .64 by the high, the average and the low efficacy group, respectively (significant at the .05 level). Finally, HE students constructed eleven assignment questions, eight relational, and two conditional questions. We
also observed an increasing trend of complexity from the first constructed problem onwards. The average number of relations per proposed problem was 2.40 for LE subjects, 2.59 relations for AE subjects, and 2.84 for the HE subjects (non-significant difference). Table 1 shows indicative problems constructed by the students in each efficacy group.

</table>

Task 2: The students had great difficulties in constructing problems given a number sentence. Most of the students explained their difficulties saying "there is no story to start with...one has to start from the beginning, to create everything in his/her own mind". Three LE students were unable to construct problems eliciting answers other than 9 2/6 (56: 6 = n) despite of being helped by the interviewer. The AE and the HE students could somehow construct a problem, but it was evident that this task was more difficult even for them.

Task 3: The second easier task was constructing a problem by modifying a given one for the majority of students (Task 1 was generally judged as the easiest). About 64% of the subjects initially thought to change the story of the problem, 56% to change the values of the variables or the unknown, 28% to introduce new information and 28% to delete some information. However, only two of the subjects thought on their own to impose new constraints or extend the problem using "what if" strategy.
Another dimension differentiating students in different efficacy groups concerns checking the constructed problems by solving them. The majority of the AE and the HE students checked the solution of the problems they constructed, in contrast to LE students of which only three attempted to check anyone of the posed problems.

DISCUSSION

The findings of this study underline the importance of students' background and involvement with problem solving and particularly with problem posing. The analysis of the questionnaire data provides support to Bandura's (1997) claim that the main source of efficacy beliefs comes from the individuals' experiences with similar and related tasks. As one LE students mentioned, "What I really lack is confidence in myself, that I will succeed in doing a problem ... my prior experience was, so far, to solve a problem than to construct a good problem to assign to students". The high school strand was related to efficacy in problem posing. Since the science students are generally involved in more extensive and rich mathematical experiences than the rest of the students, this factor is not different from one's overall mathematical involvement. Males were in some cases found to hold higher efficacy beliefs than females. One possible explanation could be the masculine "aggressive" attitude to overestimate own capabilities against the feminine moderate attitude, influenced by the well-known role stereotypes.

The significant correlations between the prospective teachers' efficacy beliefs in problem posing and their ability to construct problems indicate that efficacy constitutes a reliable predictor of the subjects performance in problem posing from the types of sources examined in the present study. Furthermore, these beliefs provide a clue about the quality of the results in such a task. For instance, the AE and the HE students were able to construct more problems and of higher complexity, as indicated by the type of the questions raised and the number of relations involved. In addition, these subjects used to test their problems and felt more comfortable with this task of problem posing, in contrast to the LE students who felt anxious, when facing a problem-posing task and seldom did they test the problems they constructed. For instance, one of the LE subjects mentioned, "What I really lack is the confidence in myself, ... that I will succeed in making a problem. My prior experience was so far in solving problems, ... not to make up a good problem to assign the to others".

In conclusion, the above findings suggest that developing efficacy beliefs in problem posing should be an integral part in any preservice teacher education program. Efficacy beliefs constitute "an important component of motivation and behaviour" (Pajares, 1996, p. 341) and consequently are important for integrating
problem posing and problem solving in classroom instruction. The correlation found among the efficacy in problem posing and the students' beliefs about teaching this activity suggests a possible focus for further research.

Abstract
This paper describes a research project that used a variation of the Draw-A-Scientist-Test (DAST) to investigate and compare the images of mathematicians held by lower secondary pupils (ages 12-13) in five countries. We report that with small cultural differences certain stereotypical images of mathematicians, and some surprising and disturbing images, were common to pupils in all of these countries. Further, we found that for pupils at this age, mathematicians are for all practical purposes invisible to pupils, and so the images they adopt to fill this void arise either from the media, or, in some cases, from negative experiences in mathematics classes.

1. Introduction
For the past decade there has been increased discussion and research about images of mathematics and mathematicians (Furinghetti, 1993; Henrion, 1997; Lim & Ernest, 1998; Rock & Shaw, 2000) as well as what has been referred to as the "mathematics image problem" (Howson & Kahane, 1990; Malkevitch, 1989; 1997). Research has shown that images of a particular field can affect who goes into that field (see Henrion, 1997), and where students may see mathematics as unattractive, and as populated with persons very different from themselves, they may be less likely to seriously consider entering it (NSF, 1998).

Lim and Ernest (1999) point out that it is only through ascertaining how popular or unpopular mathematics is, that measures can be created to change and improve its public image. And if, as Jaworski (1994, p. 218) seems to imply, learning mathematics is related to being a mathematician, what she calls "being mathematical within a mathematical community," then where pupils have images of mathematicians that are inaccurate it may hinder their study of mathematics.

The decision to investigate pupils’ images of mathematicians came after seeing images produced from a class assignment given to her pupils by a colleague in...
New York City, to: *Draw your perception of a mathematician*, one of which is reproduced in **Figure 1**:

![Figure 1](image)

**Figure 1** Female 7th Grade (UK Year 8) Pupil

We then learned of similar studies involving pupils’ drawings of scientists, the *Draw-A-Scientist Test* (DAST), (see e.g., Chambers, 1983; Finson, Beaver & Cramond, 1995; Huber & Burton, 1995; Matthews and Davies, 1999; Barman, 1999), which showed that the images pupils held of scientists were increasingly stereotypical and increasingly male, by the time pupils leave the middle grades.

2. **The Aims and Framework of the Research**

We came to feel that images held by pupils aged 12-13 (Year 8 in the U. K. and Europe; 7th grade in the U. S.) might afford us some view of pupils at a sensitive age—one in which studies show negative attitudes begin to form (see Aiken, 1970; also Lucas, 1981) and we hoped to understand whether any of these images were held in common in the different countries involved in our survey. The 476
pupils involved in the study were from schools in the following countries: USA (n= 201), United Kingdom (n= 99), Finland (n= 94 ), Sweden (n= 49), Romania (n= 33).

3. Research Methodology and Methods

The study was primarily qualitative and interpretive in design, with purposeful sampling since in some cases we had to rely on colleagues in other countries to administer the survey tool.

Pupils were given a one page two-sided questionnaire that asked them to “draw a mathematician at work.” There were also two open-ended prompts: the first asked pupils to explain and enumerate the circumstances under which one would need to hire a mathematician; the second prompt asked pupils to explain their drawings. We hoped with the first question, to ascertain what it is that pupils think mathematicians actually do. With the second prompt, we hoped pupils would give more information about the gender of their mathematician and perhaps reveal something further about their beliefs. The combination of pupils drawing and writing with interviews of some of the American pupils provided a triangulation of the data.

5. A Sampling of the Results

Pupils’ written explanations for why a mathematician would be hired showed that they believe that mathematicians do applications similar to those they have seen in their own mathematics classes, including arithmetic computation, area and perimeter, and measurement. They also believe that a mathematician’s work involves accounting, doing taxes and bills, and banking; work which they contend includes doing hard sums or hard problems; yet in interviews pupils could supply no specifics about what such problems entail. We came to conclude that for pupils of this age, mathematicians are invisible.

The drawings from the surveys showed many similarities among the different cultures. Upon examination, we identified seven sub themes among them:

- **Mathematics as coercion**, in which pupils drew mathematicians as teachers who use intimidation, violence, or threats of violence on their pupils. This was a completely unexpected theme that emerged;
- **The foolish mathematician**, in which mathematicians were depicted as lacking common sense, fashion sense, or computational abilities;
- **The overwrought mathematician**, in which mathematicians were depicted as looking wild and being overstrained, to quote a pupil from Sweden;
- **The mathematician who can’t teach**, in which a classroom is drawn which the mathematician cannot control, or in which he doesn’t know the material;
- Disparagement of mathematicians who are depicted by pupils as being too clever or in some other way contemptible;
The Einstein effect; and
The mathematician with special powers, which may include wizardry and special potions.

We detail two of these sub themes: mathematics as coercion, and the mathematician with special powers, because they afford us a surprising view of pupils’ images from their classroom experiences. And while some of the drawings could easily fall under more than one of the sub themes, the hope and intent was to highlight international commonalities amongst them.

5.1.1 Mathematics as Coercion
This sub theme can be seen in two drawings from Finland, and in drawings from Sweden, the United States and the United Kingdom. In each, the pupil has drawn a large authority figure intimidating someone smaller, sometimes with violence or threats of it. It is interesting that there was no drawing of this type from Romania, even as pupils’ mathematics classes are very demanding.

In the drawing in Figure 2 from Finland, a Svengali-like figure prompts a trembling pupil in the first panel, then, in the second panel, a devil’s tail peeks out from his coat as laughing maniacally, he beats the pupil for not knowing the answer to a simple arithmetic problem. The difference in their stature is accented by the pupil’s having to stand on a stool.

In two drawings, from Finland and Sweden (see Figure 3), there are rifles pointed at smaller figures. In Figure 3, a pupil is also being asked to do simple arithmetic. The pupil wrote about his drawing: He is a strong mathematician. If you answer wrong he [will] KILL you.
It is jarring to see images of guns and violence from countries whose societies are not known for this type of behaviour, within schools or without. Similar drawings from the United States, which however has a regrettable history of violence in its schools, nevertheless contained intimidation but in a different form, with no such threats of violence coming from a teacher.

![Drawing of a mathematician at work: can you answer this? 3+2 = 5.](image)

**Figure 3** Sweden—male pupil

The drawings from the U.S. and U.K. also contain large authority-figures. In the American drawing the girl who drew it wrote: *A white Caucasian male saying complicated things to a class of small children (only 1 child represented).* And in the drawing from the U.K., a menacing-looking teacher is drawn on a stage ordering punishment, evincing what Nolan and Francis (1992, p.46) call a teacher centred conception of teaching in which the teacher “occupies the centre stage of the educational drama.”

In these drawings again, the differences in statures between the authority-figures and the pupils is notable. And it is worth noting, too, that pupils have chosen to draw small children although the pupils creating these drawings are no longer small children, but in their early teens. It is possible that for the pupils creating this type of drawing, the experiences that have produced such images come from a time when they were much younger and felt more keenly their own lack of power. But these images are now carried into the present, with the result that the image of mathematics represented in each of these drawings is that of a bewildering and intimidating subject, placing pupils in a situation over which they have no control; of being excluded from the world the teacher inhabits—the teacher on a stage is one example of this remove—of sitting powerlessly in a class while a large adult says complicated things.
Davis & Hersh (1981, p. 282) have illuminated the origin of this perception of powerlessness in the minds of students:

Mathematical presentations, whether in books or in the classrooms, are often perceived as authoritarian...Ideally, mathematical instruction says, ‘Come, let us reason together.’ But what comes from the mouth of the lecturer is often, ‘Look, I tell you this is the way it is.’ This is proof by coercion.

The theme of power is a large one in children’s literature, often including secret and supernatural powers. It may also be a large factor in what is being referred to as “the Harry Potter phenomenon” (Jacobs, 2000), on both sides of the Atlantic, for as one reviewer of the fourth Rowling book (Acocella, 2000, p. 77) observed: “The subject of the Harry Potter series is power, an important matter for children, since they have so little of it.” In interviews, Rowling (see, e.g., Fraser, 2000, pp. 5-6, 8) has spoken about her experience of feeling intimidated in mathematics class at school.

The large size of the teachers in these drawings would seem to indicate pupils’ perceptions of having more often had to deal with conformity and authority than sense-making in the classroom.

5.1.2 The Mathematician With Special Powers
The drawings in this theme contained references to special powers, from a Superman-like S on the chest of a mathematician drawn by a Romanian pupil to a figure creating a maths potion, drawn by a pupil in the U.K., to a series of wizards who appeared less than benign.

The very idea of a maths potion or super power implies that something extraordinary is necessary in order to do mathematics. And it is also related to the general invisibility of the mathematical process, for with the process hidden, mathematical facility looks more like a power than an ability, which anyone has the possibility to learn.

And although these are not the same wizards as in Harry Potter—the books had not caught on at the time of this survey as they have since—comments on the meaning of the magic in relation to the books are still, we believe, relevant. For as Jacobs (2000) indicates, anything that is “sufficiently inscrutable” might as well be the product of wizardry.

6. Implications for Pedagogy and Conclusions
Along with our finding that for pupils of this age, mathematicians are essentially invisible, is the conclusion that pupils appear to rely on stereotypical images from the media to provide images of mathematicians when asked.
We could not have anticipated how much pupils' drawings would provide a window onto their experiences in their mathematics classes. We believe that the drawings created by the pupils contain valuable insights with significant implications for teachers, their training, and their practise.

Pupils appeared to use experiences of having been intimidated in mathematics classes (You should know this!) and their criticisms of teachers for doing this, at times to depict mathematicians in their drawings in a vengeful manner, something with which they were aided by images of mathematicians in the media. How pupils can be made to feel in a classroom by teachers, appears centrally in many of the drawings, from feeling intimidated at not knowing something, to being dazzled by a teacher's polish and ability, to exploiting a teacher's inability to control a classroom, and I think seeing all these possibilities portrayed in the drawings can spur rich discussions and significantly raise teachers' consciousnesses.

The projection of supernatural powers onto mathematicians appeared in drawings by pupils in each country. When Arthur C. Clarke (in Jacobs, 2000) observed that, "Any smoothly functioning technology gives the appearance of magic," he could as easily been commenting on what pupils perceive as a "smoothly functioning" ease many teachers exhibit with mathematics, a facility that to many pupils also looks like magic.

The dominant image of a mathematician that emerged from this study is that of a white, middle aged, balding or wild-haired man. This points to both a gender and a racial gap in pupils' images of mathematicians, which is consistent with those findings of the DAST.

This paper presents a framework to follow students' development through a formal mathematics course. Built on learning episodes of two groups of three students attending a traditional university course, it highlights different cognitive demands learners will have according to their personal learning strategy.

Introduction

In this article we trace the development of students through the learning of limit concepts in sequences, series, continuity and differentiation, using and refining the routes of learning identified as formal and natural (Pinto 1998, Pinto & Tall, 1999). In this study we focus on three levels of development in each route. Formal thinkers attempt to base their work on the definitions, but the handling of three nested quantifiers imposes great cognitive strain. Some fail to cope with the complexity of constructing meaning, often focusing on manipulating the symbols and inequalities rather than the logic. Natural thinkers reconstruct new knowledge from their concept image. Unsuccessful learners in this route attempt to interpret the definitions in a personal way that fits their imagery, rejecting the formal theory or leading to conflict. Students who get past this initial hurdle cope with the definitions and deductions in their own personalised ways. Formal learners essentially construct the theory by deduction, coping with the great cognitive strain as best they can, producing a deductive formal theory. Natural learners—working from their concept imagery—reconstruct it taking account of more general ideas met in the course. They must then develop the formal theory from their reconstructed imagery, producing a formal theory integrating both imagery and deduction. This summary of data leads to a concise framework of development (table 1).

Table 1: levels of development in natural and formal routes to learning formal mathematics
Methodology

This study builds on a cross-sectional analysis of three pairs of students selected to best approximate prototypical strategies of learning from eleven students who were studied in seven interviews at three-week intervals. At this stage of theory development we move from a study of a single limit concept (the convergence of a sequence) to take into account successive encounters with sequences, series, continuity, differentiation, and a final reflective interview with each student. Our purpose is to study the ways in which different students interpret the material presented to them by the lecturer.

The ‘formal’ route of learning

Three levels of development are identified for the ‘formal’ route, which we describe as:

1: Initial Obstacles (working with the concept definition).
   1a: routine approach, disjoint from images, focusing on rules and procedures, partially achieved.
   1b: routine approach, some link with images, causing conflict, unable to coordinate processes.
2: Theory building (with some evidence of routinising reflectively).
3: Formal deductive knowledge.

We consider three students, Rolf, Robin and Ross, who focus on the formal structure of the course. Rolf’s constructions define level 1a; he withdraws from the course after the first ten weeks. Robin starts at level 1b, and then consolidates his work at level 2. Ross distrusts his limited visual imagery and concentrates on the formal theory at levels 2 and 3. On occasion he uses visual imagery unsatisfactorily and this part of his activity is also considered.

Rolf attempts to build from the formal definitions and proofs from the outset. DEFINITIONS are rote-learned inaccurately. However, in handling questions involving direct calculation, he is able to provide ARGUMENTS that seem to be based on the formal theory. For instance, he explains the constant sequence 1, 1, 1, ... is convergent, saying:

“Take the sequence 1, 1, 1, ... the N is just any greater than zero. Big N is just 1 basically.”
(Rolf, first interview)

He relies on the authority of the lecturer to decide what is important:

“...I have been told that a formal proof is a proof involving epsilons. That’s why I think that.”
(Rolf, second interview)

He focuses on rules, procedures and his IMAGES arise from his routine activities rather than from pictures. He is confused rather than in conflict (level 1a):

“I understand the reasoning, but I mean, I can do it. And the reason I can do it is maybe because I understand it err I don’t know. I don’t know if I understand everything or I don’t, because I don’t know. If I am not understanding something that I don’t know, then I don’t know basically, you see what I mean. I mean, as far as I feel, I understand everything about this, [...] but I haven’t a clue. You see, I don’t know.”
[Okay, you are saying you can work it out.]
“Yes, I can work it out.”
(Rolf, third interview)

At the beginning of his second term, Rolf transferred to another university.
Robin begins in the same way as Rolf, routinising mechanically, but unable to coordinate processes (level 1a). DEFINITIONS and ARGUMENTS may be categorised in the same manner as Rolf. However, Robin attempts to link IMAGES built from the formal theory to previous experiences, which generates conflict (level 1b).

"I mean, the making ... I could understand it said: by finding the value of N ... it actually ... is the proof that the ... sequence is tending to zero. That was a bit awkward, I couldn't get that to start with. I could understand what the definition was saying, but, to me, it didn't seem to be proving ... that it went to zero. ... I'm not ... not fully happy with this. There's still things I've got to get sorted out. But ... I get ... I have made some progress since I started.”

(Robin, first interview)

We understand that time pressure and weakness in his elementary mathematical background hampered his attempts to construct meaning for the formal theory.

Robin sometimes evokes visual images; he explained that imagery was helpful for him to get a sense of what was being proved.

"... I was saying that in Analysis II, we did a lot ... from the theorems, he (the lecturer) would say: here is a graph for the theorem; well, he is showing what is going on, and that, to see it pictorially, helps to understand incredibly, really."  

(Robin, seventh interview)

However, he is unable to translate such analogical representations into formal language, and continued to focus on the formal route while failing to cope with the full complexity of the definitions.

Ross—the most successful formal learner—starts by constructing formal knowledge through routinising reflectively on the theory presented in the lectures (level 2). DEFINITIONS are formal, correct with occasional slips. ARGUMENTS are meaningful, based on the formal theory. IMAGES are generally built from the formal theory, usually compartmentalised from previous experiences. For instance, contrasting old and new experiences does not cause him conflict as in the limit of a constant sequence.

"Umm 1, 1, 1, ... umm yes, because it's a set of ones, so it would tend to 1, because ... it's not changing. But ... now again when she [the lecturer] first said that like 1, 1, 1, ... tends to 1, then I thought it was bit strange, because you tend to think of the sequence going up and then gradually getting closer and closer to a value so that if you go sufficiently far out then it's reached a value, whereas 1, 1, 1, ..., I mean, you can take the first term it's already at the limit umm but I mean ... this ... definition works for that, so ... so it must tend to value ... so...”

(Ross, first interview)

Ross forms strong conceptual links between successive notions of limit. For example, he perceives the link between series and the previous formal theory of sequences:

"Umm ... well, the way, I mean, in the order of the things we've done umm it makes sense the feature of relating the series back to sequences, which was what we started off doing so ... if you can convert a series into a sequence ... then you just deal with a sequence ... ... I suppose ... umm by ... relating a convergent series with convergence of sequences then ... you are building up all of this umm area of maths from a very small .... each new step that you do up series you will be relating to something you have already done so ...”

(Ross, third interview)

This aspect is a characteristic of Ross’s performance during the course.

Ross maintains his strategy of practising routines and familiarising himself with the formal theory (level 2). There are times when he is unable to solve problems, such as writing a proof that a real function defined on Z is continuous, even though he could
write down a formal definition of continuity for a function \( f : \mathbb{R} \to \mathbb{R} \). His DEFINITIONS are always formal, correct or nearly correct. He always tries to relate ARGUMENTS to the formal theory. He realises the weakness of his own visual imagery and seeks the safety of formal definitions and deductions. On the few occasions where he evokes visual IMAGES they are often linked to previous experiences, with conflicts or inconsistencies. For instance when discussing the function \( f(x) = x \sin(1 / x) \) he argues:

"...I think there is sort of ... the oscillations are getting closer and closer together and ... so I suppose a tiny change in \( x \) produces a huge change in the gradient and so at nought itself there is no way to find the gradient ... I suppose ... it's going up and down (??)"

(Ross, sixth interview)

He seems to be talking about \( f'(x) \) rather than \( \frac{f(x) - f(0)}{x} \) as \( x \) nears zero.

In this last example we see a student we have classified as a formal learner using visual links. We do not claim that formal learners never use imagery. Taking the formal route means relying on formal definitions and proof to generate the theory. Meaning arises from the formalism itself rather than from any underlying pictorial images.

**Following the ‘natural’ route of learning**

The three levels proposed for the natural learner are as follows:

1: **Initial obstacles** (based on the concept image).
   - 1a: formal theory is rejected, not assimilated,
   - 1b: formal theory is embedded within the old.

2: **Theory building** (in conflict with formal theory).
   - 2a: thought experiments reconstructing images,
   - 2b: Deductions reconstructing formal theory.

3: **Formal theory** (integrated with imagery).

Cliff, Colin and Chris are natural learners developing through the course at different levels. Cliff, the least successful, reveals some characteristics of level 1, Colin’s conflict characterises level 2a and the most successful, Chris, works at levels 2 and 3.

Cliff interprets new knowledge in terms of old, at levels 1a and 1b, ignoring the new experience if it does not fit his previous experiences, or rote-learning, to respond as he perceives being required by the course assessment. ARGUMENTS are image-based, or eventually pragmatic, and IMAGES are not reconstructed to fit the formal theory. For instance, when asked to consider the convergence of a constant sequence, he says it does not tend to a limit because

"1, 1, 1, 1... no, it’s just 1, 1, 1, 1 continuously." (Cliff, first interview).

As the course progresses, the formal theory is never assimilated (level 1a). DEFINITIONS are not reproduced formally and are given in terms of imagery:

"Err ... continuous means what ... I’ve got my definition of continuous function as ... I can draw the graph and you don’t lift the pencil if it’s continuous..." (Cliff, fifth interview)

or restricted to particular prototypes:
“Umm ... well, I think it’s any function ... any function can be differentiated ... any normal function.”

[What is a normal function for you?]

“Umm ... like y = 3x or y = 3x + x^2.”

(Clip, sixth interview)

This instance shows Cliff’s evoked images of functions as prototypes restricted not to continuous functions, but to polynomial ones (Vinner, 1983; Vinner & Dreyfus, 1989). In the seventh interview, he is back to the same strategies as in the very beginning (level 1b), rote-learning definitions in a way that is not suitable for formal deduction.

In a middle trajectory, Colin starts in the same way as Cliff and interprets new knowledge in terms of old. Sensing results and theorems are true, he does not understand why he is being asked to prove results that he believes to be obvious.

“It seemed to be a silly question that ... if a_n tends to 1 then if you question when a_n is greater than 3/4... this is a bound, it seems ... I don’t know why... ...”

(Colin, second interview)

As the course progresses, he gradually perceives his IMAGES in conflict with the formal theory (level 2a); allowing him to attempt to begin attempting to tackle proof:

“... now I am sort of getting into it (into the course)... what I am supposed to be doing... how I am supposed to be proving things... so it’s got a bit easier.”

(Colin fifth interview)

DEFINITIONS remain distorted or eventually rote-learned and ARGUMENTS are image based such as:

“... sin x is differentiable because I can always find the gradient of sin x.”

(Colin, sixth interview)

Conflict between old and new images makes him move a little:

“How do I prove this... umm well, you just show that the umm you can work out the gradient for all points on the curve.”

[Okay, but how do you prove that ...]

“How do I prove it... umm ...

\[
\lim_{x \to a} \frac{f(x+h) - f(x)}{h} = f'(x)
\]

umm ... so like that ...

(Colin, sixth interview)

In this sense the natural learner’s difficulty with formalism corresponds to the formal learner’s confusions with the underlying concept image. However, Robin’s formal trajectory discussed earlier contrasts with Colin’s conflicting ‘natural’ route. Robin does not know what he is proving so he builds a theory with weak conceptual links. Colin does not know why he is being asked to prove statements but he senses their truth.

Colin’s old images deeply interfere with any reconstruction and he appears to be in a state of conflict until the end of the course. For example, after presenting a proof that 0.999... (recurring) is 1, using partial sums and the definition of convergence of a series, he comments:

“... ... It’s sort of ... I understand it should be 1 ... and that the limit of the sequence is actually 1 just ... 1 down as notation. It just it’s a bit hard to let go of 0.9999 recurring ...”

(Colin, seventh interview)
Chris—the most successful natural learner—constantly seeks reconstruction of old knowledge to build new. (level 2) and finally develops an integrated formalism (level 3) in which he can write both the quantified form of the definition of limit and also verbalise his own image for it:

A sequence has a limit if and only if as the sequence progresses, eventually, all values of the sequence gather around a certain value.

(Chris, seventh interview)

His DEFINITIONS are always correct, or nearly correct. ARGUMENTS are based on thought experiments, most of the time articulating images reconstructed with the new theory. For example, a classical question resolved in classroom by handling inequalities:

If \( a_n \to 1 \), prove that there exists \( N \in \mathbb{N} \) such that \( a_n > \frac{3}{4} \) for all \( n > N \).

has its solution verbalised by Chris as an experiment

"I chose epsilon as 0.1 ... and showed that \( a_n \) lies between 0.9 and 1.1; so it must be greater than \( \frac{3}{4} \)."

(Chris, second interview)

In general Chris is able to present his arguments formally. However, as he builds on his imagery (level 2a), he sometimes formulates image-based thought-experiments, such as initially restricting his concept of divergence to plus or minus infinity he also visualises continuity as "drawing the graph without taking the pen off the paper". We hypothesise that solving conflicts between old and new ideas is central to the natural route (see also Vinner, 1991). For instance, the fact that a constant sequence converges according to the formal theory surprises Chris, because it conflicts with his old images:

"(Laughter) I don't know really. It definitely it will ... it will always be one ... so I am not really sure (laughter) ... umm ... it's strange, because when something tends to a limit, you think of it as never reaching it ... so if it's ... 1 ... then by definition it has a limit but ... you don't really think of it as a limit (laughter) but just as a constant value."

(Chris, first interview)

As in the case of Cliff, such images may have been evoked by the use of the word "tends to" in the formulation of the question (see Schwarzenberger & Tall, 1978; Cornu, 1991; Monaghan, 1991). Data shows Chris adding new facets as additional information, as a ‘natural’ strategy of coping with new experiences, closely related to how we function in our everyday world. In his last interview, he resolves his earlier conflicts with constant sequences:

"Umm ... it's that ... where the values are the same, it doesn't deviate at all."

[Doesn't deviate.]

"Doesn't deviate on the line ... and then that must be the limit." (Chris, seventh interview)

**Discussion: following students’ development**

Tables 2 and 3 summarise the development of the students over the twenty weeks of the course. (The shaded entries represent transitional movement into the given level.)
Rolf, Robin and Ross are classified as ‘formal learners’ who build their schemas by routinising and familiarising themselves with the formal constructs. They attempt to handle quantified statements, constructing representations which are propositional (see Eysenck & Keane, 1997). Rolf cannot cope with the formal definition and only reproduces partial procedures (level 1a) before withdrawing from the course. Robin finds great difficulty initially, with his underlying images in conflict in sequences, series and continuity, (level 1b) but persists in his formal route and manages to start making formal constructions (level 2) in dealing with derivatives. Ross works mainly at level 2, memorising the definition and working with the formal proof. He shows an understanding that the topic ‘series’ has essentially already been formalised using ideas from the previous section (‘sequences’). This is acknowledged by classifying his responses as being in transition to a full formal theory. In the final interview he is classified at level 3.

Cliff, Colin and Chris are classified as ‘natural learners’ because they use their own imagery as a starting point to build their theories. These learners support their construction with analogical representations (Eysenck & Keane, 1997), which they build using their old imagery. Cliff clings to his informal imagery, making no headway with the formal theory (level 1a) throughout the course. Colin makes an attempt at the formal theory building it first on imagery (level 1b) then modifying his imagery (level 2a) as he moves on to continuity, finally beginning to build formalism on his modified images (level 2b). Chris operates at level 2 and moves to level 3.

Drawing conclusions

This research unfolds aspects of individual construction of knowledge that differ from other proposed frameworks. For instance, the strategy of encapsulation of process into object (Dubinsky et al., 1988) does not appear to provide a model to explain the cognitive strategies of the ‘natural’ route of learning. Rather than constructing a concept image from a defined object, abstracting from ‘actions on objects’, the successful natural learner understands the defined object by reconstructing it from the concept image.

At the other end of the spectrum, we note that there are concept images not developed through formal deduction (Tall & Vinner, 1981) which nevertheless may seem coherent with the formal models. These may or not be capable of translation into formal language. The concern is that such concept images may give the learner an apparent grasp of the theory, though they may not be sufficient to guarantee long-term success.

In the teaching of advanced mathematics, this research shows there does not seem to be a single methodology or ‘formula’ that works for all students. Even first class students encounter times where they struggle badly. Learners have different cognitive demands, according to their own strategies of learning. Perhaps teachers may address the needs of both routes to learning. However, there is still a distinct possibility that natural learners may be confused by formal instructions just as formal learners may be confused by references to imagery, so that it may require more subtle treatments for different kinds of student.

MATHEMATICS SUBJECT KNOWLEDGE REVISITED.

Stephanie Prestage and Pat Perks
School of Education, University of Birmingham

Our research over the last few years about teachers' mathematics subject knowledge, has led to a model for thinking about subject knowledge which distinguishes between knowledge needed to pass examinations and that needed to help others to come to know. This paper explores this model in depth and uses interviews with pre and in-service teachers responding to questions on graphs and percentages, to exemplify the model.

Introduction

Teachers hold many professional knowledges, knowledge about pupils, systems and structures; about styles of teaching and learning; about management, resources and assessment as well as knowledge about the subject. Research offers definitions of professional knowledge and the different forms of knowledge that a teacher holds, (Brown & McIntyre 1993, Cooper & McIntyre 1996, Desforges & McNamara 1979, Ernest 1989, Marks 1990, Calderhead & Shorrock 1997, Banks et al 1999).

It is clear that learning to teach involves more than a mastery of a limited set of competencies. It is a complex process. It is also a lengthy process, extending for most teachers well after their initial training. (Calderhead & Shorrock 1997, p.194)

This paper considers mathematics teachers’ subject knowledge and describes a model for different aspects of a teacher’s knowledge about mathematics. Subject knowledge is an aspect of teachers’ professional knowledge known to be problematic, but one which ‘has provoked more controversy than study’ (Grossman et al 1989).

While one can infer from studies of teacher thinking that teachers have knowledge of their students, of their curriculum, of the learning process that is used to make decisions, it remains unclear what teachers know about their subject matter. (Wilson et al., 1987 p.108)

Research in the particular area of subject knowledge and pedagogical content knowledge (Shulman, 1986, Wilson et al. 1987, Tamir 1988, Aubrey 1997) explores the transformation of subject matter knowledge for the classroom; teachers’ knowledge about explanations, tasks and activities, about styles of teaching and learning. But it does not include explicit detail of how such subject knowledge is held in an intellectual way by teachers, other than is shown by activities or explanations given. The mathematics is rarely explicit. Whilst Shulman and others have categorised the different components of subject knowledge and discussed its transformation through classroom events, our research data was used to investigate the ways in which teachers’ subject knowledge in mathematics is held and transformed.

We agree with Buchmann (1984) that teachers need a rich and deep understanding of their subject in order to respond to all aspects of pupils’ needs: ‘Content knowledge of this kind encourages the mobility of teacher conceptions and yields knowledge in the form of multiple and fluid conceptions’ (ibid. p.46). Evidence from our earlier research led to a hypothesis that teachers’ subject knowledge in mathematics is held in two forms either as learner-knowledge or as teacher-knowledge in mathematics; the former is the knowledge needed to pass examinations; the latter is the knowledge needed to
plan for others to come to learn the mathematics. Auditing the former might be necessary (currently demanded on Initial Teacher Education (ITE) courses, DfEE 1998) but is not sufficient for the developing teacher. Such audits offer limited list-like perspectives of knowledge to be held by teachers, a view shared by others.

The shared assumption underlying [such] research is that a teacher’s knowledge of the subject matter can be treated as a list-like collection of individual propositions readily sampled and measured by standardised tests ... [these] researchers ask what a teacher knows and not how that knowledge is organised, justified or validated ... [such research] has failed to provide insight into the character of the knowledge held by students and teachers and the ways in which that knowledge is developed, enriched and used in classrooms. (Wilson et al 1987, p. 107)

It is the very ‘character of the knowledge’ in mathematics that we sought to provide insight by interviewing experienced and pre-service teachers.

A model for describing subject knowledge

The nature of the initial research has been reported elsewhere (Prestage and Perks 1999a). Analysis of teachers' responses to discussions of subject matter gave categories of phases in which aspects of their mathematics knowledge was held. This offered ways to explain the differences in the types of responses and how transitions might be described, leading to a model. Whilst the roots of the model lie in a variety of research, an explanation of its components is more easily given via our ITE students.

Graduate mathematician students to our secondary pre-service course arrive with personal subject knowledge (learner-knowledge) that enables them to answer mathematical questions. When asked to calculate the division of one fraction by another or to differentiate a function, all respond correctly. When asked why the answers are correct they do not know. They can do mathematics but they do not necessarily hold ‘multiple and fluid conceptions’. ITE students also bring with them their personal beliefs about ‘being a teacher’. Their view of teaching is to replicate the learner-knowledge they hold for others to learn, a view sometimes held by experienced teachers (Prestage 1999). Their subject knowledge is often ill-connected and they have to work on this when planning for teaching (Perks & Prestage 1994).

During ITE courses, students gain different knowledge and understandings of other professional traditions - some national like the National Curriculum and examination systems and some local traditions from particular schools such as schemes and textbooks. Learner-knowledge and professional traditions merge in the first instance to create classroom events for others to engage with learning mathematics (figure 1).

This combination is also evident from the experienced teachers. High on the list when justifying decisions about the curriculum were textbooks and other departmental resources, experiences of learning mathematics, ideas related to teaching practices (Baturo & Nason 1996; Ball 1988, 1990) and from the new legislative curriculum.

There comes a moment for many teachers (often early in their professional education) when they realise that giving their learner-knowledge directly to pupils does not work:
if you present a problem to the class and there is a need for them to know something about a particular shape and the area of it, and therefore they would set the agenda ... things are encompassed in a problem and the pupils are setting the agenda.

Reflection upon these classroom events, with the integration of learner-knowledge and professional traditions, leads to the beginnings of practical wisdom that enables teachers to adapt activities from the professional traditions to suit their particular circumstances (figure 2).

Figure 1

Figure 2

Pre-service teachers developed practical wisdom during their teaching experiences as shown in their evaluation of lessons. Many of the experienced teachers talked in the interviews about the consequences of diverse classroom interactions, of altering the teaching decisions in order to respond pupils' needs. Classroom experiences give rise to practical wisdom based on perceived learner needs and new explanations and contexts are found to support learner-knowledge. However, the learner-knowledge is not necessarily questioned, the teacher may still offer the rule "change the divide sign to a multiply and turn the second fraction upside down" but previous lessons may have included "how many quarters in one whole, how many in two etc." and other starting points to support the learning of the algorithm. Existing research makes assumptions that teachers have full access to subject matter knowledge and that it is transformed by activities developed for teaching. We argue that for both experienced and novice teachers much of this subject matter knowledge remains as learner-knowledge and is not transformed into teacher-knowledge, as Aubrey (1997 found):

There is however, little evidence to suggest that the development of project teachers' subject matter through teaching occurred. The capacity to transform personal understanding, thus, depends on what teachers bring to the classroom. Whilst knowledge of learning and teaching and classrooms increases with experience, knowledge of subject content does not. (pp.159-160)

In certain topics there was evidence from the research data that some teachers had thought more about the subject matter, beyond reacting to pupils. For one primary co-ordinator curriculum decisions were made in response to the pupils in her Y2 class 'depending on where the conversation goes'. There was evidence of her deliberate decisions about progression through the mathematics. This aspect of deliberate reflection towards teacher-knowledge was also partially evident in other interviews and also emerges occasionally in the data from the student teachers (Perks 1997).
We believe that ‘good’ teachers need to reflect upon classroom events not simply to consider their success or failure for the students but to reconsider their own personal understandings of mathematics, to reflect upon the ‘why’ not only of teaching but also of mathematics. We would argue that it is in this way that they come to own a better personal knowledge of mathematics (teacher-knowledge), that learner-knowledge (the only explicit content knowledge) requires transforming through deliberate reflection.

This analytic process requires a synthesis of the reflection on the three elements of figure 2. The model is completed in the form of a tetrahedron, where the struts represent the reflective/analytic process.

This research explores each of these vertices to provide exemplification.

The current project: methods and analysis

Four experienced teachers (ET) and four pre-service teachers (NT) (at the end of their course) were interviewed to gather data about subject knowledge. Two different areas of mathematics were used, one from number (percentages), as previous research (Prestage 1999) had shown more evidence of teacher-knowledge in the area of number and one from data handling, to compare data from another project (Soares & Prestage 2000). The teachers were asked to complete several questions (Appendix) and to talk about the solutions in construction as well as their understanding of the pedagogical issues. The interviews were recorded.

Analysis of the data looked for evidence for describing the vertices of the tetrahedron (Figure 3). Whilst certain prompts during the interviews led to particular descriptions of subject knowledge, aspects of all the phrases of the tetrahedron were interwoven through the data.

Learner-knowledge: this was the data taken as they solved each question with some interim prompts such as “Why are you doing that?”, analysed by strategy.

Professional traditions: aspects of this were found in response to ‘why’ a particular strategy had been chosen; evidence of the impact of their own schooling, texts, schemes and government policies.

Practical wisdom: this was evidenced in response to ‘how would you teach this in the classroom’ and from any pupil difficulties and errors described.

We have taken teacher-knowledge to be an amalgam of all of these categories. We looked for evidence of wider connections in the mathematics, reflections upon the integration of the three categories, and when the interviewee was aware of the consequences of choices made for teaching with a definite purpose for doing the mathematics beyond getting the right answer.
Findings

Leaner Knowledge

This was evident throughout the interviews as the teachers described their solutions. There was more variety in methods offered for the percentages questions than the graphs questions. The approach to the solutions for the graph questions focused on scale, type of graph, axes and care in plotting. There was some uncertainty on the difference between discrete and continuous data. For percentages the methods varied from mental calculations to use of calculator but the interchange of, e.g. 73% to 0.73 to 73/100 was common but there was surprising variety of solutions in a small group. There were few errors in calculation which were not corrected immediately, but for the graphs two of the novice teachers tried to use time on wrong axis.

Professional Traditions.

For percentages when asked why they had done the calculation in that way, the teachers gave three types of replies:

1. using algorithms which depend on what they had done at school - the fraction and ‘10% is divide by 10’;
2. mental methods which they were aware of having adapted from what they had done at school, or methods thy felt they had devised to make it more efficient to do it mentally;
3. the use of the calculator.

For ET1 who was using the National Numeracy Strategy (NNS, DfEE 1999) in year 7, the influence of the NNS was clear. She mentioned the examples and the ways they had make her think about methods. She felt that she had adapted her own learner-knowledge in working with this new professional tradition (our language).

For graphs, the novice teachers had done similar work at school or at university and the error about the axis for time was attributed to a learned response from school “time is the dependent variable - so it’s across”. For the experienced teachers the influence was more likely to be what they had taught - “the textbook always uses bar charts for shoe sizes” - “we have just been using spike graphs in our new scheme”.

Practical Wisdom

For the work on graphs any description of classroom activities tended to focus on children’s errors. The teachers described how to help pupils to choose the correct graph, which way to use the paper, the problem of scale, where to draw the axes, labels such as the axes and title and accuracy in general. The experienced teachers were very similar in the speed and manner in which they described what they would work on. The only noticeable difference in response lay between the two sets of novice teachers. The good novices were as good at identifying errors and activities as the experienced teachers, whereas the others were slower and had a much more limited range of possible activities which they described. The major teaching approach relied on telling the students what to do before they made errors. There was talk of such things as “discussion of scale”, but this tended to mean question and answer. It was suggested that pupils needed to work on different data sets. Only ET1
and NT1&2 talked about activities such as offering tables and ready-drawn graphs with errors for the pupils to identify or having several graphs on cards for the pupils to choose the ‘best’ and then justify their decisions.

Percentages saw a difference between the two good novices and the rest of the interviewees. Only NT1&2 felt that teaching pupils to change a percentage to a fraction and then do ‘fraction of’ was unnecessary, describing the algorithm as “usually unhelpful, it confuses rather than helps”. All of the others felt that they had to teach this algorithm - their justification lying in the professional traditions, “it’s in the school scheme” or their own learner-knowledge “that’s the way I learned it and it’s the way to understand it”. For other written methods, some teachers described using 10% as the base for teaching another routine and the others used 1%. These written methods were described by means of examples.

All but two interviewees, ET 2&3, mentioned mental work. Listening to children’s methods and to develop activities was given importance. ET1 highlighted the stress placed on this in the NNS. For the novices, this was an expected inclusion as the place of mental methods had been a major strand of the course they were just completing.

Only ET3 and NT4 failed to mention calculator work, but only ET1 and NT1&2 talked in any detail. NT1&2 offered justification for decimals, “the calculator and the way percentage keys work”. They talked about the importance of linking percentages to decimals directly, almost as pattern recognition: $76\% = 0.76$, $123\% = 1.23$

**Discussion**

The purpose of research was to find teachers’ mathematical descriptions from to exemplify the phases in figure 3. Evidence for triad at the base of the tetrahedron is easy to identify from teachers talking about mathematics. However, much teacher-knowledge appears implicit rather than explicit in the data and has to be inferred. More questions or a longer time frame would have been useful. This raises the challenge of identifying what would help teachers to articulate their subject knowledge in this way, when they have not been expected to articulate it in this form. Whereas, for us as tutors on a pre-service course, we must be able to in order to help our students come to refine their subject knowledge for better mathematics teaching.

**Teacher-Knowledge**

To identify aspects of teacher-knowledge, we were looking for evidence of the teachers knowing the connections between the areas of mathematics and having a purpose for the activity. From the data, it appears that the implicit teacher-knowledge for percentages is more developed than that for graphs. More variety of connections and approaches were given. All of the methods of calculation would be recognised by others, whereas some of the data questions might be unfamiliar even as learner-knowledge to some.
The answers from ET1 showed her using a variety of methods, including instant recall. She used connections to other methods - “10% of works the same way as divide by 10 so we shift the numbers one place”, as did NT1 “10% is like dividing by 10 or multiplying by 0.1, so 10% of means a shift of the numbers one place”. There is a strong connection to other aspects of place value and a shifting image. NT4 also appears to be connecting yet when asked why he used “10% of is divide by 10” he replied “That’s what you do”.

For the graphs questions, there is less variety; there is evidence of different learner-knowledge related to the mathematics of the data. The teacher-knowledge related to grouped data and choice of appropriate diagram is not very explicit. There is, however, some sense of purpose for the tasks ET 1 and NT 1&2, other than practising drawing, to develop pupils’ decision making skills, in choosing appropriate diagrams.

Discussion

Shulman argued that pedagogical content knowledge was the missing paradigm for teaching and we agree with its importance. We believe that designing activities for the classroom is necessary but not sufficient to develop the type of subject knowledge, the teacher-knowledge, we feel essential for the development of strong mathematics teaching. Nor is it acceptable to demand more learner-knowledge. More of this kind of knowledge is not sufficient for the development of teacher-knowledge. The analytic process has been long recognised and is essential for the intellectual professional.

Ideally we may wish to have teachers who are not only competent actors in the classroom but also who are practitioners capable of understanding what they are doing, why they are doing it and how they might change their practice to suit changing curricula, contexts or circumstances. This produces a tension between the need for teachers to understand teaching and the need to be able to perform teaching. (Calderhead & Shorrock 1997, p.195)

Teacher-knowledge in mathematics allows teachers to not only answer the questions correctly but also help to build a variety of connections and routes through knowledge, that provides answers to ‘why’ something is so (Prestage, 1999). It is our contention that only when such teacher-knowledge is informing classroom practice that the real needs of learners and the challenges of mathematics are addressed. There are threads of teacher-knowledge emerging from the data, but the interviews did not sufficiently challenge the teachers to articulate this aspect. There is still the need to delve more deeply if the model is to be strongly exemplified.

Atomistic and holistic approaches to the early primary mathematics
curriculum for addition

Alison J. Price
Oxford Brookes University, OX33 1HX, UK

Abstract

A study of teaching and learning in early primary British mathematics classrooms (children aged 4 - 6 years) has identified contrasting ways in which the curriculum is approached. Focusing on the teaching of addition, one of the first formal arithmetical concepts taught in school, the researcher identified that children taught in through an atomistic approach to the curriculum, taught sequentially with reference to psychological research on children's conceptual development of addition, made less progress than those taught through a holistic approach, where the focus was on counting and the number system. The mathematical structure of number, the opportunities given to children to mathematize, and alternate views on cognition are used to consider the reasons for these findings.

Introduction

In the twentieth century the curriculum in British primary schools, and especially the mathematics curriculum, has been heavily influenced by Piagetian constructivism (Walkerdine 1984). Sociocultural (Lerman 1996) and Social Practice theories (Lave et al. 1991) while influencing views of learning in primary education (e.g. Wood 1998) have had little observable effect on the mathematics curriculum. Activities for young primary children emphasise practical activity, with a range of structure apparatus (Dienes 1964) in order to develop relational understanding (Skemp 1979). Lacking confidence in their ability to provide for the developmental needs of individual children, many teachers have tended to rely on structured published mathematics schemes (Walkerdine 1984; Desforges and Cockburn 1987). These schemes tend to be based on research evidence on the order in which concepts and strategies are developed, with the assumption that teaching should follow the same order; despite evidence to the contrary (Denvir and Brown 1986a, b).

The development of addition strategies has been summarised by Nunes and Bryant (1996) drawing on work by Carpenter, Romberg and Moser (1992) Gelman and Gallistel (1978) and others. The first strategy, and the most naive, involves counting out each set (e.g. 1,2,3, then 1,2,3,4,5) combining the sets and counting all of the new, larger set (1,2,3,4,5,6,7,8), and is referred to as counting-all (or the sum procedure). Subsequently children realise that they do not need to recount the first set of objects, but can ‘count-on’ from this set (3...4, 5, 6, 7, 8). Baroody and Ginsberg (1986) showed that this counting-on strategy might be ‘invented’ by children, while Fuson and Fuson (1992) developed ways to teach it. At the same time children begin to learn some of the number facts, especially the double facts
(e.g. 5 + 5 are always 10) (Gray 1997), and then to use these facts to derive others (if 5 + 5 are 10 then 5 + 6 are 11) (Thompson 1997). Further developments in addition strategies require an understanding of place value to solve multidigit addition (Nunes and Bryant 1996).

**Context**

The research is part of a wider study which examined the teaching and early learning of addition in early primary classrooms in Britain. The relationship between teaching and learning was examined at the level of classroom interaction, in the carrying out of mathematical tasks. The mathematics lessons of two classes in each of two schools were observed over a period of six months, involving four teachers and 112 children aged 4 to 6 years. The mathematical focus of the study was the learning of addition, one of the first formal mathematical concepts taught in school. This formed a basis for exploring the factors involved in the teaching of mathematics to young children, and their learning.

The methodology was qualitative, with participant observation the main method of data collection. Detailed fieldnotes were taken of all mathematics lessons observed; short unstructured interviews with teachers were carried out before and after the lessons. The children’s understanding of number concepts and addition was assessed at both the beginning and the end of the observation period through a series of informal activities and games. The data was analysed using a grounded theory approach, which produced patterns of recurring variables. Analysis of these variables, grounded in the theoretical framework of the researcher, provided analytical pictures of teaching and learning, from which the findings emerged. One set of findings related to the way that the curriculum was structured and presented to the children, and it is this aspect that will be considered here.

**Approaches to the mathematics curriculum**

The study identified two contrasting approaches to the primary mathematics curriculum evident in the two schools studied.

Analysis of the addition curriculum at Ashburne School identified key characteristics of the way that the mathematics was broken down and taught to the children, which I have defined as ‘atomistic’. Atomism is defined as ‘any doctrine or theory which propounds or implies the existence of irreducible constituent units’ (SOED, Brown 1993). The most significant characteristic of the atomistic approach to the teaching of addition was that the curriculum was broken down into elements which were taught in a set order, which related to the findings on children's development of arithmetic strategies. There was an assumption that if research has found that children develop increasingly complex addition strategies, then the teaching of these strategies in a set order would result in learning. Analysis of the lessons observed showed that other significant characteristics were found to be related to this developmental approach. An Atomistic Approach showed:
• an initial emphasis on small numbers;
• teaching addition in isolation from subtraction;
• emphasis on procedures rather than patterns and relationships;
• the use of physical and predominantly cardinal representations of number;
• progression from one ‘stage of development’ to the next;
• the repetition of similar activities in order to reinforce the procedure.

These characteristics can be seen in the following transcript from one of the classes studied at Ashburne School. The lesson was designed to encourage the children (aged 6 years), who currently used ‘count-all’ to solve addition, to use a ‘counting-on’ strategy. It was one of a series of similar lessons in which the children used the number line to model addition. The children had made a 1 to 20 number track which they used to play a game. The children took turns to throw a die and put that number of counters on the track. On second and subsequent turns they were required to use the language of adding-on.

Barry threw five and placed five counters, one each on the squares marked 1 to 5. The next time it was Barry’s turn he threw another five.

Teacher M. So, count out five to one side first of all, and then count-on from that number and put the cubes down one at a time.

Barry 5, 6, 7, 8, 9, 10.

This game formed a link between the use of discrete objects e.g. counters to model addition and the use of the number track, between cardinal and ordinal number. The children were encouraged to count-on (i.e. to say 6, 7, 8, 9, 10 rather than 1, 2, 3, 4, 5 as they added on five) and the teacher reinforced the language of counting-on: “So, 5 count-on 5 is 10” [procedural]. Over time the children learnt the procedure and could use the number track and counters to model addition, but in subsequent lessons and without these aids were seen to be no further on in their use of counting-on to solve addition.

The characteristics were not only seen in the lessons observed; they were also evident in the school’s planning documents for mathematics and the mathematics scheme used in the school, showing that it was a curriculum, rather than individual teachers’, approach.

Analysis of the addition curriculum at the second school, St David’s, identified very different characteristics in the way that the mathematics was broken down and taught to the children, which I have defined as ‘holistic’. The most significant characteristic of the holistic approach to the addition curriculum was an emphasis on the number system, with calculation seen as one element of the relationship between...
numbers within the overall system. Further analysis showed other characteristics were related to this approach. A Holistic Approach showed:

- an emphasis on large numbers as well as small ones [large numbers],
- an emphasis on patterns in number and pattern spotting [pattern];
- discussion of the inverse relationship between addition and subtraction [inverse];
- emphasis on relationships rather than procedures [relationship];
- emphasis on ordinal representations of number and the development of mental imagery [ordinal];
- a eclectic curriculum in which the children are immersed in a wide range of activities, with little apparent sequence [immersion].

In both classes observed at St David's there was a heavy emphasis on counting, especially in the whole class introduction to the mathematics lessons. This was not the counting of objects, nor counting along the number track to encourage counting-on which I had seen in Ashburne School, but oral repetition of the number words in units and in larger steps, counting in twos, fives, tens etc., forwards and backwards. While I had initially not seen this as directly related to the teaching of addition, analysis showed that it was teaching essential skills towards the development of mental addition strategies where numbers are added by counting-on in units or larger steps. The children were developing mental and oral, ordinal representations of number which would help them count-on [ordinal]. The counting was not restricted to small numbers. During discussion of a hundred square [ordinal], Teacher D. highlighted the multiples of ten and she and the children (aged 5 and 6) counted in tens to one thousand.

Debbie ... count with me and we'll go all the way down\(^1\) to one hundred and then see if we can keep going, 10, 20, 30, ... 100, 110, 120, 130, ... 190, 200 ...

Some children are still counting with Debbie on two hundred, others saying a hundred and twenty, all picked up again at 210. They continued counting to 800.

Debbie I am absolutely amazed. Give yourselves a big clap. Can anyone tell me what happens after 970, 980, 990 ?

Zeb 991, 992
Will A thousand
Rita it goes on and on (Teacher D:7)

Many of the children were not confident in keeping track of the hundreds as they counted and they relied on their teacher to provide the next hundred number, but they were confident at the pattern of tens. They were praised and felt good about counting with such high numbers [large numbers]. The counting sparked further discussion which showed the children's wider understanding of the number system including negative numbers [relationships].

---

\(^1\) I believe that the teacher talked of counting 'down' rather than the more usual counting 'up' to 100, since the number square showed the tens increasing down the right hand column.
These relationships can also be seen in an earlier lesson, centred around the number seven. Before the lesson Teacher D. talked to me about what she was going to do.

"Some days we just look at a number and see how many different ways we can make sums that have that answer. Some of the children will just be able to do simple addition or subtraction, some might get into patterns [patterns]. I hope that all the children will be able at least to try. I think it is important for them to look at sums this way ... there can be lots of different sums with the same answer, you can get there by doing different things" [relationships].

( Teacher D:4 - pre-lesson discussion)

D. wrote a large number 7 in the centre of the board.

D. Who can think of a way to make seven?

Rob Three and four.

[At each suggestion D. wrote the calculation in symbols on left-hand side of the board (3 + 4). Subtractions were recorded on the right-hand side of the board.]

Nozumo Four and three.

Ruth Seven and zero.

Lucia Twelve take away three ... er ... five.

John Twenty take twelve.

D. Nearly

John Twenty take thirteen.

Nozumo Two add five.

Ellen Six and one.

Zeb Five and two.

John Twenty-one take fourteen; twenty-two take fifteen.

Ruth Twenty-three take away sixteen.

Ellen Twenty-four minus seventeen...

Beaty one add one add one add one add one add one add one, and 10 take away 3.

John Seven take seven add seven; eleven take four, twenty-seven take twenty...

( Teacher D. 4)

I observed that the children were using pattern [patterns] to generate more examples, applying their knowledge of pattern to addition. Nozumo (one of the new reception children, aged 5) seemed aware of commutativity, providing 4 + 3 after Rob gave 3 + 4, and later 1 + 6 when 6 + 1 was already on the board [relationship]. John uses inverse (7+7-7) [inverse] and equal addition. The children were working mentally and at their own level. Nozumo, Zeb and Rob (aged 5) were able to concentrate on simple one step addition, while experiencing the subtraction and more complex multi-step calculations offered by the others [immersion].

**The advantages of a holistic approach to the curriculum**

I have identified differences between the two school’s approaches to the curriculum which I have categorized as Atomistic and Holistic. While these differences were
found between the two schools, by analysing the data for counter examples, I found that the approaches were also influenced by the individual understanding of the teachers and their beliefs about mathematics and learning, though this paper does not allow for further discussion of this. In this section I want to look at why a holistic approach may be preferable to an atomistic approach to teaching addition, drawing on three areas of theory.

The first of these relates to the structure of the number system itself and, in particular, the additive composition of number, which Nunes and Bryant (1996) define as “any number \( n \) can be decomposed into two others that come before it in the ordinal list of numbers, in such a way that these two add up exactly to \( n \)” (p. 46). A special, and important, case is that of place value, since larger numbers can be decomposed into their constituent multiples of ten and units. Nunes and Bryant found that an understanding of this characteristic of number is important not only for addition of large numbers, but is also essential for children to learn to count-on. It is the basis for understanding that a number can be added to another number directly, without them having to be reduced to their unitary elements and counted singly. Nunes and Bryant emphasize the importance not only of counting, but also of “understanding the relative value of counting units and their additive composition” (p. 51). It therefore follows that teaching children to count-on using a number track is likely to be ineffective if they do not understand this additive structure of number, and demonstrates why direct teaching of small areas of arithmetic do not necessarily result in the learning of those particular areas (Denvir & Brown 1986). The concept of additive composition of number provides insight into the advantages of a holistic curriculum. Such a curriculum allows an understanding of the relationships between numbers and patterns within numbers, which characterize the additive composition of number, and are essential for addition strategies more complex than counting-all. This is more than an argument that place value should be taught in advance of addition (an atomistic approach). It is to argue that addition must be seen as an integral part of the number structure rather than a mathematical topic in its own right.

A second reason why a holistic approach to the curriculum may be preferable to an atomistic one relates to the nature of mathematics and learning. A holistic curriculum gives children greater opportunities to mathematize, to act in a mathematical way. Patterns and relationships are an essential part of mathematics which enable the development of conceptual structures (Skemp 1971; Hiebert 1986). Procedural learning, identified as a characteristic of an atomistic curriculum, can result in limited understanding: children are able to carry out the procedure but not understand why. When the procedure has been forgotten, or the necessary materials are not to hand, the learner has no way to reconstruct it. I have shown how breaking the curriculum down into very small pieces which are learnt in isolation (atomism), can result in such procedural learning. Teaching children the ‘bigger picture’ first, an understanding of the way that the number system fits together (holism), offers
them an overall structure in which constituent sub-topics within arithmetic, such as addition, can be defined.

For the third and final explanation of the advantages of a holistic curriculum I want to appeal to the wider human experience of learning. Chomsky (Chomsky 1980) proposed a language acquisition device (LAD) to explain how children learn to speak. He reasoned that, since language was extremely complex, young children must have some special way to make sense of it. They appear to learn not only by copying the language that they hear, but by constructing their own logical rules. For example, young children will often generalize regular forms of the past tense to include goed (went), seed (saw) or buyed (bought). Chomsky therefore argued for a specialized area of the brain, specific to language learning and complete with a LAD. Bruner argued that such a LAD was in fact culturally influenced, offering instead a language acquisition support system (LASS, Bruner 1986).

I believe that language acquisition is not a unique part of learning. All children’s learning in the world outside school is as an experience of immersion, in language and in culture. It is in the nature of children to make sense of the world around them. It would seem logical to assume that to teach mathematics through immersion into the number system, is to take advantage of the way that children learn. To break it down into ‘bite sized pieces’ is analogous to teaching children to speak using only nouns first, or allowing them only to relate socially to one other human being because more than one may confuse them. While the curriculum in British primary school mathematics classrooms has been based on a constructivist perspective on learning, founded on an active, practical approach to learning and a developmental (and therefore atomistic) view of progression, to view learning as resulting from ‘immersion’ is to see learning from a sociocultural perspective. Such a perspective appears to accord more clearly with the findings of this research.

Summary and Implications

In this article I have identified differences in the way that the mathematics curriculum is presented to young children found in a study of two schools and which I have described as atomistic or holistic. An atomistic approach to the curriculum breaks the addition curriculum into its developmental stages and teachers target teaching to the next stage, according to the teacher’s perception of the children’s needs. Activities are designed to address these stages, to teach counting-all, counting-on, and place value, starting from cardinal representations of number. This was the predominant curriculum experience at Ashburne School. A holistic approach to the curriculum sees addition as part of the relationships within the number system. Teachers offer children a range of activities which develop facility with number including counting and locating, and patterns in number as well as more formal addition tasks. This was the predominant way of presenting the curriculum at St David’s.
I have shown how these findings are based on the data collected in this study, and finally given some explanations for why a holistic approach may be preferable to an atomistic approach to teaching young children addition. I have considered three ways to explain why a holistic approach to the curriculum may be preferable to a holomorphic approach. These have been based on an understanding of the additive composition of the number system, an understanding of mathematical reasoning, and a personal hypothesis about children's learning.

This implies that children will learn early addition more easily if they experience a holistic curriculum. More complex addition strategies will not be developed through direct teaching of these strategies but through an understanding of the complexities of the number system. Children, offered a broad range of activities which explore the number system in its complexity, are able to develop understanding and skills which are specific to addition. However, in order to teach in a holistic way teachers may have to change their views of mathematics, addition and how children learn. Offering teachers a holistic curriculum may not prevent them from reverting to an atomistic approach if this is all that they understand.

FACTUAL, CONTEXTUAL AND SYMBOLIC GENERALIZATIONS IN ALGEBRA

Luis Radford
Laurentian University,
Ontario, Canada

Abstract: The purpose of this paper is to investigate, from a socio-cultural semiotic perspective, novice students' pre-symbolic and symbolic types of generalization of patterns. The investigation is carried out in terms of the semiotic (linguistic and non linguistic) means of objectification that Grade 8 students display in the attainment of the goals of generalizing mathematical tasks. The results suggest that while rhythm and movement, as well as differentiated ostensive gestures (e.g. 'grotesque' and 'refined' pointing), play a central role in pre-symbolic generalizations, symbolic-algebraic generalizations require a desubjectification process ensuring the disembodiment of spatial-temporal embodied mathematical experience. In order to deepen our understanding of the cognitive and semiotic requirements underlying pre- and symbolic generalizations, in the last part of the paper, I discuss the desubjectification process in terms of the relation between the object of knowledge and the through-sign-knowing-subject.

1. INTRODUCTION AND FRAMEWORK

In a certain sense, generalization is one of the more natural human semiotic processes. As John Mason remarked many years ago, in one of the sessions of the 20th PME Conference Algebra Working Group, if we were to communicate without being able to make generalizations, we would be restricted to be pointing to objects around us. Any word, in fact, is the result of a generalization: it applies to a range of objects (not necessarily present) and can be used in a variety of situations. Semiosis, as it is intended here (that is, as the use of words and other signs in human activity), allows one to go beyond pointing. Within semiosis (and only within semiosis), can objects be objectified in a process that goes from the use of signs (marks, names and the like) as pointers of attention to more and more complex presentation and representation systems involving new signs, meanings and layers of generalization.

In this paper, I want to pursue my investigation of the students' processes of generalizing by looking into the way students deploy and mobilize signs (words, letters, etc.) to accomplish mathematical generalizations. In (Radford 1999) I focused on the way novice students, interacting with their teacher, underwent a process of dynamic and differentiated understanding allowing them to achieve the elaboration of a meaning for the general term of a pattern. In (Radford 2000) the analysis was brought further and several algebraic generalizing strategies were examined. This analysis was carried out in terms of the various meanings with which signs were endowed by the students and the semiotic role that students ascribed to signs as a way to convey relations between the particular and the general. One of the reported results was the identification of the nature of the signs that the students tend to use in the elaboration of the first algebraic formulas: it turned out that these signs appear genetically related to the arithmetical concrete actions and to the objectification of these actions in speech. More specifically, novice students often use algebraic symbols as marks or abbreviations of key words belonging to a discursive non-symbolic semiotic layer. Thus, the students' symbolic expression \( n \times 2 + 2 \) mirrors the utterance “The term times two plus two” previously produced

---

during the students’ discursive activity (Radford 1999, p. 95). Following Peirce’s terminology, I suggested that the students’ first algebraic signs were *indexical* in nature, inasmuch as they stand for their objects in such a way that, like pointers, they appear as *indicating* the place of the objects to which they refer.

Given the strong genetic connection between algebraic generalizations and generalizations achieved in previous discursive layers of mathematical activity, it seems then, that the investigation of the semiotic modes of functioning of the latter needs to be pursued further if we want to envisage some pedagogical actions to promote new meanings for algebraic signs in the classroom. In this line of thought, the purpose of this article is to offer an exploratory investigation of pre-symbolic types of generalization in patterns and to contrast them with the algebraic symbolic ones.

2. **Methodology**

To do so, I will interweave theoretical reflections that draw from Bakhtin’s theory of speech (Bakhtin 1986) and Voloshinov’s philosophy of language (Voloshinov 1973) with relevant passages coming from my classroom-based research (more details about the methodology can be found in Radford in press). I will present excerpts of the discussions held by one of the Grade 8 students’ small-groups (the students will be identified as Josh, Anik and Judith) and I will make oblique reference to the work of other small-groups.

The data mentioned here involve students in their very first contact with symbolic algebra and relate to a classroom mathematical activity designed in collaboration with the teachers to immerse students into the social practice of algebraic generalization. I shall focus here on one of the activities based on the classic triangle toothpick pattern (see Table 1). The activity included several tasks, among them the following: (a) to find the number of toothpicks required to make figure number 5 and figure number 25 (b) to explain how to find the number of toothpicks required to make any given figure and (c) to write a mathematical formula to calculate the number of toothpicks required to make figure number ‘n’.

3. **Results and Discussion**

3.1 **Factual Generalizations**

In this episode, after finding out the number of toothpicks in figure 5, the students turned to the next question that asked to find the number of toothpicks in figure 25. Josh notices the following pattern:

1. Josh: It’s always the next. Look! *(and pointing to the figures he says)* 1 + 2, 2+ 3 […]
2. Anik: So, 25 plus 26…

This led them to write the answer as 25+26=51.

As evidenced by this passage, the students did not have much trouble calculating the number of toothpicks in the concrete figure 25. What is more important, they did so *not* by counting the number of toothpicks, figure after figure up to figure 25, but by a process of *generalization*. The generalization thus achieved is what I want to call a *factual generalization*, that is, a generalization of numerical actions in the form of an *operational scheme* (in a neo-
Piagetian sense) that remains bound to the numerical level, nevertheless allowing the students to virtually tackle any particular case successfully. Their objectification takes the form of a process of perceptual semiosis, i.e. a process relying on a use of signs dialectically entangled with the way that concrete objects become perceived by the individuals. In this process, the mathematical structure of the pattern is revealed and ostensively asserted by linguistic key terms in the students’ utterances. This is what Josh does in using the term ‘the next’—a term reflecting the perceived ordered position of objects in the space. Another key term is the presence of adverbs like “always” (line 1). As noticed elsewhere (Radford, in press), these adverbs underpin the generative functions of language, that is, the functions that make it possible to describe procedures and actions that potentially can be carried out reiteratively.

The semiotic means to objectify factual generalizations are varied. In another small-group, one of the students sums up her group discussion by saying: “O.K. Anyways, Figure 1 is plus 2. Figure 2 is plus 3. Figure 3 is plus 4. Figure 4 is plus 5”, and she points to the figures on the paper as she utters the sentence.

Here, the objectification is accomplished in a different manner. In this case, we do not find adverbs and spatial-positional terms. Actually, to obtain a similar generalizing effect, the students rely on the rhythm of the utterance, the movement during the course of the undertaken numerical actions and the ostensive correspondence between pronounced words and written signs. Rhythm and movement here play the role of the adverb “always”.

Although rhythm and movement are also present in Josh’s utterance (“Look! 1+2, 2+3”) we would say that, in the second group, rhythm and movement create a cadence that, to some extent, dispenses the students from using other explicit semiotic linguistic means of objectification and also provide room for a type of social understanding based on a great deal of implicit agreements and mutual comprehension. We saw how the students understood Josh’s brief utterance and agreed upon the numeric actions to be performed. In the second group, the students understood that “Figure 1 is plus 2” means “the total number of toothpicks in Figure 1 is equal to 1 plus 2”, etc. However, factual generalizations, without having or being objectified by more specific linguistic terms or specialized symbols, cannot gain a more general status—they remain context-bound.

To further objectify the factual generalization through language is not an easy task, as we shall see in the next subsection.

### 3.2 Contextual Generalizations

The next task of the mathematical activity required the students to write an explanation of how to calculate the number of toothpicks for any given although non-specific figure. The characteristics of the required explanation in the mathematical activity introduced two new elements—a social-communicative one and a mathematical one.

**The social-communicative element:** In this task, the social aspect of understanding was shifted. Indeed, the explanation presupposes an addressee who is tacitly thought of as being absent from the actual scene in which the students’ small-group activity unfolds. Implicit and mutual agreements of face-to-face interaction had to be replaced by objective elements of social understanding demanding a deeper degree of clarity in the communication.

**The mathematical element:** In addition to the social-communicative element, a new abstract object has been introduced into the discourse: the question, in fact, asks for any although non-specific figure. The two new aforementioned elements led the students to move into another
layer of discourse (for some specific difficulties that students usually encounter in understanding this level of generality see Radford 1999). As in the previous episode, we shall present here excerpts of the students’ dialogue. After a relatively long period of discussions and arguments, the students arrived at the following formulation:

1. Anik: Yes. Yes. OK. You add the figure plus the next figure ... No. Plus the ... [...]
2. Anik: (she writes as she says) You add the first figure ...
3. Josh: (interrupting and completing Anik’s utterance says) ... [to] the second figure.

Here, particular cases have been displaced and put in abeyance. Rhythm and ostensive gestures have also been excluded. What then are the semiotic mechanisms of objectification that the students display? And what are the epistemological and conceptual consequences?

First, notice the insertion of the addressee through the personal pronoun “You” (see line 1). Second, the addressee becomes interwoven with the new mathematical object: the addressee will indeed perform an action (“You add ...”) not on concrete numbers but on abstract objects (“You add the figure ...”). Abstract objects hence not only become abstract objects per se but become related to the actions required by the task and to the subject performing the actions. Third, the emergent abstract objects are objectified here by expressions like ‘the figure’, ‘the next figure’. Such terms indicate a contrast with their surrounding; they have this kind of semiotic power to fix the students’ attention (in the sense explained in our Framework: see Section 1). Through them, the students provide themselves with the capacity to achieve a fixity of reference much in the same way as ‘deictic’ or ‘demonstrative terms’ like ‘that’ and ‘this’ do in speech (see a clear example in the protocol analysis given in Radford 2000, p. 86).

We see then, that in terms of objectification, instead of a grotesque pointing, the abstract object appears as being objectified through a refined term pointing to a non-materially present concrete object through a discursive move that makes the structure of relevant events visible thereby creating a new perceptual field.

As a consequence of this linguistic objectifying process based on a refined but still ostensive way of functioning, the abstract objects are contextually conceptualized in reference to the particularities of the concrete mathematical objects. The latter stamp characteristics such as the spatial position of the sequence and a temporal sequencing action on the former, as clearly indicated in the utterance “You add the figure and the next figure”, an expression that reveals indeed tense and spatial aspects of contiguity. The abstract objects are hence abstract while bearing at the same time contextual and situated features that reveal their very genetic origin. Their genesis also relates them to the individual who performs the actions on them. Because of the specific mode of objectification, subject and object bear an almost invisible but extremely powerful contextual dimension that allows the subject to perspectively see the emergent mathematical object.

All in all, without using letters and capitalizing on factual generalizations (which function as a guiding structure), the students hence succeeded in objectifying an operational scheme that acts upon abstract —although contextually situated— objects and indicates mathematical operations with them, ensuring thus the attainment of a new level of generality. These objects, belonging to a non-symbolic language, are not genuine mathematical objects in the traditional sense of the word. However, these objects abound in classroom discourses, where they become part of the ontogenetic process of construction of the latter. This is one of the reasons to pay careful attention to their genesis and their functioning.
Let us call these types of generalizations, performed on conceptual spatial-temporal situated objects, contextual generalizations.

Contextual generalizations differ from algebraic generalizations on two important related counts. First, algebraic generalizations involve objects that do not have spatial-temporal characteristics. Algebraic objects are unsituated and atemporal. Second, in algebraic generalizations the individual does not have access to a perspectival view of the objects. As Bertrand Russell noticed, in the world of mathematics (and of pure physics), space and time are seen impartially “as God might be supposed to view it”. And to emphasize the non-subjective character of space and time in mathematical descriptions, he then added that, in such descriptions, “there is not, as in perception, a region which is specially warm and intimate and bright, surrounded in all directions by gradually growing darkness.” (Russell 1976, p. 108).

How then will the students proceed to the des-embodiment of their spatial-temporal embodied situated experience? How are they to produce the voiceless symbolic algebraic expressions? This is an extremely complex problem impossible to exhaust in the few remaining pages. I will, however, focus on one of the elements of the des-embodiment of spatial-temporal embodied experience, namely, a cognitive/semiotic dimension involving what I want to term the subject’s desubjectification process—a process that stresses changes in the relation between the object of knowledge and the through-sign-knowing-subject.

### 3.3 Symbolic generalization

#### 3.3.1 Bypassing the ‘positioning problem’

In the next passage, the students did not symbolize the factual generalization based on the pattern “the figure plus the next figure” that we discussed in subsection 3.2. Actually, they worked out a different algebraic symbolization, as shown in the following excerpt:

1. Josh: It would be \( n + n \).
2. Annie: \( n + n \)... OK. Wait a minute! ... \( n \)...
3. Judith: Yes. \( n \) plus ... yeah it’s \( n \) ... [\( n \)] plus \( n \) plus 1.
4. Annie: Yes! \( n + n + 1 \!). \text{(that is,} (n+n) + 1, \text{as it will become clear later)} [...]
5. Judith: Yes. Because, look! Look! ...
6. Annie: Your first figure is ‘\( n \)’ right? Plus you have \( n \) because it’s the same number...
7. Judith: Because, look! Look! \( 4 + 4 = 8 + 1 \).
8. Josh: \( n \) plus \( n \) plus 1.
9. Annie: Bracket plus 1. \( (n+n)+1 \)

There is an aspect of the desubjectification process in which the students have succeeded so far, namely, the insertion of a speech genre based on the impersonal voice. This is evidenced by the students’ utterances produced in lines 8 and 9. Thus, “Your first figure” in line 6 becomes “\( n \)” in lines 8 and 9. Furthermore, in contrast to the subjective utterance in line 6, lines 8 and 9 no longer make any allusion to an individual owning or acting on the figures. And with this, the traces of subjectivity start fading in a process where personal voices (e.g. “I add”, “you put”) and the general deictic objects (e.g. “this figure”), underpinning the previous mathematical experience, have to shift to the background thereby providing room for the emergence of objective scientific and mathematical discourse.
But there were other aspects of the desubjectification process that proved to be more difficult to confront. To understand this, we have to raise the following question:

Why did the students not symbolize the generalizing strategy based on ‘the figure plus the next figure’ that they objectified before?

As we shall see later, when we turn to the teacher’s intervention, the change in strategy is related to the students’ difficulty in symbolizing ‘the next figure’, something that requires finding a way to forge a symbolic link between the figure and the next figure and their corresponding ranks. This problem, previously referred to as ‘the positioning problem’ (Radford in press), results from the dramatic change in the mode of denotation that the disembodied algebraic language brings with it, caused by the exclusion of linguistic terms conveying spatial characteristics (e.g. ‘the next’) and their links with the now vanishing acting individual (“I”, “You”, etc.). As such, the ‘positioning problem’ is part of the desubjectification process that the mastering of the algebraic language requires and its presence here is a token of the difficulties that the students encountered engaging in this desubjectification process.

3.3.2 The teacher’s intervention
When the teacher came to see the students’ work, she noticed the discrepancy between the students’ explanation (written in the previous task) and their current algebraic expression. She decided to further immerse the students into the objectifying process by commenting that the symbolic expression did not say the same thing as their explanation in natural language so she asked if they could provide a formula that would say the same thing. Josh continued:

1. Josh: That would be like n + a or something else, n + n or something else.
2. Anik: Well [no] because ”a” could be any figure [...] You can’t add your 9 plus your ... like ... [...] You know, whatever you want it has to be your next [figure].

When the students reached an impasse, the teacher intervened again: Teacher: “If the figure I have here is ‘n’, which one comes next?” Then Josh, thinking of the letter in the alphabet that comes after n, says: “o”.

The teacher’s utterance shows how her attempt to help the students overcome the ‘positioning problem’ is underpinned by the spatial-temporal dimension of the general objects alluded to in the previous section (e.g. the figures are dynamically conceived of as coming one after the other). It is an open research question whether or not the mathematical meanings required to understand the denoting actions underlying the ‘positioning problem’ need to be imported (at least to some extent and probably within some variants) from previous non-symbolic contextual semiotic activities, as the teacher did here. If meaning is not seen as living in self-contained systems, the answer would be yes. At any rate, the teacher’s intervention helped to refine Josh’s understanding and to align it with the one required in the social practice of algebra. Finally, after reworking the case of figure 5, the students noticed that 6, that is, the number of the figure that ‘comes next’, can be written as 5+1, which was then reinterpreted as ‘n+1’. In an attempt to recapitulate the discussion, the teacher asked:

1. Teacher: This would be ...? (referring to the expression ‘(n+1)’ that the students had previously written on their page)
2. Anik: It’s the next [figure]!
3. Teacher: (approvingly) Ah!
4. Anik: OK! There, now. I understand what it is I’m doing.
5. Judith: OK.
The teacher’s intervention made it possible to overcome the positioning problem. It does not mean, however, that the students definitely secured new modes of denotation. The logic of signification behind the algebraic language requires a deeper engagement in the process of desubjectification. If subjective voices are no longer on the surface of the new students’ mathematical discourse genre (see line 8 in the last dialogue), they are not far from it either (see line 6). Furthermore, the relation between the acting subject and the object upon which s/he acts is still perspectival in nature. It has not reached God’s unperspectival view—to borrow Russell’s metaphor. This is why students insist so tenaciously that brackets have to be written, as in line 9 here and in line 9 subsection 3.3.1. This is why the expression reached here, that is, \((n + 1) + n\) and the expression \((n + n) + 1\), reached in the beginning of section 3.3 are seen as different by the students—the reason being that they refer to two different actions.

The relation between \((n + 1) + n\) and \((n + n) + 1\) leads us to the relation between the signified object and its signifier. This was exactly the question that Frege asked in his article *On Sense and Denotation* (Frege 1971). Within Frege’s semiotics, the alluded symbolic expressions are denoting the same mathematical object and the difference between signifiers account for differences in the modes of denotation and their respective senses. And he took sense as one of the ingredients of meaning, actually the only one related to the truly logical or mathematical aspect of the object to which the symbolic expressions refer. What the students’ dialogues suggest is that to reach desubjectification and to end up with the objective kernel of the algebraic generalization, meaning has to be disembodied and become thus pure mathematical sense.

4. SYNTHESIS AND CONCLUDING REMARKS

In this article, we identified three types of generalizations related to geometric-numeric patterns. These generalizations appear as operational schemes relying on different semiotic means of objectification. While factual generalizations remain bound to a numerical level and their objectification is based on a process of *perceptual semiosis* stressing the patterned effect through adverbs of generative actions (e.g. ‘always’) or through articulated semiotic devices like *rhythm* and *movement*, contextual generalizations take, as their arguments, general non-specific numeric objects. These proto-mathematical objects displayed on a still non fully mathematized layer of discourse, are objectified through linguistic, non symbolic terms e.g. ‘the figure’, ‘the next figure’. In doing so, in the course of a discursive practice, the students achieve a fixation of attention and extract from the undifferentiated horizon of objects certain elements that make apparent new objects that are beyond direct perception (indeed, the term ‘the figure’ is *not* ‘figure 1’ or ‘figure 2’ or figure 3, i.e. any of the figures shown on the activity page). Yet, the students’ type of denotation is one that conveys the embodiment of the mathematical experience. It provides the students with a perspectival view of the emergent general objects. As a result, the proto-mathematical objects bear a very important characteristic: they remain *contextual* objects because of their spatial-temporal mode of being. They are abstract deictic objects.

The semiotic means of objectification underpinning these types of generalization shed some light on a question that has been tormenting me for the last couple of years. The question is related to the novice students’ meaning of signs in algebraic generalization of patterns. As I
noticed in the Introduction, and the phenomenon was again visible in the episodes seen in this paper, the students' signs in their first algebraic expressions bear the characteristics of associative indexes whose primary function is that of an abbreviation. The analysis presented here suggests that in this semiotic operation, the students succeed in accomplishing the devoicing of subjectivity. The suspension of subjectivity (related to objectivity) was recognized by Kant in his Critique of Pure Reason as one of the two conditions for knowledge. The second one that he contemplated concerned the exclusion of time (that Kant related to logical necessity). It is in this regard that the major cognitive and epistemological problems appear. Indeed, as we saw, the phantom of the students' actions still haunts the algebraic symbols. The difficulty of the effacement of the individuals in the action that they produce was noticed by Piaget (1979) during the course of his investigation of children's sensorimotor stage and talked about the individuals' décentration of their actions. One of the reasons for the persistence of the action as a link between subject and object may be that, as Vygotsky (1997) suggested, actions appear as a formidable source of meaning in the emergence of the child's semiotic activity.

The question of the individuals' actions and their semiotic objectification (discussed from other theoretical perspectives and in different contexts by Arzarello 2000 and Núñez 2000) appears as an important element in contemporary understandings of the ontogenesis of algebraic language. The analysis offered in this paper evidenced some tensions caused by a shifting in the relation between the knowing subject and the object of knowledge imposed by the cultural requirements of algebraic and scientific languages. As we saw, natural language accounted for close dialectical forms of relationship between subject and object. In algebraic language, the relationship between subject and object is shattered. The dual reference subject/object becomes lost and it is no longer possible to talk about e.g. “your first figure”. The students now have to refer to the objects in a different way. Deprived of indexical and deictic spatial-temporal terms, the new objects have to be denoted in a layer of discourse where they bear a different kind of existence and where the subject denoting them has to become (to use a term from Lacanian theory of discourse) decentred (see e.g. Bracher et al. 1994). The epistemological and didactic understanding of the decentration of the subject urges us to reflect on and envision new dialogical and semiotic forms of action in the activities that we propose to students during their insertion into the phylogenetically constituted social practice of algebra.

UNDERSTANDING DATA COLLECTION

Chris Reading
Centre for Cognition Research in Learning and Teaching
University of New England, Armidale, Australia

Recent changes in the research agenda, fuelled by curricula changes, have focused on considering what ‘statistical thinking’ really means. To assist educators in both curriculum design and assessment more needs to be known about students’ statistical understanding. This paper takes up the theme by considering students’ responses to two open-ended tasks, based on scenarios involving data collection. The first task requires a suitable data collection method to be suggested, while the second task suggests the method but asks for implementation details. In both, a justification for the answer is elicited. A developmental sequence of nine levels was identified and the responses to the two data collection questions were analysed. The SOLO Taxonomy was used as the theoretical framework to assist this process.

Introduction

As more researchers focus on students’ statistical understanding, some aspects of statistics are being more thoroughly researched than others. Just as the understanding of simple probability has been identified as critical to the statistical process, so too is a basic understanding of data collection. Too often students are given data to work with or told how to collect data, rather than experiences which involve data collection decisions. Shaughnessy (1997) advocates encouraging teachers to give students a chance to show what they can do statistically. This should include making decisions about data collection and more research into students’ understanding of data collection is needed.

The SOLO Taxonomy (Biggs & Collis, 1982) is being increasingly used as a framework in both probability and data handling. SOLO levels have been used to classify student responses concerning; data representation (Reading, 1999; Chick & Watson, 1998), data reduction (Reading & Pegg, 1996), data interpretation (Reading, 1998) and uncertainty (Moritz, Watson & Collis, 1996). This paper explores students’ responses to questions concerning the understanding of data collection, using the SOLO Taxonomy as the theoretical framework.

The SOLO Taxonomy

Detailed descriptions of the SOLO Taxonomy can be found elsewhere (see for example, Biggs & Collis, 1991). The model, which allows a deep analysis during categorisation of students’ responses, consists of five modes of functioning, with levels of achievement identifiable within each of these modes. The two modes relevant to the research being reported are the ikonic mode (making use of imaging and imagination) and the concrete symbolic mode (operating with second order symbol systems such as written language). The three relevant levels identified within each of these modes are: unistructural - with focus on one aspect, multistructural - with focus on several unrelated aspects and relational - with focus on several aspects in which inter-relationships are identified. A cycle of growth forms as the three levels recur within the modes, with the relational level response in one cycle similar to, but
not as concise as, the unistructural response in the next. Different cycles of levels are identified by the nature of the element on which the cycle is based.

**Research Design**

One hundred and eighty secondary students, selected randomly over gender, mathematical ability and academic years were tested on a range of statistical questions. This paper reports on the responses to a two part question which presented short scenarios to students and then asked about some aspect of the related data collection. The question was open-ended and students were asked to explain the reasons for their answers. Part I of the question sought students’ ideas on method of collecting data, while Part II was more specific, the method was given and implementation details were sought. For a more detailed discussion of the analysis of responses to these questions see Reading (1966).

**Analysis of Responses to Part I**

The question as presented to students is shown in Figure 1. Based on the depth to which the response indicated the ability of the student to understand the collection of the data, three major groupings of the levels were identified.

![Figure 1](image)

**PART I Question**

Radio stations have their own way of working out the most popular song on the radio and they often produce Top 40 charts. Imagine that you have been asked to do this independently of the radio station and answer the following questions:

(i) Describe the best way to find out what the most popular songs are on the local radio station.

(ii) Why did you decide to find out this way?

**First Group (No Method Suggested)**

Observed responses, which were coded into two broad levels (1 and 2), attempt to rationalize the requirements of the question but show no real concern about actual data collection.

**Level 1** These responses do not fully address the question, suggesting the use of data that have already been collected rather than collecting data to address the problem. For example a Year 7 student wrote:

(i) *You could ring up the radio station, ask someone that works there, go in and ask them.*

(ii) *It was the first thing that came into mind. It would be easier than worrying about it.*

**Level 2** These responses indicate that all aspects of the question have been considered, but a suitable explanation as to why the answer was chosen was not given. For example a Year 12 student gave a reason to collect data rather than for the method chosen:
Watch programs such as Rage or Video Smash Hits then maybe listen to the radio to see if it is right, or just ring up the station and ask.

So that I know what to expect if they ever play a song on the radio.

Second Group (Concern with Physical Aspects of Data Collection)

Responses in the second group (coded as Levels 3, 4 and 5) are concerned with rationalizing the method of data collection. These responses attempt to describe suitable data collection, but are mainly concerned with physical aspects collection such as, the time or cost involved. There is no evidence of concern for the quality of the resulting sample.

Level 3 These responses indicate that, in attempting to justify the suggested method of data collection, focus was directed back to the question and not to any specific aspect of the collection of the data. For example a Year 7 student wrote:
(i) Have a piece of paper sent to all houses, get them to write their favourite songs on them and return them to the radio station.
(ii) I decided this way because I think it would be a good idea.

Level 4 These responses give reasons, with an explanation for the method chosen, which focus on physical aspects of the collection process. There is no real concern for the accuracy of the resulting sample. For example a Year 9 student wrote:
(i) Have a phone in census or a questionnaire that is put through the public for their forty favourite songs.
(ii) I decided to find out this way as you can get a larger amount of information in a relatively short amount of time.

Level 5 These responses indicate that concern for the physical aspects of the data collection have been rationalized. However, the only concern for the quality of the resulting sample is that data have been collected in such a way that the sample is fair or accurate with no indication as to how this is to be achieved. For example a Year 8 student wrote:
(i) By finding what music is bought as singles most at the music stores.
(ii) Because it is the most accurate way of finding out this.

and a Year 12 student wrote:
(i) Have people ring in and vote for their favourite song. The song that is most popular will be no. 1, the second most popular no. 2 and so on.
(ii) To give everybody an equal chance of giving their opinion of their favourite song.

Third Group (Concern with Quality or Accuracy of Resulting Data)

The final group of responses (coded as Levels 6 and 7) indicate concern for the quality or accuracy of the data in the resulting sample.

Level 6 These responses indicate the need for sample selection to be arranged so as to produce a range of data in the sample, based on one variable. For example a Year 12 student used 'time' as the variable:
(i) Do a random survey on the radio turning it on at different times of the day at different intervals noting the songs that are being played.
(ii) Because it gives you a less bias opinion and view on the popularity of certain songs. You can get a wider census area, making the results more realistic.

Level 7  These responses indicate that selection of the sample has been based on more than one variable in an attempt to improve the range of the responses which are collected. For example a Year 12 student used ‘age’ and ‘background’:
(i) Collect group of people of varying ages and background who listen to the radio and ask them their favourite songs.
(ii) Not biased to any group of people and asks people who are interested in music because they listen to the radio.

The results, arranged by academic year in Table 1, illustrate a number of interesting points. First, there are only three students (5%) from Years 11 and 12 whose responses fall within the first group (Levels 1 and 2), whereas in Years 7 and 8 there are nine students (15%), in this group. Second, there are only three students, all in Year 12, whose responses were coded as Level 7. Last, there was an overall bulge at Levels 3 and 4. This bulge is consistent in all years, except Year 12 where the bulge shifts to Levels 4 and 5.

<table>

These results suggest that, when dealing with data collection, the level of response improves progressively with academic year, although, the bulge at Levels 3 and 4 suggests that many students are more concerned with sample selection based on physical aspects rather than quality of the data.

Analysis of Responses to Part II

Answering this question (Figure 2) meant that students did not need to be concerned about the method of collection, the actual details of the sample were required.

A similar hierarchy of levels of response was observed for Part II so examples of responses for Levels 1 to 7 are not included. However, two other Levels 0 and 8, were observed.
Part II Question

There are often surveys of the community to see what T.V. programs they like to watch. The editor of the school magazine is interested in writing an article about the viewing habits of the students at A.H.S. and asked you to find out the information.

(i) You are only able to ask 30 students from the school. Which students would you select to ask? (Don't use names)
(ii) Why would you select these students?

Figure 2

Level 0 These responses (in the First Group before Level 1) indicate that no attempt at all has been made to answer the question.

Level 8 This response (in the Third Group after Level 7) indicates that the selection of the sample, based on a number of variables, also takes into account the composition of the population from which it is drawn. This is a more thorough attempt to make the sample representative. This unusually good response from a very insightful Year 8 student, who achieved at Level 6 in Part I was:

(i) I would try to select a broad spectrum of the populous, taking into account age and social groupings. I would keep the divisions proportionate to what they are in the school environment e.g. there are 80 people in one social group and 20 in another therefore i would take 4 people randomly from group 1 and 1 person from group 2.

(ii) I would use this method to be sure of getting the full range of viewing habits within the school, but so as not to overestimate the statistical effects of minority groups.

Three interesting points arise from the results, arranged by academic year in Table 2. First, there are no students from the two senior years whose responses fall within the first group (Levels 0, 1 and 2), whereas in Years 7 and 8 there are a number of students, eight (13%).

PME25 2001
Second, there are only seven (12%) students from Year 7 and 8 whose responses were coded as Level 7 or 8 compared to eighteen (30%) Year 11 and 12 students. Last, there is an overall bulge which varies from year to year, ranging from Levels 4 to 5 for Year 7 through Levels 4 to 6 for Year 9 to Levels 5 to 7 for Years 11 and 12.

These observations suggest an improvement in the quality of responses with increasing academic year and the ability to show more concern with the accuracy of the sample when the method of collection is specified.

Comparison of Part I and Part II

The framework developed appears to be adequate for explaining students' understanding of the basic concepts of data collection. An upwards shift in the level of response with increasing academic year is more pronounced in Part II than Part I. There is an association between the level of the coding and the part of the question being answered ($\chi^2 = 109.5$, 6 d.f., is very significant, $p < 0.001$). Far less responses are coded into the Levels 0 to 3, and far more responses in the Levels 6 to 8, for Part II of the question than for Part I. Even the large bulge of responses at Levels 3 and 4 for Part I has shifted up to Levels 4, 5 and 6 for Part II.

This suggests that, given a sampling scenario, students are able to discuss the practicalities of the collection of data, but find it difficult to rationalize this sufficiently to consider the consequences of the sample choice on the data produced. However, once students have been prompted with some information about the sample and are able to concentrate on which members of the population to choose, consideration is given to the aspects of selection which affect the sample selected and hence the quality of the data collected.

The significantly higher level attained in Part II suggests that, with prompting as to the physical details of the sample, students were able to demonstrate a deeper understanding taking into consideration the variables which might possibly affect the resulting data.

SOLO Taxonomy Framework

The levels established for the classification of the responses, along with the structure of the SOLO Taxonomy, were used to create a framework which could be used in future to code student responses to data collection questions. The first group of three levels exhibit ikonic features while the second and third groups represent two different cycles in the concrete-symbolic (CS) mode.

Ikonic responses suggest that the required task could not be linked with any sort of symbolic representation. Level 1 responses were coded as a mixture of unistructural (U) and multistructural (M) responses. As the task had not been addressed, it is difficult to determine how many visual cues from the question are in focus or what personal beliefs and experiences have been drawn upon, without further investigation. Level 2 responses correspond to the relational level within this mode.
The responses in the second and third groups have been able to link the concepts in the question to concrete experience. The answers include reasons linked directly to the practical aspects of data collection or to concerns about the accuracy of the sample. These responses are in the CS mode with two cycles of U, M and R levels.

The first cycle involves consideration of physical aspects of the data collection. The elements in the first cycle are the practicalities which need to be taken into consideration when data are to be collected. Typical considerations are the number in the sample and the type of data to be collected as influenced by things, such as, the cost and time involved. A relational response in the first cycle is not achieved until the student is able to consider all physical considerations as a functioning set, and hence come to the realization that more needs to be considered. The U, M and R levels in this cycle correspond to the Levels 3, 4 and 5 identified earlier.

The second cycle involves appreciating that the method of selection of the sample influences the quality of the responses. Reasons given in responses now indicate that some attention has been focused on ensuring that the data collected presents a suitable range of opinions. The elements in the second cycle are the various variables that may be used in the selection process to ensure an accurate sample. A relational response in the second cycle is not achieved until a variety of variables have been considered as concern is centred on making the sample as representative of the population as possible. In this cycle, the U, M and R levels correspond to the Levels 6, 7 and 8, as outlined earlier.

The main feature which distinguishes the concrete-symbolic mode responses from the ikonic mode responses is evidence of the recognition that data need to be collected to address an issue. Ikonic mode responses either suggest using information collected by others or consider a personal judgement sufficient. CS mode responses discuss one or more aspects of the data collection process. Within this mode, the first cycle responses are only concerned with physical aspects of data collection, while second cycle responses consider the influence of variables related to the method of selection on the quality of the data.

Conclusion

Three major findings have evolved as a result of this study. First, students are better able to consider variables influencing the selection of a sample when the physical aspects of the data collection process have already been resolved for them.

Next, the three broad groupings identified, namely, No Method, Concern with Physical Aspects and Concern with Accuracy assist in determining the stage a student has reached in understanding data collection. No Method responses are addressing the issue but not by collecting data, while the other two groups deal with data collection, Concern with Physical Aspects responses in a less statistically sophisticated fashion than the Concern with Accuracy responses. These groupings offer educators a means to better follow student thinking when planning lesson sequences within the curriculum and assessing specific student outcomes.
Last, the groups of levels identified can be categorized as cycles of U-M-R levels, based on the SOLO taxonomy. The No Method group is a U-M-R cycle in the ikonic mode where the elements of focus are the facts in the question. The other two groups represent two U-M-R cycles in the CS mode. The elements of focus in the first cycle, the Concern with Physical Aspects group, are the physical aspects of collection while the focus elements in the second cycle, the Concern with Accuracy group, are the various variables which could affect the accuracy of the sample. Educators could make use of the suggested framework when considering the quality of responses to gain a greater awareness of what students really know, understand and can do.

PREREQUISITES FOR THE UNDERSTANDING OF PROOFS IN THE
GEOMETRY CLASSROOM

Kristina Reiss*, Eckhard Klieme*, and Aiso Heinze+
+ University of Oldenburg, Department of Mathematics
* Max Planck Institute for Human Development, Berlin

Geometry is a field, which is a good starting point to teach and learn mathematical argumentation, to explore mathematical concepts, to fill the gap between every day life and mathematics, and to value mathematics as a part of human culture. Accordingly, geometrical competence has to be regarded as an important prerequisite of understanding mathematics. Our research aims at identifying aspects of geometrical competence. Based on empirical data from upper secondary school, we argue that high level geometrical competence is specifically influenced by spatial ability, declarative knowledge, and methodological knowledge.

1 Theoretical framework

The role of geometry in the German mathematics classrooms has changed considerably in the last decades. Despite the fact that geometry is part of the regular curriculum, it is often regarded by teachers as a less important topic. While this is well known for primary schools there is little research concerning secondary schools. In contrast, mathematicians as well as mathematics educators agree that geometry should be an important part of mathematics education (Lehrer & Kazan, 1998).

1.1 Understanding of proof and geometrical competence

Proofs and mathematical argumentations play an important role in the geometry classroom. Particularly in recent years, many researchers contributed to the description of the role of proofs for the development of mathematical competence. Authors like Hanna and Jahnke (1993), Hersh (1993), Moore (1994), Hoyles, (1997), Harel and Sowder (1998) have pointed out that in both, mathematical research and school instruction, proving spans a broad range of formal and informal arguments and that being able to understand or generate such proofs is an essential component of mathematical competence. In constructivist-oriented mathematics instruction, the critical exchange of arguments and elements of proof is accorded new significance.

Some empirical surveys of North American high school students (Senk, 1985; Usiskin, 1987) and pre-service teachers (Martin & Harel, 1989) have revealed wide gaps in respondents' understanding of proofs. Healy and Hoyles (1998) made a significant contribution to the field with their recent systematic investigation of students' understanding of proofs, ability to construct proofs, and views on the role of proof. Their empirical study was conducted in various types of schools spread across England and Wales. Almost 2,500 tenth grade students, nearly all of them from the top mathematics set, participated in the study. The results show that even these high-
attaining students had great difficulties in generating proofs. The students were far from proficient in constructing mathematical proofs, and were more likely to rely on empirical verification. However, most of them were well aware that once a statement has been proved it holds for all cases within its domain of validity. Moreover, they were frequently able to recognise a correct proof, though their choices were influenced by factors other than correctness, such as perceived teacher preference. Students considered that their teachers would be more likely to accept formally-presented proofs, though they were personally more likely to construct proofs which they deemed to have an explanatory character. In all domains, students with higher levels of mathematical competence outperformed less able students.

Recent research in the field of cognitive psychology has focused on the cognitive processes and specific knowledge structures needed to solve geometry problems. Geometrical reasoning has been investigated in detail by setting various types of test items, observing students and experts working on the items by means of think-aloud protocols, and computer simulation of thought processes. Koedinger and Anderson (1990) emphasize that when experts construct geometrical proofs, they do not merely retrieve definitions, axioms and theorems from the memory and combine these to make logical deductions. On the contrary, they skip details of the proving process, and outline their argumentation in broad terms, taking a constructivist approach. They use visual models, in which they are able to "see" properties and connections, and "pragmatic reasoning schemas" such as set patterns for individual steps in the proving process. As stated by Koedinger (1998), this indicates that geometrical competence is not merely a question of talent, but of specific skills and knowledge.

Geometrical competence does require specific knowledge; it is based on general psychological mechanisms that are central to other domains of mathematics as well as to thinking and problem solving in general. Where geometrical knowledge is concerned — as shown by the cognitive psychological research cited above — a distinction must be drawn between declarative knowledge and methodological knowledge. Moreover, metacognition can be identified as a general mechanism. Various components of general intelligence are relevant; according to Clements and Battista (1992), spatial reasoning is of particular importance for geometrical competence. They suggest that geometrical competence is largely dependent on spatial visualisation skills, but that spatial ability can also be enhanced by exposure to geometry.

1.2 Research Questions

The present study integrates the lines of research described above. Geometrical competence and its cognitive prerequisites are investigated by reference to TIMSS items, with a particular focus on respondents' understanding of proof. The research questions to be addressed in this paper are as follows:

- Is geometrical competence dependent on students' declarative knowledge, methodological knowledge, metacognitive competences and spatial abilities? What is
the relative importance of each of these factors in explaining interindividual differ-
ences in geometrical competence?

- Can Healy and Hoyles' (1998) findings on the connection between students' ability
to construct proofs and their views of the role of proof be replicated in another in-
structional culture, namely the German mathematics classroom? Is it possible to
identify prerequisites for the correct understanding of proof?

2. Design of the Study

In the present study, geometrical competence was assessed using nine TIMSS items
from the so-called advanced mathematics domain in the upper secondary level. The
sample consisted of 81 students from German schools (48 female), 59 of them attend-
ing a regular mathematics course and 22 an advanced course, who tackled selected
TIMSS items as well as additional tests (metacognitive assessment, declarative
knowledge, understanding of proof, spatial reasoning), and were videotaped as they
worked on the geometry items using the think-aloud method. Based on analyses of the
entire set of TIMSS items, the nine items were allocated to two proficiency levels
(Klieme, 2000). The lower level items were answered correctly by more than half of
the students in the international TIMSS population, the three higher level items by one
third or less of the students.

The first prerequisite of geometrical competence to be measured independent of the
TIMSS items was declarative geometrical knowledge. Linking up with earlier work
on the conceptual knowledge required for mathematical problem-solving tasks
(Klieme, 1989; Reiss, 1999), we chose a central concept of school geometry, namely
"congruence", for the evaluation of students' declarative knowledge. Students were
asked to give a definition, an example, a visual or graphic portrayal of the word "con-
gruent", and to name a mathematical theorem in which the concept features. The stu-
dents' open-ended answers were coded according to a specially developed category
system; one point could be earned for each of the four aspects.

Methodological knowledge was assessed using an item from Healy and Hoyles'
(1998) proof questionnaire. The item dealt with the question of whether a given trian-
gle could be proved to be isosceles. Students were presented with a correct formal
proof, a correct narrative proof and two incorrect arguments. They were then asked to
assess the correctness and generality of each of the four arguments.

As a measure of general intellectual abilities, particularly of spatial ability, an instru-
ment which is well-known in Germany – Stumpf and Fay's so-called Schlauchfiguren-
Test – was administered. Schlauchfiguren presents different views of complex tubular
figures, which have to be judged with respect to the specific point of view. This kind
of task has been shown to predict mathematical problem-solving competence
(Klieme, 1989). Validation studies have shown that the test calls for both spatial
ability and deductive reasoning. It is therefore a suitable instrument to capture those
aspects of general intellectual ability which are cognitive prerequisites of geometrical
competence.
Table 1: Distributional parameters and reliability of scales

Table 1 provides an overview of the various scales, the number of items in each, and the most important distributional parameters. The estimated reliability (Cronbach's $\alpha$) for our sample is also shown. Because of the limited test time, we were only able to administer short tests, particularly for conceptual knowledge and the two levels of geometrical competence, the scales for which consisted of only three to six items. The estimated reliability for these scales is correspondingly low. If extrapolated to tests of the standard 20-item length, however, an acceptable $\alpha$ of between .71 and .84 emerges in all cases. This suggests that the constructs behind the indicators represent dimensions of ability which may be regarded as reliable. If significant correlations are found in spite of the technical limitations and the associated lack of reliability of our instruments, it can be assumed that these are valid findings with relevant effect sizes.

3. Results

3.1 Descriptive findings

In the following we will report on certain aspects of our findings. Figure 1 shows the percentage of students providing correct solutions for each of the nine geometry items administered in our study, along with the corresponding results for the international TIMSS sample and the German national TIMSS sample.

The results show a remarkably high level of correspondence across the three samples, both in the average achievement level and in the performance in each of the nine questions. Averaged out across the nine items, 53% of the students in our sample provided correct solutions, compared to 51% in the international sample and 47% in the German sample. Across the nine items, the correlations between the performance in our sample on the one hand and in the representative German and international TIMSS samples on the other amount to .97 and .89 respectively; both of these correlations are highly significant. The relative strengths and weaknesses of the German students are thus also reflected in our small sample.
Solutions of TIMSS Items

In view of the observation that very few students (20% and 35% of the representative German and international TIMSS samples respectively) were able to construct correct Euclidean geometry proofs, we also expected the levels of performance to be rather unsatisfactory in students' understanding of proof and their views of the role of proof (taken from Healy and Hoyles, 1998). Interestingly, our students also found it much easier to judge given proofs than to construct their own proofs. This confirms the results of Healy and Hoyles (1998).

Table 2: Components of methodological knowledge (understanding proof)

As shown in Table 2, 57% of our respondents recognised the correct formal proof (using congruence) to be correct, and the same proportion of participants correctly
appreciated its generality. A similar proportion of respondents recognised a purely exemplary, empirical argumentation to be incorrect: 46% said that the argument was incorrect, and 60% recognised that it was not generalisable. However, the low item-total correlations of these two answers (see right-hand column of Table 2) showed that even students with a low general understanding of proof were aware the purely empirical argument was incorrect and not generalisable. Our findings on the respondents' declarative knowledge, are also less than satisfactory from the standpoint of mathematics education. When asked to describe the concept of "congruence", 82% of respondents were able to illustrate the concept in a sketch, most of them drawing congruent triangles. Less than half of the respondents were able to give an example of congruence, however. Only about one in ten of the students mastered the mathematically central components of the concept, i.e., were able to provide a definition of the concept and name a mathematical theorem in which it features (e.g., a theorem of triangular congruence).

3.2 Explaining Geometrical Competence

We will now explore the relations between the scales for geometrical competence, methodological knowledge and declarative knowledge. Table 3 shows the intercorrelations, calculated as rank-correlation coefficients (Kendall's tau), on which this discussion is based. In addition to the mathematical dimensions of competence and knowledge, the two general psychological predictors – metacognition and spatial reasoning – are also included in the table.

Table 3: Intercorrelations of scales (Kendall’s tau – b) *) p< .05  **) p< .01  ***) p< .001

The most important finding is that all four predictors exhibit significant correlations with geometrical competence. This lends support to our basic hypothesis that geometrical competence is dependent on methodological knowledge, declarative knowledge, metacognition, and spatial reasoning. The correlation matrix does not actually allow such causal interpretations to be made; but interpreting the results in the light of other research on geometrical knowledge (Reiss & Abel, 1999; Reiss & Thomas, to appear) makes it plausible to assume that scales (4) to (7) tap the prerequisites, and scales (1) to (3), the results of development of geometrical competence.
As expected, stronger correlations with the predictors emerge at the higher levels of geometrical competence (items on TIMSS proficiency levels III and IV) than at the lower levels of geometrical competence (levels I and II). Understanding of proof is a vital ingredient at the higher levels of competence, but is irrelevant to performance in the easier TIMSS geometry items. This confirms our assumption that the TIMSS proficiency levels really do reflect different standards of (geometrical) competence.

4. Discussion

In our study, students were presented not only with TIMSS geometry items, but with a number of additional test components. This enabled us to assess various types of mathematics-related skills and general psychological competencies that could possibly be prerequisites of geometrical competence. Where the geometry items are concerned, the performance of the students in our sample was well in line with the profile of results obtained for the national and international TIMSS samples. It is thus possible to assume that our findings can be generalised to these study populations.

Our findings provide evidence for the validity of the TIMSS advanced mathematics tests. In particular, we were able to demonstrate that items from the higher levels on the TIMSS proficiency scale really do make more complex demands on the problem solvers, calling for a broader base of declarative knowledge (e.g., comprehension of geometrical concepts such as congruence) and methodological knowledge (e.g., an understanding of proofs, their generality, etc.).

Investigation of individual items has shown that the demands made by each item vary greatly. In some cases, only spatial and deductive reasoning ability is required, in other cases conceptual and/or methodological knowledge is also essential. In other words, TIMSS items make different demands, and cover many different facets of geometrical (or general) mathematical competence. The test is nonetheless one-dimensional, as model testing indicated. This means that the various facets of mathematical competence are not independent of one another, but rather that they are highly correlated. In the German school system at least, high levels of geometrical competence are accompanied by high levels of overall mathematical competence, a good understanding of proof, and differentiated conceptual knowledge. In other words, geometrical competence does not develop in isolation.

These findings, revealing the students' inadequate understanding of proof, can be regarded as an important indication of where the problem areas in mathematics instruction lie. Indeed, this was the basic approach taken by Healy and Hoyles (1998). In the context of a theory of situated cognition, however, the discrepancy between abstract knowledge about the correct construction of proofs and (at least partly) erroneous personal preferences is easy to understand and can be positively evaluated: students bear the context in mind when evaluating differing formulations of mathematical arguments. This is precisely the sort of approach encouraged in modern, reform-oriented conceptions of mathematics instruction. After all, students should not only experience mathematics as a set of fixed rules. On the contrary, they should be able to construct
appropriate mathematical arguments both in school and in applied contexts. Our findings indicate that the topic of "proof in mathematics instruction" is particularly well suited as an introduction to mathematical argumentation — precisely because of this juxtaposition of views and preferences. "The goal is to help students refine their own conception of what constitutes justification in mathematics from a conception that is largely dominated by surface perceptions, symbol manipulations, and proof rituals, to a conception that is based on intuition, internal conviction, and necessity" (Harel & Sowder 1998, p. 237).

References

ABSTRACT: The study reported in this paper concerns the dialectic relationship between the figural register and the natural language register when students try to solve plane geometry problems. I will present a theoretical framework and some preliminary results concerning the following problem: how and to what extent does natural language act as a mediator and a control tool between the operational handling (Duval) of the drawing and the theoretical reference (in our case, Euclidian geometry)?

1. The research problem and the theoretical framework

In geometry, since we deal with theoretical objects and their representations, we need to state what we mean by drawing, figure and geometric object. I considered the definitions given by Parzysz (1988) and by Laborde and Capponi (1994).

Parzysz suggests that “the FIGURE is the geometrical object which is described by the text defining it” and “The figure is most often REPRESENTED” (Parzysz pg. 80). Parzysz calls drawing the illustration of a figure.

Referring to Parzysz’ elaboration, Laborde and Capponi propose the following definition: “Drawing can be considered as a signifier of a theoretical reference (an object of a geometric theory, like Euclidean Geometry or Projective Geometry). A geometric figure involves the joining of a given reference to all of its drawings: it can be defined as the set of all couples which have the reference as the first term, while the second term belongs to the universe of all possible drawings of the reference”.

Referring to the abovementioned elaborations, from now on I will consider geometric object the object of a geometric theory related to a definition. The description will be the verbal presentation of the geometric object (i.e. the text of the definition). By drawing I then mean one of the different graphical expressions of the definition itself.

I can now define the figure (F) as the set of couples made up by the geometrical object (O) and one among the drawings (d_i) that are material representations of that geometrical object (O):

\[ F = \{(O, d_1), (O, d_2), (O, d_3), \ldots (O, d_i)\} \]

In this way the theoretical aspect is linked to the graphic one and a kind of bridge is established between them.

The differences (and relations) between drawing, figure and geometrical object play a very important role in handling the drawing when trying to solve a plane geometry problem. Therefore, we adopted the operational handling of a drawing considered in Duval’s theory (Duval, 1994): operational handling of drawing (appréhension opératoire) involves an immediate perception of the drawing and its

1 “L’appréhension opératoire est l’appréhension d’une figure en ses différents modifications”.
different variations (\textit{mereologique}, optical or of position\textsuperscript{2}). Our research concentrates mainly on analysing the influence of natural language on the relationship between the operational handling of drawings and the theoretical reference to which it is related. We define \textit{theoretical reference} in a given geometric theory as theorems and definitions of that theory which are related to the figure by the student who is solving the problem. Since solving a plane geometry problem involves reciprocal relationships between drawing and theory, we note a two-way relationship between the handling of the drawing and the choosing of a particular theoretical reference: choosing a particular theoretical reference leads to the operational handling of the drawing and vice versa the operational handling of drawing can suggest how to choose a particular theoretical reference.

Three hypotheses can be formulated:

a) The above-described relationship is guided and controlled by natural language.

b) Recognising some useful sub-configurations or some useful geometrical properties may be due not only to the perception of the drawing, but also to the \textit{description} of the considered \textit{geometrical objects}. This might even have a certain influence on the way to consider and analyse the actual drawing.

c) A verbal discourse about the project of resolution (meta-discourse) is necessary in order to give a status of hypothesis or of conclusion to the information which we get by handling the drawing procedures and by the description of geometrical objects.

In this paper I will elaborate a research methodology suitable for testing the above hypotheses and present some preliminary experimental results (intended to support further investigations).

2. Research methodology

Hypotheses a), b) and c) bring in particular to the following questions:

1. Is natural language a tool of mediation and control between operational handling of drawing and theoretical reference in the procedure for solving a plane geometry problem?

2. What role does language play in the meta-discourses elaborated while solving the problem?

These questions immediately pose a problem concerning research methodology: How can we access the students’ solving process? Basically, I tried to elaborate a methodology that should be suitable for tackling this problem. Such a problem depends on the fact that language plays two different roles: it is a tool for the researcher (as a revealer of students’ processes) and, at the same time, it is a tool for students, because they use it to solve the problem (and our inquiry concerns its role in the solving process). We elaborated a model for analysing protocols, based on the use of language as a revealer, which allowed us to point out the role of language as a problem-solving tool for students. The model is based on the assumption that solving processes are mainly expressed through two registers: the

\textsuperscript{2} A variation is called \textit{"mereologique"} when it divides the drawing into parts; it is designated as \textit{optical} if it is an enlargement or a reduction of the drawing; it is called \textit{positional} when the figure background changes position.
linguistic and the figural. Then, the model distinguishes between two strategies: one developing from the figure drawn after reading the text of the problem, and the other developing from the question posed in the text or from the sub-questions obtained by transforming that question.

We named these strategies **drawing strategy** and **discourse strategy**.

The **drawing strategy** involves handling the drawing (in Duval’s sense of operational handling of drawing), or its perceptive apprehension (cf. Duval, 1994) in order to construct a *work environment* by means of a list of information.

The **discourse strategy** consists of a structured sequence of questions, starting from the question of the text; or from some key words taken from the text, by talking with a schoolmate, or with a teacher; or from a key configuration isolated in the drawing.

So, the **discourse strategy** is closely linked to the text of the problem but, on the contrary, the **drawing strategy** is not strictly related to the text.

Both strategies may intervene in the same student’s solution.

- **Aim of strategies**

  If the **discourse strategy** consists of a structured sequence of questions, its aim is a structured sequence of answers. On the contrary, the aim of the **drawing strategy** is collecting information starting from the drawing or by acting on the drawing itself. So, the change of aim in the procedure is the key element that reveals the intention to go on to another solving strategy. The **discourse strategy** usually is a part of a deductive strategy, in which the aim is to prove something. On the contrary, the aim of the **drawing strategy** isn’t proving (indeed this strategy is used to create a set of information that constitutes the working environment).

- **Criteria for distinguishing between the two strategies**

  We now try to provide some criteria that are useful for recognising a **drawing strategy**. In detail, language makes it possible to recognise this strategy when we can detect:

  - words that refer to perception, such as "you can see that."
  - words and adverbs indicating space, such "here, there..."; besides demonstrative adjective or pronouns, such "this (one), that (one), ...", accompanied by gestures;
  - the present tense recurring frequently
  - a descriptive rather than deductive discourse, without any connection linking the information in the list.
  - unjustified inferences: they carry the formal shape of ordinary inferences such as "since we know that..., then it follows necessarily that...". But the term "necessarily" introduces perceptive evidence and takes the place of "then, since...".

  The following is an example containing some of the above-mentioned inferences, made at the drawing level.

  123. Taina: "because, since we have OD diagonal, I go on tracing the OD line, then we have the parallel, no, the perpendicular, which is AE, since it is a circle, since we know that OA, OD and OE"
are circle radii and that AO is equal to AD and that OE is also equal to AD, then necessarily DE is equal too”.

We now try to provide some rules that are useful for recognising a discourse strategy:
- the variation in the use of verb forms and tenses. For instance a sentence like "we should be able to demonstrate that" points out an attempt to get out of the solving procedure, in order to provide a plan of it.
- the complexity of sentences: coordination between several complete propositions.
- the final structure of a sentence as “to have...it is necessary that...”. This structure allows us to determine the theoretical reference that guided the answers to the questions.
- the presence of key words such as perpendicular or isosceles triangle, height, medians. These words play a key role for the subject, which refers back to a concept belonging to his/her knowledge system. Therefore, these words are a kind of bridge between the subject’s knowledge and the text of the problem or the discussion with some schoolmates. Let’s take a look at the word parallelogram, for example: it reminds the subject of the quadrilateral figure, then the student will relate it to all the theorems and properties defining it which are part of his/her knowledge system, thus becoming capable of handling the drawing.
- the presence of Key configurations, which is recognised and isolated by the subject in the drawing.

3. Experimental situation and early research results

As pointed out above, the object of our research is the role of language in the link between the operational handling of a drawing and the theoretical reference to which it is related. By analysing the students’ oral and written texts using the model of drawing strategy and discourse strategy, we try to distinguish among various behaviours, which we call action models, in the students’ solving processes. Such models should enable us to define how these working moments are structured and what the switchovers from one to another are. Such models should be made operational by finding ways of relating them to students’ behaviour. A short description of the first experiment performed is presented, followed by the early results.

3.1 The experimental situation

We performed a preliminary experiment involving Italian and French Grade X students. They worked in pairs, trying to solve a plane geometry problem involving geometrical objects already studied by the students in the middle school. Audio and video-recordings as well as students’ written texts were collected.

---

3 This term indicates that the subject begins to search for the “cause” starting from the “effect” (consequence). The action focuses on a search of the theoretical reference to reach the “effect” that, in the specific case of our experimentation, is the rhombus.
Task

Given a circle C; its centre O; its diameter AB;
D is a point on this circle, so that AD = AO.
The perpendicular to DO through A meets the circle C again in point E.
Prove that OAED is a rhombus.

3.2 Early research results

We identified several verbal action models implemented by pupils: some of them will be described (along with the criteria for detecting them).

It is within the context of these models that we are trying to determine the role of language as a problem-solving tool.

Action models in the Drawing strategy

Among the results obtained by analysing the students' drawing strategy, there is one action model involving the creation of a list of information and the handling of such data. Let's use a French student's work as an example (Taina worked with Sophie - see later for additional excerpts).

40. Taina: diagonals AE and OD cut each other in their middle point, making a right angle, and AO is equal to EO, EO is equal to AD.

The information in the list is, obviously:
1) Diagonals AE and OD intersect each other in their middle point.
2) They both make a right angle
3) AO is equal to EO
4) EO is equal to AD.

As we can see, the information in the list is not related to each other.

How and where do students get the information (theoretical references, geometrical relations, properties, etc.) for making their own list? We already said that the information in a list can be collected from the drawing, through operational handling or through the perception of it, but it can also be collected through implicit or explicit inferences. Here are two examples: Taina - Sophie and Gaelle - Camille:

- explicit inference:
  59. Sophie: Look! AO is a radius of the circle and EO is a radius of the circle too.
  60. Taina: then, AO is equal to EO too
  61. Sophie: and AO is equal to AD too
  62. Taina: so, and AO is equal to AD, so AD is equal to OE

- implicit inference:
  36. Gaelle: maybe, look! this one is symmetrical to this one (OA and DE) then it is the same.
The above inference is implicit, since it comes out from the drawing interpretation field and not from a transition to a deductive procedure. We can see some revealing signs: the verbs "to look at", related to a perception of the figure, and indicative words ("this one").

Experience shows that students try to handle the list whenever it becomes too long to be managed. Such handling involves some operations geared to modify the list. These operations include: putting the information in the correct order, picking up useful information and leaving useless information off the list through inference, adding some information to the list. For instance, the following dialogue is an example of how information is deleted from the list:

<table>
<thead>
<tr>
<th>Intervention 26/27</th>
<th>List:</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>$C_1$: $AD = AO$</td>
</tr>
<tr>
<td></td>
<td>$C_2$: $OE$ radius</td>
</tr>
<tr>
<td></td>
<td>$C_3$: $AO$ radius</td>
</tr>
<tr>
<td></td>
<td>By inference we can get to the information $C_4$: $OE = AO$</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Intervention 31</th>
</tr>
</thead>
<tbody>
<tr>
<td>Handled list (useless information $C_2$, $C_3$ kept out of the list through inference): $C_4$: $OE = AO$</td>
</tr>
<tr>
<td>$C_1$: $AO = OD$</td>
</tr>
</tbody>
</table>

In order to point out the role played by language in the drawing and its handling in the relationship between the operational handling and the theoretical reference, let's see the result of analysing the student’s oral and written work:

1) The ordering function of language (language as an organiser): there is no order in the information carried by drawing, because it is global and two-dimensional (the operational handling of the drawing doesn't give any ordered information). On the contrary, language is straight and sequential and because of these qualities the information must come out in order.

2) The selective memory function of language (language as a selective memory tool), which makes it possible to select only the useful part of the information given in the drawing. The drawing has everything, but there's even too much! Therefore we need to select the information and thus build a system to keep such data in mind. (For instance, deleting an useless information: see the interventions 26-31)

---

4 The drawing interpretation field was defined by Laborde as the set of spatial drawing’s properties which are related to the geometrical properties of the object. (Laborde and Capponi, 1994, pp. 171 – 172).
3) The role of control in handling the drawing: the presence of language in handling the drawing is a tool for controlling the entire operation. (For an example, see the interventions 36-46)

**Action models in the Discourse strategy**

Based on the results obtained by analysing the students’ output related to the discourse strategy, two action models were identified: one related to the discourse procedure starting from the question of the problem, and the other related to the procedure started by key words. The latter will be described in detail in this report while the former will not be discussed at this time.

The key words act like a kind of label and carry out two functions: they let students recall a particular theoretical reference and they can refer to a linking concept, by which it is possible to switch to another theoretical field, leaving the given one (such a situation is not described in this report).

The action model that refers to key words can be used to recall the theoretical reference needed for the solution. In this action the word is associated to the concept (theoretical reference belonging to the subject’s knowledge system). Usually, the associative operations are started by pronouncing a word or by reading it. The concept allows us to consider particular geometrical objects. In this sense, based on the definition of Parallelogram, we can consider two equal segments which are also parallel segments. This defines a set of information that must be found again in the drawing by handling it: we need to identify two opposite and parallel segments.

Here is an example of how key words work:

36. Gaelle: maybe we can prove... well, look at it! This one is symmetrical to the other one (AO and DE), so it is the same.
37. Camille: and then?
38. Gaelle: and then we should be able to prove that (this is a meta discourse) it is parallel to that one there (AO parallel to DE).
39. Camille: yes, but what we have to say is that this one is the middle point (the diagonals intersection).
40. Gaelle: yes.
41. Camille: it is the middle point of this one and of that one (DO and AE)... wait! AO is equal to AD... and what if we could prove that (meta discourse) triangle DAO is isosceles? Because, you know, it is important with reference to this one (DO).
42. Gaelle: yes, because it is the height.
43. Camille: yes, it is the height.
44. Gaelle: Yes, it is also the median.... Yeeees!!! it is the median!!
45. Camille: and this means that it is an isosceles triangle because the height is equal to the median... AE is perpendicular to OD and AH is the height in the triangle ADO (H intersection of the two diagonals).
46. Gaelle: then AE cuts OD in the middle.

The sequence of these pieces of information (isosceles triangle, height and medians, as underlined in the text) is the standard sequence of the properties by which an isosceles triangle is described in France. After naming the medians, Gaelle realizes that it is connected to middle point; then she relates this word to the theoretical reference, the isosceles triangle, and then she goes on to the discourse procedure.
We notice that the meta-discourse usually reveals the transition to a new strategy (see the above-mentioned interventions no. 38 and no. 41) and it plays a role of control on the solving procedure.

The dialogue reported above is an example showing quite clearly how a change of aim is decisive in transforming the descriptive structure of the discourse into a deductive one, to go on to the discourse strategy.

4. Conclusion

In the previous sections I presented a description and a means of interpreting students' works in the specific field of plane geometry problem solving, in particular by concentrating on the role of language in the problem solving process. Up to now, results show that natural language plays a truly important role in plane geometry problem solving because it acts not only as a bridge but also as a guide and a mediator, in the two-way relationships between the handling of the drawing and the theoretical reference which is useful for handling the figure. By using a set of criteria to identify students' main strategies, I was able to partly describe this mediation process and give a list of same functions of the language.

I presented the first steps a long-term research project about language as a didactic tool, aimed at obtaining results to be used in classroom didactic engineering. The first experiment I carried out suggests that further steps in the research project should be made at a micro-analysis level concerning the identification of students' action models related to their macro-strategies. Action models (once identified) should make it possible to find the appropriate area where the teacher can intervene in students' problem-solving activities.

HOW DO GRADUATE MATHEMATICS STUDENTS EVALUATE ASSERTIONS WITH A FALSE PREMISE?

Janine Rogalski, Marc Rogalski

Laboratoire Cognition & Activités Finalisées Université Paris 8-CNRS
Institut Mathématique de Jussieu CNRS-Universités Paris 6 et Paris 7

Abstract

We present an empirical study focusing on diagnosis of graduate mathematical students' logical ability. Patterns of responses on evaluating non-computable implications are identified and related to answers in hypothesis testing (Wason's tasks). "Stable" categories either oriented by logic or by pertinence are strongly linked to success in the final exam. The category of "false logical" answers is the worse. Some issues about didactical consequences are discussed.

Introduction

Mathematical reasoning often requires to use assertions with uncertain or false premises. Such a situation is encountered, for instance, in proving the step in a recurrence, or in proofs needing "case by case reasoning", when the premise is not true for some set of parameters values. In order to master such situations, students must: clearly understand the concept of implication—involving or not involving quantifiers—, master the notion of counterexample, and be fully aware of the distinction between implication and equivalence. More, taking the negation or the contraposition of a given mathematical statement requires to differentiate the implicative link from its components: premise and consequent.

To our knowledge, there were few empirical studies reported on this subject with regards to the litterature on mathematical proof or on natural implication in experimental psychology of reasoning. However, some epistemological or psychological analyses can be found on this point, which all insist on the conflict between everyday reasoning on false premises and mathematical logical reasoning, or which present these situations as paradoxical ones (for instance: Legrand, 1990; Johnson-Laird & Byrne, 1991; Deloustal-Jorrand, 1999; Politzer & Carles, to appear). In a grand tour on why students cannot master mathematical reasoning, Dreyfus (1997) stressed the "shortage of research data" on students' explanations when reasoning in undergraduate mathematics. In fact, studies on reasoning emphasise global proof strategies, organisation and understanding (for instance: Balacheff, 1987; Coe & Rutven, 1994; Duval, 199; Fischbein, 1982). Among researches which focus on details on mathematical logic used in demonstration, Radford (1985) analyses implication by secondary level students; Durand-Guerrier (1996) stresses the role of contingent assessments and the importance of predicats in logic, and not only propositions, for college students.

In mathematical curricula, logic is generally not taught as such, even if textbooks may present it as a tool or as an object at the university level (Deloustal-Jorrand,
1999). The usefulness of logic in compulsory mathematics education is questioned for future non-mathematicians. At high-school or university levels, emphasis is put on mathematical contents (concepts and problem solving): the main idea is that learning to solve problems and proving statements is sufficient for learning to master mathematical reasoning. Our claim is that it is probably unsufficient, because most of the proofs encountered in mathematical cursus, including at the university level, are mainly "going from stated as true to stated as true".

The present study focuses on what happen when such a process is disrupted.

The experimental study

Students and tasks

Students were graduate students (three or four years after baccalauréat), candidates from the North Region of France for being mathematical teachers at the secondary level (107 students—59 girls and 48 boys). They answered a test about their global reasoning ability at the beginning of their preparation to the national competitive entry examination. The test duration (4 hours) was sufficient to answer all the 20 questions. It was compulsory, answers were not anonymous, and students were said that the test aimed at informing the teacher on their collective logical competence.

We will here analyse 7 non mathematical or elementary mathematical items, where the task was to assess the value of an implication. In 5 cases the premise of the implication was clearly false; the two other items were the classical Wason's selection task (Wason, 1966) and the Radford's version of it (Radford, 1988). The text of these items is given in annex, with their respective positions within the set of 20 questions. Through the forword, we intended to avoid contract effects, to obtain comments, and to avoid non responses, as far as possible.

Data analysis

We will present the first step of data analysis, based on categories of responses, without taking into account detailed procedures.

Categories of responses

• Three of the questions concerned mathematical or material implications. The implication truthfulness was non computable. These items were coded as "non-computable implication". Premises were meaningful and even provoking. There were 4 types of responses: true; false; nonsense (or variants); no answer.

• Another mathematical implication to be assessed was a computable one ("Hn⇒Hn+1"). In a previous part of the question, it was asked to prove the implication via a simple computation. It is coded "computable implication". The premise was without direct meaning for the students. There were the same types of responses as for non-computable implications.

• Two items were two versions of Wason's selection task, coded as "Wason " (W1 and W2). There were 4 types of responses: all correct; W1 correct & W2 non correct; W2 non correct & W1 correct; other or no answer. Two errors were
particularly interesting from the point of view of the research of counterexamples: missing the non-Q card (with 7) in W1 and evaluating the procedure 2 as non conclusive in W2. They were coded “non-Q missing”.

- The last item was a situation of social contract ("The teacher's sweets"): "If P then I will do Q", then P is not satisfied and Q is nevertheless performed. Four types of responses were identified: logical true; modifying the context to make P true; contract not respected; other or no answer.

**Pattern of responses in evaluating assertions with false premise**

The second step of analysis consists in defining patterns of responses on the three similar items (non-computable implication), and expressing their relationship with the other ones, and with the success to the final mathematical competitive exam.

Seven patterns were identified:

- **Logic perspective, stable (LS):** 3 "true" logical correct answers; 10 students.
- **Logic perspective, unstable (LI):** two "true" answers; 9 students.
- **Pertinence perspective, stable (PS):** three "non-sense" answers denying pertinence to the question; 9 students.
- **Pertinence perspective, unstable (PI):** two "non-sense" answers; 14 students.
- **Non-conditional answers (NC):** three "false" answers (with or without explanation: "because P is false"); 22 students.
- **Non-conditional answers, unstable (NCI):** two "false" answers; 23 students.
- **Answers with no-dominant type of answer (SD):** 20 students.

Given the global results, the probability to find a dominant pattern (all but SD) if students answered independently to each item would be quite lower than the observed percentage, while the probability to find SD patterns would be higher.

**Results**

**Global results**

They are presented, for implications with false premise, in Table 1, and for Wason's tests, in Table 2.

### Table 1. Number of students given each type of answer depending on the questions

<table>
<thead>
<tr>
<th></th>
<th>True</th>
<th>Non pertinent</th>
<th>False</th>
<th>Other</th>
</tr>
</thead>

<td>37</td>
<td>11</td>
<td>28</td>
</tr>
</tbody>
</table>

* For this item, the “non pertinent question” answer was dominantly "modifying the context in order to make the premise true"; the answer "contract not respected" is put under "assertion false".

The two first items were quite similar. For the "labyrinth" item, there were more "correct" answers and less "non pertinent" ones: it could be possible that some of the students missed the premise falsity because they "forgot" the rule of movement.
Table 2. Number of students given each type of answer on Wason's tasks

<table>
<thead>

</tr>
<tr>
<td>Wason 2</td>
<td>77</td>
<td>20</td>
<td>5</td>
<td>5</td>
</tr>
</tbody>
</table>

There were more correct answers with the Radford's version (W2) than with the Wason's selection task (W1). In fact, 43 students (40.2%) gave both correct answers; 34 correctly evaluate the procedures for testing the rule and made errors in the selection task, while only 8 were correct for W1 and made errors for W2.

Relationships between type of questions

Figure 1. Percentage of students with a correct answer to the computable assertion, depending on their patterns of answers to non-computable implications.

Figure 2. Percentage of students with correct responses to Wason's selection tasks, depending on their patterns of answers to non-computable implications.

Patterns of answers presented similar relationships with the correct answer to the computable implication and to the correct answers to the two Wason's tests. Both stable logic and pertinence perspectives (LS and PS) ensured success, while answers without dominant perspective (SD) led to the worst results.

However, a further analysis showed that 80% of LS students succeeded both the Wason's tests and the computable implication, while the other categories were all under 45% of success (17% for NC, NCI and SD groups).

Mathematical and material implications versus social contract statements

Figure 3 presents the relationship between the responses to non-computable implications and the logical answer to the social contract item.
Logical answers to the social contract question were low (less than 30%), except for students giving logical answers (stable or incomplete) to the mathematical and material implications (globally: 63% of logical responses to the social contract item). The lowest percentage (10%) was observed for students answering with a (stable) pertinence perspective (PS).

_Reasoning about false premises and mathematical success_

The following table indicates the percentage (and number) of students passing the written test (first step of the competition), and the percentage of students who succeeded in this competition (and entered a teacher training institute: IUFM).

<table>
<thead>
<tr>
<th>Table 3. Results to the competitive examination</th>

<td>National level</td>
</tr>
<tr>
<td>----------------</td>
</tr>
<tr>
<td>Attending the competition</td>
</tr>
<tr>
<td>Passing the written test</td>
</tr>
<tr>
<td>Fully succeeding</td>
</tr>
</tbody>
</table>

With regards to their success in the national competitive examination, the students in our study were above the national and regional levels. This must be taken into account for evaluating the generality of the results.
Figure 4 presents the percentage of students passing the written test depending on their patterns of answers to non-computable implications. The best results were observed for students responding from a stable perspective of logic (LS) or pertinence (PS) (70% success); the worst results concerned the students with coherent non-conditional responses (NC: less than 10% success). Students presenting variability in their answers (LI, PI, NCI and SD) were slightly above the national mean (between 30% and 50%).

Discussion and conclusion

Students' answers concerning assertions with false premise and hypothesis testing, and students' success to the final mathematical show interesting relations. Both students centered on logic and on pertinence presented similar success. Only students who focus on logic answer logically to the social contract question. The model: "implication is false when premise is false" appears to be the worse for hypothesis testing and mathematical success.

The results on Wason's tasks have to be underlined: our results not only confort Tweney and Yachanin results (1985) on the fact that scientists rationally assess conditional inferences better that non scientists, but also that graduate mathematics students can do better than the university physicians members tested by Wason.

These diagnosis results are partiel elements of a more complete study (on the 20 questions of the test) which might enable us to analyse the various difficulties —and successes— of mathematical graduate students in logical processes used in mathematics.

The long term purpose of understanding how students process at a fine grained level of their mathematical logic is to identify what could be efficiently taught in this field, while keeping in mind the shared goal expressed by Thurston: the most important in not to prove but to understand mathematics.

The main issue is to improve the logical tool, in agreement with Hanna and Jahnke (1993) who defend the position that "a curriculum which aims to reflect the real role of rigourous proof in mathematics must present it as an indispensable tool in mathematics rather than the very core of that science" (p. 879).

References

Annex. The logical test proposed to students consisted on 20 questions (11 mathematical ones, nine requiring no mathematical knowledge). Among them, seven asked to evaluate the value of an assertion or of a rule. The text of these questions is given below, with their number. The test began with the following forward: "Mathematical sentences, assertions, in the following exercises are often expressed in a naive, not formalised form, as it is done in an everyday mathematical text, or even in everyday conversation. It is deliberate, and you have to feel free in your answers, which may (must !) include many comments, and even propose "this question is a stupid one!". In italics the context of the analysed question.

Computable assertion with false premise
I. Given $\lambda \in \mathbb{R}$, let be $(u_n)_n$ the sequence defined by: $u_0 = \lambda$, $u_{n+1} = 2u_n + 1$.

Let $H_n$ be the assertion "$u_n \leq \frac{2^n}{3} - 1$".

(a) Is the implication " $H_n \Rightarrow H_{n+1}" true for some $n$ ? for every $n$ ?
(b) Compute explicitly $u_n$ as a function of $\lambda$ and $n$ [one may write $u_n = v_n - 1$].
(c) Show that if $\lambda > -\frac{2}{3}$ all assertions $H_n$ are false.
(d) If $\lambda = 10$, what can be said about the assertion " $\forall n \ H_n \Rightarrow H_{n+1} "$ ?

Non computable assertion with false premise: item I
III. What do you think about the truthfulness of the following assertion: "Every not flat triangle of the plane, whose mediatrices are not concurring, is an equilateral triangle" ?

Wason's selection task (W1)
IX. Cards are given, with a letter on one face and a number on the other one. One must test the possible rule: "behind a vowel there is an even number". For this purpose, a sample of 4 cards is disposed on the table; what is seen is represented just on the right. What card(s) is/are to be turned on in order to know is the rule is confirmed on this sample?"

PME25 2001
Radford's version of Wason's task (W2)
XV. A set of numbered balls are in an urn. Balls are black or white. The following question is "do all white balls in the urn get an even number?"
Four procedures are considered for answering the question:
procedure 1: balls with an even number are taken out of the urn; then their colour is considered;
procedure 2: balls with an odd number are taken out of the urn; then their colour is considered;
procedure 3: white balls are taken out of the urn; then their numbers are considered;
procedure 4: black balls are taken out of the urn; then their numbers are considered.
For each of these 4 procedures, chose among the two options:
(a) the procedure will certainly enable me to answer the question;
(b) there is a chance that the procedure does not enable me to conclude.

Non computable assertion with false premise (Legrand's Circuit): item 2
XVII. An electric circuit consists on six identical lamps denoted L1, ... L6, and two switches S and T; S may take three positions: S1, S2, or S3, and T may take two positions: T1 or T2.
(a) What may be said about the truthfulness of the following assertion: "if LI is turned on or if L6 is on, then L3 is on or L4 is on"?
(b) What may be said about the truthfulness of the following assertion: "If L1 is on and if L3 is on, then L2 is on and L5 is not on"?

Social contract question
XVIII. In a primary school, the teacher gives a problem to the pupils and says: "search this problem at home; tomorrow, if somebody was able to solve it, I will give you sweets". The following day, no pupil has been able to solve the problem. The teacher distributes sweets to the pupils. They protest: "It is not just, we were not able to solve the problem, we get no right to sweets!". Mocking, the teacher answers that she perfectly respected the contract... What are your comments about this story?

Non computable assertion with false premise (Durand-Guerrier's Labyrinth): item 3
XIX. Somebody, called X came through the labyrinth (on the right), from the entrance (entrée) to the issue (sortie), without going twice through the same door. Rooms are called A, B, ..., T.
For each of the seven following sentences, say if it is true, it is false, or if it is impossible to know:
(1) X went through T ;
(2) X went through N ;
(3) X went through M ;
(4) if X went through O , then X went through F ;
(5) if X went through K , then X went through L ;
(6) if X went through L , then X went through K ;
(7) if X went through S , then X went through T.
INVESTIGATING THE MATHEMATICS SUBJECT MATTER KNOWLEDGE OF PRE-SERVICE ELEMENTARY SCHOOL TEACHERS

Tim Rowland, Sarah Martyn, Patti Barber and Caroline Heal
Homerton College, University of Cambridge and Institute of Education, University of London

This paper reports recent findings from a project which investigates the mathematics subject knowledge of prospective elementary school teachers, and how this relates to classroom teaching performance. The project was initiated in 1997 in the context of UK government policy to introduce subject content knowledge as an explicit dimension of the 'standards' for the award of Qualified Teacher Status in England. We present some findings about topics that trainees find difficult and show that the extent and security of their subject matter knowledge is related to their teaching competence.

BACKGROUND

Recent changes in the curriculum for Initial Teacher Training (ITT) in England incorporate a stronger focus on trainees' subject matter knowledge (SMK). Notwithstanding the complex relationship between SMK and pedagogical content knowledge (PCK), there is evidence from the UK and beyond which would seem to support this shift of emphasis (Ball, 1990; Kennedy, 1991; Alexander, Rose and Woodhead, 1992; Ofsted, 1994; Simon and Brown, 1996). Government Circular 4/98 (DfEE, 1998) sets out what is considered to be the "knowledge and understanding of mathematics that trainees need in order to underpin effective teaching of mathematics at primary [elementary] level", and charges ITT providers with the audit and remediation of students' SMK.

Providers must audit trainees' knowledge and understanding of the mathematics content in the National Curriculum Programmes of Study for mathematics at KS1 and KS2, and that specified in paragraph 13 of this document. Where gaps in trainees' subject knowledge are identified, providers of ITT must make arrangements to ensure that trainees gain that knowledge during the course ... (DfEE, 1998, p. 48)

In this paper, we describe our approach to the audit of the mathematics SMK of 173 primary trainees in 1998-99. This was the first cohort of students following the one-year Postgraduate Certificate in Education (PGCE) course to whom the requirements of Circular 4/98 applied by statute. We had, however, piloted the audit and a draft version of the 'standards' on a voluntary basis the previous year. We present here some findings related to the trainees' knowledge and understanding of proof. Currently, there is evidence for concern in the UK about students' facility with mathematical proof, both at school and at university level (Coe and Ruthven, 1994; London Mathematical Society, 1994).

1 The official discourse in England refers to students undergoing pre-service preparation for school teaching as 'trainees'. In this paper, we speak of 'students' and 'trainees' synonymously.

2 In England and Wales, Key Stage 1 (KS1) is the first phase of compulsory primary education, between the ages of five and seven. Similarly, KS2 covers ages seven to 11.
One argument suggests that curriculum and assessment reforms in the 1970s and 1980s promoted investigational approaches to school mathematics at the same time as Euclidean point-line geometry went into decline, favouring inductive reason at the expense of deduction. One requirement of Circular 4/98 (detailed later) can be seen as an attempt to address a deficit in the current generation of prospective primary school teachers.

A number of PME papers have considered aspects of elementary teachers’ SMK, such as divisibility (Zazkis, 1994), ratio (Klemer and Peled, 1998), place value (McClain and Bowers, 2000), with comment on the relevance of SMK to the professional role of their participants.

OVERVIEW OF GOALS AND METHODS

The project sets out to investigate:
1. those areas of SMK required by Circular 4/98 which prove to be problematic for significant numbers of trainees;
2. whether the expectations of Circular 4/98 are well-founded insofar as secure SMK (or otherwise) is reflected in classroom performance;
3. ways in which trainees’ practice in school-based placements is informed by their SMK;
4. the process and effectiveness of SMK remediation through peer tutoring.

Some findings with respect to the first year and the first three goals of the project, incorporating trainees’ ability to perceive and express generalisation, can be found in Rowland, Martyn, Barber and Heal (2000). Preliminary findings concerning the fourth goal were reported in Barber, Heal, Martyn and Rowland (1999).

The structure of the primary PGCE under consideration is such that by the middle of January, with fully six months of the course remaining, the main content areas – number concepts and operations, data handling, mathematical processes, shape and space, measures, algebra, probability – have been ‘covered’ in lectures and workshops, giving the trainees opportunity to recall those topics they have forgotten (for lack of use) since they did mathematics at school. A 90-minute written assessment consisting of 16 test items in mathematics is administered at this point of the course. Each trainee’s response to each question includes a self-assessment of their ability to complete it successfully.

The course includes two extended ‘practicum’ placements in schools in the latter parts of the second and third terms. Given these and other demands of the course, the major SMK remediation opportunity comes between the first and second placements.

Table 1: The chronology of the PGCE course
From this second project cohort, 34 students who were assessed as secure in nearly all of the topics audited became mathematics peer tutors. Following training for this task, they conducted peer tutoring sessions with those students (at most two per peer tutor) who experienced most difficulty with the audit. These peer tutors wrote a feedback sheet on the post-audit progress of each of their tutees. In addition, 12 students acted in a looser ‘on demand’ support capacity to a self-support group of about five students. Members of these groups self-reported their progress with mathematics SMK.

During school placements, each student works under the joint supervision of a school-based mentor and a university tutor. For the purposes of the project, the two supervisors agreed on assessments of the student’s performance in teaching mathematics towards the end of (and in the context of) each placement, against the standards of Circular 4/98.

**TRAINEES’ MATHEMATICAL THINKING: ASPECTS OF PROOF**

One dimension of our research has been to identify what mathematics (within the remit of Circular 4/98) primary trainees find difficult, and the nature of their errors and misconceptions in these areas. Facilities in the four ‘easiest’ and ‘hardest’ of the 16 items in the 1998-99 audit are shown in Table 2.

1. The written response gives a high level of assurance of the knowledge being audited.
2. A secure response scores 2, which is therefore the maximum possible for the mean.

**Table 2: Audit topics with the highest and lowest facility ratings**

The table demonstrates some striking similarities with that for the previous 1997-98 cohort (Rowland et al, 2000) although facility with the more difficult items is lower. We discuss here aspects of the trainees’ understanding of reasoning and proof as evidenced in the audit. At another UK university, Goulding and Suggate (in press) have found, as we did, that proof is a source of particular difficulty for trainees. They add that these difficulties are particularly resistant to remediation within the span of the PGCE course. Circular 4/98 requires that trainees demonstrate:

That they know and understand […] methods of proof, including simple deductive proof, proof by exhaustion and disproof by counter-example (DfEE, 1998, p. 62)

The following item was designed to audit this ‘standard’.

³ All cohort percentages have been rounded to the nearest integer.
A rectangle is made by fitting together 120 square tiles, each 1 cm². For example, it could be 10cm by 12 cm. State whether each of the following three statements is true or false for every such rectangle. Justify each of your claims in an appropriate way:

(a) The perimeter (in cm) of the rectangle is an even number.
(b) The perimeter (in cm) of the rectangle is a multiple of 4.
(c) The rectangle is not a square.

More than one mode of justification is possible for each part, and a proof by exhaustion (listing the 8 possible rectangles) would meet the requirements of all three. We anticipated some deductive arguments for (a), counterexamples for (b) and perhaps contradiction (√120 is not an integer) for (c).

Table 2 shows that only one-third of the students made a secure response to the whole question. 30% gave insecure (or blank) answers to all three parts. The percentage of secure responses to the three individual parts were 59, 44 and 52 respectively. In the self-assessment referred to earlier, students indicated a lower level of confidence in their ability to tackle this question than any of the others. Only two percent declared themselves confident to do it, whereas 35% reported that they didn’t think they could do it, or didn’t understand it, or were too terrified to think about it.

We proceed here with further consideration of part (b) of the question, which fewer than half of the students were able to manage to our satisfaction. The difficulty with counter-examples encountered by the majority of students is consistent with the findings of Zaslavsky and Ron (1998) with top-level 9th and 10th grade school students.

Each student’s response to part (b) was categorised and assigned to one of eleven codes (the first column below, Table 3). The second column describes the type of response for each code; the third column gives the percentage of students making that response.

</tbody>
</table>

Table 3: Percentage responses to the proof item part (b), by code.

We describe responses as ‘secure’ rather than ‘correct’, because some answers were correct (e.g. that statement (a) is TRUE) but not adequately justified (e.g. “because 120 is even”). A response that we are calling ‘secure’ would consist of a correct true/false judgement and a valid justification.
Each type of response other than code 9 corresponds to a student judgement concerning the validity of the statement that the perimeter of (every) rectangle is a multiple of 4, and – codes 0 and 10 apart – to a decision concerning an appropriate means of justifying that judgement. A variety of misconceptions seem to underpin invalid arguments, and we consider some of the more interesting ones.

The fact that one third of the students erroneously believe the statement to be true resonates strongly with the findings of Zaslavsky and Ron (1998). Ten per cent of the students seemed to base this conclusion on the fact that it holds true for the 10x12 rectangle given as an example. Perhaps some of these students genuinely believed that the question required them to consider only this particular rectangle, and interpreted “every such rectangle” to mean “every 10x12 rectangle”, although this raises interesting questions about when they might consider two such rectangles to be different. Such an interpretation is supported by the response of students such as the one who wrote “The perimeter is 44. 44 is a multiple of 4. 44 = 4 x 11” The peer tutor report on another such student read “(s)he did not understand what was expected … (s)he read the question as though it referred to only one possibility, now sees the need to investigate further”. A rather different diagnosis is implied by those students who seemed to be drawing on a ‘false conservation’ misconception (Lunzer, 1968) i.e that once the area is fixed, so is the perimeter. One wrote “The perimeter has to stay the same otherwise the area will change … the perimeter is always in total 44.”

Some students (code 15) argued that (b) must be true because a rectangle has four sides. Again, we can only speculate from their written responses, but these suggest an epistemological orientation which views mathematics as a non-empirical discipline, one in which truth can only be arrived at – or even guessed - by appeal to deductive argument, albeit argument of a spurious kind. There is little or no sense of mathematics as an experimental test-bed, in which they might confidently respond to an unexpected student question “I don’t know, let’s find out.” Likewise, the suggestion that the perimeter is a multiple of 4 because 120 is a multiple of 4 (code 14) seems in some cases to privilege ‘argument’ over evidence. In others there is a clear case of confusing perimeter with area. Thus, one student wrote “the perimeter is always 120” and another “perimeter = a x b”. Confusion between perimeter and area is well-researched and documented e.g. Foxman, Joffe, Mason, Mitchell, Ruddock, and Sexton (1987).

The secure responses all gave counter-examples. Ten per cent chose to give more than one counter-example, even though one is sufficient. A quarter of these described the general characteristics of a counter-example, such as “As the addition of the two different side lengths does not have to be an even number (if one length is odd and the other is even, it won’t be) the perimeter will not necessarily be divisible by 2(2)=4.” Whilst such an analysis exceeds the requirements of the refutation, it seems to point to a desire for explanation – why it is that some perimeters are multiples of 4 and others are not. If a counter-example is deemed to be a kind of proof (that not ∀xP(x)), then a single example might typically fall short of one of the purposes of proof – to explain (de Villiers, 1990). Just under a fifth of the 44% who successfully refuted statement (b) with
one or more counter-examples actually used the word ‘counter-example’ in their response, exposing some awareness of the ‘syntactic’ structure of the discipline (Grossman, Wilson and Shulman, 1989) i.e. the nature of enquiry in the domain of mathematics, and how new knowledge is introduced and warranted.

SUBJECT KNOWLEDGE AND CLASSROOM PERFORMANCE

We move on now to data which have enabled us to build on and update our earlier findings (Rowland et al., 2000) associated with the second of our project goals – investigating the relation between trainees’ SMK and their teaching competence. To summarise those findings: with the first project student cohort (N=154), the level of each student’s subject knowledge (based on the audit) was categorised as low, medium or high, corresponding to the need for significant remedial support, modest support (or self-remediation), or none. Towards the end of that course, specific assessments of the students’ teaching of number² were made on the second and final school placement (against the standards set out in Circular 4/98) on a three-point scale weak/capable/strong. These data did not support a null hypothesis that the spread of performance in the teaching of number was the same for the three categories identified in the subject knowledge audit. There was an association between mathematics subject knowledge (as assessed by the audit) and competence in teaching number. Further analysis (Goodman, 1964) pinpointed the source of rejection of the null hypothesis: students obtaining high (or even middle) scores on the audit were more likely to be assessed as strong numeracy teachers than those with low scores; students with low audit scores were more likely than other students to be assessed as weak numeracy teachers. In effect, there is a risk which is uniquely associated with trainees with low audit scores.

For the second cohort considered in this paper, more extensive data from school placements enabled comparison of mathematics subject knowledge with teaching performance (a) on both first and second placements (b) with respect to both ‘preactive’ (related to planning and self-evaluation) and ‘interactive’ (related to the management of the lesson in progress) aspects of mathematics teaching (Bennett and Turner-Bisset, 1993). For reasons of space, Tables 4 and 5 below show two of the four 3 by 3 contingency tables, those for Placement 2 (N=164: nine students had withdrawn from the course), together with expected frequencies (in parentheses) based on the null hypothesis that audit performance and teaching performance are independent.

Each table has df=4, and values of $\chi^2$ less than 9.5 support the null hypothesis against the alternative that audit performance and teaching performance are in some way linked ($p<0.05$). The $\chi^2$ values for the preactive and interactive data are 17.8 and 13.6 respectively. In fact, the association between audit score and teaching performance was significant for each of the four analyses. These results confirm our earlier finding and

---

² The restriction to 'number' rather than mathematics was a pragmatic decision determined by the fact that, in that year, the PGCE course was subjected to scrutiny by a government agency, the Office for Standards in Education. The inspectors’ brief was to focus on Reading and Number.
point to the positive effect of strong SMK in both the planning and the ‘delivery’ of
elementary mathematics teaching.

CONCLUSION

We have chosen here to highlight the problematic nature of proof as a component of the
mathematics SMK of pre-service elementary teachers, adding further weight to the
doubts of Goulding and Suggate (in press) that much can be done to remedy trainees’
difficulties with proof within initial training, especially given the multiple demands on
them in all areas of the curriculum in an intensely pressured course. We would expect
that clarity of understanding of the nature of proof and refutation in mathematics would
inform the trainees’ approach to questioning and enquiry with their students, and we are
struck by the robustness under replication of our earlier finding (Rowland et al., 2000)
that effective classroom teaching of elementary mathematics is associated with secure
SMK at a level beyond the elementary curriculum. It may be that, even within the
constraints of PGCE courses, greater priority could be given to syntactic dimensions of
SMK, although inevitably this would be at the expense of substantive elements. In the
light of Goulding and Suggate’s comment above, we observe that the second school
placement occurred after the remediation sessions, yet the association between
classroom performance and the audit some five months earlier was maintained. It seems
clear that there is need for the development of teachers’ SMK as a component of longer-
term continuing professional development. With this in mind, it might be more honest
and realistic if the attainment of the full range of SMK standards (DfEE, 1998) were re-
conceptualised as an ongoing professional process rather than a hurdle to be crossed in
initial training.

Subject Knowledge’. Paper given at the British Education Research Association Conference,
University of Sussex. September 1999.

Goulding M. and Suggate, J. (in press) 'Opening a can of worms: investigating primary teachers’ subject knowledge in mathematics.' Mathematics Education Review.

This paper presents some results from a study whose main concern was to investigate students' developing conceptions of infinity and infinite processes as mediated by a Logo-based environment or microworld. The general findings of the study indicate that the environment and its tools shaped these students' understandings of the infinite in rich ways, allowing them to discriminate subtle process-oriented features of infinite processes; it also permitted the students to deal with the complexity of the infinite by assisting them in coordinating the different elements present. The corpus of data is based on case studies of 8 individuals, whose ages ranged from 14 to mid-thirties, interacting with the microworld as pairs of the same age group.

The concept of infinity is central to calculus: infinite processes form the basis for the concept of limit; it is also present in other important areas of mathematics. This concept, however, has always been recognised as difficult and has historically been the origin of paradoxes and confusions. Fischbein et al. (1979) claim that the concept of infinity (and specifically of infinite divisibility) is intuitively contradictory. As explained by these and other authors (e.g. Waldegg, 1988), contradictory situations arise because "finitist" interpretations tend to prevail (such as the idea that the whole is always bigger than the parts), a fact recognised more than 350 years ago by Galileo. Another finding (see also Nuñez, 1993 and Hauchart & Rouche, 1987) is that the context and form of representation are very influential in the type of responses the students give: if a geometric set is bounded, this may become an obstacle for its infinite quantification. It has also been argued (e.g. Woldegg, 1988; Sierpinska & Vwegier, 1989; Sacristán, 1991; Cornu, 1991) that the spontaneous conceptions and intuitions that people have of infinite processes and of infinite (mathematical) objects can become obstacles for the adequate construction of formalised versions of these concepts. However, both Fischbein et al. and Waldegg have found that

---

1 Galileo, in his in his Dialogues Concerning Two New Sciences (1638), wrote: “difficulties arise when we attempt, with our finite minds, to discuss the infinite, assigning to it those properties which we give to the finite and limited”.

---

PME25 2001
formal mathematics teaching does not modify students' conceptions and intuitions of infinity. Furthermore, the areas of mathematics where infinity occurs are those that have traditionally been presented to students mainly from an algebraic/symbolic perspective, which has tended to make it difficult to link formal and intuitive knowledge. However, in a context that combines numerical and geometrical contexts through the use of algebraic language, Waldegg claims that some of the obstacles observed in previous cases seemed to have disappeared. This is an important finding which supports the idea that by building connections between different types of representations (in this case through algebraic language) some of the difficulties that arise when working in a single context can be diminished. We thus took it upon ourselves to create situations in which the learning of the infinite infinity could be facilitated by incorporating the use of the computer and the representational systems it provides, even though we are aware that attempts to use the computer for the learning of the concept of limits have pointed to difficulties (e.g. Monaghan, Sun & Tall, 1994).

Our theoretical approach follows the 'constructionist' paradigm (see Harel & Papert, 1991) adopting the position that the construction of meanings involves the use of representations; that representations are tools for understanding; and that the learning of a concept is facilitated when there are more opportunities of constructing and interacting with, as diverse as possible, external representations of a concept. We thus postulated that at least some of the infinite processes found in mathematics, could become more accessible if studied in an environment that facilitates the construction and articulation of diverse types of representations, including visual ones.

A computer microworld to study thinking in change

Based on this premise, we built a computational set of open tools (diSessa, 1997) — a microworld —, using the Logo programming language, which could simultaneously provide its users with insights into a range of infinity-related ideas, and offer the researcher a window (see Noss & Hoyles, 1996) into the users' thinking about the infinite. The main research issue of the study was to investigate students' developing conceptions of infinity and infinite processes as mediated by this microworld.

The microworld provided a means for students to actively construct and explore different types of representations — symbolic, graphical and numerical — of infinite processes.
(infinite sequences and the construction of fractals, as explained below) via programming activities. In general, the computer setting provided an opportunity to analyse and discuss in conceptual (and concrete) terms the meaning of a mathematical situation. For example, drawing a geometric figure using the computer necessitated an analysis of the geometric structure under study and an analysis of the relationship between the visual and analytic representations.

There were many reasons for choosing Logo, which will not all be outlined here, but in particular Logo is easily accessible for programming activities (recursive programming, specially) by the students. The Logo procedures used in the microworld were generally not given in written form (except for the initial activities). They were usually programmed by the students using suggestions given by the researcher. It is important to emphasise that for all the above activities, "measurement" procedures were used for computing numerical data which could complement the visual models. Most of the time, tables were used for structuring this numerical (and algebraic) data, becoming an additional representation of the sequences under study.

The programming and exploratory activities included:

- **Explorations of infinite sequences, such as \{1/2^n\}, \{1/3^n\}, \{(2/3)^n\}, \{2^n\}, and \{1/n\}, \{1/n!\},..., \{1/n^2\}, and their corresponding series, through geometric models such as spirals, bar graphs, staircases, and straight lines, and the corresponding Logo procedures, with a complementary analysis of the numerical values. These models were chosen since they constitute a straightforward way of translating arithmetic series into geometric form (e.g. in the 'spiral' type of representation each term of the sequence is translated into a length, visually separated by a turn, so that the total length of the spiral corresponds to that of the sum of the terms, i.e. the corresponding series.) Through the observation of the visual (and numeric) behaviour of the models, students were able to explore the convergence, and the type of convergence, or divergence, of a sequence and its corresponding series. The different geometric models for the same sequence provided different perspectives of the same process.

- **Exploration of fractal figures.** These included the Koch curve and snowflake (formed by putting together three Koch 'segments'), and the Sierpinski triangle. The explorations involved the study of their recursive structures (apparent both visually and in the
programming code), and dealing with apparent paradoxes at infinity, such as a finite area bounded by an infinite perimeter.

**The study**

The main phase of the study was carried out with 4 pairs\(^2\) of students of varying ages and backgrounds (in total there were 4 female and 4 male students). Two of these students were as young as fourteen years of age. On the one hand we were interested in introducing younger students to infinity-related mathematical ideas. We were also interested in observing the conceptions of younger students and the ways in which they worked in the environment, in comparison to older students. The pairs were as follows: Pair 1: two 14-year old girls; Pair 2: two high-school boys aged 16 (M) and 17 (J); Pair 3: Two college students (1 male, 1 female) in their twenties in non-mathematical areas; Pair 4: Math teachers in their thirties (1 male, 1 female). Pairs 1 & 3 were not mathematically inclined, as opposed to Pairs 2 & 4. Each pair of students worked for 5 sessions of 3 hours with the microworld. The analysis of the data was carried out through detailed case studies of the interactions of each of these 4 pairs with the microworld.

The role of the researcher was that of a participant observer, suggesting the field of work (the initial procedures and activities), as well as new ideas for exploration when needed, yet allowing students to be in control of the explorations, giving them freedom to explore and express their ideas. Students were informally interviewed throughout the sessions but formal interviews were conducted at the beginning and end of the study.

**Students' shifting conceptions of the infinite**

One of the advantages of the microworld was that the behaviour of the process could be observed, rather than the end result as is usually the case in traditional school mathematics. Observing the behaviour, such as the rate of convergence, played a very important role for giving meaning and finding explanations as to why in a particular instance a process converged or diverged. The exploration of the behaviour was done in several ways which included the observation of the process through its unfolding visual and numerical

\(^2\) Students worked in pairs with one computer to facilitate the sharing and discussion of ideas (simultaneously providing the researcher with insights into their thinking processes), and give them independence from the instructor. To facilitate the analysis of students' experiences, we worked with only one pair of students at a time, using a clinical interview style.
behaviour, the possibility to compare different sequences and models, and in the case of series, coordinating the behaviour of the series with that of the corresponding sequences.

Students discovered and explored limiting (or divergent) behaviours first through the graphical representations and then carrying out a back and forth process between these representations and numeric values; only in the case of Pairs 2 & 4 was there some degree of a more traditional "mathematical" analysis of the formula. The graphical element played a role in indicating the existence of a limit when there was visual invariance through several stages. For example, in the fractal explorations of the Koch snowflake, the apparently invariant visual image conveyed the boundaries of the area, highlighting its independent behaviour from the infinite perimeter that delineates it. At a second level, students would use numeric values, organised into tables, to complement and confirm the observed visual behaviour and give an indication of the value of the limit or divergence of the sequences.

Below, I briefly describe some examples illustrating a few of the conceptions of the infinite shown by students during the study, and how these evolved through the explorations.

- **Intuition that if process is infinite, then it will diverge:** Throughout the study, a common intuition arose, particularly among the less mathematically oriented students (Pairs 1 & 3): the confusion that if a process is infinite then it will diverge. This intuition has been found by other researchers. Núñez (1993) in particular, explains that the problem arises when there are several competing components (processes) present; that is, when two types of iterations of perhaps different nature (cardinality vs. measure) are confused: the process itself and the divergent process of adding terms to the sequence. Thus, in the case where infinite sums are involved the intuition appears as: "if an infinite number of terms or elements (cardinality) is added then the measure of the sum must be infinite, it must pass any preset value". For example, in an early part of the study, Pair 1 expected the line model representing the series \( \sum_{n=1}^{\infty} 2^n \) to grow without bounds, since an infinite number of segments were being added. She and her partner were quite surprised to see that the line got "stuck" at a length twice the initial value. Because they were convinced that the line would grow indefinitely, they attempted increasing the scale, but always got a line that eventually "got stuck". By working with the microworld in different ways, as outlined above, these students gradually found ways to make sense of how a process could continue infinitely and not grow to be infinite.
In particular, they focused extensively (as did Pair 3) on the decimal structure of the real numbers, realising that in the decimal expansion of the values under study, the number of digits would increase more and more as the sequence progressed. Thus, the infinite nature of the process was reflected in the decimal structure of the numeric values. On the one hand the infinite process was seen to take place in the "infinitely small"; also, seeing the process from the point of view of the numeric, temporarily disassociated from the geometry, allowed students to cope with the visual boundaries.

However, the misconception discussed here seems to be a deeply rooted one since it would often re-emerge, and was also observed with other students (e.g. Pair 3). It is also interesting that it particularly re-emerged after the explorations of the divergent (i.e. where the value of the infinite sum is infinite) Harmonic series \( \sum_{n} \frac{1}{n} \), which is a case where the misconception would appear to be true. But generally, as the students gained more experience, this intuition would gradually lose strength and even though the intuition would often briefly re-emerge, it would be more easily dismissed than at the beginning of the study, as more meanings were constructed: e.g. the continuity of the process was found in the decimal expansion, not in the length.

- **Koch curve 'paradoxes': solving an indetermination by coordinating two simultaneous infinite processes.** Above I described how coping with a bounded infinite process requires discerning and coordinating two simultaneous infinite processes: the infinite iterative process of adding or increasing the number of terms, with the behaviour of the process itself (which could be convergent). In the Koch curve explorations we find another example involving the coordination of several simultaneous infinite processes. For some students the idea of an infinite perimeter formed by an infinite number of "zero-length" segments caused anxiety. This was particularly the case of Pair 2. One of the boys in this pair (J) was aware of the problem of having two types of processes involved in the change of the perimeter: the increase in the number of segments, and the decrease in the size of those segments. He realised that the behaviour of the numerical values pointed towards the perimeter becoming very large, infinite. But when they considered that the segments at infinity measured zero, this seemed to indicate to them that at infinity the perimeter would measure zero! In fact, by focusing on the latter process student J would challenge the idea of the divergence of the perimeter: "The segments are getting smaller... The perimeter cannot be infinite...". His
partner had a different perspective: he focused more on how the zero-sized segments would affect the shape of the figure first concluding that it would become a “smooth” curve with no segments, “an infinite sequence of points”. The students were of course dealing with what is formally defined as an indetermination (an infinite number of segments of size zero: $\infty \times 0$). The students realised it was necessary to carry out algebraic and numeric explorations to solve the paradoxes. A breakthrough came when student J became interested in how each of the factors (the rate of decrease in the size of each segment vs. the rate of increase of the perimeter in the number of segments) behaved in relationship to each other. He used numerical explorations (structured in a table) to explore the behaviour of the perimeter, verify his hypothesis, and become convinced of the divergence of the perimeter by observing that the perimeter's increase was faster than the segments' convergence to zero. Whereas limit indeterminations are traditionally solved through algebraic manipulation, in this case Jesus overcame the indetermination through analysis of the behaviour of each of the elements involved, observing specifically the difference in the rate of divergence or convergence of each of the elements and coordinating the two processes involved.

His partner (M), on the other hand, still had a conflict between what his intuitions told him, and his attempt to apply (finite) mathematics and "logical" principles ("a number multiplied by zero is zero" vs. "a number multiplied by infinity is infinite"), and his confusions would resurface during the explorations of the Koch Snowflake perimeter: “if the number is infinite the perimeter is zero, and what will happen? That all of this will become a point!” He is considering that at infinity the segments forming the curve would measure zero implying a sort of "collapse" of the curve into a point. His difficulty is related to the epistemological obstacle described by Cornu (1986) of “the passage to the limit” where "that which happens at infinity" seems to be isolated from the dynamic limiting process. Also, this situation is analogous to Zeno's paradoxes: as in that case, there are two components present: the number of segments, and the measure of the segments. This dilemma highlights the difficulties that emerge when thinking of the infinite with the schema of the finite and which are found historically and by mathematics education.

---

3 As explained by Struik's (1967, p.43) Zeno challenged the belief that "the sum, of an infinite number of quantities can be made as large as we like, even if each quantity is extremely small ($\infty \times e = \infty$), and also that the sum of a finite or infinite number of quantities of dimension zero is zero". His arguments highlighted the difficulty of saying that the line is formed by points.
researchers (as discussed at the beginning of this paper). For this student it would take a long process of (particularly numeric and algebraic) explorations and reflections to become convinced of the divergence of the perimeter and some of his doubts may not have been clearly resolved. Interestingly, this student had no conflict with bounded area of the snowflake which he attributed to the shape of the figure being such that the perimeter simply folds up as it increases, not letting the area grow any further.

As the examples above show, the perspective adopted, and the context in which the infinite is presented, are likely to have a determinant role on how it is conceived. As David Tall (1980; p.281) points out: "our interpretation of infinity is relative to our schema of interpretation, rather than an absolute form of truth."

MATHEMATICS TEACHING PRACTICES IN TRANSITION: SOME MEANING CONSTRUCTION ISSUES

H. Sakonidis¹, M. Tzekaki², M. Kaldrimidou³
1Democritus Univ.of Thrace, 2Aristotle Univ.of Thessaloniki, 3Univ.of Ioannina, Greece

Abstract. There are a number of questions still to be addressed in coming to understand teacher change in the context of mathematics education reform. In this study, we examine the impact of a change in the organisation of the mathematical content and in the pupils' engagement in activities on the teachers' instructional practices. The results show that such changes have limited effect on both teachers' management and pupils' construction of the mathematical meaning.

Theoretical issues

Until recently, mathematics classrooms were dominated by instructional practices which view knowledge as a static body of facts and techniques that can be broken down and “passed along” by the teacher through direct teaching (such as lecturing and demonstrating) to the pupils. However, in the last two decades, the findings of research in mathematics education has raised concerns about this approach to teaching mathematics and indicated a need for a reform in instruction in this area. Towards this, a number of approaches to mathematics teaching have been suggested, such as those promoted by the Realistic Mathematics Education model (e.g. Romberg, 1997) and the NCTM’s document ‘Principles and Standards for School Mathematics’ (2000).

These alternative approaches, despite their differences, accept the premise that mathematical knowledge cannot be handed over by the teacher; it must be constructed by the pupil. Here, the teacher is viewed as an informed and reflective decision maker who must provide contexts in which children’s own attempts to make sense of new ideas are valued and supported and their current understandings acknowledged. From this perspective, the teacher can no longer be seen as the ultimate source of knowledge and truth; neither can s/he be expected to be in absolute control of the class agenda.

These new forms of instruction often take teachers far beyond their traditional and familiar roles and practices, and they raise some difficult questions: How much of their professional persona can they dare to risk? How can they be sure that what is to be learned is indeed learned? What are the conditions that determine change in teachers and how can these be nurtured? How long are changes sustained? Are changes developed in one mathematical domain carried over into new topics?

For teachers, the shift from familiar instructional practice to a reformed approach is not easily accomplished (Fennema & Neslon, 1997). While they may invoke notions of “good practice”, they do so without actually carrying out the practices which are entailed (Desforges & Cockburn, 1987). Research shows that providing teachers with
experiences where their own practices are challenged and opportunities to reflect on and rethink about them, has the potential to facilitate new insights and understandings of the teaching process (Aichele & Caste, 1994). Much in the same vein, Yackel (1994) argues that making aspects of their current practice problematic for teachers constitutes a first priority for changing their teaching practice.

Teaching processes cannot be easily divested of particularity without distortion. Furthermore, a thorough analysis of processes that are not stripped of particulars can provide powerful interpretations of classroom events and explanations for common dilemmas. Groves et al. (2000) quote Stigler (1998) who highlights the importance of looking at examples and “say[ing] exactly what it is ...that you’d like to see changed”. Moreover, they note that the lack of “exemplars of conceptually focused problematic situations” is an important constraint on a more “coherent and conceptually based teaching practice”.

Based on the above considerations, we consider the examination of what happens within the mathematics classroom, by focusing on particular instances of the teaching processes, as very important in the study of changes in teaching practices. This is because we can identify specific elements of teachers’ practice that change or are resistant to change in various instructional approaches. Of course, it is evident that this study should be carried out from different perspectives - epistemological, sociological, psychological and - in order to provide a rich set of insights into the issues raised when teachers transfer from one approach to another, for example, from a traditional to a reformed one.

In previous studies (e.g. Kaldrimidou et al., 2000) we examined teaching practices in current (traditional) mathematics classrooms from an epistemological point of view. That is, we looked at the way teachers use the epistemological features of the subject matter: definitions, theorems (properties) and solving, proving and validation procedures. The results showed that in the Greek primary and secondary mathematics classrooms, independently of the mathematical topic discussed (algebraic or geometric), the teaching approach used tended to treat the epistemological features of mathematics in a unified manner. This homogeneity was seen as of crucial importance in the pupils’ attempt to construct mathematical meaning for themselves. We further noted a dialectic relation between the communicative pattern and the management of the mathematical content within the classroom, arguing that the observed teachers’ quick shifts to different pupils (communicative aspect) does not allow the control of the flow of the meaning construction by individual pupils.

Thus, communicative aspects, as they are related to the management of mathematical knowledge, seem to play an important role in pupils’ construction of mathematical meaning. In the present study, we look at these two aspects (communication and the management of mathematical knowledge) as they are realised through the teaching practices in a constructive activity-based mathematics classroom, that is, in an alternative to traditional teaching and learning setting.

The study

The data reported here come from a large project which focused on the teaching of mathematics in the ninetenn years of the Greek compulsory educational system (6-15 year olds). The study consisted of two parts: the first was concerned with the current status of mathematics teaching in Greece, while the second focused on experimentation with alternative, pupil-centred mathematics teaching approaches. In particular, with respect to the latter, the research team, in co-operation with a group of well-experienced teachers of both primary and secondary schools, designed and prepared the teaching of eight mathematical topics for five different grades (11-15 years old) within an activity-driven framework which included: (a) the construction of a set of well-structured activities for each topic (unit) aiming at the targeted mathematical ideas, (b) the preparation of the teachers so that they could respond to the demands of the activities and (c) the observation and videotaping of the lessons as well as the provision of feedback to the teachers.

In each case, the activities were sequenced and set up in a such a way as to allow: (a) a gradual but methodical and global approach to the targeted idea in accordance with the mathematical framework, (b) the constructive engagement of the pupils, according to their stage of development and (c) the formulation of a final mathematical result, in accordance with the teaching objectives of the lesson. Teachers were advised to present all mathematical activities as problems to solve, and to challenge and expect the children to: solve them in their own ways; discuss, compare and reflect on different strategies; make sense of other pupils’ solutions and strategies, and formulate generalisations.

The research problem addressed here examines the impact of change in the organisation of the content of a lesson and the children’s activation (through appropriately designed and mathematically focused activities) on the interplay between the communicative patterns and the management of the mathematical knowledge within the classroom. This serves a double purpose: first, it allows for an investigation into whether teachers’ practices using the traditional approach derive from the organisation of the mathematical content and second, it helps in the location of the “deeper” characteristics of their practice (making the assumption that in a new teaching environment, there is an activation of the strongest features of practice considered by the teachers as “good” and effective).

More specifically, in order to locate those elements of the teaching practice which resist and which may be held responsible for the “distortion” of pupils’ mathematical meanings in both traditional and reformed approaches, we focus on the way in which the management of the mathematical knowledge and the communicative aspects interact to generate the mathematical meaning, addressing the following research questions: (a) what kind of ideas and meanings regarding mathematical knowledge are encouraged by the teacher? (b) how does the course of classroom interaction hinder or

---

1The project was financed with resources from the operational plan "Education and Initial Vocational Training" of the 2nd Community Framework Support, European Commission, European Social Fund, Directorate General V.
favour the mathematical thinking of the pupils? and (c) how does the communicative pattern elevate or weaken the mathematical meaning constructed by the children?

The data collected consisted of 48 mathematics lessons (from 23 teachers) observed in various primary and secondary classes (11–15 years old) from 13 different schools in three geographical areas of the country. For each teacher, at least two 45 minutes sessions on different topics were observed; these were then videotaped and transcribed. For the present paper, the transcripts of the lessons were analysed by looking at the interplay between the communicative patterns and the management of the mathematical knowledge by the teacher in two phases of the pupils’ engagement with the activities and with respect to the epistemological differentiation that is achieved. The two phases concern the management of: (a) the pupils’ outcomes at the completion of the unit’s activities and (b) the pupils’ mathematical thinking at the completion of a unit and the generalisation of the results.

Presentation of the data and discussion

In the following, exemplary episodes from various lessons are used to illustrate the findings. The focus of the analysis is on the interplay between the communicative patterns and the management of the mathematical knowledge as realised by the teacher, with reference to the epistemological elements of the mathematics generated.

1. The pupils’ outcomes at the completion of activities: All the episodes below demonstrate the way in which the teachers dealt with the pupils’ ideas and solutions after the latter had completed a unit’s activity. The focus of the analysis is on the communicative aspects of this manipulation in relation to the mathematical meaning that may be generated by the approach employed.

Episode 1.1. [The size of the angles of a triangle (11 years old)]: The activity requires the calculation of the size of the angles of a right-angled and isosceles triangle (only the right angle is marked) and it constitutes part of similar activities. The objective is to help pupils identify those characteristics of a triangle that would allow them to determine the size of its angles.

T(eacher). Pay attention. This triangle has two characteristics. First, what type of triangle is this Nik, with respect to its angles?

P(upil). Right-angled

T. Right-angled. With respect to its sides, what type of triangle is this? Tania?

P. Isosceles

T. Isosceles. Well done Tania. That is, this triangle is right-angled and isosceles. And we know one of the angles, the right angle, Michael?

P. Angles b and c...

T. Yes....

P. They are each 45°

T. But why?

P. Ehhh. Because ....

4 - 140

1564
The triangle is ...

The triangle is right-angled and isosceles.

The communicative features of the teacher’s practice emerging from this episode are: he (a) tends to pose successive questions, often from one pupil to another, ‘hunting for the correct’ result, (b) breaks down the activities and the pupils’ responses with questions, (c) allows very little space for the children to formulate ideas and complete their reasoning and (d) repeats or completes what he thinks important to be phrased overall. As for the mathematical meaning, in dealing with this activity, the teacher accepts a ‘leap’ in the reasoning concerning the justification of the 45° for the equal angles (i.e. that \(a+b=90°, 180°-90°=90°\) and since \(a=b\), each will be \(90°÷2=45°\)). This prevents the emergence of the general mathematical idea being targeted, that is, the justification of the result on the basis of the properties of a triangle. Only the final result appears to matter, which is related to a simple recognition process of the data (the right-angled and isosceles triangle has its acute angles equal to 45°).

**Episode 1.2.** [Percentages (12 years old)]: Pupils are engaged in an activity asking for the equivalent of 36/45 as a percentage. This is part of an activity in which children learn how to turn fractions and decimals into percentages. One pupil calculates as follows: \(100÷2.22…\) and multiplies the result by 36 (=79.999…). But the teacher is looking for an accurate answer.

P. We have found it, sir. We divided 36 by 45 and multiplied by 100.

T. How much did you find?

P. 0.8 times 100 equals 80.

T. (tries to generalise) Thus, when we know a ratio of two quantities ...

P. Yes...

T. What operation should we perform in order to find the percentage?

P. Sir, division!

T. Division. What do we divide?

P. The numerators by the denominator

T. Very nice

Then the teacher generalises further with \(x\): \(x/100=36/45\) and standardises the rule. In this extract, the teacher asks for an accurate solution, rejecting an approximation. In doing so, he limits the development of an interesting process of reasoning and links the result with a rule and then with a formal procedure: we divide the numerator by the denominator. As far as the communicative characteristics are concerned, the same patterns as in episode 1.1 are observed.

2. The pupils’ mathematical thinking at the completion of a unit: In this part, the episodes focus on communicative issues in the teachers’ treatment of the pupils’ mathematical thinking in relation to the pupils’ justification which is encouraged.
Episode 2.1. [The sum of the angles of a triangle (11 years old)]: Through a series of activities, pupils are invited to conclude that the sum of the angles of a triangle is $180^\circ$. After some construction and measurements, they initially estimate the sum of the three angles of special cases of triangles and then take measurements to confirm their estimations. The activity aims at leading children to a first level generalisation through a phenomenological contradiction (for either long or short sides, the sum remains $180^\circ$). The activity should be treated as a whole in order for this contradiction to emerge.

T. George, what did you find for triangle B. Tell us.

P. $90^\circ$

T. $90^\circ$. Why do you say $90^\circ$? All together, eh?

P. All together?

T. Doesn't the exercise ask you for the sum of the angles?

P. Because they are small.

T. The angles are small. Right. Tell us Chris.

P. $130^\circ$ madam.

T. About. Why my boy?

P. Madam, estimated by the eye.

T. By the eye, right. Charoula?

P. $180^\circ$, madam

T. Why $180^\circ$ Charoula?

P. Because, for the right angle, I say $90^\circ$, for the other one which is acute, because it is very small, I say $10^\circ$ and for the other one towards the right angle .. but it is acute, I say $80^\circ$.

T. About this, I don't know, it might be correct too. .... Other pupils go on like this suggesting $60^\circ$, $120^\circ$, $185^\circ$, $150^\circ$, but the teacher doesn't ask for any more explanations, she simply says:

P. Did you estimate it by the eye?

With respect to the communicative patterns that are registered, the teacher: (a) tends to make frequently address successive questions from pupil to pupil, (b) breaks down the activities or the pupils' answers with questions, (c) provides little space for the pupils to complete their reasoning, (d) reduces the exchanges among the children, often repeats statements or completes anything she considers must be said. As for the mathematical meaning of this activity, the property targeted here (theorem: the sum of the angles) was never pushed forward, and the activity slipped into a process (estimation) of finding the result. Thus, the contradiction never emerged and the pupils missed the chance to see the necessity of resolving it by other means (checking by measuring), which would guide them to discover the common property. This also becomes apparent from the pupils' demand to be told the answer. It is clear that the children carry on considering the possibility that there are many different solutions and that it is the teacher who will provide the correct one.
Episode 2.2 [Quadrilaterals (12 years old)]: Following a series of activities, the pupils are invited to determine the characteristics of a rectangle. This last activity aims at encouraging pupils to formulate some definitions.

T. Which are the characteristics of a parallelogram? Then what does it say? Which are the features of a rectangle? A little later on

P. The parallelogram has its opposite sides parallel and has 4 sides

T. Opposite sides parallel and 4 sides. But this is true for the rectangle too. Stefania?

P. In the parallelogram, all the opposite sides are parallel and equal

T. (Repeats). Do we have to add anything else? About the angles?

P. They are right angles.

T. Right angles?

P. Acute, obtuse maybe?

T. Two acute, two obtuse. Tell us Anna.

P. In the rectangle, all the angles are right angles and all the opposite sides ...

T. Do we agree?

P. Yes (all together)!

T. Let's go for the last one, Katerina.

P. The square has 4 sides and 4 angles, that is, it is a quadrilateral and its sides are equal and parallel; its opposite sides and its angles are right angles.

With regard to the communicative patterns, we find the same features recorded in the previous episodes. In addition, the teacher very often repeats and immediately corrects their answers, sometimes explains himself why it was wrong; but he never reasons or asks for reasoning about a correct answer. As for the mathematical meaning, the fact that each shape is treated separately does not allow pupils to appreciate the purpose of creating definitions, that is, to identify and differentiate. Other basic deriving properties, i.e. those which result from the application of a proving reasoning are also missed.

Concluding remarks

In the current era of educational reform, teachers all over the world are being asked to transform their mathematics teaching. This transformation entails more than changing the types of problems and questions posed; it requires changes in teachers' epistemological perspectives, their knowledge of how people learn mathematics and their classroom practices.

In the study described above, examining traditional and reformed mathematics classrooms through the interaction between the communicative patterns and the management of the mathematical knowledge that shapes the generated mathematical meaning, we found that teachers tended to augment reformed instruction with traditional practices and then to modify and change activities so that they resemble past lessons. In particular, we identified some patterns of communication that were repeated and persisted despite a change in the organisation of the lesson's content and
the children's activation via constructively designed and mathematically focused activities.

In the exemplary episodes analysed, and in both phases of the pupils' engagement with the activities, three distinctive features were identified: (a) succession of questions and breaking down of the targeted mathematical idea with a simultaneous quick shifting from pupil to pupil in hunting for the "right" answer, (b) reduced opportunities for exchanges among children and insufficient encouragement for reasoning and justification and (c) elevation of the correct answers, repetition of pupils' formulations, acceptance or cancellation of answers and correction of their mistakes by the teacher. All these features have also been identified in the traditional approach to mathematics teaching (see our previous studies) with the exception of the breaking down of an activity and the prevention of pupils from completing their reasoning. These latter two practices emerging in the reformed instructional settings result in a distortion of the characteristics of the content's organisation with consequences on the mathematical meaning.

Thus, we can claim that the dialectic relation between the communicative patterns and the management of the mathematical content within the classroom is confirmed and argue that (a) the communicative aspects recorded are related to the mathematical meaning that emerges in the classroom and (b) the change in the mathematical context and of the classroom's functioning do not affect significantly the way the management of the mathematical meaning is managed. This has important consequences for the development of pupils' mathematical meaning in both traditional and reformed approaches.

References

This study explores third-grade students' strategies for dealing with function tables and linear functions as they participate in activities aimed at bringing out the algebraic character of arithmetic. We found that the students typically did not focus upon the invariant relationship across columns when completing tables. We introduced several changes in the table structure to encourage them to focus on the functional relationship implicit in the tables. With a guess-my-rule game and function-mapping notation we brought functions explicitly into discussion. Under such conditions nine-year-old students meaningfully used algebraic notation to describe functions.

Most mathematics educators, ourselves included, tend to view data tables as function tables. But what about the students? Are they learning about functions when they fill out tables? What does it take for third grade students to treat multiplication tables, for example, as function tables? Can they use and understand algebraic notation for representing linear functions? What sorts of activities involving tables might encourage young students to focus on functional relations?

Students begin to deal with (linear) functions and (constant) rates long before they make any sense of an expression like \( y = mx + b \). Certain curriculum materials embody these relations without making them explicit in algebraic notation. A multiplication table, for instance, might be thought of as an embodiment of the expression \( y = mx \), where \( x \) and \( y \) are integers along the margins and \( m \) corresponds to the number in the expression "times <m> table". The question we raise here is whether children as young as nine years of age can understand functions and algebraic notation for functions.

The studies by Davydov and colleagues (1991/1969) showed that young students were able to use and understand algebraic notation such as \( y = 5x + 12 \). However, in their studies \( x \) and \( y \) stand for unknowns. We know of no evidence from their work suggesting that students thought of the notation as expressing a multitude of ordered pairs and hence functions; and this is unlikely since problems were invariably constrained in such a way as to require that \( x \) and \( y \) take on single values.

To make sure that students are contemplating multiple input and output values, so to speak, it is useful to consider situations where the same function is applied repeatedly. Let us look at a sales context first; then we will move to the issue of how it is embodied in a function table. These are precisely the conditions underlying our work with third graders as we explore how, in keeping with the U.S. National Council of Teachers of Mathematics (2000) Standards, algebraic reasoning and notation can become part of the elementary school curriculum.

In our approach, we treat algebra as a generalized arithmetic of numbers and quantities. Accordingly, we view the transition from arithmetic to algebra as a move from thinking about relations among particular numbers and measures toward thinking about relations among sets of numbers and measures, from computing numerical answers to describing relations among variables. This requires providing a series of problems to students, so that they can begin to note
and articulate the general patterns they see among variables. Tables play a crucial role in this process as they allow one to systematically register diverse outcomes (one per row) and look for patterns in the results.

Our initial steps were inspired by the findings of everyday mathematics studies. When computing the price of a certain amount of items, street sellers usually start from the price of one item, performing successive additions of that price, as many times as the number of items to be sold (Nunes, Schliemann, & Carraher, 1993; Schliemann et al., 1998; Schliemann & Nunes, 1990). If we try to understand their procedure in terms of displacements in a function table, they work down the number column and the price column, performing operations on measures of like nature, summing money with money, items with items. Vergnaud (1983) describes this strategy as a "scalar approach". In contrast, a functional approach presumably relies upon relationships between variables, often variables of different natures. The latter focuses on how one variable changes as a function of the other variable.

But when we look closely at street sellers’ strategies we realize that they establish a correspondence of values across measure spaces before proceeding to the next case. The flow of thought proceeds from one measure space to the other, row by row. This is illustrated by the following solution by a coconut seller to determine the price of 10 coconuts at 35 cruzeiros each:

"Three will be one hundred and five; with three more, that will be two hundred and ten. [Pause]. I need four more. That is... [Pause] three hundred and fifteen... I think it is three hundred and fifty." (Nunes, Schliemann, & Carraher, 1993, p. 19).

The street sellers’ approach indeed involves a linking of a unique y-value to each value of x. It therefore captures the essential idea of a function and can constitute a meaningful and efficient strategy to solve missing value proportionality problems. In school young children also seem to prefer using scalar solutions (Kaput & West, 1994; Ricco, 1982). Scalar solutions can be a good start for understanding functions. But they are limited in scope and typically do not allow for broader exploration of the relationships between the two variables (Schliemann & Carraher, 1992, Carraher & Schliemann, 2001).

In the classroom study here reported we will look at some specific examples of how third-grade students’ emerging understanding of functional relations draws upon and at the same time departs from their previous strategies for dealing with quantities and number relations.

The data come from a broader study aimed at understanding and documenting issues of learning and teaching in an "algebrafied" (Kaput, 1995) arithmetical setting (see Carraher, Brizuela, & Schliemann, 2000; Carraher, Schliemann, & Brizuela, 2000, 2001). Our goal was to help children build an understanding of multiplication from an algebraic point of view and as a functional relationship. To reach this goal, we designed activities that aimed at shifting the focus from scalar relations to functional relations and to general algebraic-type notational representation. Through a discussion of children’s difficulties and successes, as they participate in these activities, we will explore some of the issues they face in trying to move from their intuitive approaches to a functional approach and from computations to generalizations.

The Study
We worked with a classroom of 18 third-grade students at a public elementary school in the Boston area, serving a diverse multiethnic and racial community. During the school year, we met with them once a week for a period of ninety minutes. The first six meetings were dedicated to additive relations (see Carraher, Brizuela, & Schliemann, 2000). In the seventh week, as the children were working on learning the multiplication tables, we started working on multiplicative relations. Our
challenge at this point was to design situations that would allow children to understand multiplication as a functional relationship between two quantities or numbers.

We used what we knew about street sellers and young children's strategies to solve price problems as a point of departure. From our perspective, the organization of data for two related quantities in a table would provide the opportunity for children to use their own scalar strategies but would also allow us to explore with them the implicit functional relationships between two variables. The sequence of tasks we designed was presented and discussed over two weekly meetings (classes 7 and 8). The first two tasks were part of class 7 and the other four were part of class 8.

**Task 1: Filling out function tables**

We began by asking children to fill out the table in Figure 1. Each child received a work sheet, but we suggested that they could work in pairs and discuss their solutions, helping each other.

![Figure 1: The incomplete table](image)

Mary had a table with the prices for boxes of Girl Scout cookies. But it rained and some numbers were wiped out. Let's help Mary fill out her table:

<table>
<thead>
<tr>
<th>Boxes of cookies</th>
<th>Price</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>$3.00</td>
</tr>
<tr>
<td>2</td>
<td>$6.00</td>
</tr>
<tr>
<td>3</td>
<td>$12.00</td>
</tr>
<tr>
<td>5</td>
<td></td>
</tr>
<tr>
<td>6</td>
<td>$21.00</td>
</tr>
<tr>
<td>8</td>
<td></td>
</tr>
<tr>
<td>9</td>
<td></td>
</tr>
<tr>
<td>10</td>
<td>$30.00</td>
</tr>
</tbody>
</table>

Most of the students in the class first appeared to treat each column, items and price, as if they were separate problems. They would fill out column one by counting by 1's and column 2 by counting by 3's. Their approach leads to correct answers but does not involve them in thinking about the general relationships between price and items. A few children related the task to the multiplication tables they were memorizing and used the latter to fill out the second column in the table.

**Task 2: Different ways to go from one number to another**

The remainder of this class was dedicated to an activity where the children had to find different ways to operate on a number in order to get to another (e.g., "How do you get from 2 to 8?" and "How do you get from 3 to 15?"). This activity constituted an attempt to have children exploring the multiple relationships between two numbers in a pair. We hoped that this would later help them to focus on determining the relationship in a function table.

The first and most popular solutions were additive solutions such as: To get from 2 to 8 you "add 6 to 2" or "add 2, plus 2, plus 2." As discussions developed, children also used multiplication as alternative ways to get from one number to the other.
Task 3: Focusing on any number (N)
The following week we first presented children with a multiplication table similar to the one they had worked with, except for an added "Nth" row. Our goal here was to encourage children to think about the general relationships depicted in the table. They were asked to answer: What do you think the N means? What is the price if the number of boxes is N?

Again, children easily filled in the blanks by counting by ones in the first column and counting by threes in the second. David, the instructor, asked them to explain how they found the number that corresponded to 4 and one child responded that he added four threes. For the same question regarding the second row, one child explained that it was three times two and another that she had added 4 to 2. For the Nth row, one of the students, Sara, stated: "add 3 up; 11 times 3 equals 33; N probably stands for 11." Other children also considered that N was 11 and that the corresponding value in the second column was 33.

David explained that "N stands for anything." A child volunteered, "It could be any number." After discussion and examples, three children maintained 33 as a response in their worksheets, three left the cell blank, five adopted N+N+N or NNN as their response, and seven adopted the notation 3N or Nx3. One girl wrote on her work sheet the expression Nx3 followed by the equals sign: "Nx3=".

Task 4: Breaking the columns' pattern
After noting the predominance of column-by-column solutions, we decided to introduce breaks in the table sequence (Figure 2), thus hoping to draw children's attention to the functional relationship.

Figure 2: Filling out a table and generalizing to higher values and to N

2. Here is another table. Can you fill in the missing values?

PME25 2001
This table was more demanding since it represented a function with an additive term \((x \rightarrow 2x + 1)\). Children did not spontaneously focus upon the functional relationship and needed external help to complete the table. With help many were able to apply the rule and to complete the table.

Task 5: Developing a notation for the function

The next step was to focus on a general notation for the function. David wrote the rule \(nx^2 + 1\) on the board and worked with the whole class, assigning different values for \(n\) and computing the result. The same was done for \(3n + 2\). He replaced \(n\) by different numbers, including zero and 1000, and children easily computed the output.

Task 6: Finding the rule from pairs of numbers

For the next activity, pairs of numbers were given and children were asked to find the rule that originated them. For the first trial of this new task, David wrote 3 and 6 as a first pair and 7 and 10 as a second pair. As the discussion below shows, the children found that they had to add 3 to the first number.

David: Let's work backwards, we'll start from the numbers, and you tell me what the rule is. Can you do that?
Student: Yes.
David: All right. I'm going to start, I'm not going to tell you what the rule is.
Student: You have to do it in pairs?
David: Well, yes. Hold on. I'm going to start with three [...] Then I'm going to go to there, to six [writes "3\(\rightarrow\)6"]. OK, attention.
Sara: Can I tell you the rule?
David: OK, and now, if I start from seven, I'm going to go to 10 [writes "7\(\rightarrow\)10"].
Sara: Can I tell you the rule?
David: Does anybody have the rule figured out? If I start from five, I'm going to go to.
Sara: Eight.
David: Yes, I'm going to go to eight. I think somebody knows the rule! Jennifer!
  What were you thinking? What's the rule?
Jennifer: Plus three?
David: Yes! If I start from \(n\), then I have to go to what?
Students: (Inaudible).
David: Three?
Student: You have to add three.
David: I have to add three to what?
Student: To the \(n\).
David: Yes, to the \(n\). So how am I going to write that down?
Students: \(N\) plus three.
David: Yeah! That's the rule!
Students: Oh, we need something harder.

The children take the rule "\(N\) becomes \(N+3\)" as applying to all three of the cases that were presented. In this way, the \(N\) stands not necessarily for one particular instance as an unknown, but as a variable in a description of the relationship between the pairs of numbers.

The transition from understanding letters as unknowns, to understanding them as variables is notoriously difficult, even for adolescents. However, in the present activity, with a simple additive function, they follow the idea with little trouble, as Melissa shows:
Melissa: Yeah, because you have eleven. Well. Lets just say you have ten, then you add three more and which...I mean, you have eleven, then you have three more, equal fourteen. And say if you did it with twelve, that equals fifteen.

David: Hold on. Twelve becomes fifteen. Yes. That’s correct.

Melissa: And, like the higher we go, the higher the numbers get.

David: That’s right. So, could you do a hundred?

Melissa: Yeah.

Students: A hundred and three.

David: That’s great.

Melissa: And if you do a thousand, it’s a thousand and three.

Melissa first offers the cases of 11, then 12, and then attempts to generalize: “the higher we go, the higher the numbers get”. This suggests that she is referring to two sets of numbers, the numbers chosen (“the higher we go”) as well as the numbers that emerge from applying the rule (“the higher the numbers get”). The numbers are connected one to one as ordered pairs; for each number-input there is a respective output number. But she can also mentally scan the diverse cases in an ordered fashion and think about how variations in input are related to variations in output. The numbers co-vary according to a remarkably simple pattern: as input values increase, the output values increase, with the constraint that the latter are in every case precisely three units more than the former.

In response to the children’s demand to give them “something harder”, David wrote the following number pairs (see Figure 3), one by one, and asked the children to guess the rule he was using.

Figure 3: Input and outputs for n→2n-1

<table>
<thead>
<tr>
<th>Input</th>
<th>Output</th>
</tr>
</thead>
<tbody>
<tr>
<td>3</td>
<td>5</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
</tr>
</tbody>
</table>

The class discusses the possible rule that generates the output numbers from the input numbers:

David: [As he writes 3 and 5 in the second row] OK. If I give you a three, you’ve got to get a five out. You think you still know? You think you know, Michael?

Michael: Yeah.

David: If I gave you an n [writes "n→" above the number pairs] then what, OK…

Michael: For the first one…

David: For the first one, how do you get from five to nine?

Michael: Add four.

David: You add four. And if I add four to three?

Students: No.

David: You could’ve been right. Cause that’s one way to get from five to nine (adding 4). However, this rule, it can’t be that rule cause it didn’t work for the second one (from 3 to 5). Because if I added four, this would become seven, and it became five. Let me give you another example. If I give you a one, do you know what you’re gonna get from this?
Children who proposed additive rules such as “n→ n+2” may have been thinking only about particular cases. However Sara’s rule, “n→ n x 2 – 1”, does not merely describe the relationship between two known values but encompasses each of the cases listed. It is remarkable that she does this in the very lesson in which mapping notation is introduced.

Subsequent discussion in the same lesson showed that only Sara and a small number of her peers were able to generate such “linear function” rules from multiple instances. However, students in the class understood how the rule could account for each of the individual instances. In fact, once a student would propose a rule, other students, including those who did not themselves generate such rules, eagerly volunteered to argue whether the rule worked for the set of instances or just for isolated cases. In this sense they were able to begin to think functionally and to make use of functional notation. Furthermore, when dealing with simpler, additive functions, such as n→ n+3, most students were able to meaningfully generate and use algebraic notation for functions.

Students may not quickly learn to identify linear functions underlying data. Despite this, and perhaps because of this, linear functions can begin to be explored as extensions to students’ work with multiplication tables. Further, even though not all third grade students will initially identify and represent the functional relationships underlying data tables, they can learn significant things in the resulting discussions and slowly work functional notation into their arsenal of representational tools.

Discussion
In introducing a data table with number of items and prices, we found that the students could correctly fill in the tables, but they did so with a minimal of thought about the invariant relationship between the values in the first and second columns. Several changes were made in the structure of
the table and the purposes of the activities to discourage students from working on each column as if it were unrelated to the column next to it.

A guess-my-rule game helped students break away from the isolated column strategies they had been using. One important feature of the game was that there was no discernible downward progression from row to row. This seemed to deter students from viewing the data from a within-measure perspective.

It surprised us that the 9-year-old children were content to look for patterns and functional relations among pure numbers devoid of quantitative reference. They did not need concrete materials to support their reasoning about numerical relations and could even deal with notations of an algebraic nature. In fact, algebraic notation seemed to help them move from computational aspects to generalizations about how two sets of values are interrelated.

The purpose of this paper is to share some of the results of a 15-week study in which pre-service teachers were provided with opportunities to learn to use the clinical interview method with children and other adults. The clinical interview is often regarded as a useful method for understanding children's thinking, and the basic hypothesis of this study was that this technique could be used to help pre-service teachers develop a deeper understanding of the ways in which children learn mathematics and devise better ways of teaching it. Results indicate that the pre-service teachers revised their ideas about the teaching and learning of mathematics, and developed a deeper understanding of the ways in which children build mathematical ideas.

Introduction and Theoretical Framework:

Providing opportunities for teachers at the pre-service and in-service levels to develop insight into their student's thinking is considered to be essential if teachers are to move away from more traditional instructional approaches which emphasize rote memorization and the execution of rules and procedures, and move toward instructional practices which provide students with the opportunity to build concepts and ideas as they are engaged in meaningful mathematical activities (Fennema, Carpenter, Franke, Levi, Jacobs, and Empson, 1996; Ginsburg, 1997; NCTM, 2000; Klein and Tirosh, 2000; Schorr and Ginsburg, 2000). The teacher who has insight into student's thinking can appreciate the sense in students' interpretations and representations of mathematical ideas, and can deal with them constructively. By contrast, the teacher who lacks understanding of student's thinking may understand a concept in a certain way, and genuinely believe that he/she is teaching that concept to his/her students. That teacher often does not realize that a student may not be learning the concept at all, or may be learning an entirely different concept from the one that the teacher has assumed. In either case, there is a wide gap between the thinking of the teacher and the thinking of the student. This can lead to problematic teaching situations, where, for example, the teacher may deal with what is seen as the student's failure to learn by redoubling efforts to teach the concept (as interpreted by the teacher)-- and remains unaware that the student is in fact attempting to learn something else entirely different.

Gaps between teachers' minds and students' minds are widespread, and occur in schools ranging from preschool through university (Schorr and Ginsburg, 2000). This is not surprising, since gaining insight into students' thinking is not easy. Piaget (1976) pointed out that it will take the psychological equivalent of the Copernican revolution for the adult to realize first that the child's thinking does not necessarily revolve around or take a form similar to that of the adult's, and second that children's minds, although often radically different from the adult's, can nevertheless make their own kind of sense.

To better understand people's thinking Piaget, (1952) developed a technique known as "the method of clinical examination" modeled after psychiatrists' methods of diagnosis. Using this method, he pursued the investigation of thinking in the following...
way: “I engaged my subjects in conversations patterned after psychiatric questioning, with the aim of discovering something about the reasoning process underlying their right, but especially their wrong answers” (Piaget, 1952, p. 244 as quoted in Ginsburg, 1997). The clinical interview, as originally developed by Piaget (1976), is a flexible and deliberately non-standardized method of questioning, which aims at providing insight into children's ways of thinking-- into their personal "constructions"-- which are often different from the adult's. In the clinical interview, the adult poses a specific task to the child, and usually begins with some predetermined questions. However, the adult is free to modify the questions as necessary, depending on the child's apparent understanding of the questions, the child's motivation, and particularly the child's response to the initial question. The interviewer has the freedom to rephrase the questions to ensure that the child understands them, to follow up on interesting remarks, to clarify responses, and even to challenge them so as to establish the child's degree of conviction. The clinical interview method has been used as the basis of a good deal of research on children's understanding of school mathematics for many years, perhaps beginning with Davis & Greenstein (1964), and is now receiving increasing recognition as a major tool for psychological research into cognitive functioning (Ginsburg, 1997).

This research focuses on one method for helping pre-service teachers reduce the gap that exists between children's thinking and teachers' thinking—namely the clinical interview. The central hypothesis is that if used effectively, the clinical interview can be a fundamental method for helping pre-service teachers better understand students thinking, and subsequently devise better ways of teaching mathematics. This research builds upon previous work which shows that it is possible for teachers to learn the clinical interview method and to develop useful forms of it for practical implementation in the classroom (Ginsburg, Jacobs, & Lopez, 1998). That research showed that elementary level teachers from very different types of schools—inner city, suburban, and private—were able to become rather good interviewers and to develop distinctive styles of interviewing appropriate for their classrooms. For example, some teachers developed forms of interviewing individual students; others developed methods for interviewing groups of students; others integrated interviewing into their teaching; and another teacher taught her students to interview each other. Almost all teachers said that the process of learning and implementing clinical interview methods was an extremely valuable experience and indeed changed their whole approach to understanding children and teaching them. The research in this paper also builds upon prior work in a similar course where clinical interviewing was shown to be effective in helping prospective teachers begin to develop new ideas about teaching mathematics (Schorr and Ginsburg, 2000).

Methods and Procedures:

The setting for this study was a course entitled “Methods of Teaching Mathematics for Elementary and Middle School Teachers”, a mathematics methods course at an East Coast university in the USA. The course had 23 prospective teachers enrolled, who met with the researcher three hours per week, for 15 weeks. As part of the course, the prospective teachers were provided with opportunities to learn the clinical interview method, interview children, and reflect on the interviews individually and collectively during classroom sessions. They were also provided with opportunities to deepen their own understanding of the mathematics that they were expected to teach, and simultaneously consider the pedagogical implications of teaching mathematics in a thoughtful manner. For example, during weekly class sessions, the prospective
teachers would investigate a particular mathematical idea by solving a problem or series of problems related to the idea, generally in a group setting. They would then share their solutions, and compare the strategies chosen, the notations that were invented or selected, and the representations built. They were always challenged to defend and justify their solutions. When appropriate, they would then watch a videotaped interview involving a child or series of children grappling with the same or similar mathematical ideas. During and after viewing the videotaped interview, they would share reflections about the questions posed and the interview techniques used. They would also discuss the child's mathematical thinking, and the pedagogical implications of teaching and learning the mathematical ideas. At times, they would also watch videotaped episodes of children working on similar mathematical ideas and again, discuss the mathematical ideas that emerged, and the implications for teaching. Afterwards, they were encouraged to actually interview a child about the same ideas, and share the results during the next class session. In addition, the prospective teachers were assigned selective readings on the same topics as well as readings taken from state and national standards in mathematics.

All prospective teachers had to interview a child (or in some cases, an adult) every other class session. They had to record what they considered to be significant aspects of the interview (noting the exact words of the interviewer and interviewee by using a tape recorder or videotape) and discuss the overall interview, their reflections on the questions that they asked and responses of the interviewee, and the implications for teaching. Each prospective teacher therefore conducted an interview with at least one child (or adult) every other week for a total of at least seven interviews. Prospective teachers also kept a journal in which they recorded their reflections on the readings, mathematical ideas, or at times, additional reflections on their own or their peers interviews. They submitted their journals on the weeks when they did not submit an interview.

The data for this research includes the written interview logs and journals of the prospective teachers, and researcher's notes.

Results and Discussion:

There are many findings to report regarding changes in the prospective teachers' ideas about the teaching and learning of mathematics and the ways in which children build the mathematical ideas that were investigated. Space limitations permit only a subset of the results to be shared in this paper. These will be limited to three main themes that consistently emerged among the prospective teachers.

**Theme 1: The prospective teachers changed their views and beliefs about the teaching of mathematics.**

All prospective teachers reported that as a result of interviewing children (and adults), their conceptions about teaching and learning changed. For example, consider

1 The tapes and corresponding guide are part of a series entitled “Children’s Mathematical Thinking-Videotape Workshops for Educators” developed by Herbert Ginsburg, Rochelle Kaplan, and Rebecca Netley. They are distributed by the Everyday Learning Corporation.

2 These tapes were often obtained through the Robert B. Davis Institute for Mathematics Education.

3 Prospective teachers often volunteered to interview additional children and/or adults about an idea that interested them, or when they sought more data about a particular idea.
one Journal entry submitted by a prospective teacher who shall be referred to as Juanita:

Before taking this course, I had a very different idea of what it meant to teach math. I thought that teaching math would be just like it was when I went to school; the teacher did a few problems in the board and we simply had to follow the steps she/he took to come up with the answers. To me this was math, until I took this course. Now I could look back and see that even though I always had good grades, it didn’t mean that I knew math. Now I realize that math is more than just finding answers. Math should involve solving problems by reasoning and understanding. After doing my interviews, I was able to see the difference between knowing how to find answers by following an algorithm and finding the answers by using our knowledge and understanding of the subject.

Juanita went on to describe how she would like her classroom to look, and the types of questions and techniques that she might employ. For example, she stated the following:

Now I realize how important and beneficial it is that we encourage students to think and come up with their own strategies. As teachers, our goal should be to challenge students by coming up with problems...good problems [that] give students the chance to solidify and extend what they know.... As teachers we should encourage students to find the reasoning behind their solutions and also be able to prove them. It’s very important that students be able to defend their answers by coming up w/ proofs because this way they will have to have more in-depth understanding of the problem. We have to help our students see that their statements need to be supported by evidence.

Other prospective teachers made similar comments regarding their beliefs about what it means to teach mathematics. One teacher, Maria, noted that she used to believe that using pictorial or concrete representations was not really “doing math”, but now she feels differently. As documentation, she recorded these observations as she was interviewing a seventh grade student. The problem she had posed to the student, “Irene” had been similar to one that she and the other prospective teachers had solved and discussed the prior week in class. Maria was interested in seeing the mathematical ideas, strategies, notational systems and representations that would be used by this student. The problem, as recorded in Maria’s interview log, was as follows: Juan has 3 pairs of pants and 5 shirts, how many different outfits can Juan wear, please show me your work.

Maria recorded the following:

Now I had a feeling the phrase “please show me your work” would be a problem [for Irene], because I knew it was for me when I was her age. Many teachers do not want to see drawings, they want a mathematical equation. Sometimes, if they don’t receive that, the question is marked wrong. I wanted “Irene” to learn that drawing pictures is okay. I remember solving a problem using my head or drawings and having to come up with an equation, So, I would use any old equation that gave me the answer I was looking for, even if it didn’t make sense...

Maria noted that Irene worked for a while and then handed her a piece of paper and said “it’s probably wrong, but I think it makes sense”. Maria included Irene’s work in her written log. The work included five circles representing the shirts, and three rectangles representing the pants, along with an answer of 15. Maria continued her interview as follows:
So I asked [Irene] how did she get that answer and if she could explain it to me. She tells me “I made circles for the amount of shirts and squares for the amount of pants, then I just paired them up.” At this point, she starts to draw lines from a circle to a square, but then she tells me that the lines got too confusing to count so she changes her format. This time she makes the shirts vertically and does something very interesting with the pants [Maria included Irene’s written work which again included five circles–each with the word shirt written inside, but this time, each circle had three lines extended, each with a small square at the end and the word pants written inside each square.] She [Irene] tells me that the lines are easier this way (to count) and that it makes 15 outfits. So, I asked her how she figured it out and she tells me “well there’s three pairs of pants, and five shirts, so I just paired up every single pair of pants with every shirt.”

Maria went on to ask Irene if there could be any other answer, and Irene said that she didn’t think so. Maria continued her interview by asking, “why did you say in the beginning that your answer is probably wrong?” Irene responded by saying “because I didn’t show my work...”. Maria noted that this student did not see “drawing pictures” as doing mathematics. As part of her written log, Maria also discussed the type of reasoning (additive and/or multiplicative) that she felt the student was using. In a subsequent class discussion, Maria used this example to underscore her desire to encourage students to draw pictures. The researcher was able to use this (and other similar examples) to provide an opportunity for Maria and the other pre-service teachers to consider the type of reasoning used by the students, and how students’ representations like “drawings” could be linked to spoken words, written words, numbers, symbols, etc.

**Theme 2: Prospective teachers noticed that children (and adults) often invent their own strategies when solving problems.**

Juanita described an aspect of one interview in which different subjects used different techniques to solve the same problem involving multiplication (one drew figures, the other used different number combinations). This, along with the other interviews and reflections of her peers prompted her to write the following:

After doing these interviews, I was able to see for myself how everyone has their own invented techniques to solve problems. Everyone sees their own ways as being easier to understand. As teachers, we must keep this in mind because if we teach children using only one method, our method, children may not understand our techniques, to them, our ways may seem complicated, even though we find them easy.

Juanita wrote that children must be able to “make the connections between the symbols and the meaning of the mathematical process”. She noted that “as teachers we should allow students to present alternative [methods]...and then lead a discussion about why a particular [method] works or doesn’t. This allows the teachers to become more aware of the diversity of different approaches that are used”.

Anna, another prospective teacher, decided to interview several adults about a simple mathematical problem to see whether or not they would use a traditional algorithm or an invented strategy. The problem that Anna chose was to find the age of a woman who had a son at the age of fifteen if the son was now nineteen. Anna wrote the following in her log:
I asked my sister and aunt [and mother] to solve the problem. I was so surprised that we each ended up with a different way of coming up with the same answer. I thought that would happen more with children.

She described their methods, along with the way that she had solved the same problem. For example, she noted that her sister solved it by taking "the tens first, which came out to twenty. She then counted the ones column. She took one from the five and added it to the nine and got ten. She then added the ten to the twenty and got thirty and then added the remaining four to thirty and got the answer thirty four." Anna included these reflections in her log:

This interview was so interesting to me because it showed me that it isn’t just children who come up with different ways of solving even a simple math problem. In the video I only saw children being asked to solve problems and I was somewhat curious how adults would respond. I thought we would be more like-minded since we’re older and have gone through a lot of similar math rules, but I was shown wrong.... This has made it even more significant to me that what may be in my mind may not be what’s in another’s mind, and I have to take that into much consideration!

While the prospective teachers had discussed the use of different strategies in class on numerous occasions, and indeed had even shared the many different ways in which they had solved different problems, Anna still needed to experience this for herself, and the interview provided just such an opportunity. For Anna, this interview continued what the class experience could only begin—help her to realize for herself, that people can approach the same problem quite differently.

Interviews often triggered extensive in-class discussions about why particular methods worked, when and under what circumstances they would work, and how they related to more traditional approaches. This provided an additional opportunity for the prospective teachers to deepen their own understanding of the mathematical ideas.

Theme 3: Getting the right answer does not necessarily mean that the student understands the mathematics.

Perhaps one of the most important “discoveries” that most of the prospective teachers made was that students can get the “right answer” without understanding anything about why their method worked. For example, consider the reflections of another prospective teacher, Oneda. Oneda decided to interview a friend of hers who is an accountant. Her reflections included the following comments:

I began the interview by asking "Jim" whether he felt completely comfortable with the subject of mathematics. Jim answered the question...with an emphatic “of course...what kind of accountant would I be if I was not comfortable with mathematics.” I continued the interview by asking Jim...to add 3/4 plus 1/2. Jim added the fractions and got the answer 1 and 1/4. I asked Jim to explain how he got his answer. Jim mentioned in his explanation that the first thing that he did was to find the least common denominator. I then asked why the least common denominator had to be found, and after thinking for a few seconds he laughed and stated that he did not know why. He seemed to be a little embarrassed and I assured him that many people simply did not know. We then got into a discussion of how he had learned to add and subtract fractions. Jim recalls learning to add
and subtract fractions by being given the math rule by the teacher followed by numerous worksheets. He basically memorized the rules and then repeated them on similar problems on tests. He did this all through elementary school, high school, and even college with more advanced mathematics. Jim always received good grades.

Her reflections went on to include the following comments:

The problem is not that one should not learn these algorithms or methods and rules of solving problems. The problem lies in that this is all that is presented to children. This is truly unfair and simply cannot be called teaching mathematics. As witnessed in the videos shown in class, children are capable of much more. They can grasp many concepts that many times adults don't think they can grasp.... Limited understanding of mathematical concepts cannot be blamed on the individual or his or her intelligence level. Rather, the blame must be put on the years of bad teaching that the individual was subjected to. Perhaps even blaming bad teaching is pretty unfair. Many of the teachers that teach in this way are simply teaching in the way that they were taught. It is basically like a bad cycle. I only hope that I can be one of those teachers that helps to break the cycle.

Another prospective teacher, Inez, interviewed a middle school student on ideas relating to fractions as well. Inez noted that while this student could add fractions with like denominators, he had no idea why he needed to have a common denominator. She noted that whenever she asked this student why the denominators had to stay the same, he responded “because it just does” or “[you] just have to”. She stated

Even though he knew the rule about keeping common denominators the same, he did not know why. I noted frustration in his voice when I tried to get him to explain to me the reason behind his answer.

Inez then posed a problem to this student where the denominators were not the same (3/8 + 1/4). She recorded this:

When adding 3/8 plus 1/4, I could tell he was confused and frustrated for forgetting the rule to solve it. He used the rule of dividing and multiplying fractions, which involved canceling out to simplify. He admitted that he was not sure that he got the correct answer. Even though he got the answer wrong, that it was due to the fact that he was thinking about which rule to use instead of really thinking about what to do. He always got good grades in math...

While the prospective teachers had spent time in class exploring ideas relating to fractions before they conducted their interviews, the interviews provided additional opportunities for them to reconsider their own understanding of the mathematical ideas, and the implications for teaching. This occurred when the interview was shared by the student and/or the researcher, and resulted in additional discussions and explorations.

Conclusions:

The prospective teachers involved in this study felt that their views of teaching and learning had greatly changed as a result of clinical interviewing. They also gained insight into the ways in which mathematical ideas can be built and represented. It would be unwise to assume that by itself, this 15-week experience could be sufficient to dramatically change the prospective teachers’ approach to teaching all areas of
mathematics. Clearly, the prospective teachers will need longer and deeper experiences in order to make the transformation from perspectives that can be difficult to move beyond (see Simon, Tzur, Heinz, & Kinzel, 2000). However, this study does provide documentation that clinical interviewing can help prospective teachers to consider alternative approaches to the teaching and learning of mathematics and develop an increased awareness of the ways in which people learn mathematics. In addition, the interviews also provided the impetus for challenging and thought provoking course discussions about mathematical ideas—ideas that became more personally relevant to the prospective teachers because they emerged as a consequence of their own interviews with children and adults. Taken together, the results appear to indicate that the clinical interview method can be a valuable tool in helping prospective teachers begin to see mathematics as a “collection of ideas and methods which a student builds up in his or her own head” (Davis, 1984, p. 92), and as a result, devise better ways of teaching it.

WHAT CONSTITUTES A (GOOD) DEFINITION?
THE CASE OF A SQUARE
Karni Shir and Orit Zaslavsky
Technion – Israel Institute of Technology, Haifa

The notion of definition is central in the study of mathematics. Several researchers discuss the significant role definitions play in understanding mathematical concepts, in problem solving and in proving. This work deals with mathematics teachers' conceptions of a mathematical definition. Their conceptions of definition were revealed through individual and group activities in which they were asked to consider a number of possible definitions of a square. Data were collected from written questionnaires and recorded observations. The findings point to a number of perspectives underlying teachers' conceptions of an acceptable mathematical definition.

Theoretical Background

Mathematical definitions play a central role in mathematics and in mathematics education. According to Pimm (1993) “The mathematical term definition is one of a meta-mathematical marker terms (others include axiom, theorem, proof, lemma, proposition, corollary), terms which serve to indicate the purported status and function of various elements of written mathematics” (p. 261-262 ibid).

The following citation from Wilson (1990) expresses the motivation for the current study:

“Although we frequently use definitions, we rarely focus on the nature of definitions. There is little agreement on what constitutes a good definition” (p. 33, ibid).

A definition is a way to create uniformity in the meaning of concepts, it is a tool for communication among human beings, and it is a foundation for proving and problem solving. Pimm (1993) brings the following citation of Ludwig Wittgenstein when speaking about definitions “… in order to communicate, people must agree with one another about the meaning of words” (p. 272, ibid). Borasi (1992) refers to the uniformity aspect of definitions through students’ thoughts regarding the use of definitions in geometry: “So we bring unity, to make things uniform…” (p. 14, ibid).

Moore (1994) discusses the connections between definitions and proving. According to Moore, there are three possible ways of operating with definitions in doing proofs: (a) using definitions for generating examples; (b) using definitions for justifying steps in a proof; and (c) using definitions for planning an overall structure of a proof.

There is a body of research dealing with the role definitions play in mathematical concept formation and concept understanding. Feldman
(1972) reports on three experiments done to determine the effect of several instructional variables on concept attainment. According to Feldman, providing a rational set of positive and negative instances with a definition was significantly more facilitative in promoting concept learning than a rational set alone. According to Wilson (1990) definitions, examples and non-examples are the building blocks needed to construct mathematical concepts. Klausemeier & Feldman (1975) and Sowder (1980) suggest a model of concept learning, which includes the following steps: recognizing examples, classifying examples and non-examples, and stating a definition of the concept. Vinner (1991) presents the notions of concept image and concept definition as two cells in which the knowledge about the concept is located. He adds, “the ability to construct a formal definition is a possible indication of deep understanding” (p. 79, ibid). Moore (1994), based on Vinner’s and others work, suggests a ‘concept understanding scheme’, which consists of a third aspect - concept usage - in addition to concept images and concept definitions.

In spite of the significant roles definitions play in learning and doing mathematics, many students have difficulties in understanding and using definitions. In a study dealing with classification of students’ mathematical errors, Movshovitz-Hadar, Zaslavsky, and Inbar (1987) found that many of the errors students perform are related to distortion of definitions. Moore (1994) found that mathematics and mathematics education undergraduate students, who either lack the knowledge of certain mathematical definitions or do not know how definitions may be used, have difficulties in constructing mathematical proofs. Many difficulties students have in constructing meaning of a mathematical concept are related to the compartmentalization between the formal definition of a concept and the (personal) concept image (Tall & Vinner, 1981; Vinner & Dreyfus, 1989; Vinner, 1991).

Several aspects of mathematical definitions are discussed by a number of mathematics educators (Leikin & Winicki-Landmean, 2000; van Dormolen & Zaslavsky, 1999; Pimm, 1993; Borasi, 1987, 1992; Vinner, 1991; Or-Bach, 1991; Leron, 1988). Most of the aspects discussed are considered critical requirements for a mathematical definition. Thus, a mathematical definition must be: hierarchical (i.e., based on previously basic or defined terms), existent (i.e., having at least one existing instance), noncircular, non-contradicting (i.e., all conditions of the definitions may co-exist), unambiguous, and independent of the representation used. In addition, two definitions of the same concept must be logically equivalent. There are two aspects on which there is no consensus regarding their ultimate need, that is, it is not commonly agreed whether or not a mathematical definition must be minimal (i.e., economical, with no superfluous conditions or information), and elegant.
Leron (1988) and Pimm (1993) discuss another relevant feature that distinguishes between definitions: a definition can be either procedural or structural (according to Leron). In Pimm’s terms, it can be either by genesis or by property. Generally, the discussions on features of mathematical definitions distinguish between mathematical requirements and pedagogical choices.

A number of recent studies, which relate to the features mentioned above, propose ways to facilitate the understanding of definitions in mathematics. Leikin & Winicki-Landman (2000) presented teachers with a number of equivalent definitions of a certain concept (e.g., absolute value). Each definition used a different term for the defined concept. The teachers, who were not aware that the definitions were equivalent and that all define the same concept, were asked to investigate the mutual logical relationships between every two definitions. Through these activities they developed an understanding of equivalent definitions and discussed the freedom to choose a definition from a collection of equivalent statements.

In another study Furinghetti and Paola (2000) asked students to consider two alternative non-equivalent definitions of a trapezoid. The authors point to the value of the group discussions focusing on the advantages and disadvantages of each definition. In this study, similar to the work of Leikin and Winicki-Landman, students became aware of the issue of arbitrariness of a definition and the underlying considerations in determining what definition to accept.

De Villies (1998) asked students to define quadrangles. Following their responses, activities and classroom discussions were conducted focusing on the advantages of economical definitions. Through these activities students’ tendency to suggest more economical definitions increased.

The current study focuses on ways in which secondary mathematics teachers view a mathematical definition, particularly, the aspects of a mathematical definition they consider critical, from both mathematical and pedagogical points of view.

The Study

The aim of the current study was to investigate mathematics teachers’ conceptions of a mathematical definition, through their justifications for accepting or rejecting specific statements as possible definitions of a certain mathematical concept.

In order to focus on the notion of definition rather than on the defined concept, it was important to use a simple and familiar concept. Thus, the square was chosen as the focal concept for the study. The research instrument consisted of a questionnaire with eight equivalent statements, all of which describe a square (see Table 1). For each statement, the
participating teachers were asked to determine whether they would accept it as a definition of a square. All along they were prompted to provide justifications for their responses.

In constructing the different statements for the research instrument, attention was given to several features. The statements differed from each other with respect to whether it is minimal or not, whether it is procedural or structural, and the degree of hierarchy in the statement (see below).

As mentioned above, one of the requirements of a definition is hierarchy. However, the kind of hierarchy for a given concept may vary. We distinguish between different levels of hierarchy. For example, we can define an isosceles triangle as a triangle that has two equal sides. We can go one step back and define it as a polygon with three sides, two of which are equal. The further back we go, the degree of hierarchy decreases. The focal concept of the present study – a square – can be defined based on a rectangle or on a rhombus (this is the 1st and highest level of hierarchy), on a parallelogram (the 2nd level), on a quadrangle (the 3rd level), on a polygon (the 4th level), and so on. Figure 1 illustrates the different levels of hierarchy that are associated with the notion of a square.

![Diagram of hierarchy levels]

Figure 1

The statements in the research instrument appear in Table 1. The level of hierarchy in statements 2, 3, and 6 is 1, the level of hierarchy in statements 1, 5, and 8 is 3, and the level of hierarchy of statement 4 is lower than 4. However, the level of hierarchy of statement 7 is not decisive, since it relies also on the location of the notion of locus in the hierarchy of geometric concepts.

All except statement 1 are minimal statements in terms of a definition of a square. Statement 4 is the only procedural statement.

Twenty-four secondary mathematics teachers participated in the study. The participants took part in a 90-minute workshop dealing with alternative ways for defining a square. At the beginning, each teacher received a written questionnaire that contained the eight equivalent statements, and was asked to reply to it individually. Then, the teachers were divided into groups of 3-5, and were requested to discuss their answers to the written questionnaire and to try to reach an agreement. The third and last stage was a full classroom discussion, based on reports from the small groups.
Findings

For each statement, there were 4 kinds of responses: (1) accept the statement as a definition of a square; (2) do not accept the statement as a definition of a square; (3) not decisive; (4) no reply. Table 1 presents the distribution of responses to the eight statements in the questionnaire.

Table 1: Distribution of Teachers' Responses to the Statements

Although all the given statements are equivalent to a well-known and commonly accepted definition of a square, and all constitute a necessary and sufficient condition for a square, only 5 teachers accepted all 8 statements as possible definitions. Moreover, there was no unanimous agreement among the teachers about acceptance or rejection of any of the given statements. The percent of agreement on acceptance varied from the minimum of 21% for statement 2 to the maximum of 92% for statement 1.

There was also little agreement on the reasons for acceptance or rejection of the statements as possible definitions of a square. The written responses included 65 arguments justifying the acceptance and 54 arguments justifying the rejection of a statement as a possible definition. These arguments were classified into 7 reasons for acceptance and 7 reasons for
rejection (Table 2) (it was mere coincidence that in both cases there was the same number of types of arguments). A further analysis grouped the different kinds of arguments according to their underlying perspective: Mathematical, pedagogical, both - mathematical and pedagogical, and embodied cognition. Table 2 presents the distribution of types of arguments that teachers used to support their decisions.

Table 2: Arguments for Accepting or Rejecting a Statement as Definition of a Square

Note that about half the arguments (49%) for accepting a statement were based on mathematical arguments, while there was hardly any mathematical support (5.5%) for rejecting a statement. On the other hand, pedagogical considerations played a significant role both in accepting (40%) as well as in rejecting a statement (63%).

**Discussion**

We begin by pointing to the potential of the activity described in this paper as a vehicle for professional development, in addition to its power of eliciting teachers’ conceptions of a mathematical definition and the role definitions play in teaching mathematical concepts. It is not surprising that many teachers drew on pedagogical considerations, which they are

---

* For example, some teachers, in reflecting on their ways of thinking about a square, referred to the diagonals of a square as non-integral parts of a square (opposed to the sides and angles of a square).
accustomed to take into account, even though they were asked to respond from their personal perspective, not necessarily as teachers.

We turn to a short discussion of the different perspectives that were identified, and offer some explanatory comments regarding each one.

The mathematical considerations teachers employed for accepting a statement as definition indicate their logical oriented view that there is a degree of arbitrariness in the choice of a definition. For them, an equivalent statement to a well-known definition, or a statement that constitutes a necessary and sufficient condition for a square, qualifies as a definition. Those who rejected a statement for mathematical reasons were convinced that a mathematical definition must be minimal (although, all of them probably teach their students the classical definition of congruent triangles that is not a minimal definition).

The pedagogical considerations that were given by the teachers indicate their expectation that a mathematical definition should be easily comprehended by students. For this reason a definition should be simple, clear, familiar, not complicated, and obvious. In addition, it should be based on students' previous knowledge. The requirement for previous knowledge may be seen as an extension and application of the mathematical hierarchy criterion to the mathematics curriculum, that is, to the order in which students learn (geometrical) concepts.

Procedural definitions seem to cause disagreement. Some teachers accepted the procedural statement from a mathematical standpoint and favored it from a pedagogical point of view, because it portrays the underlying structure of the object and lends itself well to construction of a mental image of the object. However, those who rejected the procedural statement rested mainly on mathematical grounds, and argued that a mathematical definition cannot be procedural. This view reflects the fact that procedural definitions are not very common in high school mathematic textbooks, and it is likely that many of them never came across a procedural definition before.

The last, but probably one of the more interesting considerations, is the embodied one. People are exposed to squares rather frequently in real life contexts, from early childhood. Thus, they probably conceptualize the technical mathematical concept of a square making use of their everyday concept of a square (Núñez, 2000), which appears without its diagonals. Statements 5 & 6 define a square through properties of its diagonals. For a number of teachers this was illegitimate, because the diagonals of a square are not perceived as integral parts of a square.

In this paper we reported findings of one part of a larger study dealing with what constitutes a (good) mathematical definition. Similar findings
were obtained for other mathematical concepts in other groups of in-service and prospective mathematics teachers.

Reference

Feldman, K. V. (1972). The Effects of Number of Positive and Negative Instances, Concept Definition, and Emphasis of Relevant Attributes in the Attainment of Mathematical Concepts. Wisconsin University.

The study described in this paper examined mathematics teachers’ (inservice and preservice) knowledge regarding the concept of parabola. The participants (33 preservice and 21 inservice) were asked to perform two tasks: in the first one they were given four different verbal definitions of sets of curves, and for each definition they were asked to sketch a curve, which they believed, compatible with the definition, and to describe its properties. In the second task the participants were asked to sketch a Venn-Diagram in order to describe the logical connections between the four sets of curves, which were formed by the four definitions that appeared in the first task. All the definitions concerned the parabola.

The results show that only a few possess a full concept image concerning the parabola and thus a few of them are capable of perceiving the parabola in its algebraic as well as in its geometrical contexts or to identify links between them.

INTRODUCTION

In many countries students in ninth or tenth grade learn how to solve quadratic equations, and become familiar with quadratic functions and their graphic representations. In other words they get acquainted with the parabola as the graph of quadratic function i.e., as an algebraic entity (though they are not given any formal definition of the parabola). Later on, the parabola appears as a geometrical entity in analytic geometry. Although the concept is exposed in its algebraic as well as in its geometrical contexts, teachers often neglect the connections between the two, and do not initiate a discussion about the difference between the concepts in the two contexts.

THEORETICAL BACKGROUND

During the process of learning a certain concept one builds in mind a concept image and a concept definition (Tall & Vinner, 1981). A concept image is the “total cognitive structure that is associated with a concept” and a concept definition is the “form of words used to specify that concept”. One might hold a concept definition that does not coincide with its mathematical definition or a concept definition that is not necessarily linked to his or her concept image. As a consequence, there is a gap between the mathematical definition of the concept and the way one perceives it. According to Hershkowitz (1990) individuals who possess poor concept images use a
few prototypical examples of the concept while considering that concept. They tend to reject as examples figures that do not coincide with those prototypes, because they base their judgment upon visual properties. Individuals who possess somewhat richer concept images base their judgment upon more prototypical examples plus their mathematical properties. They try to apply the properties to the figures they are dealing with, and reject those that seem not to match them. Individuals who possess full concept images hold a wide variety of examples connected to the concept together with their properties. These individuals are able to make correct judgments based upon the analysis of the properties.

Vinner (1991) emphasized the fact that a good learning process is one that integrates concept images and concept definitions, and thus enables to distinguish between examples, counterexamples, and nonexamples of that concept.

Regarding our study, representing the parabola in both contexts induce the creation of two separate concept images and two separate concept definitions, which are different from one another. It is essential to create links between the perception of the parabola as an algebraic entity and its perception as a geometrical entity in order to create a full concept image. Otherwise students may not unify the two into one concept image and never get the complete one.

Teachers should strive to help their students to create those links. Vinner (ibid.) points out the importance of students’ experience and the examples of a concept they are requested to deal with. These experiences are crucial for the formation of concept images. Since teachers’ instructional foci are constrained by their own mathematical conceptions (Lloyd & Wilson, 1998, Gutiérrez & Jaime, 1999), then only if the teachers themselves possess a full concept image of a certain concept, they would be able to convey it to their students. Research (e.g. Stump, 1999) had revealed the existence of a wide gap between the implementation of the recommendations for making changes in mathematics education (NCTM, 1989, 1991) and the actual practice. Part of it can be referred to the use of traditional textbooks, but there is no doubt that the implementation of the intended curriculum depends mostly on the teachers’ knowledge. This view motivated our study.

This paper describes the results of a study, focused on the ability of preservice and inservice teachers of mathematics to interpret various definitions that are connected with the concept of parabola and on their ability to identify links between them.

RESEARCH DESIGN

Twenty-one inservice mathematics teachers, each having at least ten years of experience in teaching high-school mathematics, and thirty-three preservice teachers who are in their third year of learning towards B.Sc. in mathematics education,
participated in the study. The participants were divided into six separate groups (three of the inservice teachers and three of the preservice teachers).

Two main research questions were addressed:
1. What kind of concept image do inservice and preservice teachers of mathematics hold regarding the parabola?
2. What are the differences, if any, between the way in which the preservice and inservice teachers perceive that concept?

In order to answer these questions the participants were asked to perform two tasks. In the first one they were given four different verbal definitions of sets of curves. The first definition was the geometrical definition of the parabola, and thus compatible for every parabola. The others were algebraic definitions of subsets of the parabolas. For each definition the participants were asked to sketch a curve, which they believed, compatible with the definition, and to describe its properties. In the second task the participants were asked to sketch a Venn-Diagram in order to describe the logical connections between the four sets of curves, which were formed by the four definitions that appeared in the first task.

The definitions given in the first task were:

1. **Set no. 1**: \( \lambda_1 \) is an element of set no. 1 iff: Given a line \( l \) and a point \( F \) not on the line, \( \lambda_1 \) is the locus of points in the plane that their distance from the point \( F \) equals their distance from the line \( l \).

2. **Set no. 2**: \( \lambda_2 \) is an element of set no. 2 iff: \( \lambda_2 \) is a graph of a quadratic function of the form: \( y = ax^2 + bx + c \), where \( a \neq 0 \); \( a, b, c \in R \).

3. **Set no. 3**: \( \lambda_3 \) is an element of set no. 3 iff: \( \lambda_3 \) is the graph of an implicit function of the form \( y^2 = 2px \), where \( p \neq 0 \), \( p \in R \).

4. **Set no. 4**: \( \lambda_4 \) is an element of set no. 4 iff: \( \lambda_4 \) is a graph of a function which its pattern is a product of two non constant linear patterns.

All the participants worked individually on the two tasks. Later on an instructed discussion was held, guided by the researchers. During that session the participants could raise questions, wonders and thoughts in a form of a dialogue or a conversation. Each discussion was tape-recorded and used for further analysis.

**RESULTS**

The first task
The participants’ responses to the first task were first classified and then ranked as poor/non concept images, partial concept images and full concept images, based upon Hershkowitz's (1990) research. Table 1 shows the types of answers obtained, their
classification and ranking, and the distribution of the answers in each group (inservice/preservice). The average level of the inservice teachers’ performance was slightly higher than that of the preservice teachers’ performance. Regarding the first task, it seemed like 38.64% of the preservice teachers possess full concept images as compared to 48.81% of the inservice teachers. Concerning the category that was ranked as “partial concept images” it was found that both groups possess the same concept images.

Table 1: Types of answers, their classification and ranking (preservice = PS, inservice = IS)

**The second task**

The most striking result was the fact that a high percent of the participants (39.39% of the preservice teachers and 57.15% of the inservice teachers) did not sketch any diagram. The most common mistake among the inservice teachers who tried to sketch a suitable Venn-Diagram was the misplacement of set no. 4 (23.81% of them had such a difficulty). The most common mistake of the preservice teachers (48.48%) stem from their inability to interpret correctly definition no. 1 or to identify links between that definition and the others. The results are summarized in table 2.

ANALYSIS AND DISCUSSION

Table 1 and table 2 show that the inservice teachers’ performance was better than that of the preservice teachers’ on both tasks and especially on the first one. It has also been found that both groups shared similar difficulties and misconceptions (except for the poor concept images related to the first task). These findings are consistent with other studies focused on preservice and inservice teachers’ mathematical knowledge (e.g. Hershkowitz, 1989, Stump, 1999, Gutiérrez & Jaime, 1999).

The first task

The results reveal a strong and clear tendency towards conceiving the parabola as an algebraic entity. It seems that definition no. 2 is the closest one to the participants’ concept images. Hershkowitz (1989) refers to that as “the prototype phenomenon”. Hershkowitz (ibid.) had found that when children build their concept image they often use a prototypical example they have in their mind. They base their judgment on that prototypical example and try to impose its properties on other examples of that concept. As was mentioned, the initial examples of the parabola the students are encountered with are graphs of quadratic functions. Such graphs are elements of set no. 2. It seems that this can explain the fact that the inservice as well as the preservice teachers used those examples as prototypes. The way the participants imposed these prototype examples’ properties are expressed in their responses to all the other definitions: Definition no. 3 should have been well known to all participants since it is an integrated part of high school analytic geometry curriculum. Yet, many preservice teachers (24.24%) could not identify the obtained curve or analyze its properties. They attributed the curve function properties. Among the inservice teachers we found a remarkable phenomenon – most of them referred only to the case in which p>0. This finding is standing in a contradiction to their responses to definition no. 2. Those responses included lists of properties designating the various possibilities for each of the coefficients that appeared in the pattern $ax^2+bx+c$. It seems like this can be attributed to the fact that the common algebra books, though deal with the two possibilities, refer only to the possibility of p>0 while exploring the
properties of the obtained curve. Since the inservice teachers have been using those books for years, it is reasonable to assume that they have developed a prototypical view towards that curve. In their responses to definition no. 4 most participants in both groups did not mention any constrains regarding the number of intersecting points between the obtained graph and the x-axis. This finding is consistent with former findings mentioned above regarding the perception of the parabola as a prototypical algebraic entity. According to that perception, if two linear patterns are being multiplied the result has to be a quadratic pattern and thus the obtained graph is a parabola, and vice versa. In the responses to definition no. 1, many participants (21.21% of the preservice teachers and 42.85% of the inservice teachers) tended to exhibit again their algebraic perception, and associated the parabola the properties of a function. Among the preservice teachers there exists a fairly large group (54.54%) that was unable to identify that definition as a definition of a set of parabolas, and as a consequence they sketched different curves. The main evident difficulty is the participants’ inability to identify links between the geometrical and the algebraic representation of the parabola. The mental formation of those links is not obvious since, as was mentioned, each representation bears its own concept definition and concept images. If the prototypical example is an algebraic one, there is a low probability that a full concept image would be acquired without any deliberate intervention. Evidence to the absence of mental links was also obtained from the discussions that were held. The vast majority of the inservice teachers designated that they use both definitions (in accordance to the grade levels). But at the same breath they admit that “the geometrical definition is embarrassing since it enables us to get a parabola that is not a graph of a function”. Others express their conflict by saying that “the parabola seems like an algebraic entity that sometimes makes problems” or “it is time for us to recognize the fact that we, as teachers, also perceive the parabola as a graph of a quadratic function”. The preservice teachers justified their poor performances by saying “we didn’t learn that subject” or “our teachers didn’t discussed the subject with us”. Those “excuses” are supporting the research findings, since teachers that do not posses a full concept image cannot convey it to their students.

The second task

Table 2 shows that both groups had great difficulties in sketching a proper Venn-Diagram. 57.15% of the inservice and 39.39% of the preservice teachers did not even sketch any diagram. We believe that coping with that task caused them a certain conflict or embracement, and therefore they have chosen not to expose their lack of knowledge, though the responses were all anonymous.

Sketching a Venn-Diagram requires the ability to identify logical links between concepts. Unless one possesses a full concept image he or she would not be able to sketch that diagram correctly. Relying solely on the analysis of the first task we could have wrongly deduced that a large portion of the preservice and inservice teachers (38.64%/48.81% respectively, as seen from table 1) held a full concept image
regarding the concept of parabola. The results described in table 2 point out to the fact that only 1 (3%) preservice and 2 (9.5%) inservice teachers had succeeded in sketching a proper diagram. We can confidently declare that all the participants were acquainted with Venn-Diagrams, since while they were asked to sketch a diagram describing the set of quadrilaterals all the participants could easily do this. Thus it can be concluded that the demonstrated difficulties can be attributed only to their deficiencies regarding the concept image of the parabola. One of the inservice teachers summarized that difficulty as follows: “it was hard to tell what drags what, since they all designate parabolas, they are all the same. It is just a matter of locating the axis correctly”.

How can the wide gap between the levels of the participants’ performance in both tasks be interpreted? As we know, definition no. 1 is compatible for every parabola, while the other three definitions describe only subsets of the set of parabolas. In addition, definition no. 1 forms a geometrical condition while the others form algebraic ones. Naturally, while one deals with a specific concept, he or she may use the possessed concept image and concept definition regarding that concept. While considering the concept of parabola the situation is slightly more complicated. One can consider it either from a geometrical point of view or from the algebraic one without identifying links between them. Thus, it is not always possible to decide whether one possesses a full concept image or not only by examining the interpretation he or she gives to each definition separately. Doing that might produce insufficient evidence. The concept of parabola cannot be fully understood unless the learner identifies links between the two concept images and associate them under the same cognitive structure. Creating the links between the two concept images is an action one has to perform in his or her mind. This analysis leads us to complete our discussion using the A.P.O. theory (Dubinsky & Lewin 1986). According to that theory the acquisition of an insight regarding a certain mathematical concept can be characterized by three sequential levels -“action”, “process” and “object”. Conceiving a concept as an action enables one to refer to it only in associate with its definition. Conceiving a concept as a process makes it possible for one to slightly discharge from that conjunction. At the advanced level one perceives the concept as an object and thus he or she is capable of performing manipulations on it. Producing the mentioned links is such a manipulation. Its performance is possible only as a part of one’s ability to perceive the concept of parabola in both contexts (algebraic and geometrical) as an object. Performing the second task successfully demands the possession of a wide concept image, one that integrates both aspects (the geometrical and the algebraic) of the parabola.

Finally, we would like to highlight the strength of using Venn-diagrams as a tool for identifying weather one conceives a certain mathematical concept in a high level or not. While sketching a Venn-Diagram it is necessary to relate to the concept images as objects and to perform manipulations upon them. The extent of which one can
successfully build a Venn-Diagram can be used as an indication to the level in which he or she perceives the concept.

CONCLUSIONS

From our study it is clear that inservice and preservice teachers do not possess a full concept image regarding the concept of parabola. Other studies (e.g. Hershkowitz, 1989, Gutiérrez & Jaime, 1999, Stump, 1999) had shown that they also do not possess full concept images regarding other concepts such as the altitude of a triangle or a slope. It seems reasonable to believe that there are plenty of other concepts in which preservice as well as inservice teachers do not possess full concept images. Additionally, we could see from our study that it cannot be assumed that the teachers’ experience would influence their ability to develop full concept images by their own.

As a consequence many doubts should be raised regarding the teachers’ ability to implement the reform’s recommendations.

METHODOLOGICAL PROBLEMS IN ANALYZING DATA FROM A SMALL SCALE STUDY ON THEORETICAL THINKING IN HIGH ACHIEVING LINEAR ALGEBRA STUDENTS

Anna Sierpinska, Alfred Nnadozie
Concordia University

Abstract

The paper gives an outline of a research on theoretical thinking in a group of 14 high achieving linear algebra students. The research was instigated by our hypothesis that one of the reasons why, even in the most 'friendly' environment, students' understanding departs in many ways from the theory is that students try to grasp the theory with a practical rather than theoretical mind. We were interested in knowing if the highly successful students in linear algebra, i.e., those most likely to have a 'good understanding' of the basic linear algebra concepts, indeed think in ways that can be characterized as strongly theoretical. The paper proposes a characterization of theoretical thinking and discusses certain quantitative methods of analyzing the students' mathematical behavior in an interview based on mathematical and epistemological questions.

Introduction: the research question

Our purpose in this paper is to briefly outline our recent research focused on theoretical thinking in a group of high achieving linear algebra students and point to some questions related to the methodology of this research.

Our research was instigated by the need we felt to refine our hypothesis that one of the main reasons why certain students' understanding of linear algebra substantially differs from the theory is that these students try to grasp the theory with a practical rather than theoretical mind (Sierpinska 2000). Taking the contrapositive form of our hypothesis, and assuming that highly successful students in linear algebra are likely to have a 'good understanding' of the basic linear algebra concepts, we asked ourselves if the thinking of these students could be characterized as 'strongly theoretical'.

The research of this question called for (a) a definition of theoretical as opposed to practical thinking on which our judgment of students' mathematical behavior could be based; (b) a research instrument capable of externalizing students' thinking in some observable form; (c) analytical means for the clarification of what we meant by 'strong' or 'weak' theoretical thinking tendency in a student or a group of students.

Research procedures

We interviewed 14 students who obtained A grades in the first university linear algebra course (vector spaces and linear transformations). Twelve of these students took the second linear algebra course (Jordan canonical forms and inner product spaces), and 6 of those obtained A grades also in the second course.
Our interview was aimed at revealing what we considered, at that time, the features of theoretical thinking in the students. However, our analysis of the students' responses led us to refine our definition of theoretical thinking, and eventually we found ourselves analyzing the students' behavior against a set of criteria that was slightly different from the one that guided us in the design of the interview.

The interviews were audio-recorded and transcribed. For each student, a 'story' was then written of his or her mathematical behavior, highlighting behaviors that would attest to the theoretical or practical features of the student's thinking. These stories were revised several times, as our definition of theoretical thinking was refined. A third step was the question-by-question description of the students' behavior, first individually and then as a group. The fourth step was to dress a 'profile' of the theoretical thinking in the group of students, from the features that were the most strongly represented in the group to those that were the weakest.

**Theoretical framework: a definition of theoretical thinking**

Mathematics education has always been concerned with theoretical thinking in its various aspects and forms. However, there has been a renewed interest in this kind of thinking in the past years (e.g., Steinbring 1991; Boero, Pedemonte, Robotti 1997). Boero et al.'s definition of theoretical knowledge was inspired by Vygotski's distinction between scientific and everyday concepts.

So was, at the beginning, also our definition. However, the concept could be derived from such classics as Aristotle, and his epistemological categories of empirical knowledge, art, craft, productive science, and theoretical science. 'Theoretical science' aims at the development of wisdom or 'knowledge of certain principles and causes' (*Metaphysics*, Book I (A), 982a). Aristotle proposed that the motor of theoretical science is the need to know for the sake of knowing rather than knowing for the purpose of carrying out some other action (ibid., 983a). In recent mathematics education research, Steinbring's work (ibid.) refined this feature, postulating the 'self-referential' character of theoretical knowledge.

Inspired by, among others, these ideas, we assumed that theoretical thinking is a voluntary mental activity which is 'self-serving' or thinking for the sake of thinking, goal-directed, and 'self-referential' or seeking meaning and validity within itself. To support its self-referential character, theoretical thinking is *analytical* and *systemic*, i.e., it distances itself from experience by filtering it through languages and conceptual systems, which it invents and uses as tools, as well as studies as objects in their own right. Aware of the existence of these 'filters', theoretical thinking has no aspiration to certainty. It considers its claims as *hypothetical* and tries to make their assumptions as explicit as possible. Rejecting any a priori assumptions about what is plausible or realistic, it aims at identifying and discussing all possible cases and implications within a system. It is concerned with the problems of *validation* of its claims. In particular, it *questions the scientific procedures* that may have become routine in solving certain type of
problems and invents alternative methodologies of research and validation. The motor of such investigations is *wonderment, and doubt* about the existing explanations, irrespective of any practical use that the obtained answers may have.

The scope of this paper does not allow us to include a justification of the relevance of the above mentioned features of thinking for the learning of linear algebra, but this justification constituted an important part of our a priori analysis of the project.

For the purposes of our analysis of the students' behavior we codified the assumed features of theoretical thinking (TT), as follows:

1. **TT is reflective**, i.e., TT1.1 self-serving, TT1.2 self referential, TT1.3 voluntary
2. **TT is analytic**, i.e., TT2.1 mediated through language which is both an object of reflection and invention; TT2.2 aware of the conventional/symbolic character of language and mathematical notations and graphical representations in particular; TT2.3 aware of the possibility of inventing/designing an artificial language; TT2.4 sensitive to syntax and mathematical syntax in particular, and especially to the quantification of variables; TT2.5 sensitive to the logical rules of drawing conclusions and negating statements.
3. **TT is systemic**, i.e., TT3.1 relational; TT3.2 has a definitional approach to meanings; TT3.3 has a systemic approach to validation; TT3.4 uses systemic categorization (see Bruner, Goodnow & Austin, 1960, p. 5-6).
4. **TT is hypothetical**, i.e. TT4.1 is aware of the conditional character of mathematical statements; TT4.2 is concerned not only with the plausible or the realistic but also with the hypothetically possible; TT4.3 believes in the relativity of truth.
5. **TT is concerned about validation**, i.e., TT5.1 is fuelled by doubt and uncertainty and hence considers validation as an important problem; TT5.2 considers proofs in mathematics as necessary for the establishment of knowledge
6. **TT has a critical attitude towards standard procedures**, i.e., it problematizes procedures and underlying concepts, does not take them for granted and does not accept them just because they have a stamp of authority.

*The research instrument: the interview questions*

There were seven questions in the interview. Question 1 asked the students to classify a set of 5 algebraic expressions into at least two groups according to their own criteria. Question 2 asked the students to comment on a flawed definition of linear independence of vectors. Question 3 cited a test question in which typographical mistakes were made: *Let u, v, and w be vectors in a vector space V over R. Show that the vectors u - v, u - w, and v + w are linearly dependent.* The students were asked to describe how they would approach the problem and then carry out their plan. They were expected to notice the flawed formulation and propose a correction. In Question 4 the students were shown two graphs in log-log base 2 scales, both looking like straight lines and asked if they think that these graphs represent linear functions. One of the graphs could represent a linear
function and the other could not. In Question 5 the students were given 5 statements about a certain class of numbers called 'brillig numbers' (odd prime + 2) and asked to pick one they would consider as best suited for (a) a definition, (b) an explanation. They were also asked to tell if another statement about these numbers was true or false and to comment on whether they found these numbers interesting. In Question 6 a four-element set was given, T = {1, 2, 3, 4} in which an operation called 'vorpal' was defined by a Cayley table (the rows were: [[1,1,4,1], [2,2,2,4], [3,3,1,1], [4,4,4,3]]. The students were asked several questions about this operation; in particular, if the operation has a right (left) hand zero element. They were asked also if it is possible to define an operation in the set T with distinct left and right hand zero elements. Question 7 aimed at identifying the high achieving students' epistemological profile, i.e. their declared attitudes towards the basic epistemological questions related to the nature of scientific truth, the ways of arriving at scientific truth, and the ways of validating scientific statements.

**Analysis of the interviews**

In this report we shall focus on the third and fourth steps of our analysis and the encountered methodological problems.

We found it necessary to represent the TT features, as formulated in our definition, by features of the students' behavior in responding to the interview questions. For example, the feature TT2.5, i.e. sensitivity to the logical rules of drawing conclusions and negating statement) was assumed to underlie three kinds of behavior, which we called 'theoretical behavior' and labeled 'TB':

TB2.5a : Analytic-logical sensitivity to logical connectives - in the 'Linear dependence typo' and 'Vorpal' questions, the theoretically thinking student would correctly use and negate the connectives 'and', 'or' and 'if ... then'.

TB2.5b : Analytic-logical sensitivity to circularity in reasoning - in deciding whether the graphs in the 'log-log scales' question represent linear functions, the theoretically thinking student would not assume that the functions are given by equations of the form $y = mx + b$ and then try to prove that the graphs represent linear functions.

TB2.5c : Analytic-logical sensitivity to implications - in the 'Brillig numbers' question, the theoretically thinking student would distinguish between a statement with the necessary and sufficient conditions for a brillig number and a statement with only a necessary condition.

This analysis led us to a list of 33 TB features. We represented our analysis of the students' responses in two tables: the Question-by-question table (Q-b-Q) and the Feature-by-Feature table (F-b-F). In Q-b-Q, each question had a rubric, in which we collected information about how the students behaved on the features assumed to be revealed in this question. The behavior of a student with respect to a TB feature was coded as a vector $[a, b]$, where $a$ and $b$ could be either 1 or 0. The vector $tt = [1, 0]$ represented the fact that the student's behavior consistently had the TB feature; $pt = [0, 1]$ - consistently the PB feature or the practical opposite of the TB feature, $tt & pt = [1, 1]$ - a mixture of TB and PB features, and $\emptyset = [0, 0]$ was assigned whenever there was no evidence of either. The behavior of an individual
student through the whole question was then represented by a coordinate-wise sum of the vectors obtained for each feature observed in the question: a vector \([x, y]\). In order to have a measure allowing to compare the individual students' behavior on a particular question, we used the number \(\frac{x}{x+y} \times 100\%\) which we denoted by itt\%. This number was not defined if both \(x\) and \(y\) were 0, i.e. if there was no evidence of any of the TB features in the behavior of the given student in the question. Had such case occurred, we would have discarded the data about the student, or about the question, from the study. Such case had not occurred, however. In Q-b-Q, for each TB feature in a question we calculated also a group index. The students' names were listed in a column. The individual student's itt\% on a question was calculated by adding the vectors in the rows of the table. The group index for each TB feature in the question was computed, similarly as itt\%, but applied to the vectors in the columns of the table: if the sum of the vectors in the column was \([x, y]\), then gtt\% = \(\frac{x}{x+y} \times 100\%\). The gtt\% for the whole question was computed by adding the summative vectors for individual students. The indeterminate case of \(x=y=0\) could not occur because we considered only those TB features for which there was some evidence in the group.

One could ask why not describe the group's behavior with respect to a TB feature just by counting the students in the tt, pt, tt&pt and o categories. For example, for the feature TB2.4c (Sensitivity to the form of definitions), these numbers were, respectively, 9, 4, 1, 0. For the feature TB3.2c (Definitional approach to meanings in a graphical context) they were 7, 0, 7, 0. We could say that there were less students in the tt category for TB3.2c than for TB2.4c, but we would not be able to compare the strengths of the features on just this basis, especially that there were less students in the pt category in the latter feature than in the former. On the other hand, using the gtt\% indices for the features did give us some ground for comparison. For both features, gtt\% = 67\%, so we could say that they were equally strongly represented in the group.

To illustrate the way we computed the itt\% and gtt\% indiced in Q-b-Q we include the results from the 'Classification' question (Table 1). As only three features were observed in this Question, the table fits within the frame of this short paper.

In our analysis, we formulated interpretations of the outcomes of our computations. Here is a sample of such commentary:

In Question 1, most students were not thinking of letters in algebraic expressions as names for concrete objects in concrete contexts: the group, as a whole, had a rather good analytic-representational approach to variables in linear algebra (71\%). The students in the group were nearly as likely as not to be systemic in tasks of classification (65\%). The group's sensitivity to the syntax of mathematical expressions was low (38\%).

In trying to grasp the students' theoretical behavior in the whole interview using Q-b-Q, we decided not to sum up the horizontal scores and then use an index similar to itt\%, because such counting could privilege those TB features that were observable in more than one question over those that could be seen in one question only. A better statistic was, we thought, the average of the itt\% obtained by a
student in the seven questions. The list of average itt% for the students in the same
order as in the table was [37, 36, 84, 50, 72, 67, 70, 56, 87, 62, 67, 70, 57, 74].

Table 1: The Question 1 part of the Q-b-Q table.

The rubrics of F-b-F table organized along the TB features. If a feature was
observable in several questions, it was counted only once. This analysis treated
the interview as a whole, not as a set of questions. In this case, we thought it
reasonable to compute the summative itt% index, adding the vectors horizontally.
The list of summative itt% scores for the students was [45, 45, 84, 53, 76, 75, 62,
57, 86, 60, 74, 64, 56, 74]. Knowing the grades in the second course of the 12
students' who took both courses ([70, 50, 90, 63, 70, 85, 80, 60, -,-, 85, 77, 90,
85]), we could compute the correlation between these grades and the two lists of
itt% scores, i.e., the average itt% from Q-b-Q and the summative itt% from F-b-F.
The correlation was 0.71 in the former case and 0.67 in the latter. While both were
quite high, it appeared that the average itt% from Q-b-Q was a better predictor of a
student's success in the second linear algebra course. A question for us was why it
would be so. We thought that perhaps the reason was that the Q-b-Q results were
structurally similar to the results of a test, where the students' performance is also
evaluated on a question-by-question basis.
The analysis in F-b-F served different purposes in our study. This table appeared to give a better picture of the students as a group, independently of their individual successes in the courses. It allowed ranking the features from the strongest to the weakest and raising questions concerning the instruction in the courses. If a TT feature was weakly represented in the group it may mean that it is not a necessary condition for the success in the course. The question is, however, if this feature can be considered as negligible from the point of view of educational objectives and values.

Taking the averages of the gtt% indices obtained for the categories of 'reflective', 'analytic', 'systemic', 'hypothetical', 'concern with validation' and 'critical' features of TT, we obtained the following ranking. The strongest feature in the whole group of students was systemic thinking (gtt% = 74%). This feature was even stronger in the group of the 6 students who achieved As in both courses (80%). Next best in the whole group was reflective thinking (72%), but the high achievers in both courses scored only 67% on reflectiveness. This implied, in particular, that these students were approaching problems more as students, trying to be effective in producing a solution that would satisfy the interviewers, than as theoretical thinkers whose aim would be to understand the problem and its implications for the sake of knowing alone. The next ranking feature in the high achievers in both courses was the concern for validation and a spontaneous need for proof (76%, compared to 65% for the whole group). Analytic thinking was also quite strongly represented in this subgroup (73%, compared to 66% for the whole group). Next came the critical approach to procedures (67%, compared to 59% for the whole group), and reflectiveness was the weakest, as mentioned above.

The question of the necessary conditions of high achievement led us to taking into account not only the itt% and gtt% indices but also the numbers of students in the tt, pt and tt&pt categories. If, for a given TB feature, one or more of the high achievers in both courses scored pt = [0,1], would this mean that the feature is unnecessary for high achievement? There were 11 such features. However, in many of these features, there was only one student in the pt category or (boolean 'or') the gtt% index was high. Perhaps only those features should be considered as unnecessary for the high achievement for which the number of students in the pt category was more than 3 and the gtt% was low? In this case there would be only two such unnecessary features: (a) approaching a problem not just as a student seeking to produce an acceptable solution, but with the goal of understanding the problem as part of a domain of knowledge; (b) being sensitive to mathematical terminology and trying to be articulate in formulating and communicating ideas. Ironically, these two features are perhaps those about which we care the most as mathematics educators.
Questions for further research

The quantitative approach we used in our research raises many questions. One of them is: would the ranking of the theoretical thinking features in the group of students be different if a different index of the strength of a feature was used? Indeed, if we look at the numbers of students in the tt, pt, tt&pt, and φ categories and apply a method of 'implicative analysis' suggested in the work of Gras (1992) then a slightly different ranking is obtained. Which of these rankings better reflects the theoretical tendencies in the group? Which one should we trust more? But, even more fundamentally, to what extent can we trust the outcome of any one of these methods in view of the fact that the assignment of the tt, pt, tt&pt, and φ vectors to individual students was based on our subjective interpretation of their behavior? These and similar questions led us to a certain skepticism about the relevance of statistical analyses in the domain of advanced mathematical thinking. We recognized, however, that, without the moderate quantitative approach that we used in our research, all we could do would be to tell 14 x 7 fascinating stories about the 14 students' behavior on the 7 questions, flavored perhaps with epistemological and historical reflection. But maybe these stories could have a bigger impact on our teaching of linear algebra than the dry numerical data? The question remains open: What is the relevance of each type of research?

The aesthetic is relevant

Nathalie Sinclair
Queen's University, Kingston, ON

Many would agree that we need to make more mathematics relevant and interesting to students, yet most recommendations for increased relevance have ignored the aesthetic dimension of student interest and cognition. In this paper, I argue that the aesthetic dimension plays a central role in determining what mathematics is personally or epistemologically relevant to children. I present an example of a learning environment that attempts to explore this dimension—both mathematically and pedagogically—and then briefly describe a small study that examined the responses of middle school students to this environment.

Recently, researchers have argued that all human abstract thinking is metaphorical, based on our sensory-motor experiences (Lakoff and Johnson, 1999) and that humans possess an innate aesthetic sensibility that acts as one of our primary meaning-making capacities (Dissanakye, 1992; Wilson, 1998). This conception of aesthetics is not limited to the formal, detached, and objective judgements of beauty and elegance. Rather, an aesthetic response is a cognisance of fit, of structure or order, perceived in part as being intuitive and recognised at an emotional level as being pleasurable. It is reflective in the sense of resulting from an awareness of the perceiver in relation to the environment. The role of the aesthetic in mathematics has been explored by many mathematicians (e.g. Penrose, 1974; Poincaré, 1956 Tymoczko, 1993). The emerging picture is that aesthetics is involved in: (a) motivating the choice of certain problems to solve; (b) guiding the mathematician to discovery; and (c) helping a mathematician decide on the significance of a certain result (Sinclair, 2000). In a challenge to traditional epistemologies, some researchers have argued that the aesthetic is in fact a mode of cognition used by scientists and mathematicians (Burton, 1999; Papert, 1978; Weschler, 1978). Based on these claims, and more generally on aesthetics’ perceived role in learning (Dewey, 1933; Eisner, 1985), a growing number of educators have argued that aesthetic considerations should be of primary importance in children’s learning of mathematics (e.g. Brown, 1993; Silver 1994; Whitcombe, 1988). However, adequate understandings of how aesthetic considerations play into mathematics learning have yet to be developed.

I propose that aesthetically rich learning environments enable children to wonder, to notice, to imagine alternatives, to appreciate contingencies, and to experience pleasure and pride. They are characterised by two facets; first, they legitimise students’ expressions of innate sensibilities and subjective impressions—they “work with” such perceptions rather than exclude or deny them. Second, they uphold Dewey’s (1933) sense of the fourfold interests of children: communicating, finding things out, making things, and expressing themselves artistically. These dual
facets—of perception and of action—permit children to become absorbed in and identify themselves with some object or idea, to become interested.

I wanted to explore the possibility of creating an aesthetically rich learning environment that would make accessible to middle school students the pattern possibilities of the real numbers and to explore the potential of students' aesthetic engagement with the much abhorred topic of fractions and decimals. I therefore developed an internet-based calculator designed to facilitate the visualisation and manipulation of real numbers.

Description of the Colour Calculator

The Colour Calculator (CC) is a regular calculator that produces numerical results, but that also outputs its results in a colour-coded table. Conventional operations are provided; the division operation allows rational numbers while the square root operator allows irrational numbers. Each digit of the result corresponds to one of ten distinctly coloured swatches in the table, as shown in Figure 1. The calculator operates at a precision of 100 decimals digits, and thus each result represented by a (long) decimal string and an array or matrix of colour swatches. It is also possible to change the dimension, or the width, of colour table.

![Figure 1. The Colour Calculator](image)

In this following screenshot, $\frac{1}{7}$ has been typed into the calculator with the table width set at 20. The associated table of colour has been generated:

![Figure 2. The Colour Calculator outputting $\frac{1}{7}$](image)

1 The calculator is part of a larger project called Alive Maths (on-line at http://math.ai.iit.nrc.ca) which, as an internet-based environment is not only platform independent and freely accessible by students both at school and at home, but allows students to chronicle—in writing and through activity recording—their discoveries and questions on their own personalised web pages. This work was funded by SchoolNet through the National Research Council of Canada.
Using the button that controls the width of the table of colours, the student can create different colour patterns, some which highlight different aspects of the number's period.

![Figure 3. Different tabular representations of $1/7$: widths 18 and 17](image)

I designed the environment with three hypotheses in mind:

1. The pattern-rich table of colours patterns resulting from rational number calculations would surprise and engage the students.

2. The students' sensitivity to visual patterns would prompt and facilitate their sense-making of some characteristics and relationships of rational numbers.

3. The CC would provide a setting in which students could develop more positive relationships with fractions and decimals.

The structure of the CC mathematical environment emphasises two aspects of learning. The first is to encourage students to make sense of mathematical ideas such as fractions, which they often find almost repelling, using some of their aesthetic sensitivities such as symmetry, repetition, rhythm, and pattern. This type of sense-making is part of the cognitive processes that students use to understand the form and meaning of objects and ideas. The second is to facilitate a process—one of exploration, research, and discovery—that potentially gives rise to a chain of sensory and emotive responses (Dewey, 1934). This process is initiated by surprise (or novelty) and ambiguity. It culminates in the grasping of new knowledge that has been experientially developed.

**Methodology**

I conducted structured task-based interviews with 15 middle school students, 8 male and 7 female, of mixed ability (as rated by their regular classroom teacher). The students were all in grade 8, and came from lower to middle class, small town backgrounds. The interviews were task-based in that each student worked through a mathematical task using the CC as I observed and asked questions. They were structured in the sense of my facilitating the problem-posing and problem-solving process for each student. Each interview began with the student reading the instructions for the CC out loud. The student then started on the task while I asked a series of questions designed to elicit some of her thought processes as well as to guide her through the exploration. I occasionally intervened to provide guidance, following a set sequence of prompts that were only given when I judged that the student could no longer progress either in identifying a problem or solving it. The interview continued until the student had concluded at least one exploration; that is, until the student had
resolved one problem. Following this, I asked each student to reflect on their experience, first asking them what they thought about what they had just done, then asking them to compare what they had just done with their other mathematics activities, and finally asking them how they felt about the open-ended nature of the activity. Each interview lasted between 20 and 30 minutes.

The interviews were all audio-taped and then transcribed. In addition, while interviewing, I kept notes of their facial and bodily reactions as they interacted with the environment, particularly at the beginning when they tried their first fraction and also when they were approaching the resolution of their problem.

Findings

I will discuss each of the three hypotheses presented above about how students would interact with the CC environment. At an obvious and almost trivial level, every student expressed that they had never seen fractions or decimals like this, together and with colours—many of them realised for the first time that a fractional and its corresponding decimal are the same\(^2\), one student noting “you never see them together like this.” Every student also expressed how different this type of mathematical activity was from their regular classroom work, one explaining that “you actually have to do things” while another observed that “you have to notice things.”

Of the 15 students I interviewed, thirteen of them showed obvious physical signs of surprise, which they expressed either through one or more of the following actions: widening their eyes, sitting upright or moving forward, making a sound such as “ooh,” or saying some form of “wow.” One student, whom I will call Nadia, showed no physical surprise at all, and answered “I don’t see anything” when I asked her what she saw in the table of colours. Nadia was either completely insensitive to the patterns in the table or, because of her timidity and lack of confidence, she may have been under too great of an affective barrier to even attempt to engage. The other student who showed no physical reaction was Cameron, a very ends-oriented student, who remarked flatly: “there are lots of colours and patterns there.”

Of course, initial surprise is only desirable if its effect is to engage the student in sense-making; that is, if it prompts the student to try to understand something about what they are seeing. This was easiest to observe with the more articulate students who provided a running commentary of their thought processes, like Sean:

Okay. Ah. It looks like an abstract painting. Not exactly like a math problem. I’m trying to figure out how it calculates that. Uh. Well, it says that the results are 0.142857 and it repeats. So this is a repeating pattern. I can see it because the red sticks out and the purple, and ooh the green. They kind of go in a

\(^2\) It is interesting in fact to recall that a regular calculator replaces its input with its output so that a student calculating \(1/7\) on the calculator never actually sees both the fraction \(1/7\) and its decimal expansion simultaneously. Though I am sure that the students think that a fraction and its decimal are equal, they seemed struck by an ontological equivalence.
diagonal which shows a standard repeating pattern but I’m trying to figure out how things are working. So the number corresponds to the colour...

There were a few other students who provided such spontaneous descriptions of their thought processes, but most of the students had to be prompted to share their thoughts and perceptions. All the students quickly made the connection between the table of colours and the colour legend (Figure 1), and between the decimal number and the table of colours. A few of the students failed to see the connection between the fraction and the table of colours, needing some further experimentation to be able to conceive of them as the same number. However, beyond suggesting these obvious relationships, I wanted to know whether the CC environment would produce a generative engagement: for example, would the students wonder why the 1/7 fraction produced the table of colour or why the table showed the patterns it did?

I judged a student to be generatively engaged if, after their initiation to the CC, they made observations or took actions that indicated an emerging question or conjecture. For example, Ann’s observation that “every seventh box is a purple” indicated a conjecture that the period of 1/7 is 6, and was followed by her experimentation with the width of the table (which, perhaps not surprisingly, she first tried at 7 before realising she really wanted 6). Sean’s immediate experimentation with 1/3, then 1/2 indicated an emerging question of how other fractions will contrast with 1/7. Julie took a slightly different approach by experimenting first with the width of the table of colours, describing a width of 7 as “it’s like a staircase” and a width of 3 as “it’s doubled up,” indicating an emerging question about the types of possible patterns. She went on to characterise diagonal patterns as those that were one more or less than the width that makes the colours of the table line up. Four other students each embarked on explorations similar to the three described above.

The other students either paused, waiting for instructions or guidance, or asked me whether I wanted them to make the colours line up (as was suggested in the instructions to the activity). These students, either because of their ends-oriented approach, their lack of confidence, or a lack of interest in the activity, did not quickly become generatively engaged. Four students required some guidance and prompts, as if they needed to know what was interesting or significant enough to pursue. After they had formed a question or conjecture, they were able to experiment and all but one of them added a personal variation to their experimentation. For example, Robert started by following my prompt of figuring out what kinds of numbers are non-terminating, but then decided to investigate what kinds of fractions gave solid tables of colours, discovering that n/9 (for 0 < n < 9) would always give a solid table in the colour corresponding to n.

I now turn to my second hypothesis about whether the students’ sensitivity to visual patterns and engagement would prompt and facilitate their sense-making of some of the characteristics and relationships of rational numbers. There were two types of sense-making exhibited by the students. The first type was around the characteristics and relationships of rational numbers that these students had
encountered or “already learned” in their regular mathematics classes. The second type was around the characteristics and relationships of rational numbers that were new to them, and mediated by the CC environment.

Of course, not all the students made the same inquiries and discoveries; in fact, the wide range of inquiries and discoveries made by the revealed much of the students’ existing understanding of fractions and decimals. Within the first type of sense-making, the majority of the students realised, some to a greater extent than others, that fractions aren’t just the canonical 1/2, 2/3, 3/4, 1/10 numbers they have often encountered during “fraction class,” but that they can have a denominator greater than 10, and that they can even be any integer over any integer, as Steve’s question shows: “You mean I can put any number on the bottom?” Several students also expressed surprise at seeing the fraction and the decimal at the same time—as I mentioned above—and seemed to gain a new understanding of their equivalency, as Alice concluded: “they mean the same number.” Related to this understanding of equivalence, a few of the students became intrigued with trying several equivalent fractions to see what the table of colours would depict, allaying any small doubts they were having that 1/2, 5/10, 20/40 were really the same number. A few of the students were somewhat fluent at the outset with decimals (i.e., knowing that 1/2 is 0.5 and that 1/3 is 0.33...) but most of the students seemed to have very little sense of which decimal would result from a given fraction, even with fractions whose denominators were multiples of 10. This is perhaps due to the situatedness of their fraction-decimal knowledge in classroom worksheets but it would be interesting to see what impact their brief exposure to fraction-decimal pairs has on their future classroom work with fractions and decimals. These findings highlight some of the basic conceptions with respect to fractions and decimals that students rarely have a chance to develop, yet that are almost assumed to be part of their ability to operate on fractions, convert them, and estimate them.

I now turn to sense-making of the second type. Since many of the students experimented with changing the width of the table, they were able to see what the period of a fraction is, how long the period of 1/7 is, and how any multiple of the period of the fraction makes the colours in the table line up. These are not typically the kind of rational number characteristics and relationships taught in school curricula, but are ones that were both accessible and interesting for this group of students in the CC environment. Other than making these common realisations, the students embarked on quite individual investigations. The different investigations were entirely student generated in that I only proposed questions during the interviews that had already been posed by other students in this study. Here is an incomplete list of the topics explored by the students, to various degrees of generality: What values of the width of the table would create diagonal patterns? What values of the denominator yield non-terminating decimals? What values yield terminating decimals? How is the period of the fraction related to its denominator? When does the decimal only start repeating after a certain point? What kinds of numbers neither terminate nor repeat? How can you get a solid
red (or blue or green) table of colour? What is the effect when you square a fraction that has a certain period?

This environment certainly prompted the students to make new understandings of fractions and decimals and in particular, to explore characteristics and relationships they are not usually encouraged to explore. The CC environment highlighted some of the incomplete fraction and decimal understanding that students have and allowed them to gain a new understanding of what a fraction is, as opposed to what you can do to fractions—add them, generate equivalent ones, etc. Additionally, the CC appears to be an environment in which students are interested and motivated to discover certain things about numbers, using fractions and decimals, that are different than what is emphasised in current school curricula. The ideas explored by these students are not easier than the ones we typically emphasise, but, in this CC environment, they are perhaps more relevant to students’ personal and epistemological interests.

This brings me to my third hypothesis, of whether the CC would provide a setting in which students could develop a more positive relationship with fractions and decimals. The only data I collected that is useful in verifying this hypothesis is the students’ reflections at the end of their interviews. In these reflections, I asked them how they compared what they had just done with their usual mathematics activities. I found it difficult to determine the cause of their unanimous beliefs that this environment provided them with a more positive experience. Comments such as it’s “fun because you can work with patterns,” or “good because it helps you out more,” or “creative because you can make patterns” or “fun because you don’t just have to look at numbers” suggest that the colourful patterns were enjoyable but do not ascertain whether the students have a different relationship with fractions and decimals now than they did before. Some students may also have had positive experiences just because they like working on the computer or because they like having an adult’s attention and help. And still, for others, the fact that they weren’t set up for failure at the outset (as often is the case in mathematics class) may have made their experiences more enjoyable. That this third hypothesis remains unclearly substantiated is due both to the paucity of data in this particular study and partly to the methodological challenges of assessing students’ emotional responses.

Conclusions

A majority of the 15 students called upon their aesthetic modes of cognition to explore and make sense of the visual patterns depicted by the CC. An even larger majority of the students initially became engaged either through surprise, novelty, or perceptual attraction, prompting them into a varying degree of sophisticated mathematical meaning making about fractions and decimals. These are promising findings given that each student had less than half an hour to interact with this aesthetically rich learning environment.
References

This paper has two main parts. First it describes some recent trends in research on mathematics teachers (sections 2 and 3). One trend concerns the development of relatively concrete pieces of methodological advice; another is to re-conceptualise the mathematical knowledge that teachers need. Both these trends are based on analyses of school mathematics and of classroom interactions. Second, I present a study of three novice teachers (section 4). One conclusion of this study is that the teachers’ activity is often directed at broader educational motives than facilitating the students’ learning. Therefore the efforts at redefining relevant mathematical qualifications for teachers should not be pursued at the expense of general pedagogical emphases in teacher education. Rather there is a need to ground both general pedagogical perspectives, pedagogical subject matter knowledge and mathematical qualifications in analyses of classroom practice.

1: AN EXTENDED VIEW OF TEACHING PRACTICE

Current initiatives in mathematics education present the teacher with very different challenges in comparison with 20 years ago. I have previously argued that the role of the teacher in reform classrooms - inspired by fallibilism, constructivism, and socio-cultural theory - may be summarised as one of forced autonomy (Skott, 2000): The teacher is required to manoeuvre autonomously and independently in order to support individual students and to orchestrate small-group and whole class discourse so as to facilitate individual and collective conceptual development by balancing communal involvement in processes of for instance experimenting, conjecturing, reasoning, generalising, formalising, and refuting with more traditional teaching-learning processes. In this sense the teacher has been recognised to move to centre stage of curriculum enactment and is expected to become involved in instantaneous decision-making on the basis of his or her reflective activity. For instance (s)he is required to

- develop and flexibly use a wide range of experientially and mathematically rich tasks and contexts, some of which have open beginnings and/or open ends;
- to interpret the students’ current understanding and potentials for learning and to decide on the types of support needed by individuals and groups of students;
- consider when and how to introduce small-group interaction, either to provoke individual cognitive disequilibria through social interaction or to pave the way for the creation of small communities of mathematical practice;
- capitalise on students’ contributions to the discourse by instantaneously evaluating their pedagogical and mathematical potential and if appropriate to involve the rest of the class to become involved in developing taken-as-shared concepts, procedures, and meta-mathematical understandings.

The majority of the teacher decisions corresponding to these requirements cannot be made de-contextually in more than very general terms. Consequently the domain of on-the-spot teacher decision making has expanded and the notion of teaching practice is extended beyond the teaching methods in the narrow sense of the term, i.e. beyond the set of observable teacher actions.
The recognition that many of the most important educational decisions have to be made by the teacher in the classroom seems to be one reason why - until recently - the literature has remained remarkably silent with regard to methodological advice: If the specific interactions between teacher and student(s) are essential to the types social or cognitive of support required, any attempt to provide a general set of suggestions for classroom teaching may be in vain. As a consequence the recommendations for teachers have in practice often degenerated into a caricature of what they are expected not to do (use whole class approaches, stand at the board, use routine tasks, etc.). Instead the situation of forced autonomy and the inherent emphasis on teachers' reflective activity has fuelled a large amount of belief research, that has focussed on their meta-mathematical conceptions and views of the teaching-learning process. One rationale behind this latter approach seems to be that the teachers' views of mathematics and of the teaching-learning process plays a fundamental role for the ways in which they cope with the extended conception of teaching practice (e.g. Schoenfeld (1992); Ernest (1989)).

2: THE DEMANDS OF FA: A METHODOLOGICAL PERSPECTIVE

Over the last few years the lack of recommendations on how to cope with classroom interactions has to some extent been remedied, and a number attempts have been made to indicate how teachers may proactively support student learning in ways that comply with the views of mathematics and learning that dominate the reform.

Cobb, Boufi, McClain, and Whitenack (1997) described how the teacher's introduction of symbolic records of the students' suggestions provides him or her with opportunities to provoke a collective meta-cognitive shift taking the students' previous activities as objects of the continued discourse. In doing so the teacher supported individual students' learning, facilitated the development of taken-as-shared concepts and at the same time contributed to the emergence of a meta-mathematical conceptions and norms for action compatible with the reform.

Chazan and Ball (1999) challenged the understanding that teachers' non-interference is the most dominant feature of reformist teaching. They suggested that teacher reflections on the mathematical value of the topic in question in relation to the students' future learning, the direction and momentum of the discourse, and the social and emotional tone of the classroom form the basis for decisions of for instance inserting disagreements in order to create a productive learning environment.

Stephan (2000), using Toulmin's model of argumentation, argued that the teacher should elicit warrants and backings from the students in order that they substantiate their initial claims. Stephan suggests that profound taken-as-shared mathematical understandings may emerge as a consequence, while reform oriented visions of mathematics and of its teaching and learning is maintained.

Skott (2000) suggests to explore the potential of intentional methodological discontinuities (IMDs) as a way of coping with situations in which the intended mathematical focal point of a classroom interaction is discarded, for instance as a
funnelling type of interaction emerges. IMDs require the teacher to play an active part in the classroom discourse by breaking with the dominant methodological and organisational framework of the situation in question, and by doing so to ensure a continued emphasis on its potential for student learning.

It is a common feature of these suggestions that they highlight and specify the teacher’s role in mathematically qualifying the classroom discourse. In other words, they are all based on the assumption that the teacher’s activity in terms of support of the students’ individual and collective mathematical learning is essential, and that even though teaching requires competent, on-the-spot decision-making some methodological recommendations are needed that facilitate it. In this sense the suggestions mentioned may be seen as attempts to present relatively concrete pieces of methodological advice that are in line with the meta-mathematical priorities and the approaches to learning that dominate the reform. The suggestions do obviously not relieve the teacher from the obligations of forced autonomy, i.e. from becoming involved in the types reflective activities described above. It cannot be decided de-contextually when and how to introduce a meta-cognitive shift, insert a disagreement, call for a backing to an argument, or propose a methodological discontinuity. The teacher has to make these decisions based on the specific set of interactions in the classroom in question. But the recommendation to consider doing so is in itself a relative concretisation of the reform’s demands, as it introduces possible focal points for the teacher’s reflective activity.

These suggestions for practice, then, share two characteristics. First, they recommend teacher activities that are methodologically oriented, but based on the set of meta-mathematical understandings and conceptions of learning that frame the reform. Second, they do not do away with the teacher’s obligations in a situation of forced autonomy, but they may assist him or her in handling these obligations more competently and with greater ease or deeper comprehension.

3: A MATHEMATICAL PERSPECTIVE ON TEACHERS’ COMPETENCE

Recently a few publications have emerged that address the issue of the mathematical qualifications required, if the teacher is to play role of flexibly supporting student learning. These studies, then, view teaching competence from the perspective of the teachers’ subject matter knowledge.

Ma’s (1999) study, at first sight a comparison between the qualifications of American and Chinese teachers, convincingly argues that teachers at the elementary levels need profound understanding of fundamental mathematics (PUFM). PUFM is more than conceptual understanding of the topic in question. The teacher must also be aware and make use of connections between different concepts and procedures in different domains of mathematics both at a given educational level and in a longitudinal sense; (s)he should be able to use multiple perspectives on a mathematical domain and various approaches to the solution of a problem; and (s)he should guide students’ mathematical activity by use of basic but powerful mathematical concepts and
principles. The essence of the argument is that one of the most significant obstacles to substantial mathematical learning on the part of the students is poor understanding of school mathematics on the part of the teacher. The teacher, then, needs profound understanding of fundamental mathematics rather than superficial acquaintance with more advanced mathematical topics, in order to facilitate significant student learning.

In a somewhat similar sense Ball and Bass (2000) focus on the mathematical qualifications of the teachers and challenge the idea that the main teacher related obstacle to reformist classroom practices is pedagogical or meta-mathematical. Using a terminology that acknowledges the challenges of forced autonomy, they claim that:

"... teachers need mathematical knowledge that equip them to navigate these complex mathematical transactions flexibly and sensitively with diverse students in different lessons" (p. 94)

Their argument is that the divides between teaching methods, mathematical qualifications and teaching practice, institutionalised in most teacher education programmes, need to be bridged, and that this may be achieved by "grounding the problem of teachers’ content preparation in problems and sites of practice" (p. 101). When doing so they also build on the research on what Shulman (1986, 1987) has called pedagogical content knowledge. Pedagogical content knowledge is "that special amalgam of content and pedagogy that is uniquely the province of teachers" (Shulman (1987), p. 8), "... the ways of representing and formulating the subject that make it comprehensible to others" (Shulman (1986), p. 9). However, Ball and Bass argue that this type of knowledge does not suffice as a basis for the teacher’s instantaneous decision making. What the teacher needs, they claim, is

"a kind of mathematical understanding that is pedagogically useful and ready, not bundled in advance with other considerations of students or learning or pedagogy" (p. 88)

Both Ma and Ball & Bass, then, point to the teacher’s mathematical qualifications as the main obstacle to the enactment of reformist intentions in mathematics classrooms, and attempt to redefine the required qualifications. They do so on the basis of investigations of teacher competence related to school mathematics and of an analysis of what it may take in terms of teacher qualifications for the conceived potentials for student learning to materialise. In other words, the argument is that significant student learning requires teacher qualifications in mathematics, that must be defined not with reference to mathematics in its own right, but to the contents and envisaged interactions of mathematics classrooms at school level. This may be interpreted as compatible with the methodological recommendations described in the previous paragraph as it specifies the types of mathematical qualifications required for the teacher to successfully employ the types of teaching methods suggested: the metacognitive shifts, mathematical disagreements, the warrants and backings and the methodological discontinuities. In short, these studies present a long-needed reversal of a dominant approach to teaching competence. This tradition asks what it takes to transform a set of mathematical ideas (concepts, procedures, conceptions) based in traditional college or university courses to classroom practice. The two studies referred here start with a perspective on school mathematics and on classroom
practice. They then use this perspective as a basis to redefine the mathematical qualifications for teachers that are deemed necessary for the realisation of the reform, for instance as conceived in the methodological recommendations described in the previous paragraph.

However in doing so the two studies disregard the need to integrate a general pedagogical perspective in the mathematical qualifications of the teachers. In the remaining part of this paper I shall argue that by doing so they in effect endanger the enactment of the very reform initiatives they seem to pursue.

4: INCLUDING A PEDAGOGICAL PERSPECTIVE ON TEACHING COMPETENCE

The study described in this section aimed to understand how novice teachers deal with the situation of forced autonomy. The study followed three teachers for 2 to 3 weeks each. The teachers were selected because they presented strongly reformist priorities of school mathematics both in a questionnaire before and in research interviews after their graduation from college. They all described the students’ activity in terms of investigations and experimentation; they conceived mathematics as a way of approaching and posing problems; and they presented their visions of teaching in terms that reflected intentions of being unobtrusively supportive in relation to student learning. In short, the school mathematical priorities of these teachers were strongly inspired by the reform, and they all seemed confident to take on the responsibilities inherent in the extended notion of teaching practice (section 1).

The teachers’ classrooms were videotaped and if possible I had an informal discussion with them after each lesson, asking a few questions based on my field notes. Also a final interview was conducted with each teacher, and he was asked to comment on a number of clips from the video recordings. These clips were selected in order to exemplify situations in which the teacher’s role appeared to be crucial for the further development of the classroom interactions and for the learning potential.

In the case of all three teachers the classroom interactions often developed in ways that resembled their school mathematical priorities. For instance, they frequently invited the students to explore open problems - often using manipulatives - and to present their own hypotheses for further investigation. In some cases the continued investigations would be the responsibility of a one or a few students, while in others the teacher would attempt to involve the whole class in it. Also the teachers all tried to support student learning by asking them to explain and reword their current understandings and by taking these understandings as the starting point for their own contributions to the interaction. When doing so the teachers generally used everyday language when discussing new concepts and procedures and only later introduced standard mathematical terminology that in turn was used to focus the students’ attention on particularly important aspects of the concepts in question.

However, there were also episodes in which the classroom interactions were at odds with the teachers’ professed school mathematical priorities. In some of these the teachers’ themselves referred to mathematical insecurity on their part as the main
reason why the interaction developed the way it did. For example one of the teachers, Larry, - after having been shown an episode from his grade 5 classroom - explained why he in effect avoided pursuing an idea developed by one of his students:

“For one thing I hadn’t considered the question beforehand, and if I am to pursue something like this at the instant, I at least have to have some idea about where I want to go, and if I’m too much in doubt about the direction, if I haven’t understood it properly myself, it becomes difficult to convey it to the children.” (From the final interview with Larry).

There were, though, also a number of episodes in which the learning opportunities were strongly inhibited by the Larry’s contributions to the interactions, but in which mathematical insecurity did not appear to be the main reason. For instance Larry, who teaches at a very conservative private school, often struggled to reconcile his own educational priorities and those of the school. In particular he often referred to school’s emphasis on covering the syllabus and preparing for the next test as incompatible with his own intentions. At other times the classroom interactions and Larry’s comments on them indicated that his contributions to the discourse were directed primarily towards manifesting his own professional authority rather than to facilitating the students’ mathematical learning. In these situations he became very direct in his explanations and at times took over the students’ suggestions.

Christopher, a 28-year-old teacher working at a municipal primary/lower secondary school, was also asked to comment on episodes in which his contributions to the interaction seemed particularly significant, especially when they appeared in dissonance with his explicit images of school mathematics. Also in his case, mathematical insecurity appeared as one reason why he did not always exploit the mathematical potential of students’ questions and comments. However, there seemed to be several other and more frequent such reasons, reasons that - in a sense similar to the situation for Larry - were related to a shift in the motives of his activity: He was sometimes more concerned with building students’ self-confidence by ensuring that they provided an acceptable solution to a textbook task than with supporting their mathematical learning, and in consequence he got involved in funnelling types of interaction that in effect depleted the task in question of its mathematical contents. Also his activity was sometimes primarily directed towards managing the rather noisy classroom in which many different (groups of) students simultaneously asked for his assistance. And - like Larry - he sometimes tried to manifest professional and mathematical authority in ways that seemed counterproductive to student learning.

John, the last teacher in the study, works at small village school with only 120-130 students. Like the others he was asked to comment on episodes in which his school mathematical priorities were challenged. In some of these episodes the interactions with the students developed very much along lines compatible with his expressed views of school mathematics, while in others this was clearly not the case. Describing his reaction in some of the latter ones he says:

“There are some children in here, some of the weak ones, with whom I’ve had to choose [...] especially with Louise, I’ve had to say to myself ‘If only she acquires a system [of how to
solve the tasks], then it doesn’t matter, if I’ve provided her with it, because at least she can follow what goes on'. I’ve chosen that. And she does [follow]. So up to now she is part of the team. She largely makes the same tasks as the rest, although she finds mathematics very difficult.” (From the final interview with John).

John was more concerned that Louise remained part of the classroom community than with providing the types of support he found best suited to facilitate her mathematical learning. In other situations he tried to integrate his support to particular students’ learning with concerns of for instance avoiding to challenge what he conceived as their weak and vulnerable self-perceptions and of taking their family background into consideration. Asked if he ever experienced a conflict between his intentions teaching mathematics and of taking broader educational considerations into account he said:

“No I don’t think so. Because I can’t imagine being a teacher without taking all the other things into account. You know. But that’s my attitude to being a teacher. [...] [these other things] are always part of being a teacher, and I don’t consider it a conflict. It is just another type of professional challenge.” (From the final interview with John).

An important characteristic of the episodes described above is the simultaneous existence of multiple motives of the teacher’s activity. In each of them the teacher’s intention of facilitating mathematical learning is challenged, as the energising element of his activity is changed to for instance complying with the dominant school culture, supporting students’ self-confidence, managing the classroom, or manifesting professional authority. The teacher, then, is often playing a very different game than one of teaching mathematics, and consequently the most dominant obstacle to the enactment of their reformist school mathematical priorities is not insufficient mathematical qualifications on their part.

5. SUMMARY AND CONCLUSIONS

In this paper I have outlined some of the responses on the part of the research community to the pressures on teachers as a result of forced autonomy. One response is to develop of a set of relatively concrete pieces of advice on how to proactively support student learning. Such advice suggests possible focal points for the teacher’s reflective activity in the classroom without relieving him or her from the obligations of forced autonomy. Another response is to investigate teachers’ mathematical qualifications, and recently it has been suggested that the most significant teacher related obstacle to the enactment of the reform is the teacher’s (insufficient) mathematical competence.

These two sets of responses are similar in that they are both based on analyses of interactions in mathematics classroom and of school mathematics rather than on general pedagogical theory or on mathematics per se. They may, then, be seen as attempts to develop conceptions of teachers’ pedagogical content knowledge and subject matter knowledge from the practices of mathematics classrooms.

The study described in section 4 also investigated teacher-related potentials for and obstacles to student learning on the basis of classroom observations. The results of
that study point not only to the teachers’ mathematical and pedagogical content knowledge as relevant factors, but to the ways in which the teachers sometimes shift the objects and motives of their activity to much broader educational issues than those related to mathematics. This change of the teacher’s activity turned out to be one of the most important challenges to his intention of unobtrusively supporting the student’s learning. It follows that teachers’ pedagogical knowledge is not irrelevant for student learning, and it should - just like the pedagogical content knowledge and the subject matter knowledge - be re-defined on the basis of analyses of classroom interactions and integrated with the other two types of knowledge. The second quotation from Ball and Bass, then should be turned upside down (cf. section 3). Maybe what is needed, is exactly ‘a kind of mathematical understanding that is [...] bundled in advance with other considerations of students and learning and pedagogy’.

1 In Zeitschrift für Didaktik der Mathematik DM 96/4 Törner and Pehkonen list 764 papers in belief research in mathematics education. This indicates an interest in the field that does not seem to have diminished since then.

ii I have previously called such episodes Critical Incidents of Practice (CIPs). For a discussion of CIPs based on the classroom observations of and interviews with Christopher see (Skott, in press).

PROMOTING MATHEMATICAL THINKING: 
A PILOT STUDY FOR INNOVATIVE LEARNING ENVIRONMENTS

Jari Sorvari and Erkki Pehkonen
University of Turku, Finland

Abstract: The aim of this pilot study was to experiment and test some novel innovative teaching methods in practical teaching situations with primary level pupils (10 year-olds). In the experiment on learning environments four different teaching methods was implemented with that aimed primarily at using of collaborative communication, supporting pupils' meta-cognition and improving problem solving processes. The development of teaching methods used in the study were based on the earlier research on word problems, the research on meta-cognition connected with them, and research done on the use of open problems. The results of the pilot study show that with the use of such a many-sided learning environment and the teaching methods used it is possible to support the development of pupils' meta-cognition and problem solving skills.

Background

The theoretical background for the pilot study was a compound of theories on mathematical thinking and learning with have been developed in the current constructivist tradition (e.g. Davis & al. 1990). Particularly our approach is based on theories that emphasise the role of communication, interaction, and meaningful tasks in supporting the development of pupils’ meta-cognition and problem solving skills. A teacher’s role in mathematics lessons is seen primarily as an activator of pupils’ thinking skills, to help pupils to understand mathematical structures and ideas as well as to help pupils when developing their own mathematical knowledge (Schoenfeld 1985, Sfard 1998, Lehtinen & al.1999). The central element in developing the teaching methods of the pilot study is the activation of a pupil’s own thinking.

Mathematical thinking should be distinguished from mathematical contents and techniques. Burton (1984, 35) states that "mathematical thinking is not thinking on mathematics, but a thinking style which is a function of special operations, processes and dynamics characteristic to mathematics". Of them especially the processes of mathematical thinking are interesting for problem solving. An individual’s meta-cognitions are regulating elements of his thinking (cf. Schoenfeld 1987). In mathematics, meta-cognitions are often connected to problem solving skills (e.g. Schoenfeld 1985). An important component of meta-cognitions is self-regulation (cf. De Corte & al. 1998). To practice problem solving is seen to promote the development of pupils’ higher order thinking and understanding (e.g. Verschaffel & al. 1999). It is stated in many sources that i.a. verbal elaboration of mathematics to be learned (e.g. Cockcroft 1982, NCTM 1996, 2000) and a pupil’s own experiences in problem solving (e.g. Schoenfeld 1985) promote the development of his meta-cognitive skills. For example, self-regulation can be promoted with proper problems and their treatment (De Corte & al. 1998). Just with the aid of many-sided communication in the pilot study, it is searched for different verbal methods with
which a teacher could support the development of his/her pupils' meta-cognitions and problem solving skills.

Research on mathematical thinking will often be operationalized through problem solving (e.g. Burton 1984). Since in the middle of the 1980's it was realized that teaching of heuristics was not a successful solution, alternative approaches were searched for (e.g. Schoenfeld 1985). Among other methods, it was developed for teaching problem solving an approach that emphasized creativity as an important part of problem solving (e.g. Mason 1982). During the last ten years, the so-called open problem solving has become popular which has near connections to creative problem solving (Pehkonen 1997a) and also to the Japanese "open approach" (e.g. Nohda 1991) and the use of investigations (e.g. Wiliam 1994).

Creativity and logic are central elements in mathematical problem solving (e.g. Mason 1982, Pehkonen 1997a). Recently one less known component of problem solving – problem posing – has been pushed up (e.g. Silver 1995). It belongs also to the open understanding of problem solving (cf. Pehkonen 1997b). A teacher's role is of paramount importance when selecting proper tasks and problems for mathematics lessons. The selection of problems and their application properly in lessons is a difficult task in mathematics teaching. The role of the teacher is very important when constructing a proper atmosphere in class where pupils can frankly investigate, make mistakes, share their success und failure, and exchange their ideas with each others without fear that they will be critically assessed (NCTM 2000). With the aid of such a learning environment it is possible to educate pupils who trust in their own abilities and who are willing to participate and investigate problems.

Hakkarainen & al. (2000) state that in order to be able to help intensive and pedagogically intentional learning with the aid of information technology, it would be very important to locate computers in classes and integrate working with computers with many different working methods and disciplines during the working phase in classroom. Computers should not be seen as separate tools for learning of an individual pupil, but rather as a method of learning in a co-operational learning environment (e.g. Reusser 1991, Lehtinen & Repo 1996). Computers should not be used as a substituting tool when striving for mathematical understanding and intuition, but their use should promote and strengthen processes of mathematical understanding (NCTM 2000).

The focus of the paper

The pilot study in question experiments and investigates the possibilities and limits of new and innovative teaching methods for promoting mathematical thinking and reasoning skills when used in the teaching practice of 10 year-old pupils. Furthermore, the focus lies in the possibilities of developing pupils' problem solving skills, pupils' communication skills, pupils' added awareness of their meta-cognitive skills and abilities as well as pupils' motivation. Based on the results of the pilot study, the usefulness of different teaching methods in the learning environment used are evaluated for the implementation of the main experiment. Teacher students who
implemented a part of teaching form an additional factor in research. A side objective of the pilot study is to clarify the possibilities to integrate such research projects into the teacher education, in order students would get experiences from a new kind of mathematics teaching.

Implementation

The pilot study on promoting mathematical thinking and reasoning skills was implemented in the teacher training school in Turku in the spring 2000. A forth-grade class (10 year-olds, N=17) formed the experiment group; the class has a special emphasis on mathematics and computers. This class has four lessons mathematics pro week during the experiment period of ten weeks there were altogether 40 experimental mathematics lessons. During the intervention special emphases was given on promoting pupils’ thinking and reasoning skills, communication, added awareness on their own knowledge and skills (i.e. meta-cognition) and motivation. The teacher of the class, Mr. Jari Sorvari (one of the authors) with five student teachers was responsible for the practical implementation in class. The teaching methods used in the pilot study were planned together by the authors, in the way that a teacher in a usual school could also implement them alone. The researcher wrote beforehand written plans for all experiment lessons. Each student teacher got in advance the written lesson plan for his future lessons with instructions. Before each lesson, there was still a brief discussion on the lesson plan with the student teacher, if needed. During the discussion, possible difficulties or lack of clarity in the lesson plan were dealt with. Each student teacher implemented during his week of practice four experimental mathematics lessons. The personal teaching style of each student teacher was not influenced in any other way.

The pilot study was built of four different teaching methods which were implemented always in the same weekday and which aimed to promote pupils’ mathematical thinking. Additionally, computers were used in routine exercises. The method called Scattered-Minded Moses was based on the teacher’s own loud-thinking, modelling of word problems, and conscious "thinking mistakes" during the solving process before the class. Pupils’ task during the lesson was to perceive these mistakes that were then discussed together. With the learning game Quest of the Golden Chalice (Vauras, Rauhanummi, Kinnunen, & Lepola, 1999) we tried to develop pupils’ solution skills in word problems and meta-cognitive skills as well as to improve their calculation skills and to promote mathematical communication in class. With the aid of the method Concrete Problem Solving, we tried to build creative, open and motivational learning situations with hand-on material. Problem solving gave an opportunity to develop pupils’ thinking skills and logical reasoning. The method Concept Lessons concentrated in mathematical concepts using problem-oriented approach and instructional discussion. Beside these four methods Computers were used to intense routine exercising Computers offered for the teacher a possibility to work with a smaller group in class.
Data was gathered in the pilot study by using multiple observation methods. Since we wanted with a small number of participants to find out the appropriateness of different teaching methods, observational methods were stressed in data gathering. There were teachers' field notes (both the researcher's and the student teachers') on implemented lessons, the student teachers' own notes and experiences of mathematics lessons, videos on the part of the lessons and pupils' interviews. Observations were unstructured, and thus, the field notes are based on each observer's own personal view on teaching situation.

Results

Based on the analyses of the video records of the lessons in which the method *Scattered-Minded Moses* was used, it seemed that the teacher-pupils interaction functioned well, especially in short word problems. Pupils were able to follow excellently the teacher's modelling and thinking process in these problems. Almost all pupils could perceive the teacher's "mistakes" in loud-thinking processes and amend them during the common discussion. The use of the method seemed really to motivate pupils to follow their teacher's loud-modelling process. Since the teacher did not make mistakes in each problem, pupils were compelled to follow very keen their teacher's thinking process, in order to perceive his mistakes. The motivational level seemed to be really high when solving so-called short word problems with the help of the loud-modelling method. Whereas in the case of long problems, similar effect was no more so clear to observe. Difficulties in long problems seemed on one hand to be partly connected with the complexity of the teacher's own thinking process, and on the other hand with the fact that pupils were simply not able to concentrate and to comprehend the structure of the long problems.

The learning game *The Quest of the Golden Chalice* is planned for small-group teaching or remedial teaching of third-graders (9 year-olds). In this study, the learning game was accommodated with small changes in rules to normal teaching in mathematics. The changes in rules done seemed, according to video analysis, to produce some especially interesting observations. Differently as in normal case, the pupils played the games during the experiment in pairs. This seemed to change the nature of the game. When playing in pairs, the communication between players (pupils) increased very much. The teacher's role as a game leader was also changed. Since the pupils played in pairs, main instructional discussion was done within the pairs, and not between the teacher and the pupils as usual. The teacher’s role was mainly to act as a discussion leader. The communication within pupil pairs seemed to increase and develop, when the pupils gathered experiences with the game. Pupil pairs advised each other and could give those pupil pairs in trouble good hints for solutions of problems. Furthermore, pupil pairs’ loud-modelling of solutions seemed to get more clear with time. The additional changes in rules done in the middle of the experiment seemed to still add spontaneous use of drawing, in order to clarify one’s own solution process. Drawings seemed to clear and strengthen pupils’ thinking processes, when they explained and described their solutions to other players.
In the analyses of Concrete Problem Solving, observations made were based on the researcher’s own perceptions as well as student teachers’ observations and field notes. On the ground of these we can state that instructional discussion had a meaningful share in the problem solving lessons with hands-on materials. Concrete materials offered a tool to “externalize” different phases of the problem at hand, and their possible problematic points. This gave an opportunity to consider also difficult topics with the aid of common instructional discussion. The pupils were very motivated to solve problems using concrete hands-on materials. Such material used were match sticks, soma cubes, multilink cubes, fraction cards and normal playing cards.

Working with matches seemed to interest the pupils very much. In addition, the problems used supported well the objectives set for the use of concrete materials. An interesting observation was connected to the behaviour of two pupils, when giving a home problem. The home problem was a continuation to the following problem dealt with in class. A square sequence should be constructed with matches, where the starting point was a square of four matches. The home problem was formulated, as follows: “How many matches are needed to construct a sequence of 500 squares? Try to find a possible formula / solution not using the help of matches.” The giving of the problem was just finished, when two boys in class wanted to give the solution: “It is an easy piece, Mister. Those matches will be needed altogether 1501, since in the first square there are four matches, thus 3*500+1 is 1501.”

During the Concept Lesson, the teacher had an opportunity to work with a smaller pupil group. Half of the class worked at the same time with computers on routine tasks connected to the topics to be learned. Based on the observations done we could state that during the Concept Lessons the interaction between the teacher and pupils could be intensified. The time the teacher used for a pupil doubled. Furthermore, it seemed that materials used for concretization motivated pupils. Working with a smaller group made it also possible that the level of pupils’ understanding was more effective secured. The big amount of instructional discussion should be also mentioned. A special emphasis seemed to be in discussions on different solution alternatives.

In this study, six computers were used in classroom. The programs used were two in Finnish, of which the first concentrated on routine tasks of mathematics to be learned, and the second contained mainly problems of proper level. Since there were only six computers at hand, and half of the group (N=17) at the same time, a part of pupils were compelled to work in pairs on one computer. Observations made during the computer working phase showed that on one hand to transfer such amount of mechanical exercises on computer seemed to be a functioning solution. On the other hand, the programs used did not offer enough purposeful and useful tasks, in order to implement instruction effectively, especially there was a lack of problems for
individual differentiation. In addition, the program did not contain characteristics needed for following effectively an individual’s learning process.

The communication and interaction within pupils pairs was very active almost all the time of the experiment period on computers. The instruction given and the awareness that the computer will remember mistakes seemed to activate the discussion within a pair. It seemed that the interaction between the pupil pairs could have acted as a feedback system, and the pairs did not need the computer's feedback system when solving the problems. Observations on those pupils working alone were slightly different. They seemed to base their work more on the computer's feedback system than their mates working in pairs.

Discussion

In Finland, a teacher is compelled to work, especially in growing counties, with bigger and bigger classes. This results that time allotted to help pupils individually, e.g. in mathematics lessons, will be decreased all the time. Therefore, one is compelled to search new ways and methods to organize learning environments. There is a need to develop different ways of group working which will support effectively the development of pupils' mathematical thinking. Research results and observations gained during the experiment showed that the methods used in this study are worthwhile developing further. With the aid of the teaching methods developed through research, we should be able to find functioning working methods for the class, and through using them to conduct pupils toward higher order mathematical knowledge and understanding.

The objective of developing such learning environments is to find out pedagogically purposeful teaching practices. Some research questions which have been seen as results of the pilot study are, as follows: Is it possible to reach deeper and better level learning with such a learning environment? Could it be shown that some individual teaching method would support some special area of learning? In the light of the pilot study, none of these questions could be answered exactly, but the study showed these questions to be sensible to ask in the main experiment.

The benefit of the pilot study lies just in its concrete context. The experiment in real teaching situation and the data gathered during it made it possible to implement the learning environment with different teaching methods at one time. On one hand, such an implementation gave much valuable information on the advantages and difficulties of combining individual teaching methods. On the other hand, we could experiment and plan the learning environment as a whole. Thus, we gained information on of what kind of changes in classroom, teaching organization, working order etc. should be taken account of when implementing such a learning experiment.

All the student teachers considered the participation to such an experiment very important. In the following, there is a comment in one student teacher's notes which comment reflects the feeling and thinking of all participative student teachers: "I am
glad of the possibility to participate the mathematics intervention. For me mathematics has always been a challenging topic, since my best method of learning has been doing, but mathematics has been traditionally very abstract and theoretical. It was absolutely wonderful to have an opportunity to experiment that mathematics, and especially challenging problem solving, could be taught so concretely. A pupil has a possibility himself to do, to experiment and to have insights.” (student teacher #2)

Such kind of developing projects on learning environments should be connected to teacher education also more generally. Thus we may construct important links, e.g. in mathematics, between research and practice. To see this connection is not necessary always self-evident. This view of the gap between research and practice has been described very hitting in a comment of a student teacher: “The mathematics project which I was allowed to participate seemed to be very interesting. In the model used, a teacher was a guide for learning instead of a knowledge transmitter. This was at last the concretization, which was long heard in the speech of the theoreticians. The ultimate aim was to get pupils aware of their thinking processes. In the matter of fact, we are in the core of learning (a pupil understands his thinking), if I have condensed rightly. This starting point awakes me a desire to know more.” (student teacher #1) The combination of learning theories, didactics and teaching pedagogy would add student teachers understanding on the teaching / learning process.

What were the pupils experiences in the learning environment? One third of the pupils could see nothing special done during last weeks in class. Another third of the pupils described the classroom working very many-sided. All pupils thought that mathematics has been nice and interesting. On one hand, some did not like mathematics, when there were too difficult problems to solve. On the other hand, many pupils experienced mathematics interesting such when having difficult tasks to solve. This view is described very touching in one pupil’s interview: “difficult tasks are really nice to solve, ... such where is some idea and not only a mere calculation, ... such where you should yourself pick the numbers, ... such straight calculations are dull” (pupil #38). Finally one student teacher’s view on the behaviour of the class during the last weeks of the experiment: “In this class, it was self-evident that questions like “Why?” and “What did you think?” were presented. I had a good feeling: pupils’ pre-knowledge and beliefs were activated, and these were the starting point for further development.” (student teacher #5)

**Literature**

We report on data from a summer institute for high-school students, part of a 13-year longitudinal study of the development of mathematical ideas. The students were invited to discuss the motion of a cat, given 24 time-lapse photographs taken in less than a second. As students explain, justify, and convince others, a re-examination of previous explorations, including prior reasoning, is often triggered. The student data are analyzed through detailed examination of how students work with a variety of representations in order to build arguments, through extended social interaction.

The work presented here is part of an extended longitudinal study of the development of mathematical ideas of a focus group of students, beginning in first grade. The members of the focus group are now first-year university students. The objectives of the study, now in its thirteenth year, are: to provide in-depth case studies of the development of proof making in high-school students; and to investigate the relationship of students’ earlier ideas and insights to later justifications and proof building; to trace the origin, development, and use of representations of student ideas, explorations, and insights relating to explanation, justification, and proof building. Within the context of the learning community, additional goals are to investigate the nature of teacher intervention in the growth of student mathematical ideas, and to study individual cognition in the context of the movement of ideas through the community of learners.

Significance. It is generally accepted that traditional approaches to “teach” students how to reason mathematically (for example, proof making) have not been successful. Most secondary teachers know this; few elementary teachers have been able even to address the issue, given the curricula with which they currently work. Robert B. Davis (1994) distinguished between what mathematics students should learn—that is, what “content” or “topics”—and what kind of knowledge students need to develop, domain by domain.

If one takes seriously the various new suggestions about the teaching and learning of mathematics—if, for example, one takes seriously the NCTM Standards (1989)—then one is faced with asking teachers to play a quite new role... It will not be easy for teachers to shift to the new role—working alongside students, trying to be aware of the student’s thinking, working to help the student modify that thinking in an appropriate way... (Davis, 1994, p. 17)
In our view, specific, detailed knowledge about how students build mathematical ideas is central to successful teaching. To build instruction based on knowledge of student thinking requires detailed research into how students reason and communicate under particular conditions.

Theoretical Framework. As students engage in mathematical investigations, they frequently reconsider prior constructs while attempting to make sense of new experience (Davis, 1984; Davis & Maher, 1990; Davis & Maher, 1997). As they explain, justify, and convince others, a re-examination of previous explorations, including prior reasoning, is often triggered (Maher & Speiser, 1997). In this way, learners come to emphasize certain features, for example, of the problem situations under study. Challenges to students (by each other and perhaps the teacher) to explain their ideas may lead to modification and/or rejection of some prior knowledge, or to generalizations which can be supported by convincing arguments. Further, emerging theories can be subsequently modified, extended or refined, often through long-term critical discussions by the learners.

The theoretical framework that guides this study comes from research on what students do when they do mathematics (Davis, 1984; Davis & Maher, 1990; Davis & Maher, 1997), recent work that traces the intricate and complex pathways for individual students’ understanding within a larger community (Maher & Speiser, 1997), Kieren and Pirie’s Dynamical Theory for the Growth of Mathematical Understanding (Kieren, Pirie & Reid, 1994; Pirie & Kieren, 1994a, 1994b), and some recent work by Dörfler (2000) on the construction of meaning in the course of social interactions.

To investigate the history, development and use of learners’ arguments, we identify events, i.e., connected sequences of utterances and actions which invite explanation by us, by the learners, or by both. An event is called critical when it demonstrates a significant advance from previous understanding (also recorded as events), in the context of an emergent narrative. We may refer to critical events (moments of insight) as conceptual leaps (see, for example, Maher & Martino, 1996b). They are obvious and striking moments, in which learners demonstrate compelling intellectual power, to each other and to us, by having wonderful (Duckworth, 1996) ideas and putting them across in forceful (Maher & Martino, 1996a) ways. In large measure, we see education as creating situations which elicit critical events and then support reflection on their consequences.

Following the same learners for several years, under conditions where instruction has built carefully on what learners have already built, helps us to understand more clearly what students might do cognitively, when proposing justifications that reflect their growth of understanding. It is clear that we need to learn much about the cognitive processes involved in making proofs, especially as students, over time.

3 More precisely, learners can retrieve and critically examine previously built notations and constructions as new knowledge enters.
advance toward higher mathematics.

**Background.** We build on an existing and extensive data base, and on considerable experience in the conduct of studies of this type. Further, our work connects to and draws from other investigations by members of a broader community of researchers with whom we have substantial common ground. Long-term studies of the type that we conduct (and with the depth of data collection we accumulate on the same learners) are almost unprecedented in mathematics education. While there are aspects of this research that are significantly different from other studies, important related research includes work by Susan Pirie, Tom Kieren, Leslie P. Steffe, Andrea diSessa, Alan Schoenfeld and his colleagues, and Jim Hiebert. Further, there are similarities between our presentation of tasks developed by David Page, and methods of Paul Cobb and Erna Yackel. Our interpretation of student performance, in some ways, resembles work by Susan Pirie and Tom Kieren, although, in other respects, our approach is different. Our research supports and then extends investigations of learning which have emphasized the central and essential role of social interaction in the growth of learners' understanding.

In the school year 1998-99, when the research subjects were third-year high-school students, after-school explorations were designed to elicit the construction of mathematical models, the making of connections, and the construction, not only of specific proofs, but of the idea of mathematical proof, at increasing levels of abstraction. In the context of this study, models and proofs were found to emerge from concrete explorations which include demands for careful and convincing explanation. In practice, the drive for explanation requires learners to support their ideas, which often triggers connections across different problem contexts.

In order to help prepare for calculus, the student subjects, during the July 1999 Summer Institute, were offered two extended explorations which drew deeply on precalculus mathematics. We discuss the second exploration here.

**Toward Calculus: the Catwalk task.** Calculus, historically, arose to study change and motion. In the task we now describe, called Catwalk, one challenge is to build connections between local rates of change and total changes, based on real-world data. The Cat task was designed originally to expose some of the complexity inherent in the use of mathematics to examine motion, and so to open opportunities for students to discuss the issues raised. Work on this task by college calculus students, and by a study group of university faculty, has been reported in three papers by Speiser and Walter (1994a, 1994b, 1996). The questions which arose seem very challenging.

At Kenilworth, the Catwalk was tried with high school students for the first time. In the context of the present study, the task was chosen to elicit rather than simply

---

4 Only one of the 17 student subjects (Victor) had studied any calculus before the Cat activity.

5 We emphasize that this example illustrates only one facet of how calculus is useful for such problems, but does so in depth.
illustrate the construction of important underlying concepts, such as the distinction, and connections, between average and instantaneous rates of change.

The **photographs** (Muybridge, 1957, Plate 124). These consist of 24 frames of a single cat, entitled Cat in Walk Changing to a Gallop.\(^6\) The photos were made in 1880 by Eadweard Muybridge, using 24 cameras, activated successively at intervals of .031 second. They show the cat against a background grid, composed of lines spaced 5 centimeters apart. Every tenth line is darker. The 24 photographs show the cat over a total time of action of .71 second.

The **task** (Speiser & Walter, 1994a, 1994b, 1996). Project the Muybridge photos from the overhead. Distribute copies of the photos to the students. Discuss briefly how speed is measured. Then pose the following two questions: How fast is the cat moving in Frame 10? How fast is the cat moving in Frame 20?

The teaching team at Kenilworth was led by Walter.

**Data.** The data we present are from July 15, 1999, from the fifth hour of work on Catwalk. Just before the first segment below, the students had built a linear representation of the cat’s position, in the form of a horizontal line of masking tape, 65 meters long, in the hallway where the students had their lockers. Along the line, two students marked locations for the cat’s position (scaled by a factor of 50) in each frame. Beating a makeshift drum,\(^7\) several students\(^8\) ran the course, striving to reach each mark just as the drumbeat sounded.

In the first data segment, attention focuses on the whiteboard, where Romina’s scatter plot of velocity vs. time has been projected. Earlier, she had plotted this graph in her calculator, using data found with members of her group by measuring the Muybridge photos. Matt has just walked to the whiteboard.

Matt: This is time and this is velocity. This is ... [points with a marker to the first few scatter points] Each of these ... little dots here, these are all his velocities at a certain time... So ... [begins to draw a line connecting all the scatter points] If you see how the line goes, that’s ...

Victor: This is ...

Matt: ... his climb in velocity.

Victor: ... acceleration graph

Matt: Yeah. This is, like... This is, like, his acceleration.

Victor: Alright. That’s, uh, vel... its velocity, uh, over time. So then its, like, uh, you know, dt over t. You know, its, like...

Matt: Acceleration.

Victor: ... dt squared... Right?

Matt: It shows acceleration.

CW:\(^9\) So, you said you saw that as an acceleration graph, Matt. Could you ... could you tell me a little more about that?

\(^6\) The photographs are reproduced in (Speiser & Walter 1994a, 1994b).

\(^7\) Roughly 70 beats per minute.

\(^8\) And two of the investigators. At the given tempo, keeping pace was strenuous. Most participating students were athletes. They chose the scale themselves, after rejecting a shorter model.

\(^9\) Charles Walter.
Matt: It just ... that ... It just basically shows you, like, how far ... how fast. Like, you can tell, like, [indicating the segment connecting the first seven points] from here to here he goes, his acceleration goes down, and [indicates the steep segment through the next four points] from here to here, it starts to skyrocket, up like that. Then [indicates the next six points] he evens out for a while, then it goes down a little bit and [refers to the next five points] then it skyrockets up again.

CW: Well, where is the acceleration?

Victor: Right there where he lands, he's slowing down, right?

Matt: These lines. [Draws arrows pointing to the two sharply increasing segments of his graph.] This line here and this line here. Where it starts to slant up.

Magda: ... he's going at a constant speed.

Matt: At these ... At these ones here [indicates the two relatively flat segments] he's going at a constant speed.

It might be helpful to consider first the surprising range of representations now in play. Reference to videotaped evidence, as well as to observers’ field notes leads to the following list of nine representations, just for the segments we discuss. For each representation, we define a code in boldface, to facilitate analysis

1. The Muybridge photographs. Ph
2. Graph of position as a function of time. P-T
3. Romina’s graph of velocity, as a function of position, projected on the overhead. [The horizontal axis, in effect, is a scaled replica of the marked line on the floor.] V-P
4. Romina’s graph of velocity, as a function of time, projected on the overhead. [The scatter points for the first few frames, for example, are now further apart than in the previous graph.] V-T
5. References to standard mathematical or scientific notations or formulas. F
6. Gestures. [For example, Victor’s hand, tracing the graph of speed against time, moving from left to right as seen by the viewer.] Ge
7. Onomatopoeia. [Sounds which mimic actions.] O
8. Mime, enacting motion. M
9. Drawing and writing, at the whiteboard, on projected images. DI

In the first data segment, above, we see V-T, F, Ge and DI. Romina’s graph has anchored Matt’s discussion, while Victor’s attempt to introduce a calculus notation has been set aside. Matt focuses on changes in the cat’s velocity, by drawing on the whiteboard onto which Romina’s graph has been projected. Almost immediately after running the linear model in the hallway, momentary speed changes seem especially evident. In our second segment, hardly four minutes later, several students

---

10 By representation, we mean presentation, but in the very particular sense that the students, by inventing a notation, for example, simultaneously create a structure which the notation represents for them by presenting it to them. Our usage is similar to terminology of Dörfler (2000).

11 The session was filmed by four cameras: three following the students group discussions, and a fourth, hand-held, operated by a documentary film-maker, to record some of the flow of conversation, especially between the student groups.

12 There were six observers, two per student group.

13 Square brackets denote researchers’ comments.
respond to an observer's question about how many steps the cat has taken in the photographs.

Brian: No way he can take four steps in a ... three fourths of a second. [referring to the total time of action for the cat photos, .0713 sec.]

Romina: Tch, I don't know. Maybe he did only take, like, a step.

Brian: Three fourths of a second is fast. That's [pauses] starting ... now. Now! [Timing three fourths of a second]

Benny: [At the overhead projector, adjusting the display of the cat photos.] There we go. Now, if you look at the, at the first step. [points to the cat in the first frame.] He begins it, he begins his step right here, and if you look, [points successively to frames 2 through 6] he is lifting his leg up gradually, gradually, gradually, gradually and he begins to put his foot down here and then his foot touches base right here [frame 6]. That's one step! Now, [points to frame 7] he begins another stride right here. Gradually lifts his back leg up. You can see. This, this is the foot we're going to judge it by, the back leg. Then [pointing sequentially to frames 8 through 12] he lifts his back leg up again, then he lifts it up higher, higher, higher, then he bends it, bring it down, touches base again [frame 12]. That's his second step! Then as his speed picks up, it starts to take him less time to take a step. So, [points to frame 13] in this, in this third one, his, his other leg, his front leg, picks up, picks up, picks up. We see he touches base here 'cause he's picking up speed, so he touches base earlier, at a quicker time. So, that's his third step! So then he's pickin' up his back leg, back leg, back leg, back leg, back leg. Back leg touches base here and then he begins another stride, right here.

Matt: Basically he takes, like, four steps.

Benny: Four steps.

Victor: All right.

Benny: [Starts back to his seat but stops.] You ask? [retrieves the cat transparency and walks slowly to his seat, his voice trailing off as he moves] Its gone. Its gone, gone, gone, gone! [Laughter.]

Matt: [At the overhead, which projects the scatter plot onto the whiteboard.] Like, this is what, this is his first two steps here, where he's walking at a constant speed. Then all of a sudden, on that third step he gains his speed and this [indicates the flat segment in the middle of the graph] is when he lands. And then that's his speed again.

Benny: True.

Matt: When he pushes off.

Benny: And did you remember what we did with the other graph? Its coming back to me. Yes!

Matt: Oh yeah!

Benny: You remember what we did with the other graph? [Refers to the position-time plot derived earlier from Romina's data.] When we weren't moving, the line was flat. [His hand traces a line in the air, resembling the first segment of the position-time plot.]

Matt: Uh huh.

Benny: So when his foot comes down, he's not movin' at that time. So, that's why the line is flat. That's why you see that gradual line.

Matt: And then when he pushes off again, he accelerates.

Benny: Acceleration then. [Leans to his left. Laughs.]

Matt: Oh, man.
Building from the first segment's discussion, the incremental changes in velocity, as graphed, have been connected to steps taken by the cat, as seen in the photographs. Again, the anchor seems to be V-T, together with Matt's added line (DI), which now extends beyond the given interval of time. Benny works directly from the photos (Ph), summarizing with an onomatopoeic "Gone, gone, gone, gone," as if to sound the rhythm of the cat's steps: first slow, then faster (O). Matt shadows Benny at the scatter plot (V-T) for velocity, checking every step against the graph. Then, suddenly, Benny connects the cat's low velocity before frame 10 (walking) to a prior discussion of position vs. time (P-T). In each of these two data segments, at least four different representations were in play. In the second segment, however, ideas built in the discussion of velocity connect both to the cat photos and the earlier discussion of position. The narrative the students build seems to demand not one but several different visual, numerical and graphic anchors.

Discussion and Conclusion. The next morning, student discussion would begin about frame 10, where the largest change in interval velocity (the spring into the gallop) had already been identified. In this way, grounded in a global picture of the motion of the cat, triggered in part by the experience of running, the two questions given in the task were broadened, deepened and then reshaped, to yield a powerful and detailed argument that the velocity at Frame 10 cannot be known, based on what might be gathered from the photographs. These students build their understanding through collective effort, in which students continually interpret and reframe each others' claims and contributions. This process of interpretation and reframing leads to clearer and more widely shared conclusions. Our data show how students jointly build from prior knowledge, with little teacher intervention, either before or during the discussions we present. Our analysis suggests that mathematical proficiency requires shared experience in social situations that promote both careful reasoning and reflective reconstruction of past knowledge. The students' work presented here is notable for the number and variety of presentations, as well as for its powerful response to the task's questions. We find these students' work astonishing.

---

14 For Frame 20, the situation is different. As several students emphasized, the cat is in the air, the change in interval velocity around Frame 20 is quite slight, and so an average should (unlike Frame 10) suffice.

Muybridge, E. (1957): Animals in Motion. New York: Dover Publ. (Drawn from Muybridge’s Animal Locomotion, 1887.)

Many students confuse decimal numbers, fractions and negative numbers. Data, some of which is new, is provided to support this observation. Interview data also identifies other confusions between number lines and number-line hybrids and between zero and one. These observations are explained by drawing attention to the use of the mirror as a conceptual metaphor in three different ways for understanding the number system. It underpins the usual positive/negative number line, links natural numbers and their reciprocals and operates in a pseudo number line related to place value columns. Students mentally merge the components that are the images under the analogical mapping of the same mirror feature. This extends recent work on metaphors in mathematics itself to their role in understanding mathematics.

INTRODUCTION

Sometime ago I (the first author) was sitting at the back of a class watching an excellent Year 8 lesson on ratio and scale. The students measured small plastic model animals and had to find the size of the real animal, given the scale factor. The girl alongside me correctly calculated that the length of the pig would be 0.9m, but then seemed puzzled. I asked her to show me how big the real pig would be, expecting her to indicate a length along the desk with her two hands. However, after a long pause, she pointed out the window to the left and said that it would be “a long way, out there”. Apparently, she was confusing 0.9 and –9. At the time, I thought that the confusion was surprising but that it was simple to explain. Mathematics lessons must have made so little impact on this girl that she had not learned adequately the meanings of the two symbols: the dot for the decimal point and the dash for the negative. Rather like an English speaker beginning to learn French might confuse an acute or grave accent, she confused the meanings of the dot and the dash. I now reject this simple explanation and propose that this confusion is in fact deep, arising from the use of the mirror as the common conceptual metaphor that underpins comprehension of negative numbers, decimals and fractions and place value. The phrase conceptual metaphor is used in the sense of Nunez (2000), who describes this as the “cognitive mechanism by which the abstract is comprehended in terms of the concrete” (p I-6).
In the following sections, we first summarise evidence that confusion between decimal numbers, fractions and negative numbers is common and report some new quantitative data. This establishes that there is a phenomenon needing explanation. Second, we report evidence from interviews conducted by the second author which provide clues to the reasons for the decimal/negative number confusion and display a surprising confusion of zero with one and fundamental problems with number lines. Third, we explain these results by demonstrating how the conceptual metaphor of the mirror is involved in three different ways in understanding the number system and propose that students mentally merging these three "mirrors" explains the observations outlined above. These ideas are explained in more depth and further evidence is presented in Stacey and Helme (submitted). Whereas previous work on conceptual metaphors has concentrated on mathematics as a discipline (e.g. Nunez, 2000), this paper examines conceptual metaphors in students' thinking.

Unless specifically qualified, in this paper the terms decimal numbers and fractions always refer to mathematically positive numbers. The term negative number is used in two ways: in the standard mathematical sense and also to indicate a number "less than zero", which some of our interviewees wish to distinguish from standard negative numbers. Space does not permit a full discussion of this.

CONFUSING DECIMALS, FRACTIONS AND NEGATIVE NUMBERS

Confusions between decimals and fractions

Misconceptions about the meaning of decimal numbers have been documented in many parts of the world and widely studied. The task of comparing the size of two or more decimals (e.g. identifying which of 2.4 and 2.375 is the larger) has been found to be very revealing and has been used as the basis for studies of misconceptions (Resnick et al, 1989; Stacey and Steinle, 1999). One innovation introduced by Stacey and Steinle in developing their decimal comparison test was to include decimals of equal length. It had not been expected that many students would make errors when selecting the larger from a pair of decimals such as 0.3 and 0.4 or 2.64 and 2.57, but a significant number of students made errors on all items of this type on the test. Stacey and Steinle were interested to identify patterns of thinking that significant groups of students were using consistently on all items. They realised that students who were consistently incorrect on comparisons where the longer decimal is larger, consistently correct on comparisons where the shorter decimal is larger and consistently incorrect on equal length comparisons (such as 2.64 / 2.57) may have been interpreting decimals as reciprocals of whole numbers or as other fractions. (Note that this is not the "fraction rule" of Resnick et al, 1989.) For example, students may be identifying 0.3 as something like one third and 2.64 as something like two and one sixty fourth or as two sixty fourths or similar. Evidence that some students think in this way comes from production tasks, as used by Irwin (1996) and others. Table 1 shows how the incidence of this type of thinking varies from Grade 5 to Year 10 (ages about 10 to 15). This is previously unpublished data,
based on a test of 24 carefully chosen comparisons from the longitudinal study reported by Stacey and Steinle (1999).

Confusions between decimals and numbers less than zero

The patterns of responses that arise from interpreting decimals as reciprocals can also arise from interpreting them as negative numbers. In Table 1, it is expected that the students in Grades 5, 6 and 7, who have not met negative numbers at school, would predominantly be confusing decimals with reciprocals. However, older students may have either confusion (and note the increase at Grade 8, when students do a lot of work on negative numbers). In order to explore this possibility, a later decimal comparison test included a group of three direct comparisons of (positive) decimals with zero: the comparison of 0.6 with 0, of 0.22 compared with 0 and 0.00 compared with 0.134. This test was given to 553 teacher education students, at various stages of their training, from four universities in Australia and New Zealand. The results are reported by Stacey et al (in press). In summary, 73 students (13%) made at least one error on the three comparisons with zero and 50 (9%) made either two or three errors. This was markedly higher than the percentages of students making at least one error on the other types of comparison items (generally about 7%). The item most likely to be correct was the comparison 0.00 with 0.134. The presence of the additional digits encouraged or permitted use of a digit-by-digit comparison strategy. As one student said “It’s the decimal point (i.e. in 0.00 but not in 0) for some reason makes the zero seem much more like a zero...the fact that there is a one in that tenths position indicates that it (i.e. 0.134) is larger... the decimal point has obviously made it easier for me to see.”

Only a handful of students (about 1%) consistently answered all items on the test according to the reciprocal/negative pattern of thinking described above and also made at least two errors on the comparisons with zero. In fact, most of the students making errors on the comparisons with zero tested as expert on the remainder of the test. This behaviour indicated that about 1% of the teacher education students completely identified decimal numbers with negative numbers and about 7% could order non-zero decimals, but thought that some such as 0.6 and 0.22 were less than zero.

The teacher education students were asked to select comparisons which children would find difficult and to explain why. The explanations canvassed two possibilities. The first was that children might think that decimals are negative or less than zero (first two quotes below) and the second explanation (3rd and 4th quotes) is that zero is bigger than a decimal number because it is a whole number.
"0.22 may be mistaken for a negative number below zero."

"Some kids have trouble with the notion of zero. 0.22, though less than one, is greater than zero. [Children] might see it as negative or less."

"Children are taught that the ones column is larger than the tenths column so assume 0 is bigger than a decimal."

"Because ‘0’ is a whole number (to the left of the decimal point) whereas .7 is a decimal number, they may choose 0, as it’s not seen as a ‘decimal’, a smaller number."

Children’s difficulties making comparisons of decimals with zero have also been reported elsewhere. Irwin (1996) reported that some 11 to 13 year-old children placed decimal numbers starting with zero (e.g. 0.5, 0.1) below zero on a number line. Irwin concluded that these attempts at ordering were consistent with a system that pivots around zero as equivalent to the decimal point, rather than around one.

**Interview results**

In order to find explanations for the data summarised above, individual interviews were held as soon as possible after testing with 7 volunteer students from one of the universities, who had made errors in the zero comparison items. Both types of explanations outlined above were given for the incorrect answers. Sometimes a student’s answers contained elements of both. Jocelyn explained her wrong answers this way and drew the number line in Figure 1:

"I think I was thinking that zero is equal to one. So I was thinking half of one is less than zero. I was thinking that 0.5, for example, was half of zero, so was thinking it is less than zero. I was visualising a number line with 0.5 on the left hand side of zero."

![Jocelyn's number line](image)

Figure 1: Jocelyn’s number line showing that small decimals are less than zero.

She commented in her interview that this line made no logical sense, because she could see that the numbers on the left were approaching one. Jocelyn believed that the decimal point must have acted as a trigger for thinking the number was less than zero:

"When I think of a fraction, decimal points, I always think of .5, and instead of thinking .5 as half of something, it’s half of—it has to be less than zero because it’s, I don’t know why I thought that. I suppose maybe because it’s got that point, the decimal point ......in some way it’s less than zero because it’s got a point there."
Stuart said that he might have been thinking of 0.6 as a negative number. When asked to draw a number line, his first attempt was not a line as such but the numbers 10, 0 and 0.1 set out from left to right. Next he drew a line with zero in the middle but with positive numbers on the left and negative numbers on the right. When he went on to explain his thinking, he also appeared to be confusing zero with one:

“I know 0.6 is a portion of one. I may have been thinking along the lines of 0.6 is less than the whole number zero. Is zero a whole number? I don’t even know . . . . . . I’m looking at whole numbers as being positives and decimals as being negatives . . . . . decimals aren’t, they’re just fraction amounts.”

Lisa was another student who may have been confusing the number line with the place value columns. When she explained her response to the comparison of 0 with 0.6 she said, “I was thinking of the number line...I was thinking it was on the right hand side of zero, so going into the negative area for some reason”. She drew a number line left-right inverted, and placed 0.6 between 0 and -1 “Normally I draw a number line in this direction (indicates conventional number line) but just when I was thinking of the decimals then I immediately drew it as a negative in this direction”. Later in the interview Lisa stated that she also thought of zero as a whole number:

“I can remember that I was thinking that ‘this is a whole number’ and that this is a fraction of a whole number. And that a fraction of a whole number must be smaller than zero which is a whole number.”

When the interviewer discussed the idea of zero being a whole number with Anna, she summarised: “Logically 0.6 has to be part of a whole, part of one, but I guess it’s like zero is being turned into one and parts are trying to be made out of nothing really.” In a revealing instant, as she spoke about zero, she made a circle with her hands, which seemed to indicate simultaneously the shape of the symbol for zero and a unit (perhaps the classic pie of introductory fraction teaching) which could be divided into parts.

THREE APPLICATIONS OF THE MIRROR METAPHOR TO NUMBERS

The data above leads us to seek explanations for the facts that some students think decimals (and fractions) are negative numbers or otherwise less than zero and some students confuse zero and one. In addition, some students confuse decimals and reciprocals, but we feel that this is well enough explained as persistence of an undifferentiated primitive idea that decimals represent the fractional parts of numbers. We propose that the confusion and interference arise from the use of the conceptual metaphor of the mirror in three different ways for understanding numbers. Recent developments in cognitive science represent a move away from the traditional role of reasoning as primarily propositional, abstract and disembodied to viewing it as embodied and imaginative. From this perspective, mathematical reasoning entails
reasoning with structures that emerge from our bodily experience as we interact with our environment.

Lakoff and Johnson (see, for example, Johnson 1987) demonstrate how reasoning with metaphors is fundamental to human thinking and communication by pointing out how everyday language uses common ideas as metaphors to convey abstract concepts. Nunez (2000) and Lakoff & Nunez (1997) apply these ideas to mathematics demonstrating reasoning through metaphors, such as “numbers are points on a line”; “variables are boxes with numbers inside” or “an equation is a balance”. These instances view a less familiar target situation (numbers, equations, variables) through the lens of a familiar, concrete source situation (lines, balances, boxes).

The key feature of metaphor is that one domain is conceptualised in terms of another. We propose that aspects of numbers relevant to the problems outlined above are conceptualised in terms of a mirror. A mirror as a conceptual metaphor has three basic components: the real objects, their images (reflections) and the mirror position (some sort of line of symmetry/balance point/pivot/axis). In order to make a conceptual metaphor, the relations between these basic components must also translate from source to target. With a mirror, each real object has its own clearly identified image. The images share many of the features of the real objects and have the same spatial relation to each other, although with an inversion so that in the image world, things are “the other way around”, but otherwise the same. There is, however, a critical asymmetry between the real object and the image: the image is a reflection of the real object, the real object is not a reflection of the image. The real object is primary and the image exists in relation to this, not in its own right. In our more extensive paper (Stacey and Helme, submitted), we link this asymmetry of opposites to the linguistic phenomena of positive and negative terms and marked and unmarked adjectives (Clark and Clark, 1977).

The conceptual metaphor of the mirror with natural numbers functioning as the real objects is used in three different ways in understanding numbers as displayed in Table 2. First, in the classic number line, the positive and negative numbers are balanced around zero. The images are the negative numbers \{-1, -2, -3, -4, \ldots\} (with later extension to other numbers). In formal mathematical terms, these images are the additive inverses of the natural numbers. Second, in an instance less commonly perceived spatially, the positive numbers and their reciprocals are balanced around the natural number 1. The images are the unit fractions \{1/2, 1/3, \ldots\} (again with later extension). In formal mathematical terms, these images are the multiplicative inverses of the natural numbers. We contend that this is also conceptually a mirror, because of the way in which the (unit) fractions are conceptualised in terms of the whole numbers and their basic relations (such as size) are similar but inverted.

The third spatial arrangement with a mirror as conceptual metaphor relates to the number line drawn by Stuart. Here the real objects are not quite the natural numbers but the values of the place value columns \{ones, tens, hundreds, thousands, \ldots\}. Their images are the “fractional” place value columns \{tenths, hundredths,
The evidence from the interviews leads us to believe that the spatial arrangement of the usual place value numeration is seen by many of our students as some sort of “number line” along which numbers are distributed. This model, which like the other two stretches out infinitely in both directions, has whole numbers of increasing value on the left side of the decimal point and “decimal numbers” of decreasing value on the right. The mirror position is unclear to many students, who may see it as the decimal point, rather than the ones column.

</tbody>
</table>

The two confusions above can now be seen as confusions between the different targets of the metaphorical mappings of the same source features. Students who think decimals (and fractions) are negative numbers are merging the different images of natural numbers. They may have merged the images in the first two columns or the first and third. Confusion of 0 and 1 is merging of the mirror positions, and also relates to the decimal point as the significant “divider” (mirror position) between whole numbers and others. Merging the number line and place value “columns”, produces a hybrid where the “whole number” part of the place value system is placed on the “positive” side of the number line and the “decimal” part of the place value system on the “negative” side of the number line. As Lisa commented: “I get my number lines mixed up”.

CONCLUSION

The discussion above outlines an explanation of the confusions between decimals, fractions and negative numbers that are certainly common amongst school
students and teacher education students. In summary, the basic elements of the explanation are:

(i) that the natural numbers are the primary elements from which concepts of other numbers are constructed,

(ii) that the metaphor of the mirror is involved in the psychological construction of fractions, negative numbers and place value notation for decimal numbers, although in three different ways,

(iii) that the observed confusions result from students’ merging (confusing or not distinguishing between) the different targets of the same feature of the mirror metaphor under the different analogical mappings.

Two of the mirrors are recognised within the formal mathematical system (additive and multiplicative inverses), but the place value mirror and its associated “number line” is only a psychological construct. It is hoped that this example will further the exploration of the role of conceptual metaphors in students’ mathematical thinking.

ON THE RELUCTANCE TO VISUALIZE IN MATHEMATICS:  
IS THE PICTURE CHANGING? 

Despina A. Stylianou  
University of Massachusetts, Dartmouth MA 

This study examined the perceived and actual role of visual representation use as a possible heuristic in advanced mathematics problem solving by experts (mathematicians) and novices (undergraduate students). While both groups perceived visual representations as a useful tool and frequently attempt to use them, further analysis showed that students have little training associated with the use of visual representations. 

The role of visualization in mathematical problem solving remains an active question in educational research. For centuries, visual tools such as diagrams, graphs, and sketches were considered to be indispensable in the work of mathematicians (Rival, 1987). Reports on the work of expert mathematicians have provided anecdotal evidence of the use and value of diagrams and other visual tools in the research work. Pólya (1945) for example, argued that the use of visual representations is an essential element in problem solving and offer specific advises to novices as to how to use visual representations in their own problem solving. But, despite the obvious importance of visualization in mathematical activity, deceiving visual clues often led mathematicians to false beliefs, resulting to the tendency to consider visual representation use as only an informal part of mathematicians’ work. Little empirical work has been done towards the better understanding of the processes related to the use of visual representations by experienced problem solvers. Detailed accounts of individual practices are still relatively rare with the personal accounts of a few mathematicians like Pólya and Hadamard being notable exceptions and bearing the limitations of self-reports. Only recently have mathematics educators begun to study empirically and systematically the nature of mathematicians’ practices. 

In the realm of education, research studies indicated that advanced students are often reluctant to use visualization to process mathematical information (Eisenberg & Dreyfus, 1986, 1991; Vinner, 1989) and that, whenever possible, students choose a symbolic framework to process information and to approach problems rather than a visual one. Eisenberg and Dreyfus present a review of the literature with several cases in which college calculus students repeatedly resist the use of visual representations in solving problems. Yet, more recent studies in advanced mathematical problems suggest that the picture may have been changing in the past decade; Partly due to the changing curricula and attitudes toward the use of diagrams, mathematics students now appear to be interested in using visual representations (George, 1999; Gibson, 1998; Stylianou & Dubinsky, 1999). 

Further research regarding use of visual representations is warranted. This study, whose purpose includes an investigation of the ways that both expert mathematicians and students reasoned with visual representations in solving advanced mathematical problems, aims to provide further insight into this issue. Specifically, this study investigated (i) the perceived role of visual representations as a possible heuristic in
advanced mathematical problem solving by experts and novices, and (ii) the frequency of visual representation use during the actual problem solving (iii) the relationship between these two aspects of problem solving behavior. The study participants were 10 mathematics professors (experts) and 10 college mathematics students (novices).

I. Perception of visual representation utility

In the first part of the study, the role of visual representation use as a problem-solving heuristic by experts and novices was ascertained. Experts and novices were asked to categorize a set of 24 mathematics problems according to their similarity in their solution process. The study aimed at finding out whether "draw-a-figure" is viewed as a viable strategy when solving a problem.

Experts produced a total of 13 categories. These included some well-established strategies such as use of induction and contradiction, or use of similar problems; they also produced three categories which were closely related to the use of visual representations: "geometry/analytic geometry", "algebra and analytic geometry" and "draw-a-figure". The first category, "geometry and analytic geometry", was used by 8 experts primarily to group together problems which were geometric in nature (i.e., they used topic as their classification criterion). The second and third categories, "analytic geometry" and "draw-a-figure", were used to describe problems which relied strongly on the use of visual representations (that is, problems whose solution can be facilitated by the use of a visual representation). The 5 experts who produced these categories argued that the problems they classified as "draw-a-figure" are different from problems they classified as "geometry" in that the problems in the draw-a-figure category were not necessarily geometry problems. These are problems which reside in other topics or areas of mathematics (such as algebra and calculus) but visual representations can be helpful in the solution process.

Novices produced a total of 23 categorizations for their groupings and 6 of these are closely related to the use of visual representations: "geometry/analytic geometry", "algebra and analytic geometry", "draw-a-figure", "circles", "area", and "physical constructions". The "geometry and analytic geometry" category was used by 9 novices primarily to group together problems which were geometric in nature. Three novices used the "geometry and analytic geometry" and "draw-a-figure" categories to classify a small number of problems which they perceived as problems which are not geometry problems but which required the use of visual representations. Finally, 3 of the novices produced categories which focused on contextual features of the problems such as "circles", "area" and "constructions".

Data was analyzed using a cluster analysis – a process which allows for the arrangement of objects into clusters. The problems within a cluster are more homogeneous than they would be if they were compared to problems that belong to other clusters. The information provided by the clustering process was transformed into dendograms to facilitate the interpretation of the data. Figures 1 and 2 show the dendograms that were constructed using the experts’ and novices’ classification data.
Figure 1: Experts' classification data

Figure 2: Novices' classification data
respectively. The 24 mathematics problems are represented as equidistant points along the horizontal axis. The measure of similarity, which is plotted as an ordinate, is the distance between problems belonging to different categories. Problems in the dendogram with greater similarity are connected at lower ordinal values.

The expert dendogram in Figure 1 contains a large cluster which was labeled as “Geometry and Draw-a-figure.” This cluster contains both geometry problem and problems for which the use of visual representations would facilitate their solutions even though they may not be geometry problems. The novice dendogram in Figure 2 also includes a “Geometry and Draw-a-figure” cluster. In fact, this was the only cluster on which novices agreed to a large extent on the labeling of the category.

In a summary, when asked to classify a set of problems using mathematical similarity (that is, similarity in the way problems would be approached, and in the strategies that would be utilized during the solution process), both experts and novices produced categories which related to visual representation use. Therefore, the results showed strong evidence of both experts’ and novices’ perception of visual representation use as a viable strategy in mathematical problem solving. We may conclude then that visual representation use is perceived by expert and novices to be a viable heuristic in advanced mathematical problem-solving.

II. Frequency of visual representation use

In the second part of the study, the frequency in the use of visual representations was determined. Subjects were asked to solve five of the 24 problems and their written solutions were coded with respect to evidence of diagram use. The coded data were converted into numerical scores for analysis purposes by assigning a 0 for the solution of a problem for which there was no evident use of a visual representation and a 1 for each solution that contained evidence of visual representation use. For each participant a visual representation use score was then computed, by summing scores across the five problems. Thus, visual representation scores ranged from 0 to 5.

The frequency of visual representation use by the two groups was determined by examining experts’ and novices’ visual representation scores. A summary is shown in Table 1. In general, most experts used visual representations when solving the five

</table>
problems. Ninety percent of the experts used a visual representations in solving all, or all-but-one of the 5 problems, and no expert used a visual representation on fewer than 2 problems. Similarly, novices also used visual representations to a great extent, though somewhat less frequently than experts. Only 50 percent of them used visual representations in solving all-but-one of the 5 problems.

The mean score for the entire sample was 3.90, while experts’ and novices’ mean scores were 4.4 and 3.4 respectively. A t-test comparison with an alpha level of 0.05 revealed a statistically significant difference in the frequency of visual representation use by the two groups (t=2.65, p<0.05). Thus, this analysis also suggests that experts were more likely than novices to use visual representations.

These results gave prevalent evidence that both experts and novices frequently attempt to use visual representations in the form of diagrams, figures and graphs when solving advanced mathematics problems. The frequency in which experts utilized visual representations in their written solutions of mathematics problems in this study provides empirical evidence for the anecdotal reports of expert mathematicians claiming that visual representation use is an essential element in their mathematical problem solving. With regard to novices’ use of visual representation, the results showed that advanced undergraduates, similar to experts, frequently utilized visual representations within their written solutions to advanced problems.

This result seemingly contradicts earlier findings by educators (Eisenberg & Dreyfus, 1986, 1991; Vinner, 1989) who documented a reluctance on the part of advanced students to use visual representations in mathematics. One way of interpreting the results of this group of studies is, as Vinner commented, to see that they reflect the current situation in mathematics learning (especially at early levels) where success is essentially measured by routine problems which do not require visual ability; students give up meaningful learning and prefer to memorize formulae and algebraic techniques since experience has shown them that this is an effective prescription for success in standard tests. This interpretation is consistent with Lean and Clements (1981) who admit that "in [their] study the mathematical variables were measured by tests which did not require the solution of difficult, unfamiliar word problems" (p.294). The problems used in this study are different in that respect; they were chosen to not resemble standard textbook tasks, so that both novices and experts would have to make an effort to first understand and then solve the problems.

Finally, the frequency in visual representation use by novices may also be explained, in part, by recognizing the difference in time and curricular trends between the empirical work conducted in the early eighties and this study. A report by the Mathematical Association of America (Tucker & Leitzel, 1995) assessing the reform efforts in American higher education institutions showed that more than half mathematics departments were engaged in some sort of reform efforts and concluded that calculus reform, in particular, is gaining widespread acceptance. This suggested that undergraduate students receive different instruction using different curricula than
students did approximately one decade ago. Reform calculus textbooks present a large number of visual representations. Further, they often encourage or expect students to use graphing technology in the form of hand-held calculators, or computers. In short, undergraduate students in the past few years have been exposed to the use of visual representations to a larger extent than their counterparts a decade ago. The novice in this study were undergraduate students who received “reform” calculus instruction. Therefore, the contradiction between the findings of studies conducted a few decades ago and this study may be explained in part by differences in experiences students have been having with visual representations as part of their mathematics curricula.

III. Perception versus use

This study focused on experts' and novices' perception of visual representation viability in problem solving, and the two groups' actual use of visual representations during problem solving. Yet, the "obvious" question of the relationship between the two has not been addressed: How consistent are subjects’ perceptions of the usefulness or viability of visual representation use in advanced mathematical problem, with their actual use of visual representations during problem solving?

The results from the first part of this study showed that both experts and novices perceive visual representation use to be a viable strategy in problem solving. Both groups' classifications indicated that they perceive visual representations to be useful not only when solving geometry problems, but also for problems from other areas of mathematics. This result indicated that visual representation use is part of the declarative knowledge of both experts and novices.

The results from the second part of this study suggested that the two groups' perception and actual use of visual representations was consistent; Both groups constructed visual representations relatively frequently. Based on these results we could argue that the "picture" of particularly novices with respect to visual representation use has been changing; Novices are no longer reluctant to visualize. On the contrary, novices are well-aware of the utility of visual representations in mathematical problem solving and are, in fact, eager to use visual representations in their own problem solving. Since the problems that were given to subjects to solve were given previously to them in the sorting task, we can compare the number of experts and novices who initially perceived visual representations as a potentially useful tool for these problems, and the number of experts and novices who actually used visual representations during problem solving.

Figure 3 shows the contrast between perception and actual use of visual representation for each of the two groups. For experts, it is clear that their actual use of the visual representations during problem solving was higher than their perception of the possible utility of visual representation. For novices, on the other hand, the pattern was reversed; more novices thought a visual representation would be useful, than those who actually used visual representations during problem solving.
With respect to experts' visual representation use, the above comparison confirms the earlier conclusion that experts perceive visual representation use as a very useful tool in problem solving (declarative knowledge). Additionally, experts have strong procedural knowledge attached to this heuristic; once an expert decides that a visual representation would be a useful tool in solving a problem, even if visual representation use was not the first tool that came to the expert's mind, the expert is very likely to pursue the use of this visual representation, and, as the results for the second research question showed, experts know how to make use of visual representations as problem solving tools (procedural knowledge). Novices, though, appear to be very different; even though they appear to value visual representation use, and to have developed an ability to foresee the potential viability of visual representation use for a certain type of problem (relatively strong declarative knowledge), novices still lack the skill to use visual representations (lack of procedural knowledge).

Closing comments

Pólya (1945) and Schoenfeld (1985) argued that visual representation use is an essential element in problem solving and offered specific advises to students of as to how to use visual representations in their own problem solving. Pólya introduced the use of visual representations as one of the main problem-solving "heuristics", and Schoenfeld’s subsequent work supported and extended Pólya’s discussion of visual representation use as a problem-solving strategy.

The results of this study gave prevalent evidence that both experts and novices perceive visual representations as a useful tool and frequently attempt to use them.

Figure 3: Perception versus use of visual representations

With respect to experts' visual representation use, the above comparison confirms the earlier conclusion that experts perceive visual representation use as a very useful tool in problem solving (declarative knowledge). Additionally, experts have strong procedural knowledge attached to this heuristic; once an expert decides that a visual representation would be a useful tool in solving a problem, even if visual representation use was not the first tool that came to the expert’s mind, the expert is very likely to pursue the use of this visual representation, and, as the results for the second research question showed, experts know how to make use of visual representations as problem solving tools (procedural knowledge). Novices, though, appear to be very different; even though they appear to value visual representation use, and to have developed an ability to foresee the potential viability of visual representation use for a certain type of problem (relatively strong declarative knowledge), novices still lack the skill to use visual representations (lack of procedural knowledge).

Closing comments

Pólya introduced the use of visual representations as one of the main problem-solving "heuristics", and Schoenfeld’s subsequent work supported and extended Pólya’s discussion of visual representation use as a problem-solving strategy.

The results of this study gave prevalent evidence that both experts and novices perceive visual representations as a useful tool and frequently attempt to use them.
when solving problems, suggesting that the “picture” in advanced mathematics instruction may be changing. However, further analysis clearly showed that the changes may only be covering the surface; students may be willing to use visual representations but have little training associated with this skill. Recognition of the willingness and at the same time difficulties identified in this study can lead mathematics educators to make more explicit and informed decisions about visual representation use in curricular materials and instruction, providing opportunities for students to become successful mathematical problem solvers.

REFERENCES

A key stage in learning multiplication and division is a capacity to move beyond reliance on physical models of problem situations and to form mental images to seek solutions. Some longitudinal data are presented to suggest that young children (5 to 8 years) progress through identifiable key stages in learning multiplicative concepts. One of these key stages is represented by movement away from a need to refer to physical models, and some children progress to this stage within the first three or four years of schooling. A clear finding is that teacher interventions facilitate this progression.

This paper reports results from the Early Numeracy Research Project (ENRP) that examined the effect on student learning of a whole school approach to improvement of teaching and learning (Hill & Crevola, 1998). As a measure of student learning, the project collected data across nine domains of mathematics, one of which was multiplication and division. The data suggest that a key stage in the learning of multiplicative concepts, termed here abstracting, presents a significant barrier to many students, but that this barrier can be overcome with teacher support. This key stage, abstracting, is characterised by students moving beyond a need to create physical models as a prerequisite to solving multiplicative problems. It is conjectured that the necessary steps include developing a conceptualisation of multiplication and division that allows students to deal with different situational contexts (e.g., partition and quotition) and generalising the concepts in a way that prepares them for future learning (Sullivan & Beesey, 2000).

It seems, for example, that there are many students in the later primary years (ages 9 to 12) who can cope with multiplication and division concepts with natural numbers, but who experience difficulty not only with multiplication and division of decimals but also with the very nature of fractions and decimals (e.g., Baturo, 1997). It is possible that the semantic complexity of the question forms and associated physical models used to assist the learning of multiplicative concepts in the early years themselves contribute to these difficulties (e.g., Mulligan & Mitchelmore, 1997; Verngaud, 1988). This paper suggests that students will develop more robust
conceptualisations of multiplication and division if teachers pose problems that gradually but explicitly remove physical prompts or supports, and encourage students to form mental images, in multiplicative situations.

**Early Learning of Multiplication and Division**

Over the past decade, there has been considerable attention to research on multiplication and division concepts in early mathematical learning (e.g., Anghileri, 1989; Carpenter, Ansell, Franke, Fennema, & Weisbeck, 1993; Kouba, 1989; Mulligan & Mitchelmore, 1997; Steffe, 1994; Wright, Mulligan, & Gould, 2000). Studies focused largely on the analysis of counting, calculation and modelling strategies from children’s solutions to problem solving tasks.

There has also been some emphasis on the importance of developing conceptual structures for multiplication and division (Greer, 1992). In longitudinal analyses of young children’s intuitive models for multiplication and division problems, Mulligan and Mitchelmore (1997) found that the intuitive model employed to solve a particular problem did not necessarily reflect any specific problem feature but rather the mathematical structure that the student was able to impose on it. Students acquired increasingly sophisticated strategies based on an equal groups structure, and calculation strategies that reflected this.

The acquisition of an equal-grouping (composite) structure is at the heart of multiplicative reasoning. For example, a composite is a collection or group of individual items that must be viewed as one thing. To understand multiplication and division the child needs eventually to co-ordinate a number of equal sized groups and recognise the overall pattern of composites of composites, such as "three sixes". Steffe (1994) described the demand on students as follows:

> For a situation to be established as multiplicative, it is necessary at least to co-ordinate two composite units in such a way that one of the composite units is distributed over elements of the other composite unit. (p. 19)

The key issue is that co-ordinating these two composite units is complex, and physical models can help initially. Clearly students must move beyond physical models partly because such models do not easily represent all multiplicative situations (e.g., Greer, 1992), and partly because these models become less feasible with large numbers and inappropriate with rational numbers. We suspect that some teachers avoid these difficulties by using limited situational contexts of multiplication and division and continuing to rely on physical models, generally restricted to repeated addition. Since the form of the models is likely to be representative of the problem structure, we argue that it is preferable to encourage students to create models or mental images of a variety of multiplicative situational contexts and to use these models or images in solving the problems. It seems desirable to pose tasks that specifically remove elements of physical models, even within the first three or four years of schooling, and to emphasise movement towards use of mental images.
The Data Collection

In order to explore various aspects of numeracy learning, the ENRP project created a framework of key "growth points" that can be thought of as conceptual signposts on the road to children's development as mathematical thinkers. The focus of interest here is on what the data can tell us about the learning of multiplicative concepts in the early years of schooling.

The source of data was a one-to-one interview over a 30 to 40 minute period with every student in the first three year levels in 35 trial schools at the beginning and end of the school year. Note that the Australian school year is February to December.

Although the full text of the interview involves around 50 tasks (with several sub-tasks in many cases), no student moves through all of these. Given success with a task, the interviewer continues with the next task in the given mathematical domain as far as the student can go with success (see Clarke, Sullivan, Cheeseman, & Clarke, 2000 for a fuller discussion). Many of the interview questions invited the children to solve problems using small plastic teddy bears.

Interviews were conducted by the classroom teacher, who was trained in all aspects of interviewing and recording. As well as moving carefully through the 18-page interview schedule, the teacher completed a four-page Student Record Sheet.

Some Growth Points and Items for Assessing Multiplication and Division

The ENRP project developed sets of growth points in nine domains of mathematics, one of which is multiplication and division. The multiplication and division domain includes seven growth points, only four of which are relevant here.

Growth Point 0 – Not apparent
Not yet able to create and count the total of several small groups.

Growth Point 1 – Counting group items as ones
To find the total in a multiple groups situation, refers to individual items only.

Growth Point 2 – Modelling multiplication and division (all objects perceived)
Can successfully determine totals and shares in multiplicative situations by modelling.

Growth Point 3 – Abstracting multiplication and division
Can solve multiplicative problems, where objects are not all modelled or perceived.

These are presented as a conjectured sequence of development. It is accepted that students can follow different pathways in their learning, but nevertheless the intention is to describe a learning trajectory (Cobb & McClain, 1999) of the majority of the students.

The four questions that addressed these aspects of multiplication and division are shown in Figure 1. It is noted that these questions address only two of the four multiplicative situational contexts proposed by Greer (1992). Multiplicative comparison (I have 3 times as many as you), and Cartesian product (2 cones, 3 flavours, how many possible combinations?) were not included.

23. Teddy cars
Put four matchboxes in a line.

24. Sharing teddies
Show the child the picture of four "teddy
Here are four teddy cars. Please put two teddies in each car.
a) How many teddies is that altogether?
b) Tell me how you worked that out.
c) If the child appear to be counting all, ask: Could you do that another way, without counting them one by one?

25. Dots task
Here are some dots. Show card (4 x 5 array of dots) for an instant. I'm going to hide some. Cover the bottom 3 x 3 section.
a) How many dots are there altogether on the whole card?
b) How did you work that out?

26. Teddies at the movies
Here comes another story.
a) 15 teddies are sitting in rows at the movies. The teddies are sitting in three equal rows. How many teddies are in each row?
b) How did you work that out?

Materials were provided for the first three questions. The interviewers asked the first two questions for all students, but only proceeded to the latter two if the responses to both the first two were correct.

The instruction provided to the coders for this domain was to rate a student at the:
- Counting group items as ones growth point if they responded to the Teddy cars and Sharing teddies questions correctly;
- Modelling growth point if they used a non-count-all strategy in Teddy cars and answered Sharing teddies correctly; and
- Abstracting growth point if responses to Dots task and Teddies at the movies questions were correct, although count by ones strategies were not allowed.

Indicators of Student Growth

To examine the way the growth points portray the nature of the increasing sophistication of the students' strategies, the following presents a profile of students' achievement over the grade levels. Table 1 shows the percentage of students at their highest achieved growth point both by grade level and overall in the March 1999 interview. "Prep" refers to students about 5 years old, in their first year of school; Grades 1 and 2 are the next years.

There are significant numbers of students at each of the first three growth points overall and by grade level. It can be inferred that the first four points, at least, are necessary to describe the growth of such students.

To consider whether the growth points represent a sequence, it is appropriate to consider the way the students develop. Given that the questions were asked in such a way that if students made an error in an early item, they were not asked the latter ones, it is not possible to draw inferences on the sequence merely from the percentages of students answering the questions correctly. To allow consideration of the growth, Table 2 presents the ratings of all students in November 1999.

An indicator of the sequential nature of the growth points is the extent to which students progress from one point to subsequent points. Note that a better sense of the growth of the students can be gained by comparing Tables 1 and 2 than merely by comparing across grade levels within either table because the comparisons are between the same groups of students.

At each of the three levels, students progressed through the growth points. Few students in either Prep or Grade 1 progressed to Abstracting, and only one third of the Grade 2 students reached that point by the end of the year.

The Abstracting Barrier

The project team examined whether the conjectured growth points are sufficient to describe growth within each domain or whether more growth points are needed in between. One possible indicator of the need for an additional growth point could be that students take too long to move from one point to the next. It can be noted that the points as conjectured represent quite major growth stages since it takes the group, on average, just over 12 months to progress one growth point.

Of a total of 3410 students, 841 were rated at Modelling in both March and November. This represents 24% of all students, and 70% of the students rated at Modelling in March were still rated at that level in November. This implies that these students were able to represent the Teddy cars question and skip count or use other multiplicative strategies for calculating the total, and to represent and solve the Sharing teddies task, but were not able to answer both the Dots task or Teddies at the movies in a non count-by-ones manner.

Not only is the next growth point, Abstracting, an important goal for most students, it seems also to present a significant barrier. There are a number of components of this
barrier. These could include the problem structure, the semantic subtlety of words like each and between, the calculation demand, and the need for the students to form some sort of mental image of the problem statement.

To explore further the nature of the development needed between these two growth points, the following tables present some characteristics of the 841 students who were rated at Modelling in both March and November.

One of the possible contributors to the barrier is the counting demand of the tasks. To examine this, Table 3 presents the responses of the students on the Counting growth points, from the same interview, for the 841 students rated as Modelling on the Multiplication and Division domain in both March and November.

Table 3: The Modelling students (%) at each Counting growth point (n=841)

<td>2</td>
</tr>
</tbody>
</table>

These data suggest that over three quarters of these students are able to skip count and one quarter are able to skip count from variable starting points by November.

While the Sharing teddies task prompts counting by 3, it seems that these Modelling students are able to calculate at a level sufficient for either the Dots task or Teddies at the movies. This suggests that the difficulty with those tasks may be related to the way the students interpreted the questions or their capacity to form the necessary mental images. To explore this further, Table 4 presents the growth points for Addition and Subtraction for these Modelling students.

</tbody>
</table>

To be rated at Count on, students find the total of nine teddies that are screened and four that are shown. This appears to require a similar imagining of the elements of the problem as the Dots task. Most of these Modelling students seemed able to do this.

To be rated at Count back, the students answer two questions about subtraction situations posed as stories but not modelled (8 – 3; 12 – 9). This seems to require similar interpreting and imagining of the representation as the Teddies at the Movies task. Of the Modelling students, over one quarter were able to do this.
It is possible that it is not so much the abstract dimension of the task, or the need to form some mental image, as it is the multiplicative conceptualisation that creates the barrier for these Modelling students. In other words, it might not be imagining generally that is required, but imagining of particular multiplicative situations.

A key issue, of course, is the extent to which the particular growth point Abstracting is defined and measured appropriately, and whether it has implications for teaching. On one hand, it is possible that there is an interim step between Modelling and Abstracting. On the other hand, it may be that the step is appropriate but the apparent barrier is as much an artefact of the curriculum and teaching approaches, or even that this is a single step but it takes time.

There are two further investigations that are appropriate to explore these possibilities. The first of these relates to the nature of any interim steps between modelling and abstracting. In examining the questions, it seems that the two division questions represent the growth being posed by the framework. However the growth between the two multiplication questions might have provided some unintended hurdles.

A second possible investigation relates to whether the issue is related to curriculum and teaching approaches. It appears that teachers do make a powerful difference. For each teacher, the number of students who moved from Modelling or below to Abstracting or above over the course of the year (March to November) was counted. Table 5 presents the number of students per grade, for just the straight Grade 2 classes and the Grade 1 and 2 composites, who progressed beyond this Modelling barrier over the year.

</table>

Clearly there is a broad spread. In some Grade 2 classes more than half of the students crossed the barrier, whereas in others it was only a few. It would be interesting to examine the approaches of the more successful of the teachers, in terms of the number of students progressing beyond Modelling, and whether this is a result of specific or intended actions on their part. Certainly these data suggest that the barrier is not impenetrable for students at these levels.

Summary and Implications

This paper reported one aspect of a project investigating the learning of mathematics in the early years of schooling. Data from individual interviews with over 3000 students confirmed that the conjectured growth points in multiplication and division
represent key stages or goals for students. It seems that the Abstracting growth point represents a significant barrier, and that, to achieve this growth point, students need to move towards solving problems without using physical models. Further, students may need experiences both with forming mental images to solve problems, as well as with various multiplicative situational contexts. For students who can solve multiplicative problems by modelling, some specific activities prompting visualisation of multiplicative situations, broadly defined in groups, and arrays, multiplicative comparisons and Cartesian products seem desirable (see Sullivan et al. (2000) for examples of such tasks). Tasks that explicitly remove the materials seem desirable as a first step. It also seems that some teachers are much more successful than others in terms of the number of students who cross the Abstracting barrier.

The Hebrew University, Israel

The activity of abstraction is central to mathematization. In the past, it has been discussed but generally not studied experimentally. The following study exemplifies a way for tracing processes of mathematization. We extend the nested model of abstraction elaborated by Hershkowitz, Schwarz, & Dreyfus (in press), to study successive activities of two Grade 7 students collaborating to solve algebra tasks in technological learning environment. The analysis demonstrates the consolidation of abstractions among the activities.

Theoretical framework

Mathematical activity, like any other human activity, is embedded in a socio-cultural environment (e.g., Voigt, 1995). This view is increasingly accounted for by the mathematics education community, which sees learning as a culture of mathematization in practice. Such an enculturation gains from alternating collective with individual activities, analytic with reflective stages, and integrating intra with inter-processes that are at the root of mathematical development (Hershkowitz & Schwarz, 1999a, see related ideas in scientific enculturation in classrooms in Woodruff & Meyer, 1997). A crucial issue concerns the relationship between construction of shared knowledge and the contribution of the individual (Hershkowitz, 1999). This issue is “hot”, especially when the analysis does not focus on sole activities but on a series of activities.

Like in several other studies conducted in the CompuMath project (e.g., Hershkowitz & Schwarz, 1999a, 1999b; Schwarz & Hershkowitz, in press), we adopted the activity theory perspective (Leonte’ev, 1981), as a framework for studying different forms of practice of the individual and of the group within an between activities. The activity theory is a descriptive tool appropriate for socio-cultural analysis. The unit of analysis is not the individual human action but the activity as a whole, that is, “the minimal meaningful context for understanding individual action” (Kuutti, 1996, p. 28). An activity is a chain of actions done (cooperatively or individually) on the same object. Participant’s motives determine their actions. Artifacts mediate actions on objects. Activities are under continuous change and development, where parts of previous activities are often embedded in following ones.

Mathematisation is central in mathematical enculturation. Abstraction is at the heart of mathematisation (Freudenthal, 1991; Gravenmeyer, 1995). To study abstraction experimentally, Hershkowitz, Schwarz, and Dreyfus (2001) gave an operational definition of abstraction: an activity of vertically reorganising previously constructed abstractions.
mathematical knowledge into a new structure. The suggested model is based on three observable epistemic actions, which are nested in each other: Constructing (C) is the central action of abstraction. It consists of assembling knowledge artefacts to produce a new structure with which the participants become acquainted. The action of Recognising (R) a familiar mathematical structure, occurs when a student realises that the structure is relevant to the problem situation on which participants are engaged. The Building-With (B) action consists of combining existing artefacts in order to comply with a goal such as exploiting a strategy or justifying a statement. The RBC model of abstraction will be used in this article to trace the construction of new mathematical knowledge between different activities.

Collaborative problem solving in an interactive setting takes many forms. Kieran and Dreyfus (1998) recognised different types of peer interaction. The types designate the interaction itself and the same pair may adopt various types of interaction during the same setting (Kieran, 1999).

The study

We focus here on the work of two Grade 7 students who participated in a one-year algebra course. The basis for the selection of these two students was that they were used to talk to each other. Five activities were chosen out of an algebra course. The algebra course, an introductory course in the Compu-Math project (Hershkowitz et al, in press) consists of a sequence of activities organized around problem situations. Students had a spreadsheet program (Excel) at their disposal. The tasks in the algebra course were designed to give opportunities to students’ construction of structures of mathematical concepts (algebraic variables and models) and of various mathematical processes (hypothesizing, making generalizations, testing hypotheses, interpreting representational information, solving and justifying). In the present study, we examine one socio-cultural setting in which these constructions took place. That is, we observe (a) the types of interactions while collaborative work is taking place and (b) the construction of a shared knowledge of the pair and, the contribution of each participant, as well as what is left of it in the individual. All these aspects are examined within and between five activities as one continuum along the academic year.

All activities were open - no guidance for solution was provided, neither instruction for making use of the Excel. The tasks in each activity were of increasing difficulty.

The work of the pair in the class was videotaped and written work was collected. The videotapes were transcribed. Following Chi (1997), the protocols were divided into "cognitive segments". The dimension of interaction was considered and analyzed as well (Resnick et al., 1993; Hershkowitz, 1999), so that the chronological flow of the interaction and its logical flow might be seen clearly, including the underlying assumptions and motives of the students.

In this presentation we will analyze selected parts from the last activity (The Sequences of Dots activity) in which the creation of new structures of knowledge
takes place while students collaborate together. Conclusions concerning knowledge constructing and ways of interacting will be drawn.

**The Sequences of Dots' activity.**

This activity took place at the last month of the year while students were quite familiar with the spreadsheet, and were accustomed to work pair with dedicated peers. The activity consists of 6 tasks, two of which we focus on here. In each of the first two tasks students observed a sequence of dots (see Figure 1a & 1b), were asked to discover a pattern for the number of dots in the shapes of the sequence, and to express it algebraically. Such a kind of activity was quite new to students.

![Figure 1](image)

**Figure 1 – a. the first three shapes in Task 1; b. the third and fifth shapes in Task 2.**

**Possible path for solving the tasks.**

Note: Students may obtain a sequence of numbers describe a given pattern on a spreadsheet by using one of the following generalizations methods: (a) Relating recursively to the previous number in the sequence (usually appearing in the previous cell of the same column) (b) The explicit generalization - using the position numbers (usually appearing in the same row in an adjacent column). Whenever possible, most students tend to use the recursive method, in which they consider locally the difference between two consecutive numbers of the sequence. With the spreadsheet tool, the recursive strategy, which is primarily local, may turn to be global when the dragging operation is used, thus leading to a recursive generalization. It is obvious that educators valorize more explicit generalization - the position number method - in an algebra course, because it articulates the algebraic method of modeling which is general, and can be used in learning equations and functions.

Each of the first two tasks in the Dots activity was designed to promote generalizing of the dot pattern into an explicit algebraic expression, using the position number method (b). The design of the task supports the connection between a specific counting method of the dots number in the specific elements of a given dotted sequence and the corresponding algebraic expression. For example, in the sequence in Figure 1b one may see a central dot and four "arms" each of which containing n dots, leading then to the expression 1 + 4n. Alternatively, one may count the horizontal "arm" with 2n + 1 dots, and the vertical "arm" with 2n + 1 dots, and subtracting one dot counted twice. This counting method is reflected in the
expression \(2\times(2n + 1) - 1\). In short, various counting methods lead to different expressions, which are all equivalent. Linking together the counting method and the algebraic expression may support and help student at an early stage of instruction to generate symbolic generalizations.

In the first sequence (Figure 1a), the three first shapes are presented, to help students to familiarize with the idea of sequence of shapes. In the second task (Figure 1b), two non-consecutive shapes are presented. Our experience from experimental classes, showed that presenting a sequence of consecutive elements leads students to express the pattern they could generalize through a recursive method.

Analysis of the collaborative work of a dyad on the first and second task

In this part we will describe shortly the work done by a pair of students Avi&Ben on the task. We will present selected parts from the full transcript of their work in this activity.

Avi (A) & Ben (B) started working on the first task of the activity (Figure 1a). They made several trials to generalize the given sequence of dots. Some of the trials were wrong. Finally they counted the first sequence of dots systematically in a correct way, generalized it through the use of verbal informal explanations, but failed to generate an algebraic expression. They moved on to the second sequence, and initiated a correct counting method. Yet, as Ben himself mentioned it, they did not generate an algebraic expression. Following the intervention of the teacher (T), they succeeded in finding an expression using the position number method. Then, they voluntary went back to the first task, counted it globally, using a correct method -- in a sense an application of the method they used in the second task, to generate also an explicit algebraic expression, using the position number method.

We go through some episodes to clarify the above general description:

In the first episode Avi is about to find a correct way to count the number of dots in each shape of the first sequence (Figure 1a) using the position number method.

\[
A52 \quad I \text{ think I found something here}
B53 \quad \text{What?}
A54 \quad \text{In the first we add 4, in the second we add 6, in the third we add 8, in the fourth we add 10. Its place A...}
A55 \quad I \text{ don't know how to write this expression. I found the pattern: the first add 4, the second, you take the second and add to it 6, the third, you take the third and add 8, the fourth, you take the four that is its place and add 10.}
\]

\[
... ~ B87 \quad \text{I know what can we do}
A88 \quad \text{What?}
B89 \quad =A1+1, \text{ NO, it will not do it. We need something that each time what we are adding will grow by 2.}
\]
We see that Avi generates a systematic counting method (A54-A55), and expresses it by using the positing number. But, he does not know how to formulate it as an algebraic expression (A55).

After a while (B87-B89), Ben tries to write Avi's idea on the spreadsheet and fails as well.

The two boys move to the second task (Figure 1b). So far, Avi was dominant. We will see in the next episode that this dominance will vanish. Both students observe the shapes in Task 2, and try to find how many dots there are in the 20th shape.

A105 How do you know that there are 81?
B106 What? Because always on each line there are three at each side, or one, it depends on n, it depends on the number, it depends on the order.
A107 If it is 3 you add 1?
B108 No, here, this is the third place, so I have here 3, 3, 3 and here another one. [Ben waves his hand successively to the left, right, up, down, and finally points to the central dot.]

B114 Did you find the expression?
A115 No.

T118 Can you describe how the fourth shape is going to look like?
B119 Yes, four, that's like, four from every side, and here, an extra dot. [pointing to the central point]
T120 Four on every side and...
B121 And one point in the middle.
T122 And at the 200th place?
B123 Then it will be, how much is 199 divided by four?
T124 Wait, how the shape is going to look like at the 200th place, not the one that is made of 200 dots.
A125 Yes, a dot and another 200 on each side. [draws in the air, lines at every side. Ben acquiesces]
T126 A point in the middle and...
A127 200 on the right, 200 on the left, 200 up and 200 down.
B128 No
T129 Do you agree? Yes or not?
B130 Oh, yes, yes.
T131 So how would the n shape look like?
AB132 Oh, one plus n times 4.
A133 No, a dot and n here, n here, n here and n here [show with his hand]

As we can see here, Ben is aware that he is invited to construct an algebraic model of the pattern. He fully understands of the pattern governing the sequence of shapes (B106, B108). He explains it to Avi, and yet, cannot find the algebraic expression (B114). We can see that Ben Recognizes the structure of the given shape in the sequence as being symmetric, consisting of four equal sides with one dot at its middle. Ben can Build-With it numerical solutions for various elements (B119, B123). The intervention of the teacher (T124) pushed the students to work on the shape at the 200th place. The students cannot use direct counting strategies anymore and are led to imagine the 200th shape, which is a significant step towards generalization. In this intervention, the teacher helps them to consolidate the pattern constructed before. Ben is even able to answer a question requiring "backwards" numerical thinking (B123), but he needs the support of the teacher in order to express the algebraic expression explicitly with the position number method. Both
peers show understanding of the expression (AB132). The mediation of the teacher makes it possible for them to make the necessary Construction that leads from the verbal model to the algebraic model based on the position number method.

In the next episode, the two boys are going back voluntarily to the first task, in which they failed generalizing the given pattern algebraically:

B155  So here, that's what I'm saying, each time it's like, here we have to add four, here six and here eight.

...  
T173  The counting method that was used there didn't give you any idea? What was the idea there?
B174  Oh, I get it. I know what. It is like one of the lines, and we can double.
A175  Oh, I found it, here we add one, one here and one here. = A1 + 3
[writes the expression in the computer and drags down], oh, no!
B176  OK, I found it
A177  Yes?
B178  N + (N + 1) * 2

We can see that Ben capitalizes on Avi's idea in their last attempt of generalizing the sequence (B155). Following an additional intervention from the part of the teacher (T173), Avi phrases a wrong generalization, combining together generalization by recursion and generalization by position number (A175). Ben implements successfully the Construction he made by himself in the second task, and generates a correct explicit algebraic expression, based on the position number. The knowledge, which was constructed in the second task, was recognized here, in a similar mathematical task, and was used for Building-With the needed generalization.

Conclusion remarks

We described here a pair of students working in collaboration in order to solve a problem. Both of them were determined to solve it, listened to each other, and tried to explain their ideas to each other. Kieran and Dreyfus (1998) designate this interacting style as inhomogeneous, each of the student trying to make an effort to understand his partner's thought (Trognon, 1993).

The analysis of the collaborative work of Avi&Ben is an additional example in which the RBC nested model of abstraction (Hershkowitz, Schwarz, & Dreyfus, in press) can be used. Here as well we can see that the first two actions (Recognizing & Building-with) are nested at the Construction action. Hershkowitz, et al. did not show that newly created knowledge structures are consolidated, as they are used as artifacts in further activities. In the present we succeeded to show how such a transition may happen; where the previous Constructed knowledge is becoming Building-with in the second cycle of the pair work on Task 1. The importance of this example is beyond the specific knowledge that was constructed and used later on in the activity. It shows that the suggested RBC model can be used as a methodological tool, by which consolidation of abstracted knowledge can be observed and investigated.

Cognitive Mechanism of Constructive Activity Development

Mourat A. Tchoshanov
University of Texas at El Paso, El Paso, TX, USA
Kostroma State Technological University, Kostroma, Russia

In this paper, with respect to works of L. Vygotsky, A. Leont'iev, P. Anokhin and others, I will analyze the key concepts of the modern activity theory: structure of activity; zones of cognitive development; and instructional sequence of cognitive development. I will also consider comparative issues on the relationship between activity theory and constructivist approach. Based on this analysis, the conception of constructive activity will be considered as an integrated theory. The main philosophical idea of this integration is that if constructivism intends to understand the world, and activity theory appeals for changing the natural and social reality, then conception of constructive activity aims on changing the reality through understanding.

First, what is activity? “Activity is a specific form of the societal existence of humans consisting of purposeful changing of natural and social reality” (V. Davydov, 1999, p. 39). Activity theory rooted in philosophy, psychology, sociology, and anthropology. The major beliefs of activity theory are: human activity changes nature; human beings change their own nature by activity (how people work implies how people think); social, cultural, and historical processes are important for understanding of individual’s development.

Activity theory has its own view on the knowledge construction. There is no such a debate “whether knowledge can be transmitted by a teacher or it can be constructed by the learner” in the activity theory. The main principle of activity theory is knowledge can only be constructed through the activity. Studying the concept of activity in Soviet psychology J. Wertsch mentioned: “According to them [Leont’iev and his fellow researches], neither the external world nor the human organism are solely responsible for developing knowledge about the world. They argue that the key to the process is the activity in which the human agent engages” (J. Wertsch, 1979, p. 38). Some constructivists already paid attention to this principle. Activity, in whole, and mental actions, in particular, might be a starting point in the integration of constructivism and activity theory. L. Steffe and H. Wiegel (1996, p. 486) write: “Mental operations form strong connecting links between Soviet activity theory and constructivist approaches.”

The term "constructive activity" was first introduced by E. von Glasersfeld (1987).
Comparing the two philosophical ideas, I would underline that if constructivism intends to understand the world, activity theory appeals not only for understanding but changing the natural and social reality. Though the activity theory “was born” as a philosophical and anthropological doctrine, nevertheless, it had and continues to have tremendous influence and importance for educational practice. Below I will consider “three elephants” or three main educational issues of modern activity theory: structure of activity, zones of cognitive development, and instructional sequence of cognitive development.

**Structure of Activity**

The issue of structure and components of activity is still remaining one of the unsolved problems of activity theory (V. Davydov, 1999). According to the fundamental work of A. Leont’iev on activity theory “Activity. Consciousness. Personality” (1977), the structure of activity includes such components as motives, goals, conditions, actions, and operations. There are three pairs of components in this sequence: activity – motive, action – goal, and operation – conditions. In other words, activity is motivated, actions are goal-directed, and operations are depending on conditions. Leont’iev explains that “the difference between actions and operations emerges ... in the case of actions involving tools. For example, one can physically dismember a material object with the help of a variety of tools, each of which defines a way (an operation) for carrying out the given action (the dismemberment)” (Leont’iev, 1977, p. 107). Analyzing Leont’iev’s structure of activity V. Davydov mentioned: “If we examine this structure, we notice the absence of the means of solving a problem. It seems clear that this component should be added” (Davydov, 1999, p. 45).

Actions usually come from an emerging problem or task (e.g., real-life situations, inquiries, surprise situations, puzzles, paradoxes, sophisms) which reflects a cognitive conflict or intellectual difficulty and encourage student's curiosity. The way for carrying out goal-directed actions in the problem solving process is called an operation. The set of goal-directed actions and conditionally determined operations we call a technique. The set of techniques to accomplish the activity we call a method. Technique corresponds to actions and operations, and method corresponds to activity. Techniques and methods are means or instruments of solving a problem. Activity systems represent different aspects and domains of social and cultural life. Culture as a set of activity systems is relevant to social needs, activity is relevant to motives, techniques and methods – to instruments of solving a problem, operations – to conditions of problem, and actions – to goals of given problem (figure 1).

**Zones of Cognitive Development**

This concept is another "elephant" of activity theory. Vygotsky noted that the possibilities of genuine education depend not so much on the already existing student's knowledge and experience (level of actual development) as on the characteristics that are in the zone of proximal development. He wrote: "Pedagogy should be oriented not toward yesterday, but toward tomorrow in child development. Only then will it be able to create, in the process of education, those processes of development that are at present in the zone of proximal development" (Vygotsky, 1996, p. 251). Zone of proximal development is the distance between what child knows and his potential for knowing with the help of "more knowledgeable other". It is necessary to stress that in Western pedagogy the main attention is paid to the ZPD (zone of proximal/potential/nearest development) though Vygotsky considered ZPD as one of the domains between the lowest and highest levels of cognitive development. "We always should determine lowest threshold at which instruction may begin. But it is not the end of the deal: we should be able to determine the upper threshold of instruction as well. Only between these thresholds instruction might be fruitful" (Vygotsky, 1996, p. 251). The lowest threshold is the level of actual development (LAD) which contains the
student’s actual knowledge, skills and experience. Then follows the zone of proximal development (ZPD) which aims on cognitive change basically connected with the guided development of student’s understanding. “The ZPD is the locus of social negotiations about meanings, and it is, in the context of school, a place where teachers and pupils may appropriate one another’s understandings” (D. Newman, P. Griffin, M. Cole, 1989, Foreword by S. White). There is one more zone after ZPD. When Vygotsky wrote about the upper threshold, he didn’t mean that it is equal to ZPD. Till now nobody has paid attention to this important fact in Vygotsky’s work. It is a new zone - zone that goes beyond the development of understanding. It is a zone of formation of student’s creativity. Whereas in ZPD the functions of comparison, reproduction, assimilation, and coping are of primary importance, in a new zone the functions of construction, generation, and creation are most important. This upper threshold of instruction and cognitive development we call a zone of advanced development (ZAD). If ZPD is the interpsychological dimension where social activity and interpersonal dialog is taking place, ZAD is the intrapsychological dimension where advanced individual activity and intrapersonal dialog is going on.

Activity cannot be understood as simple internalization of ready-made standards and rules. S. Rubinshtein (1973) stressed that human activity presupposes not only the process of internalization but also the process of externalization when humans create new standards and rules. So, if the psychological outcome of ZPD is internalization, for ZAD – it is externalization. According to L. Vygotsky the guidance is crucial in helping student move from LAD to ZPD. We cannot say the same about student’s transfer from ZPD to ZAD. In other words, if ZPD is a domain of guided cognitive change (understanding), ZAD is a zone of student's individual (independent) activity. Therefore, we consider ZAD as a domain of higher cognitive achievement and creativity which student may reach in the process of intense individual studies (figure 2).

![Fig. 2. Zones of Cognitive Development](image-url)
Sequence of Cognitive Development

Human activity is conscious and it exists in both collective and individual forms. L. Vygotsky argues that determination of individual consciousness and cognition might be presented by the following sequence: collective (social) activity – culture signs/symbols – individual activity – individual consciousness. That is why, for Vygotsky and his fellows, it is very important to examine the transformation of all aspects of this schema in the study of the sequence of cognitive development. Based on this schema, P. Gal'perin and N. Talyzina (1968) worked out the conception of orientation and stepwise formation of intellectual actions that includes the sequence of following stages: orientation, “hands-on” actions, thinking aloud, inner speech, and mental actions. The conception of orientation is a central idea in Gal'perin and Talyzina's (G&T) theory. There are actions with complete and incomplete orientation bases. For operating in the zone of proximal development complete and detailed orientation is efficient. At the same time, theoretical and experimental studies (O. Tikhomirov, 1999, p. 349) show, that in accomplishing creative activity and operating in the zone of advanced development incomplete but systems orientation is required. "Hands-on" actions is the "doing" stage in G&T model which include manipulations, modeling, physical actions, and experiments with external representations. During this stage "public" (peer and small groups learning, whole group discussion, etc.) discourse is crucial. This corresponds with "collective (social) activity" in Vygotsky's schema. Then "private" discourse (e.g., thinking aloud, inner speech) accompanies the development of student's mental activity. Needless to say, that two of these activity schemata complement each other by pointing out different aspects. In our research, we integrated Vygotskian and G&T models in order to design a cognitive structure of constructive activity development. This structure includes the following stages:

1. **Orientation stage:** cognitive entrance to the problem/activity/thematic unit guided by instructor (who defines the level of completeness of the orientation base), creating an intellectual difficulty (cognitive discomfort) by using challenging problems, real-life projects, paradoxes, misconceptions, surprise situations, fallacies, etc. From psychological point of view this stage reflects such elements of afferent synthesis as actualization and motivation.

2. **Hands-on stage:** approaching the problem using standard external representations given by instructor or chosen by students (manipulatives, physical objects, visual tools, etc.) as well as expression of initial students' representations through a "public" discourse (e.g., exchange of students' ideas, peer learning, small groups, whole class discussion).

3. **Minds-on stage:** a "private" discourse (e.g., students’ thinking aloud, inner speech) and development of students’ conceptual understanding. In this stage
the primary attention should be on making inter- and intra-subject connections and development of students' internal representations (e.g., mental images, schemata, metaphors).

4. **Generalization stage:** reflection, extension, and construction. Focus should be on development of students' creativity using general methods for advanced problem solving and reasoning. It is also a stage of efferent synthesis and evaluation. If orientation stage reflects the level of actual development (LAD), hands-on and minds-on stages reflect the ZPD, then generalization stage is the zone of students advanced development (ZAD).

The advantage of this model is that it contains an attempt to create a sequence of instructional stages for cognitive development. One of the main disadvantages of constructivism is an absence of such kind of instruments. Unfortunately, the point of confusion for teachers who are trying to implement a constructivist approach is that there is no clear procedure how to do it. Hopefully, an integrated conception of constructive activity "takes care" of this confusion.

Another concern is a difference in views on the role of representations in cognitive development. Constructivists P. Cobb, T. Wood, and E. Yackel (1992) reject the "representational view of mind". They ignore basic principles of theories of L. Vygotsky and J. Piaget according to which representations (culture signs and symbols) are necessary tools in the process of transition from collective (social) accomplishment of an activity to individual accomplishment. Sign systems "are the real bearer of human culture, the means by which individual activity and individual consciousness are socially determined. The incorporation of signs into the structure of a mental function (mediation through signs) links that function to culture. On the one hand, a sign is always supra-individual and objective since it belongs to the cultural world, but on the other, it is individual since it belongs to the mind of particular person" (V. Davydov, V. Zinchenko, 1993, p. 102). Therefore, an involvement of multiple representations into the process of constructive activity plays a significant role in mediation between an external reality and student's internal cognitive growth.

We also consider the cognitive structure of constructive activity development as a **functional system.** The main feature of functional system is its invariance. P. Anokhin and A. Luria stressed an importance of functional systems in brain research: it could sustain functioning regardless of partial damage of the brain. Approaching a situation of cognitive change, D. Newman, P. Griffin, and M. Cole (1989) "view the activity in the ZPD as constituting a functional system". At the same time they erroneously consider that "the zone of proximal development is a
functional system for cognitive development” (ibid.). They wouldn’t have come to this conclusion if they had taken into account an existence of ZAD along with ZPD and the structure of functional system which includes afferent synthesis, decision making, anticipation, goal-oriented action, efferent synthesis, and evaluation (Anokhin, 1978). Because then it would become evident that functional system is a cognitive mechanism for the ZPD and ZAD construction, opposite to what D. Newman, P. Griffin, and M. Cole thought it to be.

Outcomes of the experiment on implementation of the conception of constructive activity in teaching and learning of secondary mathematics show important cognitive changes on students’ motivation, attitude, and confidence. The experiment took place from 1990 till 1996 in number of Russian high schools (Moscow, Kazan) with total enrollment of 650 students. After the experiment students’ self-evaluation showed that 88% of them considered their progress on high level, 8% - on average level, and only 4% of students responded that there was no progress in their learning of mathematics. 85% of students reduced their anxiety and obtained confidence in mathematical problem solving and reasoning. 76% of students changed their attitude from negative to positive toward mathematics. Before the experiment only 16% of students were interested in mathematics, but after it 84% of students were ready to continue study mathematics on the advanced level (M. Tchoshanov, 1996, p. 148).

**Conclusion**

Current stage of development of psychology of mathematics education is characterized by growing new learning theories and pedagogical approaches (e.g., constructivism, situated learning, etc.). There is an emerging necessity of integration of “new” theories with more traditional ones. It will create a polyphonic pedagogical environment and help to avoid artificial contradictions between relatively close pedagogical theories. The key advantage of polyphonic pedagogical systems before monophonic ones is that they can accumulate new integrative quality, which will allow improving education in a global community. Based on this idea, we considered an integration of activity theory and constructivist approach with respect to development of conception of constructive activity. The key pedagogical idea of new conception is that knowledge can only be constructed through the oriented activity, which follows the sequence of instructional stages: orientation, hands-on and minds-on actions, and generalization. The basis of orientation (complete or incomplete) determines the level of cognitive development: beginning with understanding in the zone of proximal development up to creativity in the zone of advanced development. The pedagogical strength of this conception is that some details of learning process may change but the
pedagogical functional system, as a cognitive mechanism of constructive activity development, remains intact.

Representations as Conceptual Tools: 
Process and Structural Perspectives

Michael O. J. Thomas and Ye Yoon Hong
The University of Auckland

Much has been written about the apparent duality of many mathematical concepts as processes and objects. Further, the importance of the representational forms in which mathematical concepts are presented has been analysed. In one of these representations, the symbolic form, the idea of a procept linking process and object forms, has proven a valuable concept. However, this analysis has been lacking from other representations. In this paper we look at the characteristics of the process and object view of some other representations with a view to beginning a classification of interaction with them and give examples to indicate the validity of the classes.

Process and Object

Many mathematical concepts take the form of objects, and these may arise in a number of different ways. Tall, Thomas, Davis, Gray & Simpson (1999, p. 239) have distinguished three types of object construction: perceived objects; procepts; and axiomatic objects. The second of these has been given considerable attention over a number of recent years, with researchers describing in detail both the distinction between the dynamic process and static object view of mathematical concepts, which Sfard (1991), calls an operational and structural duality, as well as the manner in which the former is transformed into the latter in the mind of the learner. Sfard (ibid) proposes that processes are interiorised and then reified into objects, while Dubinsky and his colleagues (Dubinsky & Lewin, 1986; Dubinsky, 1991) talk about processes being encapsulated as objects and have imbedded this in an Action-Process-Object-Schema or APOS theory, for the construction of conceptual mathematical schemas. The term procept, as used above, arose in the work of Gray & Tall (1994) to describe the use of mathematical symbols to represent a process (which the symbols may invoke) or a concept (which they may represent), or, depending on the context, the viewpoint, and the cognitive aim of the individual.

These theoretical ideas have proven useful, with widespread applications in algebra, calculus, and advanced mathematical thinking, as described by Tall (2000), and others (e.g., Cottrill, Dubinsky, Nichols, Schwingendorf, Thomas, & Vidakovic, 1996; Clark, Cordero, Cottrill, Czarnocha, Devries, St. John, Tolias, & Vidakovic, 1997).

Representations of Mathematical Objects

We note that in the discussion on the nature of mathematical concepts and their description in terms of process and object, and especially in the case of procept, there has been a firm emphasis on the symbolic representation. This is understandable of course, because of the tremendous power of symbolism, and algebraic symbolism in particular. However, a key component of schemas is the representation of conceptual
processes and objects in a number of associated but different ways (Kaput, 1987, 1998). How then do representations other than the algebraic symbolic relate to the process-object conceptualisation of much of mathematics? If this is a valid view of the underlying mathematical concepts then there should be corresponding perspectives for these. In particular, the graphical and tabular representations which are so common in secondary mathematics should be amenable to such an analysis. In the symbolic representation it has been proposed that the object view enables one to take the object and perform an action on it, using it for example in a further process. An example of this is the construction of groups of functions. But this is due to the power of the symbolic notation, mentioned above. What is the corresponding position with tables and graphs, and other representations, and how would we recognise this shift in perspective for them?

We argue here that a representation can be seen as a multi-faceted construction which assumes different roles depending on the way that students interact with it. When an image is on a computer screen, for example, Mason (1992) has suggested that students can be looking at the images or looking through them depending on the focus of their attention. In this sense we say that students can interact with a representation in at least two different ways, by observing it or acting on it. The observation can be at a surface level, looking at, or at a deeper level, looking through. For example, looking at a representation a student may comment on a property of the representation itself but by looking through it students may use it to assist them to notice properties of the conceptual processes or object(s) represented. This is in line with the property noticing of Pirie & Kieren (1989), who talk about how images can be examined for specific or relevant properties. An example occurs in the paper by Ainley, Barton, Jones, Pfannkuch, and Thomas (2001), where, looking at a graphical representation on a spreadsheet of five data points, two of the students comment on surface features of the representation, saying, for example, that “It’s a hill” and “It’s like a mountain there” (p. 3). In contrast, if they had been looking through the graphical representation they may have commented on properties of the function, such as its maximum or minimum values.

While this idea of observation of representations is important, in order to build rich cognitive structures more is needed. When he goes beyond such acts of observation of a representation and performs an action on it, doing in the sense of Mason (1992), in order to obtain further information or understanding from it, then we maintain that the representation becomes a conceptual tool for that student. The metaphor of a tool is appropriate here since it is not the shape of a spade, or its properties that make it a tool, but the actions of a person using it. Such learning from activity has been described as construing by Mason (1992) and it is this type of activity which gives rise to a conceptual representation tool. However, thinking back to the process/object views of concepts, the ways in which a student observes or acts on a particular representation will depend on whether they have a process or an object view (or both) of the concept(s) it represents. For example a student may use a table
or a graph and perform linear interpolation on values obtained in order to approximate an intermediate value of the function. Whether the student sees the function as the sum of the discrete results of an input-output process or as a function object may not be clear. In contrast, to be given the graph (or table of values) of a function \( f(x) \) and being asked to draw the graph of, say, the function \( f(x+1) \), when there is no specific function given, may require a structural or object view of the function.

Table 1 *Possible Modes of Interaction Between Student and Representation*

<table>
<thead>
<tr>
<th>Interaction</th>

<tr>
<td>Action on the Representation</td>
<td>Conceptual Process</td>
</tr>
<tr>
<td></td>
<td>Representation Tool</td>
</tr>
</tbody>
</table>

This gives a matrix of six different possible modes of interaction with a conceptual representation, as delineated in Table 1. We have tried to exemplify each of these modes below, choosing to talk about a structural rather than an object view of concepts in this context, since it seems to convey the idea better. One should not get the impression from the discussion so far that because it is the primary source of examples that these concepts are only applicable to the learning of function. An example from group theory may help support this contention. Figure 1 contains a representation of the klein four-group, namely the multiplication table of the set \{1, 3, 5, 7\} under the operation of multiplication modulo 8.

\[
\begin{array}{c|cccc}
\times \text{ mod } 8 & 1 & 3 & 5 & 7 \\
1 & 1 & 3 & 5 & 7 \\
3 & 3 & 1 & 7 & 5 \\
5 & 5 & 7 & 1 & 3 \\
7 & 7 & 5 & 3 & 1 \\
\end{array}
\]

*Figure 1. A multiplication table representation of the klein four-group.*

A student with a process view of a group as the sum of the combinations of elements under the law of composition may interact with this representation by (for example): spotting that combining elements in the set gives rise to only elements of the set, since these appear in the body of the table (with no reference to closure) (PSO); noticing that every element is self-inverse (PPO); using the table to verify that \( ab=ba \) for all \( a, b \in \{1, 3, 5, 7\} \) (CPRT). Alternatively the student who has a
structural view of a group may interact in quite different ways by (for example): noticing that there is a leading diagonal of ones in the table (SSO); observing that there is a subgroup \( \{1, 3\} \) or that the symmetry of the table means that the group is Abelian (SPO); demonstrating by rearranging the columns of a table (we assume here the necessity of this) that the group is isomorphic to the group represented by a multiplication table of the matrices:

\[
\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \] (CORT, action to compare two object structures).

It needs to be said at this point that it is often difficult, even with student interviews, to be sure whether a particular student has a process or object view of a given concept. However, we can still say whether he/she is acting on the representation and using it as a conceptual tool rather than simply observing it or even for abstracting properties. In cases like this we may call such usages *surface observation (SO), property observation (PO) and conceptual representation tool (CRT)*, leaving out the process or object distinction.

**Experimental Exemplars**

Space does not allow us to exemplify from our research each one of the six categories here, but we will try to present sufficient examples to allow the reader to see how they arise. What we have found in our recent research is that students often interact with function graphs and tables of values in a *process-oriented* manner (Thomas, 1994), as series of discrete pairs of values or points. In Figure 2 we see an example of a student who, in trying to solve the equation \( 4-2x = 3x-1 \) has a process perspective of the two given tables, stating (translated from Korean) “because the values have \((-\)\) on the table”. This is a surface property of the representation and so the interaction is a PSO.

\[\begin{array}{|c|c|} \hline x & y \\ \hline 1 & 6 \\ 2 & 1 \\ 3 & -2 \\ \hline \end{array}\]

**Figure 2.** Student A’s process surface observation (PSO) use of tables.

This student has been asked to use the table as a tool to solve a linear equation, but because of his process-oriented perspective he was unable to relate the input-output values to the solution of an equation. In contrast, some students, after they had experienced the different related representations using calculators were able to solve these equations. Student B for example, who although unable to solve the equation correctly in the algebraic representation, making several errors, is able to use the
tabular representation as a conceptual tool (CRT) to solve the equation (Figure 3), stating that the solution is $x=1, y=2$ because "when $x=1$ they are consistent with each other." We cannot be sure whether he has a process or a structural view of the tabular representation.

![Figure 3](image)

**Figure 3.** Student B's use of tables as a conceptual representation tool (CRT).

Other students were also using the tables as a CRT were able to give similar reasons for the same type of solution. We have also come across evidence that some students appear to see graphs in process terms, as a sequence of discrete points which happen to be joined with a curve. In Figure 4 we see an example of such thinking.

![Figure 4](image)

**Figure 4.** Student C's graph used as a conceptual process representation tool (CPRT)

Here student C, asked to solve $x^2 - 2x = 3$ using the graph, has acted on the graph in a process manner (CPRT), executing an inter-representational shift to produce a table of a discrete set of 6 integer-valued points. The answer happens to be incorrect in this case simply because of an error finding $f(-1)$.

![Figure 5](image)

**Figure 5.** Two examples of using a given graphical representation as a CRT.
In Figure 5 students D and E employ the graphical representation of a function, whose symbolic formula is not given, as a CORT in order to explain conceptual ideas, namely, how the successive approximations in the Newton-Raphson method approach a root $a$, and when $x_1$ is a suitable first approximation for the root $a$ of $f(x)=0$. These students are thinking conceptually using the graph and have no need to carry out a process. Students have also been able to operate conceptually on a graphical representation involving the relationship between the area under the graph of a function and its symbolic representation when the function undergoes a transformation which can be described as parallel to one of the axes, i.e., $x \rightarrow x \pm k$ or $f(x) \rightarrow f(x) \pm k$. Figure 6 shows two examples of students' work where they have interacted with a graphical representation they have constructed to answer a question with a symbolic presentation, namely:

If $\int_{a}^{b} f(t) \, dt = 8.6$, then write down the value of $\int_{2}^{3} f(t-1) \, dt$.

The first student has drawn separate graphical representations of the unknown function $f(t)$ (possibly using $y=t^2$), and the second has put both graphs on the same axes, but they have both acted on these by clearly marking the area represented by the symbolic definite integrals and operating on this area as a structural object, to answer successfully the conceptual question about the transformation. Once again these students are using the graph conceptually with no need to carry out a process. These are therefore examples of CORT interactions with the graphical representations.

![Graphical representation of a problem and solution](image)

Figure 6. CORT use of graphs for area conservation under a transformation $t \rightarrow t-1$.

**Discussion**

We believe that the start we have made here on a classification of interaction with various mathematical representations of concepts has potential benefits for the teaching of mathematics. It is the teacher that is the key to benefits emanating from any theoretical position, and the types of interaction proposed above suggest possible ways in which teachers could address student learning. One approach they could be encouraged to consider is to construct lessons which build meaningful uses of different representations of concepts into modelling activities based on real world problems. Lesh (2000) has suggested that helping students to be able to construct conceptual tools that are models of complex systems in such a way that they can
mathematise, interpret and analyse using these tools is a key goal of mathematics teaching. We strongly agree with his further statement that "... representational fluency is at the heart of what it means to "understand" many of the more important underlying mathematical constructs" (p. 74). Such 'fluency' includes the ability to interact with these representations, using them as conceptual tools, but doing so, as Kaput (1998, p. 273) suggests being aware of the potential "inadequacy of linked representations and the strong need to provide experiential anchors for function representations."

A second consideration for teachers of ways to approach the building of representational fluency is to consider use of the graphic and super-calculators, since the primary representations needed in schools arise naturally, in a dynamically related way, in the context of these machines (Kaput, 1992). For example, in many classrooms students may initially learn about functions only through the symbolic representation, becoming immersed in algebraic manipulations and equation solving. Only some time later will they approach the graphical solution of equations. By then it may be much harder for many students to build inter-representational links, if they are constrained to a process view of function. They may employ a surface, procedural method of solving equations graphically by drawing the graph of each function and reading off the x-value(s) of the point of intersection without engaging with deeper relationships of the four different representations: algebraic, tabular, ordered pairs and graphical. To build rich relational schemas based on these external representations, it seems a good idea that, where possible, students should interact with the sub-concepts of one-to-one, independent and dependent variable, etc. in each representation in close proximity, exploring the links between them.

The third implication for teachers is one of assessing diagnostically the type of thinking with which their students are approaching representational use. The term versatile thinking was used by Tall and Thomas (1991) to refer to the complementary combination of the sequential/verbal-symbolic mode of thinking and the more primitive holistic visuo-spatial mode, in which the individual is able to move freely and easily between them, as and when the mathematical situation renders it appropriate. However, with the theoretical stance we have presented here we can now enlarge this concept of versatile thinking and say that this would include the ability to move between the PSO, PPO, and CPRT modes of interaction with any representation and the SSO, SPO and CORT modes of interaction as and when each is considered applicable. Thus a useful goal for teachers would be to try assess the extent of their students' versatile thinking and aim to assist them to build it further so that they are not limited to a purely process approach to mathematics, important though that is.

THE DEVELOPMENT OF CHILDREN'S UNDERSTANDING OF THE QUOTIENT: A TEACHING EXPERIMENT

Zulbiye Toluk
Abant Izzet Baysal Universitesi
Turkey

James A. Middleton
Arizona State University
United States

Abstract: The conceptual development of the Quotient in four children in the US was studied through a series of parallel individual teaching experiments. At the beginning of the study, children viewed whole number division and fair sharing as two different domains: Division and fractions. By requiring children to confront fractional and division situations involving similar contexts, quantities and symbolization, children moved from a Whole Number Quotient scheme to a Fraction-as-Division scheme. At the end of the study, children were able to think about fractions in terms of division and were able to solve problems involving division of fractions.

Introduction

Research on understanding children's rational number concepts has been of keen interest to mathematics educators in the last two decades. Children's solutions to problems involving fractions and ratios have shown that children use additive schemes to solve such problems (Lamon, 1993; Resnick and Singer, 1993), and that children have difficulty in conceptualizing the rational number as a number (Mack, 1990, 1995; Behr et al., 1985). Children's difficulties with rational numbers can be attributed to the fact that rational numbers take different meanings across different contexts (Kieren, 1976; Behr, et al. 1983). Rational numbers are used to represent and control part-whole relationships; they are fundamental to measuring continuous quantities; in particular, they are involved where quantities are divided; and they are used in multiplicative comparisons of two quantities. Therefore, when we consider the variety of interpretations of rational numbers, it is not surprising that children have difficulties with rational number concepts.

One of these personalities that rational numbers takes on is the quotient interpretation (e.g., Kieran, 1993). Building phenomenologically from the contexts of fair sharing, under the quotient interpretation, rational numbers become quotients of whole numbers. More specifically, a rational number can
be defined as the yield of a division situation. Considering this meaning, the relationship between division as an operation and fractions as quotients becomes evident. It is reasonable to assume, therefore, that interpreting rational numbers as quotients of division situations requires one to have a sound understanding of the division concept. Moreover understanding of the division concept beyond whole number partitioning should address the relationship between quotients as numbers and the operation of division as embodying a multiplicative relationship.

Although the quotient is considered the phenomenological source of rational numbers (Freudenthal, 1983; Streefland, 1991; Kieren, 1993), the question of how children conceptualize the quotient subconstruct still remains unanswered. Within the quotient subconstruct, any fraction can be seen as the result of a division situation that requires the distribution of the quantity represented by the numerator equally into the number of groups represented by the denominator. For example, $6/4$ can be thought as the quotient of 6 things distributed into 4 equal groups.

Children first learn the concept of division partitioning whole numbers—e.g., fair sharing—and they express quotients as whole number partitions. Division situations with remainders are found to be difficult because instruction fails to engage students in the interpretation of resulting fractional quotients appropriately within the given problem context, instead putting off fractional quotients for later study. However, in research on division, there is a lack of study addressing the relationship between rational numbers and division of whole numbers and whether this traditional separation of whole number quotients-with-remainder and fractional quotients is pedagogically sound practice. Moreover, developmentally, there is little research that documents plausible trajectories by which children come to see the two as isomorphic conceptually (see Behr, Harel, Post, & Lesh, 1992, p. 308 which illustrates the limits of our current understanding in rational number research).

At any rate, current curricular offerings in the United States present whole number division and fractions as separate and distinct topics. Division is treated as an operation one performs on Whole numbers, and fractions are taught almost exclusively as Part-Whole concepts. Only in the late middle grades, when an understanding of quotient becomes necessary for dealing with algebraic entities such as rational expressions, are children expected to connect these two heretofore distinct topics. At no point in the preceding 7 or 8 years is explicit attention focused on teaching fractions as division, nor on teaching division as expressing a rational number: A quotient.

The purpose of this research was to study four fifth graders’ conceptualizations of the quotient subconstruct under instructional conditions that expressly required them to confront and connect the isomorphisms inherent in thinking about fractions and in thinking about division. Specifically, it was intended to understand the transitional understandings children constructed as
they moved from division of whole numbers to the description of a fraction as the quotient in division situations. Therefore, a special focus was put on how children conceptualized the remainder as the fractional part of the quotient in whole number division and how they moved to the conceptualization of a fraction as a quotient itself. In short, the research was designed to understand how children come to understand fractions as division, and concomitantly division as a number.

Method

A set of four parallel individual teaching experiments were conducted in studying the development of four fifth graders in an inner city school in the southwest United States. The primary goal of this teaching experiment was not aimed at uncovering how children thought about a given set of tasks, but at determining how children went about making sense of, and structuring their experience towards learning novel content, and in particular, the sense that they made in confronting the subdivision of the remainder of whole number division. The teaching experiment lasted approximately 8 weeks.

One of the students was Anglo, the rest were Hispanic and bilingual. Subjects consisted of two boys and two girls. A clinical interview at the beginning was conducted to determine baseline data and another clinical interview at the end was conducted to determine changes in children’s schemes over the entire teaching experiment. Between the clinical interviews, children participated in teaching episodes. The researcher constantly modified the tasks to draw finer-grained details of schemes children were constructing at a particular moment of time (e.g., Steffe & Thompson, 2000).

Each teaching episode lasted approximately 60 minutes. Tasks were presented either in the form of a word problem or a division number sentence. The general strategy we employed was to present word problems that involved fair sharing contexts, which we felt would have the highest probability of eliciting quotient thinking in children, wording the problems to guide the students to both fractional and whole number division solutions. By pairing mathematically isomorphic problems that afforded these different interpretations, we forced students to confront their common qualities, and to draw connections between symbols in their respective notational forms. With symbolic problems, we paired problems that involved the same quotient relationship, but that utilized different notation (e.g., 13/4 vs. 13 ÷ 4). In particular, we presented problems that required students to deal with the partitioning of the remainder in whole number division, or re-conceptualizing the unit in the case of improper fractions.

Each child was interviewed individually. Children were asked to explain their thinking and show their work as they solved the problems. Interviews were audio-recorded. The researcher also took notes during the interviews. Therefore, there were three main sources of the data: Audio-recording of verbal interaction, student’s written work and field notes of the researcher. All recordings were
The results of this study indicated that children constructed four schemes that embodied their progress in conceptualizing the quotient. These schemes appeared to follow a developmental order of 1) Whole Number Quotient, 2) Fractional Quotient, 3) Division-as-Number, and 4) Fraction-as-Division when children progressed toward an understanding of fractions as quotients. Based on the regularities in conceptual development evidenced by the children, and supported through the sequence of teaching episodes, a schematic illustrating how children coordinated these schemes to come to a more full understanding of the quotient subconstruct was generated (see Figure 1). More specifically, it describes children's progress from a disconnected understanding of fractions as representing part-whole comparisons and division representing a whole number operation, toward a more connected understanding of fractions as quotients of division situations.

**Figure 1. Schematic Illustrating Children's Developing Connections Among Fractions and Division Schemes**

In the rest of this section, each scheme will be described in detail.

**Fractions-as-Part-Whole Comparisons.** At the beginning of the teaching experiment, all four children conceived of fractions as representing part-whole relationships exclusively. When asked to describe the meaning of a number presented in fractional form (e.g., \( \frac{1}{2} \)), they attempted to describe the given fraction in terms of part-whole relationships by partitioning a whole into the...
denominator and coloring the number of parts specified by the numerator. Beside part-whole comparisons, they were unable to provide a different explanation for the given fraction. Because in part-whole comparisons, the unit whole is limited to one, three of the children had difficulty in identifying the whole to explain a given improper fraction. One of these students, Juan, referred to these fractions as “bad fractions.”

Whole Number Quotient Scheme. The Whole Number Quotient scheme appeared when children tended to provide whole number quotients for all division situations. It was also evidenced by their inclination to write quotients with remainders even when they converted the remainder to a fraction. In cases when the problem situation allowed the equal distribution of the remainder among the groups, they avoided writing fractional quotients as answers to division number sentences. It appeared that when they conceived of a situation as division, they provided the quotient with remainder even when they realized the possibility that the remainder could be further subdivided.

Fraction as a Fair Share. The Fraction-as-Fair-share scheme was illustrated by children’s ability to solve given fair sharing problems in which the answer was less than one. In such situations, children were able to find the answer by partitioning the given quantity. However, when they were asked to write a number sentence representing their solution, they were unable to do so. Transcripts indicate that children did not initially conceive of fair sharing situations as cases of division even though they easily found the fractional quotients through partitioning. It was also evident that they held a conception of division in which the dividend is always bigger than the divisor. In such conception, the quotient of a division situation is never less than one. This was also supported by children’s tendency to reverse the dividend/divisor order in solving symbolically represented problems in which the dividend was less than the divisor.

Fractional Quotient Scheme. The Fractional Quotient scheme (which appears to be a key transitional phase) was characterized when children started to symbolize fractional quotient situations as answers to “division problems.” Children were comfortable with fractional answers when solving partitive word problems. However, for symbolically represented problems, they provided fractional quotients only after the problem was put in a partitive context. They started to conceptualize fair sharing situations as division because they recognized that fair sharing situations involved the creation of equal “groups” (i.e., partitions) similar to whole number division.

Division-as-Fraction Scheme. The Division-as-Fraction scheme was illustrated in children’s ability to anticipate the quotient of a given division situation without applying any analytic way of solving it. Children came to this understanding after they started to symbolize fair-sharing situations with an answer less than one. This notion can be summarized as: If any a quantity was divided into b equal groups then the resulting quotient is always a/b. Hence,
when a fair sharing problem was given, children first anticipated the answer using this rule. Once the answer was anticipated, they then were able to solve the problem conceptually. When children didn’t get the same answer as the one they had anticipated, they had to verify whether their answer and the anticipated result were equivalent or not.

**Fraction-as-Division Scheme.** The Fraction-as-Division scheme was revealed when children reasoned about fractions in terms of division situations. For example, this scheme entails that ¾ can be considered as 3 things divided into 4 equal groups, equivalently 6 things divided into 8 equal groups and so on. Children began to use this reasoning as a parallel explanation to Part Whole to explain what a given fraction meant. Under this scheme, children were able to reverse the Fraction-as-Division scheme. In other words, without probing, they were able to realize that if any division situation could be represented as a fraction, the reverse was also true.

**Division-as-Number Scheme.** This scheme was illustrated by the children’s ability to generalize the two way relationship between a division situation and the fraction representing its quotient to all division cases. In other words, \( \frac{a}{b} \) was equal to \( a \div b \) for every \( a > b \), where \( b \neq 0 \). However, only Kate constructed this scheme. The rest of the children did not generalize this relationship to all division cases. These children tended to write given any improper fraction as a mixed number so this hindered their ability to recognize this relationship.

**Discussion**

Previous research has shown that young children deal with quotient situations- fair sharing- easily (Lamon, 1996; Kieren, 1988). In a fair sharing situation, a typical behavior is to partition quantities and write the resulting fractions as the quotient of a given situation. From their partitioning behavior, it is concluded that children conceptualize those fractions as quotients. The results of the present teaching experiment, however, suggest that ability to partition quantities into its parts didn’t necessarily indicate that children actually conceptualized the resulting fractions as quotients. This was evidenced by the general reluctance in symbolizing quotients less than one as division number sentences.

Children were reluctant to symbolize the situations in this manner for a variety of reasons. First, for them, “division” always yielded a whole number quotient with or without a remainder. It was not that they didn’t recognize the partitionability of the remainder, it was the fraction, the result of the partitioning that they didn’t conceive of as a part of the quotient. Typically, in their minds, “fractions” resulted from fair sharing situations which involved cutting or splitting of whole quantities into parts less than one, whereas “division” resulted from partitioning quantities into groups with number greater than one. Second, students’ resistance to consider a fraction as a quotient was due to the the fact that children had such a strong understanding of the Part-Whole subconstruct.
which, from prior experience, was the only way they were used to thinking about a fraction.

Moreover the existence of an understanding of fractions representing fair shares and part-whole relationships and division as a whole number operation as separate entities does not necessarily imply that children will connect these understandings into a coherent quotient scheme without intervention. Rather, the results of the teaching experiment showed that some explicit connections have to be made between these concepts. By making the commonalities in context and notation between whole number division and fraction situations problematic, children need to be encouraged to reflect on the equivalency of fair sharing situations and whole number division. Using a common symbolization; children’s conceptions of division can be challenged. In this teaching experiment, division number sentences were used to show that the result of a division operation is a fraction represented by the common divisor/dividend notation).

The findings of this study suggest that a fragmentary approach to teaching quotients, which arranges instruction into two distinct and separate conceptual dimensions, i.e., division as an operation and fractions (as primarily part-whole quantities, but also applying to simple fair sharing), may lead children to develop a fragmentary understanding of the quotient. Instead, the present cases suggest that providing common problems in both fractional and division forms, and confronting children with the basic equivalencies of these forms may be fruitful in developing a more powerful understanding of the quotient subconstruct. In addition, the commonalities among cases in this study suggest that instruction on quotient should be cognizant of how the linkages between division as an operation and fractions as numbers are made. In particular, the order children followed as they moved towards the quotient subconstruct suggests that both whole number division and fraction instruction can proceed fruitfully in concert, intertwined but not parallel.

INVESTIGATING YOUNG CHILDREN'S STRATEGY USE AND TASK PERFORMANCE IN THE DOMAIN OF SIMPLE ADDITION, USING THE "CHOICE/NO-CHOICE" METHOD

Joke Torbevns, Lieven Verschaffel and Pol Ghesquiere
University of Leuven, Belgium

Abstract. In this study we investigated young children’s strategy use and task performance in the domain of simple addition, using the “choice/no-choice” method. Second-graders, divided in 3 groups according to general mathematical ability, solved 25 problems in 3 different conditions. The results showed use of multiple strategies, adaptive strategy choices, and group differences in strategy choice and strategy execution in parallel with differences in task performance. Furthermore, the use of the “choice/no-choice” method revealed that freedom of choice enhances task performance, and that “retrieval”—although mastered only marginally by children of this age—is a highly efficient strategy to solve simple addition problems up to 20.

1. Theoretical and empirical background

During the last decades, researchers have intensively studied the strategies people use to solve cognitive tasks, the way people choose between these strategies, and the changes that take place in these processes during lifetime. A major finding of all these studies is that young children, as well as adolescents and adults, make use of, and choose adaptively between, multiple strategies to solve cognitive tasks in diverse domains, including mathematics. The theoretical and methodological ideas of Siegler (1996; see also Lemaire & Siegler, 1995; Siegler & Lemaire, 1997) deepened our understanding about this topic. In his “model of strategic change”, Siegler distinguishes among four dimensions of strategic competence and strategic change, namely: (1) strategy repertoire, i.e. the repertoire of strategies a person uses to solve a task, (2) strategy distribution, i.e. the relative frequency with which each strategy is used to solve a task, (3) strategy effectiveness, i.e. the speed and the accuracy with which each strategy is executed, and (4) strategy selection, i.e. the adaptiveness with which each strategy is chosen. According to this model, at the beginning of the learning process, the learner frequently chooses rather primitive “back-up” strategies (like, for instance, counting), which he or she executes rather ineffectively (i.e. slowly and inaccurately). With experience, the learner uses more efficient “back-up” and “retrieval” strategies, which he or she executes ever faster and more accurately, and also more adaptively.

Furthermore, Siegler proposes the use of the “choice/no-choice” method to obtain unbiased information concerning both the efficiency of the strategies an individual uses and the adaptiveness of the strategy choices he or she makes. This method requires testing each subject under two types of conditions. In the
"choice" condition, subjects can freely choose which strategy they use to solve a series of problems from a given task domain. In the "no-choice" condition, the experimenter forces them (experimentally) to solve all problems by means of one particular strategy. The number of "no-choice" conditions can vary according to the number of strategies available to the subject, research interests, technical possibilities, etc.

Taking into account Siegler’s theoretical and methodological ideas, we aimed at investigating which strategies 6-7-year-old children with strong, medium, and weak mathematical abilities use to solve simple addition problems up to 20, and how adaptively they choose between these strategies, in relation to task performance. In order to get an accurate picture of both the efficiency of the strategies used and the adaptiveness of the strategy choices, we used the "choice/no-choice" method.

2. Method

Subjects were 77 second-graders from two Flemish schools in the beginning of the school year. Based on their overall scores for mathematics in the first grade and on the second-grade teacher’s judgement, subjects were divided in three groups according to mathematical ability (strong, medium, and weak, further referred to as, respectively, the S-, M-, and W-group).

All children were asked to solve a series of 25 simple addition problems up to 20 in three different conditions. These 25 problems were constructed from the 49 possible pair wise combinations of the integers 3 to 9. The problems belonged to five different problem types (with five problems in each type): one type of easy additions up to 10 (T1; e.g. 3 + 4 = .), and four types of additions up to 20: (1) problems with a large first addend and a small second addend (T2; e.g. 9 + 3 = .), (2) problems with a small first addend and a large second addend (T3; e.g. 3 + 9 = .), (3) "tie sums" (T4; e.g. 7 + 7 = .), and (4) "almost tie sums" (T5; e.g. 7 + 6 = .). Problems were presented on a computer screen and the computer registered the reaction time (RT, with an accuracy of 0.01 sec) as well as the answer.

All children solved the problems in three different conditions. In the first condition, the "choice" condition (= condition CHO), children solved each problem by means of the strategy they preferred. Meanwhile their problem solving behaviour was observed by the experimenter. Immediately after solving each problem, children were asked to report verbally which strategy they had used. In the second condition, children were explicitly instructed to solve all problems with one particular strategy, namely “adding up to 10” (= condition ADD). Note that, as a consequence of the obligatory use of this strategy, the five easy additions up to 10 (T1) were not administered in this condition. To further enhance children to use the strategy “adding up to 10”, the computer presented the problems in the following format: X + Y = X + ( . + .) = . In the third condition, the maximum solution time was limited to 2 seconds, to force
children as much as possible to solve all problems by "retrieval" (= condition RET). All children first solved the problems in condition CHO (day 1). Half of the children solved the problems in condition ADD on the second day, and ended with solving the problems in condition RET on day 3. For the other half the order of the two “no-choice” conditions was reversed.

Generally spoken, we expected a variation in strategy use in condition CHO, in the sense that all children would use different strategies to solve the problems in this condition (see Siegler, 1996). Next, we expected group differences in strategy choice and in task performance (i.e. accuracy and speed of problem solving), in favour of the S-group (see Geary, 1990). Finally, we expected differences in strategy use and in task performance between the different problem types and between the three conditions (see Siegler & Lemaire, 1997).

3. Results

Strategy use

As expected, all children used multiple strategies to solve the problems in condition CHO. The number of strategies used varied from 2 to 8 different strategies, ranging from counting strategies like “counting all starting from 1” or “counting on starting from smaller/larger” to “adding up to 10” and “retrieval". As shown in the table below, “retrieval" and “adding up to 10” were the two most common strategies (respectively, 42.29% and 37.51% of all strategies used in this condition), followed by the use of a counting strategy (14.60%). As expected, we observed clear group differences in strategy choice ($\chi^2$(6) = 268.51, $p = .001$), in the sense that S-children used the “retrieval” strategy more frequently than M- and W-children, whereas W-children solved more problems by means of counting than S- and M-children.

Accuracy

Scores were analysed using a 3x3x4\(^1\) ANOVA (group x condition x problem type). The scores (maximum score = 5) of the three groups of children on the four different problem types in the three conditions are given in the table below. All differences reported are significant at the 1\% level.

As expected, an effect of group was found: S-children scored higher than M-children, who scored higher than W-children. We also found an effect of condition: As expected, scores in condition CHO and in condition ADD were higher than scores in condition RET, but there was no difference in score between condition CHO and condition ADD. The effect of problem type was also significant: Subjects scored highest on T4 problems; the scores on T2 problems were higher than those on T3 and T5 problems, which did not differ mutually. Finally, an interaction between condition and problem type was found: There was no difference in score on the four problem types in condition CHO and in condition ADD, whereas T4 problems were answered more accurately than T2, T3 and T5 problems in condition RET.

Speed

Reaction times were analysed using a 3x2\(^2\)x4 ANOVA (group x condition x problem type). The reaction times of the three groups of children on the four different problem types in condition CHO and in condition ADD are given in the table below. All differences reported are again significant at the 1\% level.

First, an effect of group was found: As expected, the S-group answered the problems fastest, whereas the W-group answered the problems slowest. Second, we found an effect of condition: As anticipated, lower RTs were observed in condition CHO than in condition ADD. Next, we found an effect of problem type: T2 problems were answered as fast as T4 problems; T2 and T4 problems
were answered faster than T3 and T5 problems, which did not differ in RT. Furthermore, there was an interaction between group and condition: The difference in RT between condition CHO and condition ADD was biggest for the M-group, and smallest for the S-group. Finally, we observed an interaction between condition and problem type: There was no difference in RT between T2, T3 and T4 problems in condition CHO, whereas T5 problems were answered much slower. This pattern was not observed in the ADD condition: In this condition, RTs on T2 and T4 problems, T3 and T5 problems, and T4 and T5 problems did not differ, whereas we did find a difference in RT on T2 and T3 problems, T2 and T5 problems, and T3 and T4 problems.

4. Conclusions

In line with earlier studies concerning young children’s strategy use in the domain of simple addition (e.g. Geary, 1990; Siegler, 1996), we observed a rich variation in strategy use (in the “choice” condition) as well as considerable group differences in strategy choice and strategy execution, resulting in group differences in task performance. Furthermore, a first global analysis of the data in the three different conditions revealed, first, that children in general made adaptive strategy choices in the CHO condition: They obviously chose those strategies that allowed them to answer the problems in a relatively fast and accurate way. Second, the overall difference in RT between condition CHO and condition ADD demonstrated that freedom of choice enhances (at least partly) task performance: Forcing children to solve all problems in a standardised and stereotyped way (by means of the “adding up to 10”-strategy) influenced their response time negatively (although it did not influence their accuracy). Finally, the data obtained in condition RET indicate that children of this age are typically not (yet) able to solve simple addition problems up to 20 by means of “retrieval” (except for the “tie-sums”). Nevertheless, when a child succeeded in responding by “retrieval” in the RET condition, the answer was mostly correct. Ongoing
more fine-grained and individualised comparative analyses of the nature and the efficiency of the strategies used in the different conditions will shed further light on the adaptiveness of children's strategy choices.

References

1 Taking the central topic of the study into account, namely second-graders' strategy use and task performance on simple addition problems up to 20, data concerning problem type 1 were not included in the analysis.

2 Because of the strict time limit in condition RET, data concerning condition RET were not included in the analysis.
On “How to Make Our Ideas Clear”:
A Pragmaticist Critique of Explication in the Mathematics Classroom

Triandafillos A. Triandafillidis
University of Thessaly, Greece

Instruction in the mathematics classroom often involves a paradigmatic explication of material. Children are asked to follow along the reasoning of an “experienced” adult who actually acts on the part of the children. Knowledge and understanding of the material by the children are measured by the ability of the children to catch up with the reasoning of the teacher. In this paper I intend to argue that paradigmatic instruction is based in false interpretation of a pragmatic logic as the translation of ideas into action. I will support my argument with discursive analysis of a short interactional sequence between teacher and children in a sixth-grade class in a primary school in Greece.

At Easter last year I was busy organizing a conference for primary school teachers. A local school—the only one with an amphitheatre large enough to accommodate all the teachers—offered to host the event. While the principal was giving me a tour, he happened to describe another in-service session on mathematics education that had taken place recently in that same amphitheatre. Participating teachers, he told me, observed a tutor teaching a class, which, for the purposes of the session, had moved to the amphitheatre.

Later on, I stood alone in the amphitheatre, trying to imagine the scene: the tutor teaching the class, while the teachers looked on. My musings brought to mind two of Thomas Eakins’ most famous paintings, The Gross Clinic and The Agnew Clinic. In the painting reproduced here the master surgeon and his assistants operate on a patient. While several students observe the operation, the patient’s mother sits in the corner, writhing in agony. The master surgeon is depicted in a state of apparent withdrawal from the act of operating, still holding his surgical blade, his facial expression revealing intense thinking.

Ostensibly, paradigmatic instruction follows a pragmatic logic since the master-teacher must translate ideas into action. Even if the “experts” might be said, in this way, to bridge

Readers should not perceive this description as prototypical of current in-service training programs in Greece, even though it was characteristic in the past. Nevertheless, the mentality it reflects still prevails in beliefs on learning and teaching, albeit in more subtle ways.
the gap between theory and practice, the fact remains that “novices” are taught to observe the center of activity from a distance. In the case of the in-service session, paradigmatic teaching contributed not only to the formation of methods for teaching the content of mathematics, but also, even if it was not explicitly stated, to the formation of the essence of belief concerning how the learning and teaching of mathematics should be approached in the classroom.

In this paper I will analyze an episode from a mathematics lesson in a sixth-grade class in Volos, Greece. The purpose of my analysis is to bring attention to certain linguistic phenomena that characterize social encounters and, therefore, are partly responsible for framing the interactional space of the encounter. Elaborating on Peirce’s pragmatic maxim, which locates the utmost clearness of ideas in “all the conceivable practical bearings we conceive the object of our conception to have” (Peirce, 1991: 169), I differentiate a ‘pragmaticist’ framework for mathematics education from an instrumental one, which presents itself as ‘hands-on’.

From paradigms to the production of a “Practionary”

“Well, that’s what we do first. We open the little trunk where we keep the materials for the circle, we empty it, and what do we have? We have a center, a diameter, a curve … Everything I might need I take out. Same thing as if we wanted to install a faucet. I go and take the toolbox…”

[6th grade teacher addressing his class] (Volos, Nov 2000)

The phrasing of Peirce’s pragmatic maxim can easily mislead. In his famous essay on “How to Make Our Ideas Clear” (1878), Peirce identifies the first stage in the clarity of ideas as familiarity with the common uses or nature of an idea. Standard dictionaries provide us with linguistic definitions, which for Peirce comprise the second degree of clarity. It is tempting to consider, then, the possibility of composing a kind of super-dictionary of praxis—a practionary—that would furnish the reader with descriptions of all the conceivable practical effects a thing could have in experience, which is Peirce’s third stage in the clarity of ideas. The possessor of such a “practionary” could acquire a clearer understanding of an idea simply by emptying its “little trunk”—to use the metaphor of the teacher, whose pedagogical style I will describe below. For Peirce, though, knowledge of the practical effects of an idea can only be achieved through personal hands-on experience with an idea or a thing (Parker, 1998; Peirce, 1991).

Peirce’s discussion of the three grades of clearness of ideas and the notion of practionary are all too relevant for mathematics education. A number of researchers have stressed, for instance, the fallibility of the assumption that concepts are acquired mainly through their definitions (Sfard, 2000; Vinner, 1991). A definition is a configuration of signs that assists in establishing the meanings of other signs. The definition of an idea is an exercise of power over the idea: its utterance conveys an appropriation of complete knowledge of the idea. Even within the deductive theory of mathematics education, signs are depleted of meaning, if considered without reference to their anthropological milieu (Cobb, 1990). Characteristic of the irreducibility of mathematical concepts to strings of
words are the notions of “concept image” (Tall and Vinner, 1981) and “figural concept” (Fischbein, 1993).

The processes of symbol manipulation present in traditional school mathematics is often linked with a mechanistic instruction of “basic skills” and ideas (Romberg and Kaput, 1999). Even though research suggests otherwise (Hewitt, 1997; Voigt, 1995), teaching is still considered, or at least approached, as an act of explication. In his critique of the “explicative order,” Jacques Rancière describes explication as a series of reasonings used in order to explain a series of reasonings that already exist within the material being taught. If a student cannot understand the first series of reasonings, why should we assume that he or she will understand the teacher’s reasonings. And, if the teacher’s reasonings themselves need to be explained, we can see how, in Rancière’s words, “the logic of explication calls for the principle of a regression ad infinitum” (1991: 4).

Over-reliance on the act of explication inevitably places emphasis on what Jackobson defined as the poetic function of language, a focus “on the message for its own sake” (1960: 356). Indeed, what speakers say is always evaluated according to aesthetic rules, in other words, for its efficacy, in “moving” an audience. The master-teacher of the in-service session described above had to employ a series of reasonings in order to explicate to the students the material that he himself had chosen. The outcome of the series of reasonings, including those of the attending teachers, judged by the standards of the explicator, created the illusion of an instance of successful mathematics teaching. The ability of the master-teacher to “move” the audience of teachers made this session a successful instance of paradigmatic teaching—judging from the story that was told to me by the school’s principal.

I suggest that teaching, conceived as an act of explication, represents an attempt to produce a practionary, a false substitute for Peirce’s third step in the clarity of ideas. Reaching or, to be more precise, approaching this third stage is, thus, trivialized and reduced to cramming practices or a series of reasoning, stored in a “little trunk.” The appropriation of knowledge by the students is measured by their ability to follow and/or reproduce these practices, even if this requires, in many cases, an act of collusion by all the engaged parties (McDermott and Tylbor, 1995).

**Explication as action? Analyzing instances of explication**

I now turn to the description and analysis of an episode from a mathematics session from a sixth-grade class in Volos, Greece. The educational system in Greece is nationally standardized. Mathematics syllabi are prescriptive in the sense that they allocate a specific number of hours to the teaching of each area. Instruction in the classroom is restricted to the textbook provided by the state, with teachers usually teaching “from the front.”

With its 140,000 inhabitants, Volos is the fifth largest city in Greece and the third largest port. The primary school that I visited is in a lower middle-class area far from the center of the city. My almost daily visits to the school began in October, 2000, though I was familiar with the school from a project I had carried out there two years before. It was then
that I first met with the children of this year’s sixth-grade class. Their teacher had changed, though. I was not surprised to find a male teacher; reflecting gender hierarchies and stereotypes, the few men among primary school teachers tend to be overwhelmingly represented in the higher grades of primary school. My presence in the classroom was limited to observing and audio-taping the mathematics sessions. I was conscious of the fact, though, that even as a bystander I was co-constructing the course of events (Goffman, 1981).

Linguistic anthropologists view language as a set of practices “which play an essential role in mediating the ideational and material aspects of human existence, and, hence, in bringing about particular ways of being-in-the-world” (Duranti, 1997: 4-5). Delineating types of organization that characterize the interactional space of a mathematics classroom will highlight how particular ways of “being-in-the-world” are formed, sustained and altered.

The extract that follows comes from a session on geometry. The class is discussing the concept of perimeter, having already described the characteristic features of a square. Perimeter is a concept formally introduced in the fourth-grade, so the current lesson served as an opportunity for the teacher to freshen up children’s memory of the concept. In the transcript that follows, I interpolate brief explanatory comments and theoretical elaborations. (A description of the transcription symbols are explained below.)

(The class has already discussed equal angles and equal, parallel, and perpendicular sides in a square. The teacher had drawn a square EZHK on the board.)

1 Teacher: NOW. (3.0) We are looking for (2.0) the perimeter of the square EZHK. WHAT INFORMATION do we have for this unknown quantity you see here?

2 Child 1: Sir!

3 Teacher: Yes Elena.

4 Child 1: We know the length of all sides.

5 Teacher: Well LENGTH (0.5) TOTAL LENGTH (0.5) of all sides. Splendid!

6 Child 2: Sir it also has equal sides.

The teacher takes the turn to speak as soon as he receives the first response (line 4) from the class. He restates what Child 1 has just said, adding the phrase “total length,” an expression that frames the concept of perimeter (line 5). At the same time, he speaks louder in an assertive tone, underlining the significance of what he had just mentioned for the wanted answer. As soon as Child 2 chips in another piece of information (line 6), the teacher interrupts the process once again to restate the task and suggest how to proceed (line 7). Child 2’s comment concerning the equality of sides is ignored.

7 Teacher: = What we have to do is take this information, what we know (0.5) and apply it here in this certain (0.5) square.

8 Child 3: Sir! Sir!
Teacher: = TOTAL length (0.5) of ALL (0.5) sides. What element do you think I get from this information that I can match up here?

The teacher refuses to give to Child 3 permission to speak (line 8). He repeats and emphasizes the words “total” and “all” using them as cues that would evoke further information about the concept of perimeter. Child 3’s hesitant and faintly-uttered responses in line 10 and 12 below indicate the bafflement of the class as to what the aim of the process is.

Child 3: °Perimeter? Perimeter? °That the::
Teacher: It says (0.5) length (0.5) of (0.5) all (0.5) sides.
Child 3: We know how many: °are all the sides:: ((almost like asking))
Teacher: BRAVO! How many are all the sides. = Where are they? Here. (1.0) We write them down again (12.0) ((teacher writes on the board))

I made the BEST OUT (0.5) of the element that says (0.5) SIDES. Did I know? = I-did—know. = I—took—them—and (1.0) I—placed—them—there. = WHAT—ELSE—DOES—THIS—INFORMATION—TELL—US? = It—says—sides—only? = It—says—perimeter (1.0) TOTAL (1.0) length. = A::::: that’s right! Addition.

Child 4: Total (1.0). Total (0.5) with addition.

Sensing the hesitance of the class, the teacher interjects another explication in line 11. This time he pauses briefly between words, implying that “this is it!” Child 3 strives to follow the teacher’s line of argument. Even though her response is expressed in almost a questioning mode (line 12), the teacher congratulates her and proceeds with yet another explication of the argument so far (line 13). Next he asks the children to think of other characteristics of the square that would be relevant in finding its perimeter. Child 4 (line 14) interprets correctly the cues given by the teacher and takes the process a step further. Notice that in line 13 there are no “transition-relevant points,” i.e. moments when a change of speaker may take place (Sacks, Schegloff, and Jefferson, 1974). Besides speaking too fast, the teacher leaves no interval between the end of a prior unit of speech and the next piece of talk.

Child 5: Sir we have done these before.
Teacher: Everything’s fine?
Child: Yes.
Teacher: What else did we discover today or better did we mention again? = WE KNEW IT BUT WE SEE IT AGAIN (0.5) FOR THE SIDES:
Child 6: That these ((pointing towards the board)) are:: opposite to one another.
Child 4: That these:: are:: parallel and do not meet.

Teacher: They are parallel. Yes. This element (3.0) can it be used? (6.0)

At—the—point—where—we—are—now? = In order to see let’s say =
Child 4: The parallels?
Teacher: YES. That they are parallel (2.0) does it interest us in finding the total length?
Child 6: Eh sir::
Child 4: Ho? How much are all the parallels? ((she wants to say how long))
Child 7: SIR the parallels are equal! ((the child does not express himself adequately))
Teacher: A:::::! We have another element. = Look here. = That sides::=
In line 16, the teacher seeks reassurance that the class comprehends. More information is needed in order to calculate the perimeter, though. Children 4 and 6 suggest that the missing link is the fact that the sides of a square are parallel to one another (lines 17 and 18). The teacher interrupts (line 19) making an implicit statement that the concept of "parallels" is not the information missing. Child 4's question in line 20, though, indicates that the class is not following the process consciously. Children appear to be choosing information at random from the "little trunk." The teacher attempts again to lead the argument away from the information "parallel sides" (line 21), and Child 6 with the help of Child 7 seem to be making the required connection (line 23 and 24).

Teacher: They are (2.0) equal. Therefore

Child 4: We can multiply.

Teacher: BRAVO! We move to the property that says that multiplication is a SHORT:?

Class: Addition.

Teacher: Addition. When--the--terms--ARE?:

Class: Same.

Teacher: THE SAME. That's righ-. = Instead of saying 4--and--4--and--4--and--4--say 4 times
4. = Or 3--and--3--and--3--and--3 (0.5) I--say 4 times (1.0) 3. Is that so? If here then (1.0) instead of saying side EZHK I put a general name (2.0) a ((he writes a on all sides of the square)) for the sides (0.5) of the square a ZH a and KH a (0.5) and this (1.0) and the other (1.0) = ((pointing to the figure on the board))

Child 4: 4 TIMES a

Teacher: With a 4 times a then I define:

Child 4: The::: the:: perimeter!

Teacher: BRAVO! I define the magnitude that is called perimeter (1.5) of a square.

Concluding remarks

Participation in any social scene requires a minimum consensus on what is getting done (Gumperz, 1992; McDermott and Tylbor, 1995). On a micro-perspective level, teacher and children appear to be discussing already familiar concepts in an attempt to deepen or widen their understanding of the concepts (see lines 15 and 16). Despite this observation though, the fact that children's responses, like those in lines 14 and 18, are overlooked, indicates that the teacher ranks the correct use of information and the pious following of a process higher than understanding the concepts. On a macro-perspective level, children are disciplined into following the series of reasonings used by the teacher in explicating the process of finding the perimeter of a square with side a.

As McDermott and Tylbor suggest, "it is possible to live lies without having to tell them" (1995: 281). Judging by Child 5's response in line 36, we remain puzzled as to whether the teacher actually moved through this series of reasoning alone or not. A fair amount of collusion was involved in this process of explication, both by the teacher and the children, in the sense that a particular state of affairs was sought that could be accepted as
an indication of understanding and, therefore, of closure and successful or satisfactory teaching (see lines 5, 12, 13, 16-17, 29-30, 31-32, 37).

The confusion of the class concerning the task at hand, along with their hesitant decision to follow the teacher's explication of the task, may suggest a form of resistance to the way of "being-in-the-mathematics-classroom" proposed by the teacher. One cannot force reasoning to follow a specific order of steps. What the teacher does is lay out his own interpretation of what "being-in-the-mathematics-classroom" might mean. Knowledge and understanding are then measured by the degree to which the students collude in the teacher's mode of explication. Analyzing modes of explication can show us the subtle ways that states of "being-in-the-mathematics-classroom" are being sustained and reproduced. A discursive analysis of conversational exchanges in the classroom may be one tool for understanding this process. Further research would entail connecting these to a broader fabric of social structures and relationships.

Transcription features

Boldface indicates emphasis signaled by changes in pitch and/or amplitude.
A left bracket, connecting talk on separate lines, marks points at which one speaker's talk overlap the talk of another.
A right bracket marks the place where the overlap ends.
Colons indicate that the sound just before the colon has been noticeably lengthened.
A dash marks a sudden breaking-off of a particular sound.
A degree sign (°) indicates that the talk following it is spoken with noticeably lower volume.
An equals sign is used to indicate that there is no interval between the end of a prior unit of speech and the next piece of talk.
Capitals indicate increased volume.
Numbers in parentheses mark silence in seconds.
Text in italics between double parentheses mark the author's comments.

A FRAMEWORK FOR ASSESSING QUESTIONS
INVESTIGATING THE UNDERSTANDING OF
PROBABILISTIC CONCEPTS

John M. Truran
Private Practice, Adelaide, South Australia

Research has suggested that two well-regarded tests of probabilistic understanding measure different constructs. Here a framework is proposed for classifying questions on probabilistic understanding and used to analyse the structure of the tests. It provides a way of predicting some differences found by post factum statistical analysis. This suggests that it may have more general validity for evaluating instruments assessing probabilistic understanding.

Probability has come into many school curricula at much the same time as schools have been expected to raise the quality of their assessment procedures. Here a framework is proposed for classifying questions on probabilistic understanding, and is used to help explain some research findings about two well-regarded tests.

Some mathematics educators argue, with some validity, that written assessment instruments are inappropriate for assessing complex concepts like probability. Alarcon (1982), for example, has shown that, when probabilistic concepts are examined in discussions and then in a written questionnaire, many students change their responses. These arguments are not addressed here because the external demands on schools for increased assessment mean that we need to be able assess the quality of those instruments which are likely to be used, and the principles outlined are equally applicable to more interactive modes of assessment.

Two Instruments Assessing Probabilistic Understanding

Green (1982a, 1982b) reported a study of 3000 children from Years 7 to 11 in the East Midlands of England. He hoped that his carefully developed assessment instrument could be related to Piagetian levels as had been done for other school topics by the Concepts in Secondary Mathematics and Science Project. He obtained informative responses to a wide variety of questions, but was unable to link all of them to a Piagetian stage-model. Only eighteen of the original, quite diverse, fifty items satisfied the requirements for validity and reliability, so these constituted the sub-test he used to establish his Piagetian stage-model.

Soon after, Fischbein & Gazit (1984) developed two instruments to assess the effect of a programme of instruction in probability with about 300 Israeli pupils from Years 5 to 7 in the experimental and control groups. The first (A) contained procedural questions directly related to the instruction, the second (B) comprised eight questions specifically designed for the experiment to reveal several well-known probabilistic misconceptions which were potentially present. The authors found that the questions were able to detect changes in understanding, although sometimes the effect of instruction seems to have led to decreased understanding.
Subsequent Use of These Instruments

Both tests have been used by subsequent researchers (e.g., Watson, Collis & Moritz, 1994; Glencross & Laridon, 1994) as source of questions, sometimes with minor modifications. Green (1986) used his experience to develop a new test to assess understanding of randomness, but has not re-used his original test. However, Izard (1992) administered Green’s eighteen items to about 1100 students in Hungary, Brazil, and francophone Canada and found a general confirmation of Green’s work but with some variations. He considered that the test had acceptable test reliability and item fit, but that the decision rules for grading the open-ended questions needed further examination. Surprisingly, he did not make comparisons between the different countries.

All these researchers seem to have believed that their questions were valid tests of the concepts being investigated, although Green was concerned that his statistical analysis had removed some of what he saw as his more interesting questions. Later Godino, Batanero & Cañizares (1994) presented both these tests of primary probabilistic reasoning to the same group of 251 Spanish children in Years 6 to 8, so the opportunity arose to examine just what the questions were assessing.

Godino et al. constructed a detailed analysis of the skills and understandings being tested in both tests (using all fifty of Green’s items). They argued that if Green’s test were a test of probabilistic reasoning then the whole test, and perhaps its reduced form would have high predictive value for results from some other such test. They found significant correlation between some of the Israeli questions and Green’s test, but not for all comparisons, and concluded, inter alia, that the Israeli test contained components of probabilistic reasoning not included by Green. A factor analysis of the Israeli test found two factors (one based mainly on qq. 6, 7 & 8, and the other on qq. 2, 3, 4 & 5), the second of which did not correlate well with Green’s results. A factor analysis of Green’s test produced fifteen factors, thus confirming its diversity of coverage. They concluded:

The multitude of factors included in Green’s test and the low predictive value of the “probabilistic level” and of the other scores in the said test, with respect to the success in Fischbein & Gazit’s test, suggest that a critical review is needed to consider the probabilistic knowledge of the subjects as a linear structure.

More research is needed to explore in-depth the nature of probabilistic reasoning and its structure. At the same time it shall be necessary to compile and analyse the banks of items that make up a representative sample of [Primary Probabilistic Reasoning] and of the universe of appropriate contextual variables ...

A Framework for Classifying Questions on Probabilistic Understanding

At the same time as Godino et al. were doing their work, J. Truran (1994) was preparing a framework, of which a modified version is presented in Table 1, for class-

Type of Question

- α: Prediction of Outcome
- β: Prediction of Set of Outcomes
- γ: Selection of Outcome
- δ: Statement of “Likely” Outcome
- ε: Comparison of RGs
- ζ: Fair Allocation of Payout for Bets
- η: Examination of Sequences of Outcomes
- θ: Linguistic Questions of Technical Knowledge
- I: Listing of Outcomes

Type of Probabilistic Situation

- I: Single Trial
- II: More than One Trial
- III: Previous Results
- IV: Previous Predictions of Results
- V: Concurrent Operation of Another RG
- VI: Previous Experience with Similar RGs
- VII: Changes in RG from Trial to Trial
- VIII: Long Term Reward Maximisation

Spinners may be further divided in three categories:
(a) those where only the pointer is free to move;
(b) those where only the sectors are free to move;
(c) those where both pointer and sectors are free to move (as in a roulette wheel).
ifying random generators (RGs) and questions about them. He saw this as useful for assessing the comprehensiveness of a test or unit of work, and it now also seems to be able to fulfil some of the gaps identified by Godino et al. It has three parts—the first describes the nature of the RG and its relationship to the student, the second the type of question being asked, and the third the type of probabilistic situation in which the question is used. For simplicity the classification deals only with outcomes from a single RG, not with compound RGs. It has been based on many research findings about the types of probabilistic situations which seem to influence students’ responses. There is not space to list all these findings here, but, for example, Category E, which considers who actually operates the RG, follows in part from Zaleska’s (1974) finding that responses may differ according to whether the subjects or the experimenters actually draw the balls from an urn. It has been tested for its ability to classify more than fifty questions developed by a wide range of researchers, including Green, but not Fischbein & Gazit, and the modification presented here summarises the experiences gained in this preliminary testing.

To help to clarify the complex detail of Table 1, the classification of one of Green’s questions is presented in Table 2. The question is:

When an ordinary 6 sided dice is thrown which number or numbers is it hardest to throw, or are they all the same?

Answer

The right hand column summarises of the meaning of the alpha-numeric terms to clarify the links with Table 1. The only potential ambiguity here is the classification “8”—statement of “likely” outcome. Here the student is being asked for an “unlikely” outcome, and this meaning is implied by the use of quotation marks.

| Table 2 |

| I | 1 | Symmetric |
| J | 1 | Known |
| K | 1 | No Reward |
| | | “Likely” Outcome |
| | 1 | 1 Trial |

Analysis of the Two Tests

All the items of Green (G) and Fischbein & Gazit (FGB) concerned with a single RG have been classified using this framework, and the results are summarised in Table 3 with Green’s items first. His test seems to have 53 items, not 50 as ment-
ioned above, and it has not been possible to explain all the reasons for the discrepancy. The term “u” refers to “unknown” and “na” to “not applicable”—cases where the questions are not dealing with operations of a single random generator. Those questions which comprised Green’s final statistically reliable form are in bold, apart from G10 and G26 (a) which do not fit in the framework. This makes nineteen items, not eighteen: both parts of G3 were probably taken as one item.

</table>
Probably not all workers would agree with all these classifications. For example, the channels in G21 & G22 have been treated as single RGs, and for FGB2, which deals with a child's view that entering a classroom right foot first will increase his chance of gaining good marks, it is certainly arguable whether good marks may be seen as an outcome of a random generator. However, the discussion below does not require agreement for each and every classification, so any debate about a small number of difficult classifications should not affect the general conclusions.

**Discussion**

Table 3 shows that Green's final set of questions are predominantly about comparison of urns, only three items deal with situations more complex than that of considering just one trial, and all but one deal with "likely" outcomes or comparison of RGs. Furthermore, using the classification as a guide to comprehensiveness, shows that although the test covers four different RGs, it does so within restricted contexts and does not address many ideas necessary for a good understanding of probability. So it does not seem appropriate for Izard's international survey unless his concerns were more to do with statistics than assessing probabilistic understanding.

The framework shows clearly just why Green felt that his final test omitted many interesting questions. For example, most of the questions involving asymmetric RGs have been omitted, as well as all the questions directly addressing language and almost all of the questions incorporating outcomes of previous trials.

When we consider the FGB questions, we see that the first factor identified by Godino et al. involves all the questions concerned with comparison of random generators (ε), and the second involves questions about "likely" outcomes (δ).
ino et al. see the second factor is concerned with the students’ "biases and deep-rooted beliefs"—ideas more likely to be elucidated by questions of this type.

Godino et al. state that Green’s test does not contain questions like these second factor questions. But the framework is able to show that G21 does have some similarities, but also differs in not involving hypothetical rewards, large numbers of elementary events, or considering more than one trial. Furthermore, G21 deals with an RG—channels—which may well have been less familiar to students, and is not very clearly explained in the test. So the framework taken with the statistical analysis can assist in clarifying the nature of a statistical claim.

The first six factors identified in Green’s test each contain items from different parts of particular questions (in Factor 3, the item “5dr” must be a misprint for “6dr”), sometimes with other items as well. Factor 3 contains G18, which is clearly of a different structure from the other three items, and Factor 4 contains two items of a quite different type. On the other hand, the markedly similar items arising from the comparison of urns in G6 have not all grouped themselves into one factor.

So while factor analysis has identified some factors in both tests which framework analysis might have predicted, it has also highlighted some questions which are surprising linked or not linked, and the framework provides a starting point for examining why these discrepancies might have occurred. For example, although the comparison of urns questions have a standard format they form a single factor in the Israeli test, but separate into different factors on Green’s, as well as indicating different Piagetian levels. Green (1982b, p. 338) suspected that children did not consider the problems as being essentially similar. J. & K. Truran (1999) summarised research into such questions and showed that children’s responses to slightly different sets of numbers are often idiosyncratic, subconscious, and unpredictable. We do not yet understand the reasons, but it would clearly be unwise, for example, to deduce much from an assessment instrument containing just one “comparison of urns” question, because the development of understanding seems to be non-linear.

The framework approach rests predominantly on an analysis of question format; the statistical approach more on understanding of meaning. Neither is an all-purpose tool, although, as we have seen here, their strengths do overlap to some extent.

Conclusion

Researchers often report new tests for assessing probabilistic understanding, e.g., Batanero, Serrano & Garfield (1996), Reading & Shaughnessy (2000). The framework and statistical analysis can be complementary partners for analysis and building up the item-bank mentioned above. The framework is simple, and applicable before administering a test as well as after obtaining statistical results. It can provide a guide to the comprehensiveness of a test or unit of work, which may be of value for analysing the complexity of probabilistic knowledge and deciding whether its acquisition is linear or holistic. While it needs a little modification, further testing, and much extension, this paper has shown how useful a research tool it can be.

Cultural Activities as Learning Arenas for Children to Negotiate and Make Sense Mathematical Meanings

Wen-Huan Tsai
National Hsinchu Teachers College, Taiwan

Abstract: The main purpose of this study was to develop a model called the "Cultural Conceptual Learning Teaching Model" (CCLT) that addresses the ways in which children's real experiences and cultural practices can be connected to mathematical classroom lessons and to improve children's understanding of mathematics. Eight second-grade classes participated in this study in Hsin-Chu, Taiwan. The results showed that school mathematics for those who are involved in CCLT model based on cultural activities improved more than for those who were involved in the control group. Children learned more in the transfer of learning in the CCLT group than Children in the control group.

Introduction

In recent years, many studies have focused on mathematical cognition related to individual competence in daily life context (Bishop & Abreu, 1991; Carraher, 1988; Lave, 1988; Saxe, 1991; Tsai & Post, 1999; Tsai, 2000). A review of children's out-of-school mathematics raises critical questions about how children come to understand mathematics and how they connect informal knowledge out of school with formal knowledge in school. (Hibert & Carpenter, 1992; Millory, 1994; Resnick, 1987). According to Resnick (1987), teachers should concerned about the role of cultural aspects, constructing meaningful ways for students to make sense of the abstract symbols of school mathematics. She emphasized that culture contributes to better understanding in students' learning and it therefore needs to be integrated into mathematics teaching. Central to this study is the view that an understanding of mathematical meaning is the ability to connect different learning environments or situations (Greeno, 1991). Brown, Collins, & Duguid (1987) also emphasized the importance of the relationship among activity, concept and culture and claim that learning must involve all of them. Hiebert & Carpenter (1992) further proposed that children's informal knowledge could serve as a basis for the development of understanding of mathematical symbols and procedures in school setting,
regardless of the content domain.

Based on these points of view, this study develops a learning-teaching model called the Cultural Conceptual Learning-Teaching Model (CCLT) (Tsai, 1996) that attempts to combine individuals, activities, concepts, and culture together. The hypothesis of the study stated that establishing a link between children’s cultural activities and school mathematics will improve children’s learning of mathematics in school and their ability to solve daily mathematics problems out of school. There were three questions raised in this study: (1) Did children achieve differently in school mathematics when they participated in different programs? (2) How did children involve in the CCLT group perform in solving addition problems as compared to control group? (3) How different were children’s strategies of solving the word problems between CCLT group and control group?

The Cultural Conceptual Learning Teaching Model (CCLT)

The CCLT (Figure 1) contains three learning environments: construction environment; connection environment; and practice environment; and six learning stages: Play Stage; Construction Stage; Connection Stage; Reapplication Stage; Practice Stage; and Reflection Stage.

Play Stage: Play Stage provides children with an activity of playing monopoly. In this stage, children share, negotiate, and construct their immediate experiences to achieve the emergent goals of arithmetic problems with peers and more advanced children (the expert children).

Construction Stage: In the Construction Stage, the teacher designs a worksheet that has structural objectives that need to be accomplished by students. For example, children need to count the total money they have at the end of game.

Connection Stage: In the Connection Stage, based on children’s experiences or strategies, the teacher tries to help children construct a connection between their experiences and concrete materials like ten-based blocks or mathematical symbols and procedures.

Reapplication Stage: In the Reapplication Stage, the teacher provides another similar or same cultural-conceptual activity for children to reapply to the learned mathematical concept.

Practice Stage: In the Practice Stage, children try to practice school mathematics in everyday situations by using opportunities provided for them.

Reflection Stage: In the Reflection Stage, children are trained to monitor their thinking and to be aware of where and how they can apply school mathematics in
everyday activities.

In the CCLT, four kinds of cultural activities are integrated into classroom teaching, these activities include Pick-Ten-Point Game, Counting Lucky Money Activity, Shopping and Selling Toys Activity, and Monopoly Activity. This paper discusses only some findings from the Monopoly Game.

Figure 1: The Cultural Conceptual Learning Teaching Model

Methodology

Eight second-grade classes in a school located in the city of Hsin-Chu participated in this study. Four classes were randomly assigned to the CCLT group and the rest were assigned to the control group. Teachers from the control group classes met in a half-day workshop to discuss the arithmetic content of the textbook. On the other hand, teachers from the CCLT group classes met every Friday to design the cultural activities and sharing their experience of teaching.

Three tests, The Situation Test, The Standardized Test, and The Achievement Test, were conducted to examine the effects of teaching approaches and the children’s ability to solve everyday task problems. The classroom instruction of each teacher was observed and videotaped. Students’ worksheets and journals were also collected and analyzed.

Space allows us to present and discuss only the some findings of the Situation Test problems (some results will be presented in the meeting of PME25 conference).

The Situation Test problems contain two problems. The first problem was
presented in a story form, such as “John plays the monopoly game with his friends. When the game is over, John sorts the bills he won and recorded all the bills. In all, there are fifteen ten-dollar bills; six fifty-dollar bills and three one-hundred-dollar bills totally. Could you help John count how much money he won?” The students were asked to count how much money John had and write down the process in which they calculate the amount. The second problem was also presented in the same form but asked them to calculate more and different values of bills as follows: seven ten-dollar bills; two fifty-dollar bills; eight one-hundred-dollar bills; four two-hundred-dollar bills; two five-hundred-dollar bills; three one-thousand-dollar bills; three two-thousand-dollar bills; two five-thousand-dollar bills. Children’s strategies and processes of calculation were analyzed and recorded.

Results

The teaching effects. Each part of the results was described in accordance with each research questions. The first part documented the effects of the CCLT teaching model on children’s ability to solve the two problems described previously when compared to a regular teaching program.

</table>

Though by the end of the year second graders are expected to learn to add 2-digit numbers with a sum of no more than 100 and to learn numbers up to 1,000 by counting, the result of table 1 show that children who learn addition through the CCLT model gained more transfer learning than the national standard goal for the elementary school curriculum when compared with the control group. For the first problem, 60.3% of CCLT group children were able to solve the addition problems involving 3-digit numbers. On the contrary, only 23.1% of control group children were able to solve them. The difference between these two groups was tested significantly.

For the second problem, 16.7% of CCLT group children were able to solve the addition problems involving 4-digit and 5-digit numbers, while only 2.3% of control group children were able to add the same 4-digit and 5-digit numbers.
This difference was also tested significantly.

**Achievements in different levels of addition.** Some children couldn't express the processes of the problems correctly, but they do some parts of the solutions. This part describes the different levels of addition between the children involved in the CCLT group and those involved in the control group when they calculate two problems.

</table>

When we analyzed students' calculating procedures, seven levels of addition were identified. Level 0 coded as the symbol (O) is characterized as students who were incapable of solving the given problem. Level 1 is characterized as students who were able to add the 2-digit numbers (2D). Level 2 is characterized as students who were able to add the 3-digit number, but the sum is less than 100 (3D). Level 3 is characterized as students who were able to add the 3-digit numbers with the sum up to several thousand (3DTH). Level 4 is characterized as students who were able to add the 4-digit numbers with the sum of less ten thousand (4D). Level 5 is characterized as students who were able to add the 4-digit numbers, with the sum of more than ten thousands (4DTH). Level 6 represents that students who were able to add the 5-digit numbers, but with a sum of less than several ten thousands (5D).

The data sketched in table 2 show that CCLT group had higher percentages at each level to the control group. In the first problem, the CCLT group standing at the highest level (3D) had significantly higher percentage (86.5%) than the control group (61.5%). In the second problem, the CCLT group at each level possessed a higher percentage than the control group. This difference was tested
significantly. Therefore, children learning of addition using the CCLT model based on cultural activities achieved a higher level than the control group based on the textbook.

**Strategies used.** This part described the comparison of strategies used to solve the situational problems between CCLT group and control group. According to children’s solutions, six children’s strategies for solving the two given problems were identified.

</table>

O indicates that children were unable to solve the given problem or the strategies can’t be identified. AI indicates that children calculated the addition problems with iterating method (one by one). For example, children solved the first problem as 10+10=20, 20+10=30, 30+10=40...140+10=150, 150+50=200...650+100=750. GAI indicates that children calculated the subtotals within each group using iterating method then calculate the subtotals to get the total. For example, 10+10=20...140+10=150; 50+50=100...250+50=300; 100+100=200, 200+100=300; 150+300=450, 450+300=750. GVA indicates that children calculated the subtotals with visualization and then calculated the subtotal. For example, children wrote 150+300=450, 450+300=750. Children understand that fifteen ten-dollar bills equivalent to $ 150, six fifty-dollar are $ 300, and then add up the total. During the Monopoly game, most children made use of the visualization method to count the total automatically. There was no time for children to calculate the
answer slowly. MIGAI indicates that children used the multiplication method to calculate the subtotals one by one within each group, and then add up the subtotal. For example, children wrote 10×1=10, 10×2=20...10×15=150; 50×1=50...50×6=300; 100×1=100...100×3=300; 150+300=450, 450+300=750.

MVGA indicates that children used the “within each group with visualization method” and then added up the subtotals. For example, children wrote 10×15=150, 50×6=300, 100×3=300, then 150+300=450, 450+300=750.

From table 3, the data show that the CCLT group more frequently utilized the GA! strategy than the control group, while control group used the AI strategy significantly more often than CCLT group. The CCLT group using other strategies had higher percentage than the control group, but there were no significant differences. However, since the Monopoly game was arranged in the last month of the school year; it needed to take more time for children to complete the Connection Stage and the Practice Stage.

Conclusions

A previous study (Lin & Tsai, 1999) found that children had a rich store of cultural experiences in daily life that can be applied in the classroom. From the results of this study, learning arithmetic through children’s cultural activities not only affects children learning of school mathematics but also improve their ability to solve task problems. This evidence is consistent with the effect of the CCLT teaching model in previous studies (Tsai & Post, 1999; Tsai, 2000). One of possible reason is that this study chose popular cultural activities for classroom teaching; therefore, children brought rich experiences to take and share. Another possibility is that the CCLT model provides a learning environment for children to connect their everyday experiences to school mathematics and to practice the learned mathematics in everyday activities again.

As the Taiwanese national curriculum standards described, second graders are merely expected to be able to solve two-digit additive problems and the place value of the number less than 1,000 at the end of the school year. According to the findings of this study, children learned more in the transfer of learning in the CCLT group than children in the control group. In the CCLT, children not only need to know the mathematics concepts but also need to know how to apply them in the cultural activities. Children make sense the mathematical meanings gradually when they connect their everyday experiences with school mathematics then reapply them in the cultural activities again. However, we need more time to validate this model.
Reference

This paper describes some findings of a study regarding Israeli and Italian students' solutions to standard (commonly taught) and non-standard (not commonly taught) inequalities. The findings presented here show similarities in students' difficulties, in both countries, regarding $x = 3$ as the solution of an inequality even in cases where they correctly identified $x = 0$ as the solution of the task $5x^4 \leq 0$. We also found that a substantial number of the participants encountered difficulties in solving the inequality $5x^4 \leq 0$, claiming either that the set of solutions was empty or that the set of solutions was $x \leq 0$.

Inequalities play an important role in mathematics. They are part of various mathematical topics including algebra, trigonometry, linear planning and the investigation of functions (e.g., Chakrabarti & Hamsapriye, 1997; Mahmood & Edwards, 1999). They also provide a complementary perspective to equations. Accordingly, the American Standards documents specify that all students in Grades 9-12 should learn to represent situations that involve equations, inequalities and matrices (NCTM, 1989). They further recommend that students would “understand the meaning of equivalent forms of expressions, equations, inequalities and systems of equations and solve them with fluency” (NCTM, 2000, p. 296). To implement these NCTM recommendations it is crucial to consider students' ways of thinking about inequalities.

However, so far, research in mathematics education has paid only little attention to students' conceptions of inequalities (e.g., Dreyfus & Eisenberg, 1985; Linchevski & Sfard, 1991; Tsamir & Almog, 1999; Tsamir, Tirosh, & Almog, 1998). Most of the related articles dealt with teachers' and researchers' suggestions for instructional approaches, usually with no research support. They recommended, for instance, the sign-chart method (e.g., Dobbs & Peterson, 1991), the number-line method (e.g., McLaurin, 1985; Parish, 1992), and various versions of the graphic method (e.g., Dreyfus & Eisenberg, 1985; Parish, 1992; Vandyk, 1990).

Those few studies, which have been published, tended to describe students' reactions to a few inequalities of the types commonly presented in class, and usually reported only one or two difficulties. For instance, studies pointed to students' tendency to make invalid connections between the solution of a quadratic equation and its related inequality (e.g., Linchevski & Sfard, 1991; Tsamir, Tirosh, & Almog, 1998). Other studies related to students' tendency to regard transformable inequalities as being equivalent. They further identified
the need to use logical connectives (Parish, 1992), and found the solutions of inequalities with “R” or “⌀” results extremely difficult (Tsamir & Almog, 1999).

The present study was designed in order to extend the existing body of knowledge regarding students' ways of thinking and their difficulties when solving various types of algebraic inequalities. During discussions of Working Group 2 at PME22 (1998), and of Project Group 1 at PME23 (1999), it was found that in both Italy and Israel, algebraic inequalities receive relatively little attention and are usually discussed only with mathematics majors in the upper grades of secondary school. Discussions are usually limited, emphasising the "practical" algorithmic perspective of algebraic manipulations. Attention is paid mainly to "How to solve?" instead of "Why solve it this way?" or "How can I be sure that the solution I have reached is the correct solution?" Moreover, in both countries, the two researchers witnessed students' and teachers' frustration with the difficulties encountered when dealing with inequalities. Consequently, an Italian and an Israeli researcher who attended these conferences decided to collaborate their research in this area.

A collaborative study was designed to investigate students' ways of solving standard and non-standard tasks with similar, underlying mathematical ideas. The students were given six tasks, presented in the manner to which they were accustomed in their classes, i.e., "solve" tasks, designated as "standard tasks". They were also given nine tasks, related to the same mathematical issues, which were presented in a non-customary manner, and designated as "non-standard tasks".

In this paper we focus on 2 of the 15 tasks that were give to the students. Both tasks dealt with the same underlying mathematical situation, i.e., single-value solutions to inequality tasks. The main related research question was: Do Israeli and Italian secondary school students accept the expression x = a as the solution of an inequality – Once, presented in a standard multiple-choice "solve" task, and once as a "reversed order" task, asking whether a given set can be the truth sets (the solution) of any equation or of any inequality, and are the students' reactions to the two tasks consistent?

Methodology

Participants

One-hundred-and-seventy Italian high school students and 148 Israeli high school students participated in this study. Both the Italian and the Israeli participants were 16-17 year old mathematics majors. That is, in both countries we examined students who were aiming to take final mathematics examinations in high school. Success in these examinations is a condition for acceptance to academic institutions, such as universities.

In their previous algebra studies, the participating students had studied the topic of algebraic inequalities, including linear, quadratic, rational and absolute
value inequalities. In both countries, the participating students were taught this topic in a traditional way, being presented with different methods for solving the different types of inequalities. For example, parabolas or the number line to solve quadratic inequalities, and “multiplying by the square of the denominator” for the solutions of rational inequalities.

Tools

A 15-task questionnaire was administered in both countries. Italian and Hebrew versions were given to the Italian and Israeli students respectively. The two tasks analyzed here are Task 1 (a non-standard task) and Task 9 (a standard task).

Task 1
Consider the set \( S = \{ x \in \mathbb{R} : x = 3 \} \) and check the following statement:

\( S \) can be the solution of both an equation and an inequality. Explain your answer.

Task 9
Indicate which of the following is the truth set of \( 5x^4 \leq 0 \)

\[ \begin{align*}
A &= \{ x : x > 0 \} \\
B &= \mathbb{R} \\
C &= \{ x : x < 5 \} \\
D &= \{ x : 0 < x < 1/5 \} \\
E &= \phi \\
F &= \{ x : x = 0 \} \\
G &= \{ x : x \leq 0 \}
\end{align*} \]

Task 1 demanded proving the existence of a case where \( x = 3 \) is the solution of an equation, and also proving the existence of a case where \( x = 3 \) is the solution of an inequality. The easiest way to go about this was by providing suitable examples. This kind of assignment, asking the students to examine the existence of a case where \( x = 3 \) is the solution of either an equation or an inequality; then, if possible, to provide tasks to match a given solution, was not dealt with in either the Israeli or the Italian classes we investigated.

We expected the first part that related to the existence of a suitable equation to be easy, and the second part, where the students had to examine the existence of a case where \( x = 3 \) is the solution of an inequality, to be problematic.

Task 9 was a standard task, similar to other tasks presented in Israeli and Italian classes. We assumed that most students would solve it correctly.

Procedure

In both countries, the mathematics teachers of the classes distributed the questionnaires, during mathematics lessons. The students in each of the countries were given approximately one hour to complete their solutions, which usually was enough time. The researchers analysed, categorised and summarised the different solutions. In two additional meetings the researchers decided on possible ways to present the data.
Results
The results will be presented in the following order. First, an analysis of Israeli and Italian students' responses to Task 1, then their responses to Task 9, to conclude with an analysis of the consistency in students' reactions to the two tasks.

Students' Reactions to Task 1
In both countries, none of the students had any problems in correctly responding that $x = 3$ can be the solution of an equation. Most of them accompanied their responses by an example, usually of a first-degree equation, such as $2x-6=0$. This, however, was not the case with the participants' responses to the question whether $x = 3$ can be the solution of an inequality, in both Israel and Italy.

</table>

* Correct response  
** Irrelevant or missing justifications

Table 1 shows that in both countries, only about 50% of the students who responded to this task, correctly claimed that $x = 3$ can be the solution of an inequality. Still, most of them did not accompany their claims by any justification and only a few students, Israeli or Italian, gave valid explanations. These latter explanations were usually the presentation of the following example of the quadratic inequality $(x-3)^2 \leq 0$. More prevalently in Israel, but also in a few Italian cases, explained that the claim “$x = 3$ can be the solution of an inequality” is true, because $x = 3$ can be the solution of a system of inequalities. Such justifications were often accompanied by an uncomplicated, linear example, such as

\[
\begin{cases}
2x-6 \leq 0 \\
x-3 \geq 0
\end{cases}
\]
Another type of interesting justification, given by a small number of Israeli and a small number of Italian participants was that “the claim is true, because \( x = 3 \) can belong to the set of solutions of an inequality.” This justification was accompanied by illustrations, such as, \( 5x - 10 > 0 \), further explaining that “the truth set (solution) of this inequality is \( \{x : x > 2\} \), and 3 is one of the values that satisfies this condition, and therefore \( x = 3 \) belongs to the truth set of \( 5x - 10 > 0 \).”

**Students’ Reactions to Task 9**

Only about 50% of both the Israeli and the Italian participants who responded to this task, correctly identified \( x = 0 \) as the solution of the inequality (see Table 2).

<td>17.1</td>
<td>26.7</td>
</tr>
<tr>
<td>Other</td>
<td>5.8</td>
<td>0.9</td>
</tr>
</tbody>
</table>

* Correct solution

A substantial number of the participants claimed that the set of solutions was empty (Phi, or ‘there is no solution to the given inequality’). Some of them volunteered the explanation that \( x^4 \) has an even power and thus it can never be negative, showing that they ignored the “zero-option”. Another interesting phenomenon was the Israeli and Italian students’ tendency to answer that the set of solutions of \( 5x^4 \leq 0 \) was \( x \leq 0 \), which was further explained by a number of them, claiming, for instance, “I simply computed the fourth root of both sides of the inequality.”

**Examining the consistency in students’ reactions to Tasks 1 and 9**

As can be seen from Tables 1 and 2, and as mentioned before, about half of the participants from each of the two countries claimed that “\( x = 3 \) can be the solution of an inequality”, and about half of the participants identified \( x = 0 \) as the solution of \( 5x^4 \leq 0 \). That is, about half of the participating students pointed to the possibility of having \( x = a \) as the solution of an inequality, either in Task 1 or in Task 9. A question that naturally arose was, were these the same students? That is to say, did the students consistently express their understanding that \( x = a \) could be the solution of an inequality in their reactions to both tasks, by responding “true” to Task 1 and “\( x = 0 \)” to Task 9? Table 3 shows that the answer to this question is no.

Only about 29% of the Israeli participants and about 24% of the Italian participants exhibited a general view that \( x = a \) can be the solution of an inequality and also correctly reached this type of a solution in reaction to the
"solve" drill in Task 9. It is also notable that a similar percentage of each group rejected the option of $x = a$ being the solution of an inequality, and did not reach the correct $x = 0$ solution in Task 9 as well.

* Providing no response to at least one of the two tasks.

More than 35% of the participants in each country were inconsistent in their reactions to the two tasks. Part of them correctly claimed that $x = 3$ could be the solution of an inequality, but did not identify $x = 0$ as the solution of the inequality in Task 9. More interesting were the inconsistent reactions of about 20% of both the Israeli and the Italian participants. On the one hand, they claimed that $x = 3$ can not be the solution of an inequality, usually explaining that "an inequality can only be the solution of an inequality". On the other hand, within the same questionnaire they reached an $x = 0$ solution to the inequality presented in Task 9.

Discussion

Our findings indicate that, as expected, all students in both countries were aware that $x = 3$ can be the solution of an equation, and that many of them encountered difficulties in identifying the possibility of $x = 3$ being the solution of an inequality. These findings can be examined by means of the Intuitive Rules Theory, formulated by Stavy and Tirosh (2000). Students expressed the views that "an equation-result can only be the solution of an equation task" or that "an inequality task must have an inequality-solution." These claims are in line with the intuitive rule Same A (equation / inequality relationship in the solution) – same B (equation / inequality relationship in the task).

Quite surprising were the findings showing students' difficulties in responding to the standard "solve" task. In both countries only about half of the participating students identified $x = 0$ as the solution of the inequality $5x^4 \leq 0$. It
seems that, similar to previous studies, reporting "strange" solutions like Phi and R as problematic for students (Tsamir & Almog, 1999), this study identified that the $x = a$ type of solution is also problematic in cases of inequality-tasks, and should further be investigated. A wider analysis of students' reactions to this task, embedded in different theoretical frameworks (e.g., Fischbein, 1987; Arzrello, Bazzini, & Chiappini, 1993; Bazzini, 2000; Maurel & Sackur, 1998) will be provided in the oral presentation.

Most interesting were the findings related to the consistency of students' reactions to the two tasks. We should remember that both tasks were included in the same questionnaire and students were free to move back and forth among the different tasks. In this manner, students' correct solutions to Task 9 could have served as an example for correctly solving Task 1. Still, no student explicitly mentioned Task 9 when correctly responding to Task 1. Furthermore, a non-negligible number of students (Italian and Israeli) responded to tasks 1 and 9 in a contradictory manner. They wrote, "an inequality can only be the solution of an inequality" (Task 1) and then, that $x = 0$ was the solution of the inequality $5x^4 \leq 0$ (Task 9). A possible explanation for this phenomenon could be that sometimes zero is regarded as a special number. Thus, students could accept $x = 0$, but reject $x = a$, when 'a' is other than zero, from being a solution of an inequality. Naturally, further research is needed to investigate such assumptions.

Moreover, our findings call for interventions that deal with the specific issue of algebraic inequalities and with the general issue of consistency in mathematical reasoning. Questions that arise are, for instance, how to introduce inequalities? How to cope with inconsistencies in students' reactions to inequalities? and how to validate the correctness of specific solutions to inequalities? Suggestions for research based instruction will be presented and discussed in the oral presentation. Clearly, the impact of such interventions should be further investigated.

INVESTIGATING THE INFLUENCE OF THE INTUITIVE RULES IN ISRAEL AND IN TAIWAN

Pessia Tsamir*  Fou-Lai Lin**  Ruth Stavy*
Tel Aviv University*  National Taiwan Normal University**

Mathematics education researchers are always on the lookout for theories with explanatory and predictive powers – i.e., theories that enable the analysis of students' reactions and the prediction of their likely responses to given tasks. One such theory is the intuitive rules theory, which has been described in a series of articles. In this paper we describe a study which was carried out in Israel and in Taiwan to examine the influence of the intuitive rules More A – more B and Same A – same B on Israeli and Taiwanese students' responses to comparison tasks. Our findings confirm that in both countries the reactions to such tasks of students in various grades were indeed influenced by these intuitive rules.

In their work in science and mathematics education, Stavy and Tirosh have observed that students react in similar ways to a wide variety of conceptually non-related tasks (e.g., Stavy & Tirosh, 2000). Although these tasks differ with regard to their content area and/or to the type of reasoning required, they share some common, external features. So far four types of responses were identified, two of which, i.e., More A - more B and Same A - same B, are related to comparison tasks. For example, when students are told that Tom saves 15% of his salary, and Marry saves 20% of her salary, they tend to claim that Marry saves more money than Tom, because 20 is larger than 15, in line with the intuitive rule more A (percentage)-more B (money). Similarly, when students are told that John saves 10% of his salary, and Daffy also saves 10% of her salary, children tend to claim that John and Daffy save the same amount of money, in line with the intuitive rule same A (percentage)-same B (money).

Based on these observations, the intuitive rules theory has been proposed to explain and predict students' responses to mathematics and science tasks. Many responses that the literature describes as alternative conceptions could be interpreted as evolving from the intuitive rules More A - more B, Same A - same B, which are activated by specific external task features (for detailed
descriptions see, for instance, Tsamir, Tirosh & Stavy, 1997; Tsamir, Tirosh & Stavy, 1998; Tsamir & Mandel, 2000).

The intuitive rules theory is based on data collected in the western world. It is, however, very interesting and important from both the theoretical as well as practical points of view to test the universality of this theory. For this purpose a study, parallel to the one conducted in Israel, was carried out in Taiwan, relating to a wide number of comparison tasks. Here we focus on Israeli and Taiwanese students’ reactions to tasks related to three topics: vertical angles, temperatures, and the volume of cylinders, with regard to the intuitive rules More A - more B and Same A - same B.

Methodology

Background

In Israel, the topic of angles is introduced in Grade 4 and the proof that vertical angles are equal is dealt with in Grades 8-9. The topic of volume is introduced in grade 3-6 and formally discussed in Grades 10 to 12, when dealing with three dimensional geometry, trigonometry and analysis (e.g., extreme problems). The concept of temperature is presented in Grades 4 -5 and children are introduced to the terminator as a measuring tool. Further issues related to heat and temperature are and discussed in Grades 7-9.

In Taiwan, the topic of angles is introduced in grade 3-4 and the proof that vertical angles are equal is presented in Grade 9. The topic of volume is introduced in grade 3-6 and formally discussed in Grades 9 and up, when dealing with three dimensional geometry, trigonometry and analysis (e.g., extreme problems). The concept of temperature in presented in Grades 3-6 and children are introduced to the terminator as a measuring tool. Further issues related to heat and temperature are and discussed in Grades 8-9.

A question that naturally arises is – Are Taiwanese children similarly affected by intuitive rules as are Israeli children? More specifically, will Taiwanese students tend to claim, in line with the intuitive rule more A more B that "The larger the arms the larger the angle"? "The more water- the higher the temperature"?; and in line with the intuitive rule Same A - same B, that "Same area-same volume?"
Participants and Procedure

In Israel: Two hundred-and-forty-three students from Grades 2, 4, 6, and 9 – sixty nine, 65, 70 and 60 students, respectively, answered a written questionnaire that included a comparison-of-vertical-angles task.

One-hundred-and-twenty students, from Grades 2, 3, 5, 6, 7, 8, twenty from each grade, were individually interviewed regarding the comparison of temperatures task.

Three-hundred-and-seventy-five students from grades 1-6, and 10, 12, forty students each from grade levels 1-6, 110 10\textsuperscript{th} graders and 29 12\textsuperscript{th} graders. In Grades 1-6 each participant was individually interviewed, and the 10\textsuperscript{th} and 12\textsuperscript{th} graders were given a written questionnaire regarding the comparison of volume of cylinders task.

In Taiwan: Nine-hundred-and-sixty-six students from Grades 3, 4, 5, 6, 10 -- 206, 339, 345, 67, respectively, answered a written questionnaire that included a comparison-of-vertical-angles task.

Nine-hundred-and-twenty-one students from Grades 2, 3, 4, 5, 6, 10, -- 33, 197, 210, 205, 209, 67, respectively, answered a written questionnaire that included a comparison of temperatures task.

On-thousand-two-hundred-and-sixty-nine students from Grades 1-6, 10, 11, -- 28, 33, 34, 117, 443, 428, 65, 121, respectively. All participants answered a written questionnaire that included a comparison of cylinder volumes task.
Materials

Comparison of Vertical Angles Task
Consider the following drawing:
Is angle $\beta$ smaller than / equal to / larger than / angle $\alpha$?
Explain your answer.

Comparison of Temperatures Task
Consider the following drawing:
The water from Cup A and the water from Cup B were poured into Cup C. What is the temperature of the water in Cup C?
Explain your answer.

Comparison of Cylinder Volumes Task
Take two identical rectangular (non-square) sheets of papers (Sheet 1 and Sheet 2):

Rotate one sheet (sheet 2) by $90^\circ$
Is the area of sheet 1 smaller than / equal to / larger than / the area of Sheet 2?
Explain your answer.

Fold each sheet (as shown in the drawing).
You get two cylinders: Cylinder 1 and Cylinder 2.
Is the volume of Cylinder 1 smaller than / equal to / larger than / the volume of Cylinder 2?
Explain your answer.

The tasks were originally formulated in Hebrew, the language in which they were administered in Israel (see for instance, Stavy & Berkovitz, 1980; Stavy, Tirosh & Tsamir, 1997; Tirosh, Stavy & Ronen, 1996). The mathematics and science educators who conducted these researches in Israel were familiar with the intuitive rules theory. They were responsible for writing, editing, administering the tasks as well as for the analysis of the data.
In order to use these tasks in Taiwan a workshop about the intuitive rule theory was carried out by one of the authors. Forty-five Taiwanese mathematics and science educators participated in ten four-hour weekly sessions, in which they studied the theory and had to carry out a relevant mini study in school classes. The tasks were translated into English, and then one of the workshop participants re-translated it into Chinese. In order to validate the translation, the other participants commented on the translated version. The final agreed upon version was again translated into English and the meanings were verified. Then, the tasks were administered by the workshop participants, in the form of a written questionnaire, in several cities in Taiwan. Students responded in Chinese and the results were analyzed by each of the researchers.

Results

First we present the results related to the intuitive rule More A - more B, and then the results related to the intuitive rule Same A - same B.

Results related to the intuitive rule more A - more B

Vertical angles

Figures 1 and 2 show that in both Israel and Taiwan the tendency to correctly solve the comparison of vertical angles task increased with age. While among young children only about 30% of the 3rd graders in Taiwan, and about 10% of the 2nd graders in Israel provided correct responses, most Israeli 9th graders (over 80%) and all Taiwanese 10th graders correctly responded that the angles were equal.

Of the participants who did not respond correctly, almost all answered in line with the intuitive rule more A (longer arms, larger enclosed area) -- more B (larger angle).

Comparison of Temperatures Task

Figures 3 and 4 show that both Israel and Taiwan the tendency to correctly solve the comparison of temperatures task increased with age. While among 2nd graders of both countries there were no correct responses at all, most Israeli 8th graders (over 80%) and all Taiwanese 10th graders correctly responded that the temperature remained thirty degrees.
Of the participants who did not respond correctly, almost all answered in line with the intuitive rule more A (amount of water) -- more B (higher temperature).

**Results related to the intuitive rule** *Same A - same B*

**Comparison of Cylinder Volumes Task**

Figures 5 and 6 show that in both Israel and Taiwan the tendency to correctly solve the comparison of surface area of cylinders task increased with age, accompanied by an incorrect response to the comparison of volume task. In all cases students claimed in line with the intuitive rule *Same A - same B* that the volumes of both cylinders were equal as they were made from identically sized sheets of paper.

**Final Comments**

The findings of this study clearly indicate that Taiwanese students, much like the Israeli peers are strongly affected by the intuitive rules *More A - more B* and *Same A - same B*, when presented with relevant comparison tasks. When relating to tasks whose correct answer was not in line with the intuitive rules, two main findings should be highlighted. First, to all three tasks two major types of responses were evident – the correct, and an incorrect response in line with one of the two intuitive rules. Also, the developmental pattern with age was rather similar.

Consequently, we suggest that the intuitive rules affect students’ responses in both countries regardless of culture. As mentioned before, additional data were collected with regard to other relevant tasks, and similar findings pointing to the influence of the intuitive rules *More A – more B* and *Same A – same B*, were obtained.

These conclusions should be taken with some caution, due to practical constrains: the methodologies applied were not completely identical. Still we find the picture presented by these preliminary results a very relevant one. Clearly, further research is needed to bolster our knowledge about the universality of the role of the intuitive rules in students’ mathematical and scientific thinking.

RE-EVALUATING ASSESSMENT IN LIGHT OF AN INTEGRATED MODEL OF MATHEMATICS TEACHING AND LEARNING

Ron Tzur

The Pennsylvania State University

Abstract: This is a preliminary report on a study that examined, in practice, an integrated model of mathematics teaching and learning. The paper addresses a combination of two problems—how credible is a key theoretical distinction about learning a new conception and how does that distinction inform teacher’s assessment of students’ thinking. I conducted the study as a whole-class teaching experiment in a 3rd grade classroom over a 4-month period. The analysis indicates that the distinction between a participatory and an anticipatory stage is theoretically sound and practically useful in setting the teacher’s goals for and activities of assessing students’ thinking. The study highlights how the model provides a new way of thinking about the role for and organization of assessment.

In this paper I present part of a comprehensive study that examined an integrated model of mathematics learning and teaching in a real classroom setting. Examining the model was a multi-faceted task and reporting on it goes beyond the scope of a single article. Therefore, in this paper I address a combination of two problems—how credible is a key theoretical distinction about learning a new conception and how does that distinction inform teacher’s assessment of students’ conceptual understanding. This focus highlights the interplay between teacher goals of precisely assessing students’ thinking and advancing their understanding. I begin with a brief description of the model and what its examination in practice might consist of, then I present the methods used for the study and an analysis of data regarding the combined focus, and finally I discuss the significance of the study.

Conceptual Framework

The integrated model of conceptual teaching and learning of mathematics (cf., Simon et al., 2000; Tzur & Simon, 1999) is an elaboration of the psychological aspect of the emergent perspective (Cobb and Yackel, 1996). The model evolved as a response to a theoretical problem known as the “learning paradox” (Pascaul-Leone, 1976). This paradox is implied by Piaget’s fundamental notion of assimilation. If one can only recognize and respond to aspects of reality by assimilating them into existing conceptions, how is one to ever construct new conceptions? The model untangles the paradox by addressing three questions: what is a conception, how is a new conception formed (mechanism and stages), and how can teaching promote formation of intended conceptions. I briefly describe each of the three below.

The primitive unit of knowing in the model is a dynamic compound, a relationship. The relationship is between an activity and its effect(s) (abbreviated as A-E relationship). The unit is not mainly the activity nor mainly the effect(s) but the dynamic compound consisting of both. Terms such as scheme, concept, mental object, cognitive process, and the like are various notions used by different scholars to refer to A-E relationships. In this paper I will use the term conception and A-E relationship interchangeably.
The primitive unit of learning in the model is the mental mechanism of reflection on A-E relationship (abbreviated as Re*A-E relationship). The term reflection refers to the ceaseless mental comparison between one’s goals for and effects of her activities (von Glasersfeld, 1995). Note that from the learner’s point of view, Re*A-E relationship does not need to be directed toward making specific conceptual advances (i.e., it does not imply awareness).

Through Re*A-E relationship a learner might make a distinction between desired effects she anticipates of an activity and the effects she notices during or after carrying out the activity. This type of distinction, termed the initial phase, is thought of as a critical precursor for forming a new conception. However, the initial phase is not considered a stage because no new A-E relationship has been abstracted, yet. If goal and effects do differ, the cognitive system searches for some new recurrence, that is, a new regularity in A-E relationship other than the regularity—existing conception—that triggered the activity.

Forming new, regular A-E relationships is postulated to occur in three stages. First is the participatory stage. Knowing at this stage is marked by the learner’s ability to relate effects and activity only when one is somehow oriented to focus on the activity. Thus, at this stage it is assumed that the learner does not know, spontaneously, to call up the activity for the particular goal. The second stage is the anticipatory stage. In contrast to the participatory stage, the learner, upon setting her goal in a situation, can spontaneously select the activity she newly related to that goal(s) and figure out its effects. Though the effects cannot yet be known immediately, the learner can spontaneously initiate the activity from within the A-E relationship, generating and reflecting upon its effects. The third stage is the reified stage. Unlike in the anticipatory stage, the learner can immediately identify the anticipated effects whereas the activity that generated the A-E relationship fades to the background. To an observer it appears as if the learner uses a type of “idle” knowing, knowing without activity. This misleading appearance is probably one reason why “knowing” is often mistaken with quick recognition of facts. However, an activity of a reified A-E relationship is always implicit and it reappears when, for example, the learner is asked to justify her solution. I use the term reified because the third stage seems consistent with Sfard’s (1991) notion of reification. The formation of a reified conception completes a learning cycle such that it can then afford a new distinction among effects, and so on.

Building on the learning process as postulated above and on Simon’s (1995) and Tzur’s (1999) works, the component of teaching in the integrated model is cyclic in nature and consists of four principal phases:

1. assessing (inferring) learners’ current conceptions based on their actions and language;
2. hypothesizing (trying to predict) a learning trajectory for the learners on the basis of what they know, that is, identifying a higher stage and a potential process of change toward that stage;
3. selecting and engaging learners in tasks (problem situations) they are likely to understand and use in service of the intended advance, that is, to assimilate into available conceptions, to set appropriate goal(s), and to initiate appropriate activities;
4. using probing questions and/or comments both to foster reflection on patterns of A-E relationships and to re-assess learners’ current conceptions, and so on.
Regarding phase 3 in the cycle, four types of tasks that correspond to the four postulated transformations from an available conception into a new, intended conception are proposed. (Note: The name refers to the intended phase or stage.) The teacher uses initial tasks to foster the use of activities available in current conceptions to make new distinctions among effects of that activity. For example, consider children who already constructed whole numbers at least as an anticipatory relationship between the activity of iterating the unit of one and the effect of having established a composite unit of a certain amount (e.g., 3=1+1+1). Then, using paper strips, the teacher can engage learners in using the repeat strategy (see next) to share a paper strip among a given number of people. The repeat strategy consists of four activities that learners can already initiate and use in sequence: estimating the size of one piece, iterating that piece the desired number of times, comparing the whole produced in iteration to the given one, adjusting (re-estimating) the size of the piece, etc. The repeat strategy is likely to foster learners’ initial distinction between a piece that is too short, too long, or exactly the size needed. The teacher uses participatory tasks to orient learners’ to reflect on and identify a new relationship between the activity and the newly distinguished effects. In the repeat strategy example, a participatory task can be the question, “Why did you make that piece shorter than the previous one?” Such a question might orient learners’ reflection on the magnitude relationship between the activity of adjusting the size of the estimated piece and the uniqueness of that size relative to the whole. Moreover, the learners may notice a new (inverse) regularity between the number of times the piece is iterated and its size (e.g., 1/6 is larger than 1/7 because each of the 6 pieces has to occupy more space). The teacher uses anticipatory tasks to foster learners’ abstraction of the participatory A-E relationship into an anticipatory A-E relationship. If learners are to advance from the participatory stage, it is critical that anticipatory tasks do not indicate what activity the learners should use. In the repeat strategy example, an anticipatory task might be, “You received 1/7 of a pizza; can you figure out a way to cut another piece of the same-size pizza so that your friend gets a smaller piece than yours? What fraction of the pizza is your friend’s piece?” It is the learner who translates the question into another one, “How could I share a pizza among 7 people?” which triggers the activity (repeat strategy) she was already using prior to the initial phase, which fosters mental reprocessing of the activity and its effects. The learner realizes that she has to iterate the piece more than 7 times and regenerates the magnitude relationships in her thinking. The teacher uses reified tasks to foster learners’ abstraction of anticipatory A-E relationship into a new, reified A-E relationship. Unlike at the participatory stage, at the anticipatory stage the learner can assimilate abstract symbols and mentally reprocess the anticipatory A-E relationship. Through further reflection, the anticipatory A-E relationship becomes the signified “object” encapsulated within the symbolic, signifying entity and the construction of the new conception is established at the reified stage. In the repeat strategy example, a reified task might be, “What is bigger, 1/4 or 1/7?” because it calls upon the anticipatory inverse relationship between size and number of pieces and fosters further reflection on and reification of that relationship.

Methodology
I conducted the comprehensive study as a classroom teaching experiment (Cobb, 2000) in the context of fractions. I chose fractions because research (cf. Tzur, 1999) identified a
developmental sequence of fraction conceptions that could guide my teaching. In a public elementary school in Israel, I selected a 3rd grade classroom that had not yet received any instruction on fractions. Thus, for all 28 students the following two-part description applied. First, they could reason about whole numbers. Some were also able to engage in part-whole numerical reasoning. For example, they could think of 12 as composed of 5 “ones” and 7 “ones,” and, when told that a dozen-egg carton already contains 7 eggs, could figure out how many more eggs would fill the carton. Second, as students’ responses to a pre-program problem-solving questionnaire indicated, none used any fraction conception beyond, maybe, primitive, generic notion of half. Thus, I could begin fostering in these students a sense of magnitude of, and operation on, unit fractions (1/3, 1/4, etc.).

As a researcher-teacher I collected data by conducting two videotaped lessons a week, for a total of 26 lessons. I taught the lessons consecutively, on Friday and Sunday, because I wanted to have a sense of continuation while allotting the time needed between lessons for analysis and planning. The ongoing analysis after each lesson focused on students’ conceptions and whether or not a conceptual change took place. As part of that analysis I conducted audio-recorded conversations with the classroom teacher and 1-2 other teachers who observed every Sunday lesson. On the basis of my reflections on each lesson I created and/or adjusted tasks for the next lesson. Besides the reflective sessions with the teachers, I systematically documented (audio recorded and/or wrote) my reflections about students’ evolving understandings and my past and future teaching.

Upon completion of data collection, I will conduct a retrospective analysis of the teaching-learning process. However, teaching is not over, yet. Thus, the analysis in the next section represents a work in progress—my first screening of data from three lessons that are relevant to the combined foci of this paper. This screening included careful reflection on lesson segments (videotapes) of the three lessons and on chunks of transcripts of my notes (written or recorded) regarding my teaching activities and decisions.

**Analysis**

I did not set the goal to specifically examine the aspect of assessment from the outset. Rather assessing students’ conceptions became a perturbation for me in the practice of teaching. In this section I present how I resolved the perturbation. In the first take at the perturbation my goal of promoting students’ learning overruled the goal of making subtle distinctions among students’ ways of thinking. In the second take the order was reversed. Through paying attention to considerations of both ways of organizing assessment, a pattern emerges that highlights both the credibility and power (in terms of assessment) of the theoretical distinction between the participatory and anticipatory stages.

**First Take at the Perturbation: Promoting Learning Overrules Subtle Assessment.** After a few lessons in which the students were engaged in using the repeat strategy, I had a rough sense that some already formed a participatory sense of the inverse relationship between size and number of pieces while others did not. However, I made several notes that indicate that I became frustrated because of my initial inability to get to know how each student was thinking. For example, I wrote in reflection on the lesson of November 11, 2000:
I thought, intensively, about the problem: How to overcome the enormous difficulty I have to get to each and every student and observe what they do, to “interview” them on the spot … so I can understand how they think. I realized that I need to give them some task that requires written responses that will give me a more detailed information than I currently am able to gather, information that is structured by the model I use.

Consequently, my planning for the next lesson turned to creating a task that would delineate students’ thinking. After several hours of thinking and jotting down ideas for different tasks, I designed a set of 7 questions that I hoped would provide insight into students’ current thinking about the conceptual aspect at issue—direction of adjustment in size of the estimated piece (make it shorter or longer). I considered this aspect as the conceptual root of the uniqueness of the size of a unit fraction and of the inverse relationship between size and number of unit fractions in a given whole (cf. Tzur, 1999). For example, questions #1 & #2, and #5 & #6, read as follows (figures are not presented):

Question #1: In Figure 1 you see a paper strip that Pat tried to share among 3 people and underneath it is the piece Pat used to mark the strip [Note: the piece was a bit short]. Please draw, under Pat’s piece, another piece that you think will fit better for sharing the strip among 3 people.

Question #2: In the second attempt to share the strip among 3 people, Pat used a piece that was longer than the piece in Figure 1. Do you think it was smart to do so? Why?

Question #5: In Figure 4 you see a paper strip that Danielle shared equally among 3 people and underneath it is the piece she used to mark the strip. Please draw, under Danielle’s piece, a piece that you think will be appropriate to share the strip among 4 people.

Question #6: In the previous question, did you draw a piece that is shorter or longer than Danielle’s piece? Why?

On the basis of my rough assessment that many students did not yet form the intended relationship, I planned a two-part lesson: administering the questionnaire and engaging the students in using the repeat strategy some more (share paper strips among 7 and 11 people). Once the questionnaire was ready, I turned to think about ordering the two parts. My notes indicate how the model informed my decision to do the activity before the questionnaire:

I was aware that this order will not allow me to evaluate anticipatory conceptions, but decided to do it because I thought that otherwise many students would not be able to participate at all.

The note above is important because questions #1 and #5 above, if asked prior to being engaged in the activity, could be used to make a subtler distinction between students who used only a participatory conception of the inverse relationship and those who already used it in anticipation. Although I was not aware of this at the time, the short note indicates that promoting all students’ learning of the conception at least at the participatory stage overruled the desire to make a subtler distinction among the more knowledgeable students. In this sense, the model informed my teaching, and the first take at the perturbation, in that it highlighted a local trade-off between two phases of the teaching cycle, assessing students’ thinking and engaging students in tasks that promote their learning. In the case where my rough assessment of the class suggested the lack of even a participatory way of thinking on the part of many students, promoting learning overruled subtler assessment.

Second Take at the Perturbation: Subtle Assessment Overrules Promoting Learning. After the two-part lesson, I read the students’ responses to the questionnaire and found that 14 of them knew the direction of adjustment. In my post-lesson conversation with the teachers, I emphasized that due to the order chosen the most I could claim about these students was the formation of a participatory conception. I was aware of and said that there was no way to
distinguish if they had formed a higher stage. To promote all students' understanding of the direction of adjustment, we planned to engage pairs of students in using the repeat strategy some more. We paired each of the 14 students whose responses to the questionnaire indicate a participatory conception with another student who seemed not to understand the direction of adjustment. The idea was that both students in each pair could benefit from reflecting on direction of adjustment offered by the more knowledgeable one.

After the next lesson (Friday, 11-17-2000), a short conversation between the teacher and me indicated that both of us assessed, roughly, that all but maybe 2-3 students knew the direction of adjustment at least in a participatory sense. But I was still perturbed:

The lesson was difficult in terms of my ability to follow and analyze what each child does and thinks. While I was trying to help a pair I had to focus mainly on their execution of the repeat strategy and often other children would come and pull my sleeves to get my attention. I trusted that the videotape will give me the data needed for retrospective analysis, but in terms of monitoring and documenting while interacting with the students I was still unable to follow what’s going on.

This time, the ongoing perturbation regarding the lack of precision in assessing students’ thinking, along with my indefinite sense that most students advanced at least to the participatory stage, turned into a new, model-rooted perturbation. I wanted to devise a tool and organize the lesson so that I could distinguish students who could use the inverse relationship in anticipation from those that could not. Interestingly, this goal was accomplished semi-accidentally, while I was relating my research proposal of conducting occasional interviews with the idea to let the class do silent reading while the teacher and I work with pairs of students. Below are my notes from Saturday, 11-18-2000.

Last night I went to a concert. During the concert I was intensively thinking about the continual difficulty I have to assess students’ thinking during the lesson and about how to use the organization of the lesson for that purpose. [Initially] I was thinking about my research proposal to conduct occasional interviews as part of the data collection methods. Then, something “clicked”—I realized that the idea to work with one pair at a time actually created the possibility to conduct mini-interviews with students … Thus, I immediately began to think what questions will I ask as well as who among the students I would like to interview. I started with a question that seemed promising in terms of making a distinction between participatory and anticipatory thinking regarding the direction of adjustment: “You have a piece that fits, exactly, for sharing a whole among 6 people and now you have to share the whole among 7 people. Show me what will you do.”

It took only a short, focused reflection to create a set of 3 questions that would enable me to make the intended distinction and to design a form that would enable me to document how each student responded to the question. Moreover, I immediately chose a different order than in the previous assessment event. Because students would be engaged in reading and not in the repeat strategy, I would first ask the “hard” question where students are not prompted what activity to use and thus I would be able to distinguish those who used the conception in anticipation from those who did not. Then, I would present the questions that give some orientation. The three questions were:

**Question #1:** (The teacher presents a drawing of a paper strip marked into 6 equal parts and the piece “he used” to create the sharing underneath it. He gives the students another piece of paper, and says: Can you mark (or cut) a piece that could serve in equally sharing the paper strip among 7 people? (Pending students’ drawing he asks): Any reason why you made it shorter/longer than the “sixth”?

**Question #2:** (The teacher puts, underneath the “sixth,” two pieces that he prepared ahead of time, or shorter and one longer than the “sixth” and says): Which of the two pieces would fit better to share the strip among 7 people? Why?
Question #3: (The teacher asks the students to observe how he accurately iterates each of those two pieces and asks): Which piece helped more in sharing the strip into 7 equal pieces? Why?

According to the model, if question #1 is asked after some time during which students did not use the activity that fostered the participatory stage of their thinking (here, the repeat strategy), one can answer it only if one already formed the inverse relationship at least at the anticipatory stage. The reason is that Question #1 does not call upon the size aspect of the relationship; it is the student who must attribute it to the situation. In contrast, Question #2 orients the student to the activity of comparing between sizes of pieces that are shorter or longer than a given piece and hence brings forth the next activities in the repeat strategy sequence, adjustment and iteration. Thus, students who already formed the participatory stage of the inverse relationship could solve Question #2. Question #3 allows an even finer distinction within the participatory stage, by bringing forth the entire activity sequence.

Due to scheduling and time limitations, I conducted the mini-interviews with students over 5 lessons. During those lessons, the class was engaged in non-related tasks while the classroom teacher worked with pairs I already interviewed on a specific way of executing the repeat strategy. Once they used it systematically and equally shared the paper strip among 3 people, she asked each pair: “Next, we have to share the strip among 4 people; should we make the piece shorter or longer than the share of one-out-of 3 people?” In response to her question, all students but one appropriately suggested to make it smaller.

Bearing in mind that only 12 students answered Question #1 in a way that indicated clear understanding of the reason to make the “seventh” shorter than the “sixth,” a significant, twofold conclusion emerges. First, organizing the three questions that way resolved my perturbation about assessment. At last I was able to make fine distinctions in students’ thinking that corresponded to the first two stages of the model. Second, the very distinction between the two stages was supported by the results of the assessment tool and process that I have designed. In part, this twofold conclusion was made possible because of my model-based choice to give the goal of precisely assessing students’ thinking a priority over the goal of promoting students’ learning. In turn, this precision allowed for better planning of the next lessons to fit the two sub-groups within the class.

Discussion

In this paper I examined two interrelated aspects of an integrated model of mathematics teaching and learning: the key theoretical distinction between participatory and anticipatory stages and teacher assessment of students’ evolving conceptions. The analysis of the researcher-teacher activities to resolve a continual, model-based perturbation and of students’ responses to several assessment tools that were devised accordingly supported the theoretical distinction. That is, if students appear to clearly understand a specific conception while using certain activities to solve mathematical problems, but on the next day they revert to lack of understanding, the reason may well be conceptual and not bad teaching or lack of effort on the students’ part. For example, about a half of the class reverted to making the “seventh” larger than the given “sixth” (Q. #1, Second Take) even though they clearly knew, while engaged in the activity in the previous lessons, that it must have been smaller. The reason for that change in students’ understanding can be explained in terms of competition between
two, unevenly formed conceptions. The students have used at least an anticipatory and probably a reified conception of magnitude relationship among whole numbers, but only a participatory conception of inverse relationship between size and number of pieces in sharing situations. Thus, when not prompted for the activity to use, the problem situation was assimilated into the stronger conception of whole numbers and they made the “seventh” bigger than the “sixth” precisely because seven is bigger than six.

The study provided supporting evidence not only to the key theoretical distinction but also to the claim that teaching or assessing anticipatory conceptions is sensitive to orienting prompts. It demonstrated that order of teaching activities matters. Moreover, it provided a way of thinking about the relationship between what the teacher intends the assessment to accomplish and how she should organize it in practice. In particular, the study contributed to better understanding the conceptual goal underneath the potential organization of assessment tools from “hard” to “easy” questions and demonstrated specific ways in which the model can inform teaching (e.g., individual vs. pair work; mini-interviews vs. observation of the entire class, ordering questions). In this sense, the model both provides an articulated “map” of the conceptual terrain to be assessed and guides the teacher’s organization and design of assessment tools and activities that fit to where, conceptually, students are.

A MODEL FOR THE USES OF VARIABLE IN ELEMENTARY ALGEBRA

Sonia Ursini

Maria Trigueros
Departamento de Matemáticas
ITAM, México

This paper presents a theoretical framework we will call the Three Uses of Variable model (3UV model) that can be used as a guideline in the design of tools intended to make diagnostic analysis, to design teaching activities and to analyse textbooks and other teaching materials related to the concept of variable in elementary algebra. Essentially the model consists of a detailed description of the different aspects that underlie a basic understanding of the three main uses of variable in elementary algebra: specific unknown, general number and related variables. We present results that show the possibilities of applying this model in diagnosis, in the analysis of textbooks and in the design of teaching materials.

Antecedents
The development of algebraic knowledge implies the development of the concept of variable. This concept is central as well to the understanding of more advanced topics in mathematics. Its versatility makes it an important object of study. Given the multifaceted character of variable, no matter which starting point is taken, its different uses are very often concurrent within the same problem or situation and this has to be faced during the teaching process. From our point of view, disregarding any of its fundamental aspects in a problem situation may be the cause of many of the difficulties faced by students when working with algebra. In contrast, paying attention to the flexibility of the use of the concept of variable may be the source of a richer understanding.

The Mathematics Education literature, ever since the beginning of the XX century, has highlighted the difficulties students have with the different uses of variable (Thorndike et al.; 1923, Van Engen, 1953; Menger, 1956; Kuchemann, 1980; Wagner, 1983; Matz, 1982; Philipp, 1992; Warren, 1999). Several research studies point out that students encounter tremendous difficulties in grasping the essentials of the notion of variable and in being able to apply flexibly these uses at different levels of abstraction (Matz, 1982; Usiskin, 1988; Trigueros and Ursini, 1999). All these studies have stressed the importance of being able to move flexibly from one use of variable to any of the others, in order to be able to master this concept and work proficiently with algebra.

The understanding of each one of the uses of variable entails the mastering of many different aspects underlying each use at a different levels of abstraction. From our perspective and based on several years of research on the teaching and learning of the concept of variable, an understanding of variables at an elementary level could be described in terms of the following basic capabilities:

• to perform simple calculations and operations with literal symbols;
• to develop a comprehension of why these operations work;
• to foresee the consequences of using variables;
• to distinguish between the different uses of variable;
• to shift between the different uses of variable in a flexible way;
• to integrate the different uses of variable as facets of the same mathematical object.

The 3UV model

Further analysis of students strategies when working with problems related to the different uses of variable and of the mathematical requirements to master this concept led us to the design of a theoretical framework that enable us to analyse students’ productions, to design instruments for diagnosis, for research, and to develop didactic approaches. We call this framework the 3UV (three uses of variable) model. It involves a decomposition of variable in its three main uses in elementary algebra: specific unknown, general number and relationship between variables. For each one of these uses, we have stressed different aspects corresponding to different levels of abstraction at which they can be handled. These requirements can be presented in a schematic way as follows:

We consider that the understanding of variable as unknown requires to:

U1 - recognise and identify in a problem situation the presence of something unknown that can be determined by considering the restrictions of the problem;
U2 - interpret the symbols that appear in equation, as representing specific values;
U3 - substitute to the variable the value or values that make the equation a true statement;
U4 - determine the unknown quantity that appears in equations or problems by performing the required algebraic and/or arithmetic operations;
U5 - symbolise the unknown quantities identified in a specific situation and use them to pose equations.

We consider that the understanding of variable as a general number implies to be able to:

G1 - recognise patterns, perceive rules and methods in sequences and in families of problems;
G2 - interpret a symbol as representing a general, indeterminate entity that can assume any value;
G3 - deduce general rules and general methods in sequences and families of problems;
G4 - manipulate (simplify, develop) the symbolic variable;
G5 - symbolise general statements, rules or methods;

We consider that the understanding of variables in functional relationships (related variables) implies to be able to:

F1 - recognise the correspondence between related variables independently of the representation used (tables, graphs, verbal problems, analytic expressions);
F2 - determine the values of the dependent variable given the value of the independent one;
F3 - determine the values of the independent variable given the value of the dependent one;
F4 - recognise the joint variation of the variables involved in a relation independently of the representation used (tables, graphs, analytic expressions);
F5 - determine the interval of variation of one variable given the interval of variation of the other one;
F6 - symbolise a functional relationship based on the analysis of the data of a problem.

The 3UV model was applied to the analysis of secondary school mathematics textbooks, to the diagnosis of secondary school mathematics teachers conceptions of variable and to the design of school activities involving the different uses of variable at different abstraction levels. In each of these cases an appropriate instrument was designed to serve the specific purpose it was intended for. The instrument was applied and the results were analysed in terms of the 3UV model.

### Analysis of textbooks

#### Method

A grid that takes into account all the aspects involved for the different uses of variable was designed. The grid consists of a table with a column for the number of the lesson, a second column for the theme of the lesson (arithmetic, algebra, geometry, basic statistics, and probability), then each of the uses of variable has its own column subdivided into new columns where the different aspects of the use are taken into account. In Mexico there is an official program for secondary school mathematics education. The books used at this level have to be authorised after a process of evaluation. Three books officially authorised by the ministry of education were analysed. These books correspond to 1st, 2nd and 3rd year of secondary education in Mexico. These books consist of 44, 45 and 41 lessons respectively. Each lesson was analysed to see which aspects of the different uses of variable, if any was included. (Benitez, 2001)

#### Results

The purpose of this analysis was to study the way the concept of variable is included in secondary textbooks, to see which of the uses of variable was stressed and to analyse what kind of relationships were established between the different uses of variable.

The percentages of lessons in which each aspect of the three uses of variable is used in each of the three secondary school textbooks are shown in the following table.

PME25 2001
As can be seen in this table, the way in which variable is used at secondary school is centred mainly in the use of variable as unknown, but its different aspects are not taken into account in a balanced way. The main emphasis is always directed towards U1 and U4. Even if the variable as a general number is considered in some lessons, there is nothing explicit to make sure that the student will develop the ability to differentiate it from the specific unknown, to develop general methods and to work fluently with it. Variable in a functional relationship appears only in few occasions. Even if in several lessons two or three aspects of a specific use of variable or different uses are presented in conjunction, there is no indication helping students to distinguish between them or to shift from one to the other. The 3UV model permits us to see that these textbooks don’t provide enough opportunities for the students to integrate the different facets of variable and this lack of flexibility is reflected in the results obtained as they progress through their schooling (Trigueros and Ursini, 1999).

**Diagnosis of teachers’ conceptions**

**Method**

A questionnaire was used in this case. This questionnaire had been used with students before and the results obtained have been discussed in previous studies (Ursini and Trigueros, 1997). This time the questionnaire was applied to 74 secondary school teachers and their responses were analysed and classified. After reviewing the responses, six teachers were selected to be interviewed. The interviews were also analysed in terms of the model.

**Results**

The percentage of correct responses per teacher is shown in the following graph.

![Percentage of correct responses per teacher](image)

It is striking to see that secondary school teachers results are very similar to those obtained by starting college students (Ursini and Trigueros, 1997) and that their incorrect responses are very similar. Again, none of the questions was answered correctly by all the teachers and no teacher answered correctly all the questions.
High school teachers have problems to differentiate between the uses of variable as unknown and as general number (U2,G2), but in the case of equations they are able to correctly recognise the unknown and find it. Even though their ability to manipulate equations and algebraic expressions (U4,G4) is good, they struggle with the recognition of the unknown and its symbolisation in problem situations (U1, U5). A tendency to avoid the use of algebraic methods and a strong preference for arithmetic approaches was found. Teachers have difficulties to accept open expressions as valid (G2), this is demonstrated by their tendency to complete them by adding an equal sign and thus changing their meaning to that of equations (G2 changed into U2). When an equal sign is present they feel compelled to find a specific result. Their idea of general number can be described more in terms of “any specific number” than in terms of a way to represent a generalisation (G2). They are able to manipulate the general number in different situations (G4) but they always think about it as something that can be determined sooner or later.

The use of variable that teachers have more problems with is variable in a functional relationship. This was also found in the study with college students. Teachers recognise and work with correspondences (F1) and can determine the value of one of the variables when they know the value of the other (F2, F3), however they have trouble with joint variation questions (F4) and their symbolisation (F6). Their description of intervals was always in terms of discrete numbers, that is, they have difficulties with the idea of the continuum in the number line (F5). For them only even and rational numbers are possible as response of several of the problems discussed (Juárez, 2001).

**Design of activities**

*Method*

Several activities of different levels of abstraction were developed in terms of the 3UV model. They were designed to take into account the possibility to differentiate and integrate the different uses of variable and to encourage the flexibility in their use. A whole precalculus course for college was designed in terms of the 3UV model.

*Results*

In order to illustrate the use of the model in the design of activities we show here one of such activities:

*For which values of X the area of the following rectangle varies between 168 and 288? If the value of X increases or decreases what happens with the area?*

\[
\begin{array}{ccc}
  & (x+3)^2 & \\
 6 & & 12
\end{array}
\]

This is not an easy problem. It was proposed for pre-calculus students at college level. The answer to this problem requires the identification of two non contiguous...
intervals and it implies working with several of the aspects of the three different uses of variable. The variable X has to be recognised as a general number, it has to be manipulated and used in order to obtain new expressions. It has to be recognised that there are unknown quantities involved in the problem that can be determined. Correspondence, variation and determination of intervals are as well involved. Different strategies can be used to solve this problem and students can explore the use of one or another depending of their previous knowledge and mathematical experience.

Some guiding questions that can be used with students in order to help them solve this activity are:

What does X represent in this problem? How many values can it take? The idea of this question is to help the student see the variable X as a general number (G2).

How do you express the area of this rectangle? Students have the tendency to use the memorised formulae for areas without taking into account the specific data given in the problem. This question intends to focus students' attention on the givens and on symbolisation (G5) using the general number and its manipulation (G4) to obtain the expression $6((X+3)^2 + 12)$.

For what values of X the area is equal to 168 and equal to 288? This question can be formulated to help students who use as a starting point for solving an inequality the common strategy that involves solving the equations $6((X+3)^2 + 12) = 168$ and $6((X+3)^2 + 12) = 288$. When students use this strategy they often assume that all the values between the solutions obtained make the inequality true. But this is not always true. With appropriate guide the use of this strategy can help them question its validity. In terms of the uses of variable answering this questions involves posing the quadratic equation (U5), develop the general expressions (G4) and solve both equations (U4). As each equation has two solutions students have to consider that both of them are possible and meaningful in terms of the given problem (U3).

For what values of X the area is bigger than 168 and smaller than 288? For students who used the above mentioned strategy, to answer this question implies the use of the values they already found in order to establish the appropriate intervals (-9<X<-7 and 1<X<3). In other cases, students must form the inequalities (15) $168 \leq 6(X+3)^2 + 12 \leq 288$, develop the general expression involved in it (G4) $168 \leq 6(X^2 + 6X + 9 + 12) \leq 288$ and solve them (14).

Another possible strategy to solve this question is to relate the expression for the area of the rectangle with a functional relationship between X and area (F1). In this case, answering this question implies defining variation intervals for the dependent variable (F5) and determining, from the graph of the function, the corresponding intervals for the independent variable.

What happens to the area of the rectangle when X varies? The answer of this question involves the recognition of joint variation (F4) of the two variables, determine the values of one of the variables when the values of the other are known (F2). A graphical representation of the relationship can also be used in the solution (F1-F5).
How does the area vary when the value of X increases/decreases? This involves the recognition of the joint variation (F4) and the realisation that while varying X some of the values of the area are a solution to the problem and some of them are not and finding the required intervals for X.

The same problem can be posed using different expressions instead of \((X+3)^2\), that involve different difficulties for the students, for example, for beginning algebra students \(X\) or \(X+2\) can be used, and for more advanced students one can introduce more complex expressions such as \(1/X\).

The detailed description included in the 3UV model is very useful in the design of problems and didactical sequences for algebra courses at different school levels. It can guide the design of didactical sequences to introduce beginning students to the concept of variable so that they can differentiate between its different uses. It can be used to design sequences aiming to foster students’ comprehension of variable by introducing relationships between the different aspects of each use and between the different uses, helping them in this way to integrate the different uses of variable in a single concept.

Conclusions
The concept of variable appears in any branch of mathematics. It is widely used also in application of mathematics, but this versatility makes this concept a very difficult one to be mastered by students. The different uses of the concept are on the basis of the difficulties students face when trying to learn algebra.

Research developed during the last thirty years has shown that each use of variable is linked with specific epistemological and didactical obstacles. When algebra is taught taking only one of these aspects as the central focus, the possibility of flexibility and the richness of the relationships between the different uses is lost or obscured and students’ understanding of algebra stays limited.

The 3UV model presents a very detailed analysis of each of the main uses of variable in elementary algebra: as a specific unknown, as a general number and in a functional relationship. A lot of research about students' understanding of the concept of variable has been incorporated in the model and it is at the basis of the wide range of possible applications.

The possibility to integrate a collection of related ideas in a single concept, with a specific name, can help students focus their attention on it, manipulate it and use it with ease in applications. Such concepts have rich potential precisely because they carry with them powerful links that enable the users to invoke them to solve problems. If the diverse elements that integrate the concept are not connected sufficiently fluently, it may be very difficult for students to consider such concept as a unit and it may be impossible for them to make links with it. The student can access only some elements of a loosely connected structure, instead of a rich conceptual entity and the possibilities of its invocation are reduced considerably (Skemp, 1970).

But identifying the components that have to be linked in that unit can be a very
difficult task and cannot be left as something to be done by each teacher. Research is necessary to make this task possible.
The 3UV model is precisely an attempt to fill this necessity in the case of the concept of variable. We have shown here examples of the application of the model to different educational activities: diagnosis, design and analysis of teaching material. These examples show that the analysis of the concept incorporated in the model is detailed enough as to make it possible for researchers and designers to use it in a wide variety of contexts. The possibility to design teaching activities that can help students make the necessary links between the aspects that constitute each one of the uses of variable, and the possibility of identifying them with a specific name may help beginning students to develop a stronger concept of each of the uses of variable. The posterior emphasis in relating the different uses of variable into a single conceptual unity can foster the development of a multifaceted concept of variable.

References
This paper addresses a study on assessing student learning in mathematics education. The study is connected to a teacher enhancement project at primary schools in New York City. The eventual goal of the project was to improve the students' mathematical achievements. Among other things, this goal includes the use of clever ways of applying mathematics for solving problems. Because standardized tests are not an adequate tool for revealing this kind of student learning a test was developed by means of which the process of mathematization was supposed to become visual. Results gained from this test in 17 classrooms with students ranging from grades 3 through 5 show that strategy-focused assessment is a valuable extension of the regular answer-focused assessment.

Introduction

The dichotomies product-process and answer-strategy play an important role in the assessment of mathematics achievements. If not earlier, this became apparent in the recent worldwide reform of mathematics education. One of the characteristics of the new approach to mathematics education is that it gives more room to processes and strategies. Nevertheless there is yet a large distance between both ends of the respective dichotomies. The answers belong to the product side and the strategies to the process side, and answers and strategies each have their own purposes. The gap is reflected above all in the difference that still exists between standardized tests and tools for classroom assessment.

Although the ways in which students solve mathematical problems are regarded as important information for educational decisions, solution strategies are scarcely covered by standardized tests. More often than not achievement scores are purely related to the number of correct answers. In tests, the answer is usually considered as the ultimate indication of the achievement level. The strategies that the students applied to find this answer are generally beyond the scope of standardized testing and belong more to the field of interviews and observations.

For a long time, only within the context of diagnostic testing, attention was paid to strategies. Data about the process of solving problems, and especially data about errors, was used to identify students' misunderstanding and find indications for remedial teaching. Errors in strategies were regarded as "windows on children's internal thought processes" (Baroody, 1987).

As said earlier, the reform in mathematics education has opened the door now for strategies as a more general focal point of assessment. They are no longer restricted to a remedial setting. As expressed in standards and curriculum documents of many countries, the new ideas about mathematics education emphasize that in addition to product information, process
information is needed to get insight in the students’ thinking. This particularly implies that special attention is paid to the various ways by which the students solve mathematical problems. A wide range of alternative assessment tasks and formats has been developed to reveal strategies. The main purpose of this alternative assessment is to inform the teachers about the students’ way of thinking in order to provide clues for further teaching.

In other words, there is, nonetheless, a distinction between process and product. Strategies are still considered as a process variable and the answers are still the pivot of all. They are considered as the real output variable that counts for determining the achievement level. The question is, however, how tenable this is. Is this strict distinction not an unnecessary curtailment of the assessment of mathematics achievements?

The present paper cannot answer this question extensively. It only reports about a study in which was tried to use the students’ strategies as an output variable, or – adapting Baroody’s words – as “windows on achievements level”.

The MiTC project

The study was part of the “Mathematics in the City” (MiTC) project. The MiTC Project is a large-scale project on teacher enhancement project funded by the National Science Foundation and the Exxon Educational Foundation (see Fosnot and Dolk, 2001). The City University of New York and the Freudenthal Institute of Utrecht University carried out the project jointly. Over a period of five years, the project worked on systemic reform in mathematics education from pre-kindergarten through grade 5 in five school districts in Manhattan. The project started with ten schools and in the last stage of the project about forty schools were involved.

The two key points that characterize the MiTC project are its model of improving teachers’ classroom practice and its idea about mathematics education.

Approach to teacher enhancement

The heart of the project consisted of a very intensive collaboration between staff members of the project and the participating teachers. The mathematics classrooms in the project were co-taught by the project staff and the school teachers. Through joint observations and discussions between teachers and staff members the team worked continually on the development of better ways of teaching. By means of a two-week summer institute in the beginning of the school year, followed by weekly-organized institutes during the year, the teachers were offered opportunities for further deepening their professional knowledge and abilities. The structure of the project was that after a year of participation some of the teachers became staff members, which implied that they coached new teachers in the project. This mushrooming pattern meant that the initial number of forty involved teachers rose up to four hundred.

Approach to mathematics education

The project was strongly related to both the constructivist and the “realistic” view on mathematics education. Moreover, a strong basis was found in the Piagetian and Vygotskian theories on children’s cognitive development. These two theories actually constitute the
The socio-constructivist view in the MiTC project is recognizable in the fact that the students are seen as active learners within the social community of the classroom. The mathematics "congresses", in which the students, while seated on a rug, share their thinking and build up new understanding, reflect this approach to mathematics education exceedingly. In addition to this, within MiTC classrooms the Piagetian concepts of assimilation and accommodation play an important role. Teachers have to recognize the present cognitive schemes and structures of the students and must learn how to design problems and situations that can evoke new or re-ordered schemes and structures.

The key beliefs about what should be taught, and how it should be taught, are heavily inspired by Realistic Mathematics Education (RME), which is based on Freudenthal’s view that mathematics must be connected to reality, stay close to children and be relevant to society, in order to be of human value (Freudenthal, 1977). Instead of seeing mathematics as subject matter that has to be transmitted, Freudenthal stressed the idea of mathematics as a human activity. Education should give students the “guided” opportunity to “re-invent” mathematics by doing it. This means that in mathematics education, the focal point should not be on mathematics as a closed system but on the activity, on the process of mathematization (Freudenthal, 1968).

Actually this mathematizing ability, including also attitude to mathematize, is the overall core goal of mathematics education. In short, this ability involves that students can use and develop mathematical tools, including models and strategies, which can help to organize and solve real life problems and pure mathematical problems.

Evaluation of student learning

In year five of the project an evaluation was planned. Because of the large-scale character of the project with its focus on change at different levels, i.e. students, teachers, and whole schools, a uni-dimensional evaluation was felt to be insufficient. Instead a multi-focus assessment was designed including macroscopic and microscopic lenses (Van den Heuvel-Panhuizen, Dolk, Fosnot, and Glick, 2000). This approach to assessment was based on the belief that the different perspectives would provide a fuller understanding of the effectiveness of the in-service intervention. The assessment contained the following three foci: student learning, teacher change, and school change. Each of them has various aspects to be examined.

The present paper will only deal with the assessment of student learning and will concentrate on student competence deduced from the strategies they applied to solve the problems.

The main question to be answered about the student learning was what the project students gained from the project. To answer this question the achievements of the students from grades 3, 4 and 5 were compared to the achievements of non-project students.

Comparison by means of the standardized tests

The first analysis was done based on the results from the Corrected Terra Nova Math Test (for third-grade and fifth-grade students) and the Corrected New York State Math Test (for fourth-grade students). Although these standardized tests are not entirely in line with the
project goals of mathematics education, it was decided to have the test scores from these tests as one criterion for evaluation. If students in reform project do not score well on mandated tests, the reform will fail simply because of political forces at play regarding testing. Moreover, results on sub test items can be helpful in understanding how well the reform project appears to be aligned with standardized achievement outcomes. The comparison of the tests scores revealed that in all the three grades the project students (experimental group) scored significantly better than a group of non-project students (control group). A covariance analysis controlling for entering score at the beginning of the year (which only was possible for grades 4 and 5) showed also significantly better results for the experimental group (Fosnot, Dolk, van den Heuvel-Panhuizen, Hilton, Wolf, and Bailey, under review).

Comparison by means of the MiTC test
From the very beginning of the project it was planned to have an additional evaluation of student learning more aligned with the goals of the project than the regular standardized tests mostly comprised of closed and answer-based items.

For this purpose an alternative test on number sense was developed for grades 3 through 5 using a RME assessment paradigm (van den Heuvel-Panhuizen, 1996).

Assessing mathematizing
Assessment grounded in the RME theory of mathematics education requires that the assessment tool must provide information about the process of mathematization, since that is considered as the overall core goal of mathematics education. The ability of mathematizing involves that students can solve problems by means of mathematical knowledge and concepts that can lead to models and strategies that are adequate for the problem to be solved. This goal is different from the goal of most traditional assessments, where strategies are assessed but only as process, or as a bi-product, or as an additional proof that the student had a clear understanding of what he or she was doing. In contrast, when mathematizing becomes the goal of instruction, the strategies are seen as an outcome, as the goal itself.

Within the process of mathematization several levels can be distinguished, each reflecting a certain level of the students’ understanding. Regarding the content domain of number sense related to operations with numbers up to one thousand the mathematization includes concrete or mental activities ranging from carrying out a standard algorithm to making use of number relations and properties of operations in order to find shortcuts and clever and elegant procedures by means of which the answers can come across. Crucial for evaluating the mathematizing activity is to what degree the strategies show a level of maturity that includes both flexibility and effectiveness. Simply carrying out a standard procedure without taking into account the numbers involved is not judged as a high level of mathematizing.

For paper-and-pencil assessment to capture genuine mathematizing it is necessary that the students’ own mathematical activity becomes visual on paper. Therefore all problems were put in a work area that the students could use as scratch paper. Another requirement for assessing mathematization is that the tasks allow several levels of mathematizing. The most important requirement, however, is that there is something to mathematize.
The following two problems may illustrate the kind of problems that were used in this test. The long addition problem that was in the test for grade 3 (see Figure 1) looks like an ordinary bare number problem and can trigger an algorithmic procedure. A student with number sense, however, will recognize how nicely the numbers fit together, and will adapt her or his strategy to this knowledge.

\[38 + 39 + 40 + 41 + 42 =\]

Figure 1 Problem included in the MiTC test for grade 3

In the problem on the chain of beads (see Figure 2) the students have to figure out the color of the 1000th bead. In addition to this the students have to explain why they are sure about their answer. In this problem, that is from the test for grade 5, the students can apply their knowledge of multiples of three. But other, less advanced ways of working are also possible. Again, this inherent multi-level quality of the problem makes it very suitable for providing information about the students' achievements.

Figure 2 (Part of the) Problem included in the MiTC test for grade 5

Data collection

The MiTC test was administered in 17 classrooms in spring. The classrooms ranged from grade 3 through grade 5. Eight of the classrooms had a teacher from the control group and nine had a teacher from the experimental group. In total four schools were involved, situated in three school districts. The control classrooms were selected to match the experimental ones. In order to avoid large differences between the background of the students and the general school environment, the control teachers and the experimental teachers, in some cases, came from the same school or from the same school district. In both groups two teachers had a mixed-grade classroom. This means that in total 21 grade groups with a total of 17 teachers were involved in the data collection (see Table 1).

Together with the development of the test a double coding system was developed: one for the answers and one for the strategies. For the answers, the literal answer given by the student could be coded. The strategy coding was done by means of a two-digit code. The first digit referred to a general description of the strategy and the second digit specified a particular way of working within this category. It is important to explain that the categories and in particular the subcategories are not holistic but task-specific rubrics.

The coding of the students' response was done blindly. The coder did not know whether the students belonged to the control group or to the experimental group.

Results

A t-test analysis showed that the average percentage of correct answers in the addition problem (grade 3) did not differ significantly between the two groups (see Table 2). For the beads problem (grade 5) this is slightly different (see Table 3), but on the whole the control students and the experimental students did not diverge with respect to the total number of correct answers (see Table 4). The latter means that if this test would only have focused on the answers, the two groups might have been considered as equal in achievement.

</table>

However, the situation with the applied strategies is quite different. Here, a Chi-square analysis showed highly significant differences between the two groups (see also Table 4).

In the addition problem (grade 3) the majority of the control group students used column arithmetic. An example of such a ciphering strategy is shown in Figure 3.
The students from the experimental group, in contrast, brought their number and operation knowledge into play and applied a smart calculation strategy that is called “tinkering” (see Figure 4) or they used either a stringing strategy (e.g. 38 + 30; + 9; + 40; + 40; + 1; + 40; + 2) or a splitting strategy (e.g. 30 + 30 + 40 + 40 and 8 + 9 + 1 + 2). The stringing and splitting strategies are summarized by the term “decomposing”.

For the beads problem (grade 5) three quarter of the experimental students used a reasoning strategy based on knowledge of number relations. For instance, one student said:

“I counted 10 and I know 10 go into 1000, so the last color for 10 which is white is the same color for 1000”.

Compared to the experimental group, the control group contained more students who, for instance, could not explain their strategy or students who did a long division (see Figure 5) together with the following explanation:

“There are 2 white beads between each black bead that’s why I did 2 ÷ 1000. Then I did 1 ÷ 1000 which gave me my answer”.

As is shown in Table 4 the difference in strategies was consistent in the study. Sensible tinkering strategies were applied more often by the experimental students (E+) and the ciphering strategies – in problems in which these strategies are not the most adequate solution strategies – were more often found in the work of control students (C+).

Concluding remarks

The data need further analysis (e.g. correlation between correct answer and strategy; influence of particular teachers) to conclude what the students gained from the MiTC project. The results so far give strong support to the idea that the mathematics achievements of the students in the experimental group are higher than those of the non-project students. Regarding assessment this study made clear that the measurement of mathematics achievements cannot be restricted to the answers only. This thinking fits with other developments in this area, like the work done by Suzuki (2000) who is developing a new assessment methodology in which the process of thinking in problem solving can be scored. Suzuki used the QUASAR general scoring rubric as a bedrock to develop a scale that can identify characteristics of achievement levels. In contrast with Suzuki's scale, in the MiTC study the categories were more mathematical and task-specific. The future will show what approach will be most helpful for understanding mathematics achievement.

A CASE STUDY OF FOUR GRADE 7 GEOMETRY CLASSES

Suriza van der Sandt
Graduate School of Education, Potchefstroom University, Potchefstroom, South Africa, 2520
E-mail address: primeteams@mweb.co.za

Traditionally, geometry at school starts on a formal level, largely ignoring prerequisite skills needed for formal spatial reasoning. This tradition may lead to ineffective teaching and learning. The Van Hiele theory postulates learner progression through levels of geometry thinking, from a Gestalt-like visual level through increasing sophisticated levels of description, analysis, abstraction, and proof. Progression does not depend on biological maturation or development only, but also on appropriate teaching/learning experiences. A Van Hiele-based geometry learning and teaching program was designed and implemented in four Grade 7 classes (133 learners) at two South African schools. The study investigated some factors and conditions influencing the effective learning and teaching of spatial concepts, processes and skills in different contexts. Results suggest that the implementation of a Van Hiele-based learning and teaching program had a positive effect on the learners' levels of geometric thought. Learners who completed the program reasoned on a higher level, gave more complete answers, demonstrated less confusion, and generally exhibited higher order thinking skills than their counterparts who did not take part in the program. For efficacy of this program, a prerequisite is that the teacher should consistently teach from a learner-centered approach.

INTRODUCTION

South Africa has a history of inadequate geometry instruction in primary schools (Van Niekerk, 1997:270). Taylor and Vinjevold (1999:143) state that lessons are generally characterized by a lack of structure, and the absence of activities which promote higher order skills such as investigation and understanding relationships. At present in most schools geometry teaching and learning in the school curriculum starts on a formal level, ignoring prerequisite skills needed for formal reasoning. The effect of ignoring the sequential and hierarchical nature of the learning of geometry causes ineffective teaching and learning because learners are expected to perform without the necessary prior knowledge and/or prerequisite skills (Clements & Battista, 1992:421). It is necessary that the foundation of formal geometry learning (that starts in grade 7) be laid according to a widely respected and acceptable theory, for example the Van Hiele theory.

THE VAN HIELE THEORY

The Van Hiele theory postulates that learners progress through progressive levels of geometrical thought from a Gestalt-like visual level through increasing sophisticated levels of description, analysis, abstraction, and proof (Van Hiele, 1986:39). At the first level (Recognition) learners identify and operate on shapes and other geometric configurations according to their appearance alone (Mason, 1997:39). On the second level (Descriptive / Analytic) learners are able to recognize and explicitly characterize shapes by their properties (Van Hiele, 1986:40), but can not recognize relationships between classes of figures (Battista, 1994:89) or even redundancies (repetitions) (Spear, 1993:393). Learners at level three (Abstract / Relational) can form abstract meaningful definitions (Mason, 1997:39), distinguish between necessary and sufficient sets of conditions for a concept, classify figures hierarchically (by ordering their properties), give informal arguments to justify their classification (Battista, 1994:89), and understand and sometimes even provide logical arguments in
the geometric domain (Clements & Battista, 1992:427). At level four (Formal Deduction) learners are able to establish theorems within an axiomatic system. They recognize the differences among undefined terms, definitions, axioms, and theorems and are capable of constructing original proofs (Clements & Battista, 1992:428). At the fifth level (Rigor / Metamathematical) learners reason formally about mathematical systems, understand the formal aspects of deduction (Presmeg, 1991:9), establish and compare mathematical systems (Mason, 1997:40), and reason by formally manipulating geometric statements such as axioms, definitions, and theorems.

Gutiérrez, Jaime and Fortuny (1991:237-238) theorized that the Van Hiele levels are not discrete and presented an alternative method to evaluate and identify those learners who are in transition between levels. Gutiérrez et al. (1991:238-241) quantify the acquisition of a level by representing it with a segment from 0 to 100 thus creating a scale of degrees of acquisition. A division is also made to divide this continuous process into five stages (no-, low, intermediate, high and complete) acquisition characterized by the qualitatively different ways in which the learners reason.

Progression from one level to the next does not depend only on biological maturation or development (Piaget,1970), but also on appropriate teaching/learning experiences (Koehler & Grouws, 1992:123). The effect of appropriate teaching/learning experiences (in accordance with the Van Hiele theory) on South African grade 7 learners in varied context will be investigated. Attention will be given to the (possible) change in geometric thought levels as well as specific details emanating from the implementation of the program. The impact of second language instruction and it's inevitable influence was noted but will not be discussed in this paper but in a later paper.

METHOD

SUBJECTS
The study population consisted of Grade 7 learners (n=221) from a large town in the North West Province of South Africa. A non-randomized experimental-control group design was used with 133 learners in the experimental group and 88 learners in the control group. The experimental group was further divided into two naturally occurring classes, C1 and C3, and similarly the control group consisted of C2 and C4 (naturally occurring classes). Class 1 (C1) and Class 2 (C2) were both instructed in their second language, while class 3 (C3) and class 4 (C4) received instruction in their first language.

PROCEDURE
Before the beginning of the program the two teachers in classes C1 and C3 were trained for one month in the Van Hiele theory as well as the activities developed by the researchers. The activities were implemented after completion of the training and the progression through these activities was continuously videotaped. Despite the initial training and re-training C1's teacher continued with a teacher-centered approach, as she believed that a program such as this would take up too much time, which could result in her not completing the syllabus. The learners in C1 and C3 were randomly arranged into sub-groups. A sub-group was randomly selected to be the group on which the videotaping would focus. The other groups in each class were still included in the videotaping for comparison when analyzing the progress. The learners remained in the same groups for the duration of the study. The mathematics teacher taught the classes while they were being taped for analyses and transcription afterwards. The same sub-groups (school C1: 12; school C3: 13) that were focussed on in the video taping were also used to complete the Van Hiele post-test.

At the same time that the C1 and C3 groups were progressing through the designed program (as developed by the researcher), the C2 and C4 groups continued with their spiral syllabus system where the teacher and the textbook formed the main sources of information with little or no learner...
involvement in the classroom activities. From the C2 and C4 group, a randomized sample was taken to complete the Van Hiele post-test (from C2: 11 and C4: 13 learners were selected).

**INSTRUMENTATION**

Post-testing took place after conclusion of (both) programs. The post-test was compiled using selected items of The Mayberry Test (Lewin and Pegg Version) and items from a test developed by the unit for Research in Mathematics Education of the University of Stellenbosch (RUMEUS -1984). The final product (post-test) included 21 items (with some sub-items), on the concept of parallel lines and shapes such as the square, right angle and isosceles triangle. The answers to the items were quantified according to the acquisition scales of Gutiérrez et al. (1991:237-241). No pre-testing could be done as the C2 and C4 groups started Geometry teaching already at the beginning of the year (January) while the (experiment and the) C1 and C3 groups started only in May. No interviews were conducted with the learners thus the analysis can not attain the fine grain of qualitative depth that interviews would have provided.

**RESULTS AND DISCUSSION**

*Degrees of acquisition*

Investigation through the post-test into the differences of degrees of acquisition in geometric thought provided encouraging results (see figure 1).

![Degrees of Acquisition](image)

**FIGURE 1: DEGREES OF ACQUISITION**

The experimental groups consistently achieved higher degrees of acquisition than the control groups, leading to the conclusion that the program did have a positive effect on the acquisition of high(er) degrees of geometric thought.

Class 3 achieved the highest degrees of acquisition in all 3 levels considered. Between C1 and C3 clear differences exist. Possible reasons can include the complex influence of the difference of mother tongue and medium of instruction. A second and maybe more important reason for the difference is the teaching approach followed, with C1's teacher following a content-based teacher-centered approach and C3's teacher following a problem orientated learner-centered teaching approach. C1's teacher persisted in the teacher-centered approach in spite of the training (and re-training) by for example denying learners the opportunity to sort (for example triangles) for themselves and so discover properties. This teacher sorted the triangles herself on the board (with little to no learner participation) and later even provided the properties in the way she wanted them "back" in the test/exam.
**Right angles and triangles**

In testing the general acquisition of concepts of triangles, learners were asked to decide if certain figures were triangles and to explain their answers (see table 1). While doing analysis of relevant data concerning triangles, confusion was noticed between right angles and a right-angled triangle in some groups (see table 1). It is not clear whether the incorrect answers concerning a right angle and/or a right-angled triangle were given because of confusion between the concepts (due to second language instruction) or just because of carelessness on the part of the learners. To shed light on this uncertainty more in depth investigation would be necessary.

These answers were classified as being correct, but unconvincing or incorrect motivation was given.

**Class 1**

Learners in C1 who decided that the shapes were not triangles rejected them because the sides were not equal (as for an equilateral triangle). Learners pertinently stated "no, because triangle all side are equal" and "no, triangles it has two equal size at the sides and the bottom one is shorter than two equal size in the sides\(^2\). Most of the learners who decided that the figures were triangles gave more than one answer that usually consisted of a reference to the angles and sides. In total four learners correctly drew a right-angled triangle. The eight learners who drew the right angled-triangle incorrectly all drew it as a right angle without a third side (\( \square \)). Seven learners in total could correctly identify the right-angle but only three could also correctly draw a right-angled triangle.

**Class 2**

Learners who decided that the figures were not triangles all motivated their answers by referring to the shapes' visual gestalt as the following answers\(^3\) demonstrate: "no it is not triangle because is not the same" and "no Because they don't look like the triangles". Responses such as these demonstrate classical level 1 responses. Only one learner tried to give a more specific answer, but even this learner's thoughts seem scattered: "Yes Because they are all the same but the shape is very different but is all the same way but the shape are not the same\(^3\). Of the four learners who incorrectly drew a right angled-triangle, one learner tried to draw the triangle but only managed to draw an acute-angled triangle (\( \triangle \)). Two learners' confusion surrounding these concepts was clear when looking at their drawings:

\[
\begin{align*}
\text{[}[\text{[} & \frown \rightarrow \bigtriangleup \text{] [} & \Rightarrow \bigtriangleup \text{]} \\
\text{[}[ & \text{[} & \Rightarrow \bigtriangleup \text{]} & \Rightarrow \bigtriangleup \text{]} \\
\end{align*}
\]

\(^2\) These answers are reported in verbatim from the (written) Van Hiele post-test.

\(^3\) These answers are reported in verbatim from the (written) Van Hiele post-test.
It is noticeable that the learners who incorrectly identified right angles even drew more “strange” figures ( ) that resembled a rectangle or a trapezium, instead of a right-angled triangle. It is disappointing to notice that C1 faired very poorly in correctly drawing a right-angled triangle. Their statistics are as low as C2's and even worse in correctly identifying a right angle and drawing a right-angled triangle. A possible reason for C2's and C1's poor performance could be the influence of second language instruction – an issue for further investigation.

Class 3
Most learners gave a combination of answers that included references to the number of sides and angles needed to be classified as a triangle, for example: “Yes, it has three sides, three angles” and “Yes, Because they all have three sides and they are have three angles they just have different names and sizes.” Three learners gave some additional information even when not required to for example: “Yes, There are 3 corners, They don’t have to be equal as long Their are 3 sides and 2 acute angles.” An overwhelming number (82%) of learners correctly identified a right angle and correctly drew a right-angled triangle. Most of these learners' drawings also appeared to be “classical text-book” right-angled triangles ( ) while one learner drew the triangle in an “unusual” position ( ).

Some of the learners also exhibited more detailed drawings by placing a right angle sign in the relevant angle ( ).

Class 4
Learners judged shapes by appearance as this learner's answer demonstrates: “... all 4 looks like triangles...” - typical level 1 reasoning as defined by various authors (Mason, 1997:39; Flores, 1993:152; Spear, 1993:393; Presmeg, 1991:9). Motivation for defining a triangle was varied, ranging from answers referring to angle shapes (“it has 3 sharp points”) to answers referring to sides (“their sides al have angles....they are sharp”). A learner that indicated that the shapes are not triangles motivated his answer by writing: “the sides are not the same length”. It seems to be a common phenomenon that learners perceive a triangle to have equal sides, as some learners in all the groups rejected isosceles and scalene triangles on the grounds that their sides were not all equal.

All four learners who drew the right-angled triangle incorrectly, drew it as an acute angled triangle ( ). It stands to reason that these learners may have focussed on the “triangle” part of the question without giving attention to the specification (right-angled). Confusion surrounding right angles in this group seems to be deeper than first discovered as the following drawing shows when learners were asked to draw a rectangle:

In summary it can be concluded that C3’s answers proved to be more correct and complete with a total of 19 reasons (from 11 learners) explaining why the figures were triangles (see table 1), compared with C4’s 9 reasons (from 13 learners), C1’s 10 answers (from 12 learners) and C2’s 3 answers (from 11 learners). A synopsis of the data reveals that C3 emerged as to be the top achiever once again with 81.8% of the learners being able to correctly identify a right angle and drawing a right-angled triangle (see table 1).

Spatial Orientation
Some questions in the Van Hiele post-test require learners to identify specific concepts in a variety of orientations. These concepts (such as a right-angled triangle and isosceles triangle) appear with other concepts in the “classical or conventional textbook form” ( ) as well as in an “unconventional or turned form” ( ). When analyzing the answers to these two questions (see table 2) it was believed

---

3 These answers are reported in verbatim as transcribed from the videos recorded during the class activities.
and confirmed that recognizing one kind of triangle (right-angled triangle) in a "rotated form" does not guarantee recognition of a different kind of triangle (isosceles triangle) in a "rotated form" (as illustrated in the data shown in table 2).

| TABLE 2 IDENTIFICATION OF A VARIETY OF SHAPES IN DIFFERENT SPATIAL ORIENTATIONS |
|-----------------------------------------------|---|---|---|---|
| Identify right-angled V only in "traditional form" | C1 | C2 | C3 | C4 |
| (12) | (11) | (11) | (13) |
| Identify right-angled V only in "rotated form" | 7 | 1a | 5a | 0 | 3 |
| Do not identify right-angled V in "traditional form" | 1 | 3 | 1 | 3 |
| Identify right-angled V only in "rotated form" | 0 | 0 | 2a | 1 | 1 | 1b |
| Identify right-angled V in both forms | 3 | 0 | 9 | 1 | 3a |
| Identify isosceles V only in "traditional form" | 1 | 2b | 0 | 4a | 0 | 1a | 0 | 1b |
| Do not identify isosceles V in "traditional form" | 2 | 1 | 2 | 5 |
| Identify isosceles V only in "rotated form" | 0 | 0 | 0 | 0 |
| Identify isosceles V in both forms | 7 | 3 | 2a | 1b | 6 | 1a | 1b | 3 | 3a | 1b |

* Learners identified figure in specified manner but also identified incorrect shapes with the correct answer.
* Learners correctly identified figure in specified manner, but the answer is incomplete.

Of the four categories for each figure, the last category that entailed identification of figures in both the "traditional" and "rotated" form, is considered the highest category of identification. C3 consistently achieved the highest number of correct answers (when comparing the number of learners in this category with the number of learners in this category with the number of learners in the group) in both of these categories. In the light of the results of C3's learners' recognition of the two kind of triangles (81.8% and 72.7% respectively) a conjecture was formed that if a learner could recognize one kind of triangle (right-angled) in both forms, he/she could most probably recognize any other kind of triangle (e.g. isosceles in both forms). This conjecture was not supported in the data from C4. Only 30.8% of the learners could recognize a right-angled triangle in the "traditional" and "turned" form, but this percentage reached 53.8% in recognizing an isosceles triangle in both forms. It is noticeable that C1, C2 and C4 found recognizing the right-angled triangle problematic, as it is here that they scored the lowest marks of all the figures. It becomes evident that C1 fared as well or as poorly as the classes who did not partake in the study in many aspects, leading to the conclusion that the program is not efficient in raising understanding if it is not implemented using a learner-centered teaching approach.

IMPLICATIONS AND CONCLUSIONS

It can be theorized that reaching higher order thinking in geometry relies not merely on a suitable choice of activities, but also on the active participation of both teacher and learners. The program in a teacher-centered environment (as in class 1) can produce results that are higher than the comparable class, but it is probable that the results could have been more dramatic if the program had been taught in a learner-centered problem solving environment (as in class 3). The fact that class 1 received instruction in their second language could, also have had a great impact on their results. The results that were achieved in class 1 (second language education) are comparable with class 4 (mother tongue education) which may indicate that class 1 has shown some progress, and to such an extent that their results are equal or higher than the learners who received first language instruction such as class 4 (and whose school is considered to be an advantaged school).

Results furthermore suggest that the implementation of a Van Hiele based learning and teaching program had a positive effect on the degree of geometric thought. Learners who completed the program reasoned on a higher level, gave more complete answers (see table 1), demonstrated less confusion (see table 2), and generally exhibited higher order thinking skills than their counterparts who did not take part in the program. The possible influence of receiving instruction in a second language (class 1) on learning was not investigated, but could have had extensive influence on these learners performances. A prerequisite for achieving success is that the teacher should consistently teach from
a learner-centered approach as the program will deliver little or no advantages if the program is presented in a teacher-centered content-based context.

Teachers should take note of the profound part they play in the learning that takes place in their classrooms. The learning profit of their students could (partly) be determined by the teacher's interaction with the learning material and it is therefore necessary for teachers to make sure that their teaching approach and style complement rather than hinder the function of learning material.

ACKNOWLEDGEMENTS
Grateful acknowledgement to Prof. Norma Presmeg for all her constant and expert guidance, immeasurable patience and unconditioned support during the writing of this paper. Sincere gratitude to Dr. Hercules Nieuwoudt and Prof. J. L. de K. Monteith (my supervisors) for their ceaseless interest and advice in the original research from which this paper emanated.
The financial assistance of the National Research Foundation, SOSI-project and the focus area of the Graduate School (Potchefstroom University) towards this research is hereby acknowledged. Opinions expressed in this paper and conclusions arrived at, are those of the author and are not necessarily to be attributed to the National Research Foundation.

SCIENCE TEACHERS' LEARNING ABOUT RATIO TABLES

Ton van der Valk
Harrie Broekman

Centre for Science and Mathematics Education / IVLOS Institute of Education
Utrecht University, Utrecht, The Netherlands

e-mail: a.e.vandervalk@phys.uu.nl, h.g.b.broekman@phys.uu.nl

Abstract

In Dutch lower secondary mathematics curricula, the ratio table is used as a tool for developing ratio and proportion calculation skills. Some recent physics and chemistry textbooks use ratio tables when dealing with proportional quantities. This makes the ratio table a suitable issue for cooperation between mathematics and science departments in schools. This article reports a developmental research study to starting science teachers attending the ratio table part of the IVLOS teacher education course. Factors that promote or impede teachers using ratio tables in their classrooms were identified. Main promoting factors appeared to be teaching lower secondary science and consulting mathematics teachers and textbooks. A main impeding factor was senior chemistry textbooks linking the ratio table to cross multiplication, affirming teachers' idea of the ratio table as a trick instead of a tool for promoting understanding.

Context of the study

Ratio and proportion is a core topic in primary as well as in secondary mathematics education. To many pupils it causes various conceptual problems (Streefland 1984, 1985; Tourniaire and Pulos 1985). In Dutch primary and secondary mathematics ratio tables are used as tools for structuring and doing calculations.

In science, many quantities have a proportional character, e.g. speed, density, concentration, concepts that usually are explained taking the mathematics of ratio and proportion for granted. In fact, students face many problems when using proportional reasoning in the sciences, even in the upper secondary (Akatugba and Wallace 1999). Many science teachers complain that students “cannot calculate any more”. These problems can only be solved when science teachers and textbooks account for the ratio and proportion tools pupils have learned in mathematics. Recently, some physics and chemistry textbooks are published that do use ratio tables.

Nowadays, a curriculum reform being introduced in Dutch secondary education urges science and mathematics department to co-operate. The reform aims at presenting students a more coherent curriculum and opportunities for autonomous learning. In some schools, participating in the BPS-project of Utrecht University, departments are...
supported in finding ways to co-operate (Van der Valk et al. 1998). As it was noted in the BPS-school that some science teachers in the schools were apt to bring ratio tables in their classes but others objected, it was suggested to focus on ratio tables as a topic for co-operation. That resulted in an inventory of knowledge about the ratio table teacher have to master (Broekman et al. 2000) and identification of issues related to applying it into the sciences (Van der Valk et al. 2000). These results were used to introduce the ratio table in initial science teacher education.

The ratio table in mathematics education

A ratio table is a tool for structuring and calculating ratio and proportion problems. It can be described by the following characteristics:
1. the table consists of two rows and a variable number of columns
2. the rows have a label, indicating the meaning of the numbers and specifying, if needed, the units used
3. the upper or lower row can be changed: there is no preference
4. the ratio between the numbers in the columns is the same for all columns; this can be used to calculate an empty place in a column
5. so to get the numbers of a column, the numbers of another column can be multiplied or divided by a certain number; proportionately adding or subtracting are possible as well.

</table>

\[ \times 7 : 2 \]

Fig. 1: Example of a ratio table from a Dutch 7th grade textbook.

These characteristics indicate that the ratio table attaches to intuitions young children already have (Lo and Watanaba 1997, Singer et al. 1997).

Ratio tables provide students with a structure they can use to find an answer to ratio and proportion problems in several ways. They:
- are allowed freedom which one of the steps that are admitted to choose for filling in numbers into a next column;
- are allowed to use as many steps as (s)he needs or finds useful
- however, have to be careful that the ratio between the numbers in the upper and lower row stays the same.

This is an example of what Dolk (1997) called ‘construction space’. It can be seen as a sixth characteristic of the ratio table in mathematics education. Growing insight

4 - 352

1776
results in increasing efficiency. An efficient strategy is normalising to one. Thus, every proportion problem can be solved in two steps. For the actual calculating, the pocket calculator can be used. This way of working provides an alternative for ‘mechanistic’ algorithms like cross multiplication. Middleton and Van den Heuvel-Panhuizen (1995) described how the ratio table can be used in US middle school (grade 5-8).

**The ratio table in Dutch science textbooks**

In recently published secondary science textbooks (junior and senior level), several versions of ratio tables can be found. They are used to introduce physics and chemistry quantities having a proportional characteristic.

| First way of working: [use of formula, not transcribed here] |
| Second way of working: use the ratio table. |

\[
\begin{array}{c|c}
1,000 \text{ mol FeCl}_3 & 162.2 \text{ g} \\
\hline
n (\text{FeCl}_3) & 16.4 \cdot 10^3 \text{ g} \\
\end{array}
\]

\[n = \frac{162.2 \text{ g}}{16.4 \cdot 10^3 \text{ g}} \cdot 1,000 \text{ mol} = 101 \text{ mol} \]

\[
\frac{162.2 \text{ g}}{16.4 \cdot 10^3 \text{ g}}
\]

**Figure 2. Text taken from: Antwerpen et al (2000) Curie 1, p. 129**

To show that some ratio tables in science textbook are quite different from the one used in mathematics, one textbook, *Curie*, chemistry for grade 10, is analysed. In *Curie*:

- rows and columns are changed, compared to a mathematics-like table
- there are no more than 4 cells
- labels are missing; the cells contain information, like units and ‘FeCl₃’ that should be included in the labels
- no choice of strategy within the ratio table is allowed as only cross multiplication is suggested (however, some choice of algorithm: formula or ratio table).

**The ratio table as a topic in IVLOS teacher education**

IVLOS teacher education is post-graduate and takes a full year (Wubbels 1992). The participants are pre-service as well as in-service teachers. They do their teaching practice in secondary schools and come to the university for the institute-based part of their teacher education. Main characteristics are its focus on reflection (Korthagen...
1993), the integration of theory and practice and its attention to teacher learning (Korthagen and Kessels 1999). A course ‘didactics of science and mathematics’ is incorporated, focusing on areas of common interest to science and mathematics teachers, the ratio table being one of them.

In the 1999 ‘didactics of mathematics and science’ course, the ratio table class was taught for the first time. It was noted that part of the started science teachers embraced the ratio table as an important solution for the problems they met in their classes, but others refused it. A phenomenon that was also observed in BPS-project schools. Therefore, it was decided to investigate during the 2000 course what factors impede or promote starting science teachers’ willingness to use ratio tables in their teaching.

**Research design and data collection**

The research design was based on ‘developmental research method’ (Lijnse 1995; Gravemeijer 1994). This method is useful to get insight into problems of teaching and learning and to develop ideas how to solve them. Emphasis is mainly on the use of interpretative qualitative methods, which includes classroom observation, content analysis, interviews and analysis of student notes.

We regarded the following as candidate factors:

- teachers’ own secondary school experiences with ratio and proportion
- experiencing the ‘construction space’ possibilities of the ratio table
- discussions with mathematics and science colleagues in the school
- (not) successful experiences with ratio tables or other tools in the classroom.

With these factors in mind, the ratio table part of the ‘didactics’ course was structured consisting of a 2½-hour class, a pre-class and a post-class assignment that aimed at promoting reflection and integration of theory and practice. The pre-class assignment had three tasks:

- study the way ratio and proportion are dealt with in your student textbooks
- look at the ways your students deal with ratio and proportion
- have a discussion with school colleagues about the ratio table.

At the start of the class, the participants reported about the assignment. They discussed the question ‘what is ratio and proportion?’ Then a short introduction was given into the way the ratio table is introduced in grade 7 mathematics, along with activities and discussions aiming at teachers experiencing ‘construction space’ in ratio tables in mathematics as well as in the sciences.

The post-class assignment asked the teachers to read a paper on the ratio table and to write a report about one of three tasks:
The study focused on nine science teachers (2 female, 7 male) that handed in their pre- as well as post-class reports, 3 physicists and 6 chemists. All of the physicists and 3 chemists taught combined science (physics/chemistry) to junior students. Their reports were analysed by two researchers in discussion with each other. Comparing pre- and post-class arguments resulted in identifying factors that promoted or impeded the use of ratio tables in the classroom.

The implicit premise of the post-class assignment was that ratio tables can help students. One teacher did not agree: he refused to use the ratio table in the classroom because¹ it will not be a success as I don’t believe in it, and excused himself to the teacher educator, writing: it seems too much a trick that the students have to follow (I hope I don’t offend you, it is just my opinion). No indications were found that this premise was a problem to others doing the assignments.

Results

Only one teacher referred to her experiences as a student.

In their pre-class reports, four teachers already were positive about the ratio table. Three of them had some experience with using ratio tables in junior secondary science, the fourth had studied ratio tables in a mathematics textbook. Their arguments referred to:

- developmental psychology² (3): [in the ratio table] the relation of the three quantities (m, V and density) is illustrated; this could make somebody with few feeling for formulae, with few sense of abstraction, more sensible to it
- structuring (2): To me, it is important that proportional calculations are taught in a structured way
- students like it (2).

In their post-class reports, all four gave new arguments in favour of using the ratio table in science teaching.

The other 5 teachers, all chemists, related the ratio table with the cross product algorithm: it is a kind of crosswise multiplication, but because there is no × sign it suddenly is proportional calculating, three of them referring to senior level chemistry textbooks. In their pre-class reports they argued that students can use the ratio table/cross product as a calculation trick, e.g.:

¹ Statements from teachers' reports translated from Dutch, are reproduced in italics.
² The number indicates to how many teachers it applies.

PME25 2001

BEST COPY AVAILABLE 1779
some students just try the trick and hope the answer will be 'a bit normal'

students will fill in figures on the wrong place in the ratio.

However, four of them knew that it can be a support to students as well:

I have heard from a colleague that the number of mistakes made using ratio tables is much less than before. Calculating with formulae apparently is more difficult than filling in a ratio table

Students remarked that using the cross product felt like a trick. They did not understand better how the calculations worked, but made less mistakes.

Two of these five teachers left the 'trick' argument in their post-class report. The other three, however, left the help-argument. They did not use the ratio table in their teaching, but invited studied senior chemistry students to use it. Studying the results, they were reinforced in their 'trick' argument as all students applied cross multiplication. In their analysis they only used some of the features of ratio tables that were taught in the 'didactics' class. They:

- did not refer to tables having more than two columns (3)
- showed no (2) or few (1) knowledge of strategies alternative to cross multiplication (e.g. of 'reduction-to-one', multiplication factors)
- did not consult mathematics colleagues and books (3)
- reported about disagreement on the use of ratio tables in the science departments (2). One of them met a difficulty: my mentor teacher did not like the students to use ratio tables.

The six teachers that got more positive about the use of ratio tables in science:

- consulted maths and science colleagues (5) science textbooks (5) and studied a mathematics textbook (2)
- applied it in the classroom teaching in junior level combined science (4)
- using labels (3): "now I pay attention to writing the quantities and units in it"
- using multiplication factors (3)
- applying the reduction-to-one method and so tables with more than two columns (3)
- analysed their students' ratio tables (6)
- experienced success (3): the students now looked less glassy, asked less questions and showed understanding.
Conclusions

All starting science teachers initially had the feeling that the ratio table can help students in calculating proportional science problems. However, some teachers feared that it would only support students in doing calculations and would not help them in understanding the proportional character of the science concepts. With three teachers, this fear was not taken away by the ratio table class nor by the assignments because their idea of the ratio table being a 'calculation trick' because of its link to cross multiplication was affirmed:

- by studying upper secondary chemistry textbooks
- by analysing upper secondary students' use of the ratio table.

Indications were found that they were affirmed by colleague teachers in the schools as well, as they met departments that did not agree on using the ratio table in teaching science.

However, with six teachers the idea that the ratio table can support the understanding of proportional science concepts was affirmed by:

- consulting mathematics colleagues and textbooks
- having the opportunity to use ratio tables in lower secondary science classes.

An important factor appeared to be to have some experiences with ratio tables in lower secondary classes before teacher education on ratio tables. Teachers who had, were able to improve their lessons using 'construction space' alternatives to cross multiplication strategy of the ratio table, like indicating multiplication factors with the table, normalising to one. The ones that did not teach the ratio table in the classroom, did hardly apply the construction space aspects of the ratio table doing the post-class assignment, however involved they had been in applying ratio tables during the ratio table class.

To teacher education it is recommended to stimulate science teachers to discuss ratio tables with their mathematics colleagues and to let them reconstruct ratio tables from science textbooks that link to cross multiplication, applying the 'construction space' aspects of the ratio table.

Literature

Abstract

This study investigated the arithmetic and algebra word-problem-solving skills and strategies of pre-service primary and secondary school teachers both at the beginning and at the end of their teacher training, and the way in which these groups of pre-service teachers evaluated different kinds of algebraic and arithmetical solutions of pupils. The results showed that future secondary school mathematics teachers clearly preferred algebra, even for solving very easy problems for which arithmetic is more appropriate. About half of the future primary school teachers adaptively switched between arithmetic and algebra, while the other half experienced serious difficulties with algebra. Finally, it was found that the problem-solving behavior of the future teachers is strongly related to their evaluations of pupils' solutions.

1. Theoretical and empirical background

Acquiring an algebraic way of reasoning and problem solving is one of the major learning tasks for pupils in the transitional stage from primary to secondary school. However, a vast amount of research has shown that learning algebra creates serious difficulties for a lot of pupils (Kieran, 1992; Filloy & Sutherland, 1996). The focus of the current study is somewhat different; its attention goes to the mathematics teacher who has to stimulate and support the transition from arithmetical to algebra.

The starting point of our study was the work of Schmidt (1994; Schmidt & Bednarz, 1997). She states that the complexity of the algebra learning process makes appeal to both primary and secondary school teachers. Primary school teachers should develop in pupils a rich base of mathematical concepts and skills which are the psychological foundations and precursors for algebraic thinking. Secondary school teachers should have a very good understanding of the 'arithmetical histories' of pupils entering secondary education, and be able to show pupils the validity and necessity of the new algebraic way of thinking. At the same time, they should develop in the pupils a disposition to apply arithmetical and algebraic strategies flexibly, taking into account the characteristics of the problem to be solved. In sum, Schmidt claims that primary and secondary school teachers must understand, master and appreciate both arithmetical and algebraic problem-solving strategies themselves, and be able to use them whenever necessary.
These considerations led Schmidt to conduct a study with three different groups of
Canadian students at the start of their teacher training. By means of a paper-and-pencil
test with typical arithmetic and algebra word problems (see the Method section), and by
means of semi-structured interviews, she studied their spontaneous problem-solving
behavior, their arithmetical and algebraic skills as well as their related domain-specific
beliefs. The first group were students who just subscribed to a training to become a
remedial teacher (in primary or secondary school). She found that the majority of them
had to rely exclusively on arithmetical strategies because they had no good
understanding and/or mastery of the algebraic approach. This need to rely always on
arithmetic had a negative influence on their performance on the (complex) algebra
problems. The second group were students wanting to become primary school teachers.
Schmidt found that about half of these students were adaptive problem solvers, using
arithmetical strategies for easy arithmetic problems, with good success, and algebra for
more complex algebra problems, with moderate success. The other half of this second
group had a similar profile as future remedial teachers. The third group consisted of
beginning pre-service secondary school teachers. Here, the vast majority of participants
exclusively used algebraic strategies (with good success), even for those problems that
could easily be solved arithmetically. This preference was accompanied by a perception
of arithmetic as being a primitive, mathematically worthless approach.

The study presented in this paper replicates Schmidt's study in the Flemish teacher
training context, but at the same time elaborates it in two important aspects First we
expanded the research group with students arrived at the end of their teacher training.
Second, we wanted to shed light on the relationship between the student-teachers'
pedagogical content knowledge and beliefs, on the one hand, and the quality of their
future teaching, on the other hand. Therefore, we also collected data about the way in
which the pre-service teachers evaluated pupils' arithmetical and algebraic solution
strategies.

2. Method

Participants were 97 pre-service teachers of one typical training institute in Flanders.
These future teachers belonged to four different groups according to the specific training
they were subscribed to (primary versus secondary school) and the moment in their
training (the beginning of their first year versus the end of their third and last year of
teacher training). In the group of future primary school teachers, there were 26
participants in the first and 36 in the third year. In the group of future secondary school
teachers, these groups contained 19 and 16 participants, respectively.

Two research instruments were administered: a paper-and-pencil test containing 12 word
problems, and a questionnaire wherein the student-teachers had to score pupils' solution
strategies for six problems from the test.

The paper-and-pencil test contained – in randomized order – six word problems that
could easily be solved with a few arithmetic calculations and six more difficult word
problems for which an algebraic strategy was more efficient. The problems were generated by means of an analysis method designed by Bednarz and Janvier (1993, in Schmidt & Bednarz, 1997). This method schematizes data in such a way that problems can be characterized as "connected" (two known values can easily be used to calculate a third, and so forth, so that arithmetic solutions are easy), or "disconnected" (a calculation with two known values to generate a third cannot be made, so that an algebraic strategy, which represents all known and unknown data in one equation, becomes more appropriate). In the table below we give an example of an arithmetic and a (semantically equivalent but structurally different) algebra problem.

<table>
<thead>
<tr>
<th>Arithmetic problem</th>
<th>Algebra problem</th>
</tr>
</thead>
<tbody>
<tr>
<td>In our farm we have 140 animals: cows, pigs and horses. The number of cows is the double of the number of pigs, and there are 20 horses less than cows. We have 44 horses in the farm. How many pigs and cows do we have?</td>
<td>In a large company, there work 372 people. There are 4 times as many workmen as clerks, and 18 clerks more than managers. How many people of each group are there then in the company?</td>
</tr>
</tbody>
</table>

Student-teachers' solutions were analyzed according to the correctness of the answer, and according to the solution strategy used. For this last scoring we applied a classification schema that was influenced by the findings of several researchers (e.g. Filloy & Sutherland, 1996; Hall, Kibler, Wenger & Truxaw, 1989). The table below presents a global characterization of the strategies for solving algebra and arithmetic word problems distinguished in this classification. For more details and examples we refer to Van Dooren, Verschaffel and Onghena (in press).

### Strategies for algebraic word problems

<table>
<thead>
<tr>
<th>Algebra</th>
<th>Manipulating the structure</th>
<th>Guess-and-check</th>
</tr>
</thead>
<tbody>
<tr>
<td>An equation is written and transformed to calculate the unknown.</td>
<td>The problem is restructured in a clever way so that it becomes solvable arithmetically.</td>
<td>The value of one unknown is &quot;guessed&quot;, the correctness of the guess is checked. Repeats this until the correct value is found.</td>
</tr>
</tbody>
</table>

### Strategies for arithmetical word problems

<table>
<thead>
<tr>
<th>Algebra</th>
<th>Manipulating the structure</th>
<th>Generating numbers</th>
</tr>
</thead>
<tbody>
<tr>
<td>Same as for algebra problems.</td>
<td>Same as for algebra problems.</td>
<td>The missing values are directly calculated by performing the correct arithmetic operations on the known values.</td>
</tr>
</tbody>
</table>
Immediately after finishing the paper-and-pencil test, the student-teachers received a questionnaire with three arithmetic word problems and three algebra problems from this test. Each problem was accompanied by three handwritten correct solutions (one of each category from the table mentioned above). Student-teachers had to give a score on 10 points to express their appreciation of the quality of each of these three strategies. By presenting only strategies that led to correct answers, we could interpret differences in scores as evidence for differences in appreciation of the underlying solution strategy. We also asked the student-teachers to motivate their scores in a short written comment. As in the paper-and-pencil test, the order of the word problems (as well as the answers accompanying them) was randomized.

3. Research questions and hypotheses

**Question 1: How (well) do pre-service teachers solve arithmetic and algebra word problems?**

Our main hypothesis here was that the Flemish student-teachers would have a similar pattern of solution strategies as in Schmidt’s (1994) study. More particularly, we predicted that future secondary school teachers would use mainly algebra to solve the word problems (including the arithmetic problems), and that they would do it successfully (**Hypothesis 1a**). Furthermore, we expected to find two groups of future primary school teachers: an "adaptive" group using alternately arithmetic and algebra with moderate success, and another group with a strong preference for arithmetic strategies (and, therefore, a weak performance on the algebra problems) (**Hypothesis 1b**). With respect to the factor "years of teacher training", the following two effects were expected. First, we predicted that the initial differences in strategy use between future primary and secondary-school teachers would increase during teacher training. In the training of secondary school teachers, pivotal attention is given to algebra; therefore, we expected that they will use more algebra at the end of their teacher training. In contrast, in the primary school teachers' training program, large attention is paid to the arithmetical method "manipulating the structure"; therefore, the use of this strategy among pre-service primary school teachers should increase with years of training (**Hypothesis 2a**). Second, we predicted that the test performance of the student-teachers would improve, since the Flemish teacher training does not only aim at the development of the students' pedagogical content knowledge, but also of their mathematical knowledge and skills as such (Van de Plas, 1995) (**Hypothesis 2b**).

**Question 2: How do pre-service teachers evaluate pupils' solution strategies for arithmetic and algebra word problems?**

Our main hypothesis with respect to this second research question was that the way in which the student-teachers solved the word problems themselves would be reflected in
their evaluations of pupils' solutions (Hypothesis 3). This hypothesis was based on the
general claim – which is supported by a lot of research (e.g. Fennema & Loef, 1992;
Verschaffel, De Corte & Borghart, 1997) – that teachers content-specific knowledge and
skills shape to a large extent their teaching behavior. Therefore, we predicted strong and
positive correlations between the number of times a student-teacher used a certain
strategy and the average score he gave to a solution that works with that strategy.
Furthermore, we predicted that all (solution-strategy related) differences we
hypothesized with respect to the first research question would also be present in the
student-teachers' evaluations (i.e. differences between primary and secondary school
teachers, and between first and third year student-teachers).

4. Results for research question 1

To statistically test the hypothesis concerning the solution strategies used by the student-
teachers, we performed a 2x2x2 ANOVA on the number of algebraic strategies: type of
word problem x group (primary versus secondary school teacher) x study year (1st
versus 3rd year). This ANOVA first of all showed that the algebra problems elicited more
algebraic solutions (on average 3.65 for 6 problems) than the arithmetic problems (1.75
on average), Wilks' $\lambda(1, 93) = 0.47$, $p < .00015$. Moreover, there was a significant
difference in the use of algebra between the future primary and secondary school
teachers, $F(1, 93) = 11.33$, $p = .0011$. The table below gives an overview of their
solution strategies for the arithmetic and algebra word problems, together with the
percentage of unanswered problems.

<td>2.9%</td>
<td>1.4%</td>
<td>2.4%</td>
</tr>
</tbody>
</table>

As expected, the solution patterns of the future primary and secondary school teachers
were very different. Among future secondary school teachers, using algebra was the
most common method for solving both types of word problems (which is in accordance
with Hypothesis 1a). The large majority of the future primary school teachers solved the
arithmetic problems arithmetically, and, more particularly, by the most straightforward
strategy called generating numbers. For the algebra problems, many of them switched to
algebra, while several others tried to solve these problems using more cumbersome
methods like manipulating the structure or guess-and-check, and left problems
unanswered. Again, this is in line with our expectancies (Hypothesis 1b). In additional
analyses, it was found that there were two subgroups among the future primary
school teachers: about half of them exclusively used algebra, the others almost exclusively applied arithmetic. These additional analyses also revealed that this last group was responsible for the unanswered problems.

The ANOVA showed no significant differences between the solution strategies of first and third year student-teachers, \( F(1, 93) = 1.84, p = .2564 \), which means that Hypothesis 2a was rejected: contrary to our expectations, future primary school teachers did not use more arithmetic at the end of their training, and future secondary school teachers did not use more algebra.

To test the hypotheses about the student-teachers' performances on the word problems, another 2x2x2 ANOVA was performed with 'correctness of answer' as the dependent variable. This ANOVA firstly revealed a main effect of the type of problem, Wilks' \( \lambda(1, 93) = 0.58, p < .00015 \), indicating that the average score on the arithmetic problems (5.19 on a total of 6) was much higher than on the algebra problems (3.69). Second, the future secondary school teachers (with an average score of 9.89 on a maximum of 12) scored significantly higher on the word problems test than the future primary school teachers (8.31), but this effect was, as expected, only caused by a different performance for the algebra problems (with respective average scores of 3.19 and 4.57), \( F(1, 93) = 15.97, p < .00015 \).

The ANOVA revealed no significant main effect of grade, \( F(1, 93) = 3.62, p = .0601 \), but again there were differences on the algebra problems (a significant type of problem x study year effect was found, Wilks’ \( \lambda(1, 93) = 0.91, p = .00038 \): third year students (with a mean score of 4.04) performed considerably better than first year students (3.29), and this difference was observed for future primary as well as secondary school teachers. This finding confirms Hypothesis 2b. A further analysis of our data showed that the student-teachers became particularly more skillful in the strategy that is envisaged in the educational level of their future pupils: future secondary school teachers became considerably more skilled in using algebra from the first to the third year, while the future primary school teachers showed an increased mastery of manipulating the structure from first to third year.

5. Results for research question 2

According to Hypothesis 3, student-teachers' evaluations of pupils' solutions would reflect their own problem solving pattern. The correlations between the future teachers' use of a certain strategy and their appreciation of the strategy, already confirm this hypothesis. All correlation coefficients are positive and significant at the .05-level, varying from 0.30 to 0.46 Further evidence for this hypothesis was provided by a 2x2x2x3 ANOVA on the scores given by the student-teachers, with the same independent variables as for the previous ANOVA's, but with one extra variable: the type of solution (consisting of 3 categories). The table below gives the average scores of the two different groups of student-teachers for the three distinct kinds of solution
strategies for the arithmetic and the algebra problems. Since there were no differences between the strategies of first and third year student-teachers on the word problems test, there are no reasons to expect differences here either. Therefore, we will not differentiate in the evaluations of the first and third year student-teachers here.

</tbody>
</table>

The ANOVA showed that – as for the effect on the solution strategies on the word problems test – the overall score of the future secondary school teachers for the algebraic strategy was higher than the primary school teachers’ score, Wilks’ $\lambda(2, 93) = 125.16$, $p < .00015$. Here too, future secondary school teachers had a strong and overall preference for algebra, independent from the problem to be solved. Although the future primary school teachers adapted their appreciations more to the nature of the problem, their score for algebra remained lower than the future secondary school teachers’ score, $F(1, 93) = 13.51$, $p = .0004$. In sum, as expected in Hypothesis 3, the differences we found in the solution pattern of future primary and secondary school teachers were also present in their evaluations.

6. Discussion

The findings of the present study confirm Schmidt’s (1994) concerns about the ability and the inclination of (future) teachers to support their pupils in the difficult transition from arithmetic to algebra. Our findings force us to be even more seriously concerned, because they show that at the end of their teacher training future teachers demonstrated still problem-solving behavior with the same problematic characteristics as the student-teachers who were just starting their teacher training. Moreover, we documented that these problematic characteristics of future teachers' problem-solving behavior have an impact on at least one crucial aspect of their teaching behavior, namely the way they appreciate and score pupils’ solution strategies. We doubt whether the subgroup of future primary school teachers experiencing great problems with algebra will have the proper disposition to prepare their pupils for the transition to algebra, but also whether the future secondary school teachers will be empathic towards pupils coming straight from primary school and bringing with them a strong arithmetic background.

MECHANICAL LINKAGES AND THE NEED FOR PROOF IN SECONDARY SCHOOL GEOMETRY

Jill Vincent Barry McCrae
Department of Science and Mathematics Education
The University of Melbourne, Australia

Mechanical linkages, which abound in everyday objects as well as in historic "mathematical machines", provide a rich source of geometry appropriate for secondary mathematics. Explaining why these linkages work the way they do offers a rationale for mathematical proof. The results of a small pilot study suggest that, with the emphasis on the underlying geometry, linkages provide a visually-rich, motivating environment in which to encourage students to explore, conjecture and construct geometric proofs.

Recent decades have seen a general decline in Euclidean geometry in Australian school mathematics curricula, with the geometry that remains becoming largely empirical and students having little idea of the significance of proof. One outcome of this has been renewed debate amongst mathematics educators concerning the inclusion of geometric proof in school mathematics, a debate partly driven by the development and introduction into schools of dynamic geometry software, such as Cabri Geometry II™ and The Geometer's Sketchpad®. While concern has been expressed that dynamic geometry software is contributing to the empirical approach to school geometry (for example, Healy and Hoyles, 1999), there is also the strong feeling that the dynamic imagery associated with use of the software has the potential to play a significant part in geometric reasoning.

Although mathematical proof has several functions, one of its roles is verification, that is, conviction or justification of the correctness of mathematical statements. However, while some students may have a cognitive need for proof as conviction, many see little point in proving something which they already ‘know’ to be true. De Villiers (1998) has criticised the emphasis on the verification aspect of proof in school mathematics, arguing that a more meaningful activity for secondary school students is to focus on proof as explanation. Bell (1976, p. 24) claims that the emphasis on proof as verification/conviction/justification often results in a neglect of other important aspects of proof, noting that “a good proof is expected to convey an insight into why the proposition is true” and that “conviction is normally reached by quite other means than that of following a logical proof”.

Healy and Hoyles (1999, p. 1), reporting on the project, Justifying and Proving in School Mathematics, note that the National Curriculum in the UK

prescribes an approach to proving ... in which the introduction of formal proofs is reserved for ‘exceptional performance’, and thus delayed until after students have progressed through early stages of reasoning empirically and
explaining their conjectures. Most of the requirements to explain and justify take place within investigations driven by numerical data.

Garuti, Boero and Lemut (1998) note that students who are actively involved in the conjecturing process in geometry problems are more successful in constructing proofs than students who have been asked to construct a proof without prior involvement in producing a conjecture. They use the term “cognitive unity” to signify the continuity which they assert must exist between the production of a conjecture and the possible construction of its proof. Hoyles (1998, p. 171), cautions against the assumption that the computer and dynamic geometry software will automatically “help to build bridges between the empirical and the deductive”, noting that “there remains the question of how to develop a ‘need for proof’”. She suggests that

we need to design new learning contexts which require the use of clearly formulated statements and definitions and agreed procedures of deduction but which also allow opportunities for their connection with empirical justification and the conviction this engenders. (p. 169)

The research focus

The proposed research to be conducted in 2001 aims to explore the potential of mechanical linkages, or systems of hinged rods, to engage students in conjecturing and deductive reasoning and to foster a greater understanding of the need for geometric proof. Mechanical linkages occur in many everyday items, for example, umbrellas, folding tables and car jacks, as well as historical “mathematical machines”, such as Pascal’s angle trisector. Many linkages are based on simple geometry, such as isosceles triangles, similar triangles, parallelograms and kites (see Vincent and McCrae, 2000). The linkages used in the research have been carefully selected because their particular geometry is within the understanding of above-average students in Year 8 (approximately 13 years of age). Dynamic geometry software models of the linkages, which permit accurate measurements and tracing of loci, form a bridge between the concrete and the theoretical, assisting students to visualise the linkage as a geometric figure.

Using both physical models and pre-prepared dynamic geometry (Cabri Geometry II) models, students will be encouraged to conjecture about the behaviour of each linkage, propose a conjecture which seems fundamental to the operation of the linkage, and so prove why the linkage operates in the observed way. Such proofs embody the multiple roles of verification, for example, that apparent invariants are in fact invariant, understanding of geometric relationships, and explanation, that is, giving an insight into why the linkage works the way it does.

The main research questions are:
1. Does the modelling of mechanical linkages provide a motivating environment in which to introduce secondary school students to conjecturing and proof?
2. Does the static and dynamic imagery provided by dynamic geometry software models of mechanical linkages assist students to produce relevant conjectures?
Does active involvement in the conjecturing process facilitate secondary school students' transition to construction of proofs?

**Methodology**

The participants in the multi-case study research to be conducted in 2001 will be approximately 20 students from an extension Year 8 Mathematics class at a private girls' school in Melbourne. The students are selected for this extension class on the basis of their non-verbal reasoning (Ravens' Progressive Matrices) scores, their performance on mathematics tests throughout Year 7, and teacher recommendations. They have no previous formal exposure to deductive reasoning and could be expected to benefit in some way from the research tasks. Prior to commencement of the research the following geometry will be taught/revised: properties of angles in parallel lines, triangles and quadrilaterals; Pythagoras' theorem; similar and congruent triangles. Pre-testing will include a Proof Questionnaire (Healy and Hoyles, 1999) and a van Hiele level test (Levels 1-4) (see Vincent, 1998).

The students will work in matched ability pairs according to high/low Ravens' Progressive Matrices scores and van Hiele levels, and will be videotaped and interviewed during their work on some of the tasks. For each linkage, worksheets will direct the students to operate the linkage, record their conjectures, select the conjecture which seems to underlie the design purpose of the linkage and then construct a proof of that conjecture. Students will also complete a questionnaire for each linkage, requiring them to explain how they obtained the data on which they based their conjectures (for example, physical/Cabri model, measurement, loci of points) and which aspects of the models assisted them in constructing their proofs. Unless directed otherwise, students will be free to work with their constructed physical geostrip models and the Cabri models provided, perhaps, for example, checking the action of the physical linkage again after exploring the computer model. Post-testing will include conjecturing and proof tasks as well as re-testing with the van Hiele test and the Proof Questionnaire (Healy and Hoyles, 1999).

**Pilot Study**

A small pilot study was conducted with 29 students from the corresponding extension Year 8 class in 2000 with the aim of testing the feasibility of using mechanical linkages to stimulate conjecturing and deductive reasoning. Before undertaking any of the proof tasks the students were asked to give a brief written explanation of what "proof" in mathematics meant to them. While many students were unable to demonstrate any understanding of mathematical proof, 16 students were able to articulate at least one aspect of proof. The collective responses of these students illustrate the many facets of proof; for example, verification (10 responses) - "If you have proven something you have given evidence that undeniably shows that something is the truth. Proof cannot be denied"; acceptance (2 responses) - "Proof is required for people to believe and use a new mathematical theory"; explanation (4 responses) - "Proof is essential in order to explain a solution or idea. It should enable..."
a viewer to comprehend the meaning”. These responses may be compared with those of the high-achieving Year 10 students studied by Healy and Hoyles (1999), where approximately half of the sample of 2459 students recognised the role of proof in establishing the truth of a statement, just over one third believed that proof should be explanatory and over one quarter of the sample had little or no sense of proof.

While most of the 16 appropriate responses of the pilot study students focused on the role of proof, several referred to how proof is achieved. However, with the exception of one student who wrote: “Proof in mathematics is like proof in anything: using facts to support an argument. Any answer must be backed up using existing common knowledge and theorems”, the responses referred to empirical, rather than deductive, methods. Typical responses included: “Proof in mathematics is when someone may have a theory and they have shown that it actually works by trying out every possibility (though that is very unlikely). They have tried or used something that shows that it works in every situation”, “Proof of a theory needs to be tested and then again to make sure it’s true so you don’t make a theory that doesn’t work”. Some responses indicated uncertainty about the generality of a proof, for example, “A proof has to prove that it works most of, if not all of, the time, not just in a handful of cases”.

The familiar linkage of the elevated work platform, commonly known as a “cherry-picker”, was used to introduce the class to conjecturing in a geometric context. Using plastic geostrips, card templates and paper fasteners, the students worked in pairs to construct the linkage and explore its behaviour. They enjoyed operating the linkage and their observations were accurate, as reflected in their individually-written conjectures (for example, see Figure 1). All students conjectured that there were two parallelograms in the linkage (see Figure 2) and that the safety cage remained vertical (or its base remained parallel to the ground). Most were able to represent the linkage as a geometric diagram, although there was variation in the degree of accuracy of portraying the lengths of equal links and in the positioning of pivot points (for example, see Figure 2), despite the parallelogram conjectures.

Figure 1. Student A’s conjectures for the “cherry-picker” linkage.
Tchebycheff’s linkage (see Figure 3) was then introduced to the students as a means of demonstrating that visual evidence could sometimes be misleading. The linkage consists of a crossed quadrilateral where A and B are fixed and AB = 4 units, CD = 2 units and AC=BD = 5 units. The students constructed the linkage from geostrips and were directed to trace the loci of various points on the strips. After conjecturing that P, the midpoint of CD, moved in a straight line parallel to AB, they were provided with a Cabri construction of the linkage. By tracing the locus of P in the Cabri model and accurately measuring the distance PX (Figure 3) the students realised that the motion of P was only approximately linear. In this case empirical evidence was accepted, as the mathematics involved in determining the path of P was beyond these Year 8 students.

The students were then introduced to the car jack linkage, shown diagrammatically in Figure 4, where AB=PB=BC, A is fixed and P moves horizontally.

---

**Figure 2.** Students A, B and C: drawings of the “cherry-picker” linkage.

**Figure 3.** Cabri model of Tchebycheff’s linkage.

**Figure 4.** Diagram of the triangular car jack linkage.
Students D and E, who worked with the actual jack (see Figure 5) while the other students constructed geostrip models, explained their observations of the jack:

We found that when you draw a line from this point [attachment point for car] to this point [point directly below attachment point] this line is always perpendicular to the ground. So even when it’s moving up and down, the ... er ... sort of line down here is always perpendicular even though it’s attached and this here [base of jack] holds it in place and so the part where the screw is is always the same. This part [pivot at centre of long arm of jack] rotates.

Figure 5. Students D and E: exploring the operation of the triangular linkage car jack.

Figure 6 shows the written conjectures of three students, A, F and G, each implying the same property of the linkage but expressed in different ways. Student A has focused on angle CAP (see Figure 4) without reference to a line AC, whereas students F and G observe that a line from C to A, drawn in the case of student F and imagined by student G, would be perpendicular to the ground.

Figure 6. Students A, F and G: conjectures about the operation of the jack.

When asked to draw two different positions of the linkage, some students, for example, student H (Figure 7), accurately demonstrated that point C moved vertically upwards as P moved closer to A and that the lengths PB, BC and AB were preserved. In contrast, student I shows neither the increase in height of C or preservation of lengths.
Investigation of Tchebycheff's linkage had demonstrated that visual evidence, particularly if based on crude measurements, could not be trusted so the students were aware of the need for proof. Some students recognised that the linkage contained two isosceles triangles, but they were uncertain how to proceed from there, as illustrated by the recorded explanation by students B and J:

The angle $BAP$ [see Figure 4] equals the angle $APB$ because that's an isosceles triangle. And the same thing happens with the angle $BCA$ and $BAC$ because that's an isosceles triangle. Therefore angle $CAB$ and $BAP$ should both [together] equal 90 degrees. But we need to work out exactly why and that's what we're still trying to figure out.

The failure of these students to construct a proof may be due merely to lack of familiarity with proofs, but may also be due to failure to recognise $\Delta ACP$. Figure 8 shows the proof constructed jointly by students A and H (written by student A). Having commenced their proof with angles $ABC$ and $ABP$, they realised that they could instead use the angles of $\Delta ACP$. Their equation: $2x + 2y = 180$, thus led them to the proof that $\angle CAP$ is a right angle. Student A (and H) had conjectured that $\angle CAP$ was a right angle (see Figure 6) and they had now proved their conjecture. It may be significant that students F and G, whose conjectures referred simply to CA being perpendicular to the ground, were unable to construct proofs.
Conclusion

The results of this very brief pilot study are encouraging and suggest that Year 8 is an appropriate level for introducing able students to geometric proof. The students enjoyed working with the mechanical linkages, were able to produce conjectures relevant to the operation of the linkages and were motivated to try to find a geometric explanation for their observations. Not all students, however, were able to progress from conjecture to construction of proof when working with the physical (geostrip) models of the car jack linkage. This may be due to lack of familiarity with the concept of geometric proof, but may be related also to how a geometric figure is perceived. Further research may demonstrate whether the feedback from dynamic geometry software models can facilitate visualisation and analysis of geometric figures and assist the progression from conjecture to proof, particularly with more complex linkages. It is also important to investigate whether any positive effects of working with the linkages and with dynamic geometry software transfer to students' deductive reasoning and proof construction in pencil-and-paper proof tasks.

SOLVING EQUATIONS WITH NEGATIVES OR CROSSING THE FORMALIZING GAP

Joëlle Vlassis

Abstract
We designed an experiment in teaching the solving equations to 8th grades students. This experiment shows that students encounter many difficulties not really when passing through equations with the unknown in both members but rather when passing through equations with negatives. A clinical study was carried out with 13-14 year old pupils to investigate which obstacles students must overcome to solve equations with negatives. This article presents the principal results from experiment and from interview. The results show that the presence of negatives in the equations represents a cut with arithmetical knowledge and requires from students a formal reasoning in both semantic and formal aspects. The different levels of conceptualization of negative numbers proposed by Gallardo (1994) must be reached by the students in order they can give sense to the equations (with negatives) themselves and to the solving methods.

INTRODUCTION
In the research literature, we found authors such as Kieran (1981), Filloy and Rojano (1984), Sfard (1991), Colomb (1995), Linchevski and Herscovics (1996) who stressed cognitive obstacles met by students in their learning of first degree equations with one unknown: the algebraic sense of the equal sign, the presence of the unknown in both members (didactical cut), the complementarity of the procedural/structural conceptions of the expressions, the operations performed on the unknown, ... In order to help the students to overcome these difficulties, we conceived a set of situations aimed to learn how to solve first degree equations with one unknown. These activities have been tested in two 8th-grade classes (aged 13-14). They are built on students' arithmetical knowledge and lead them to evolve towards algebraic methods, using among others the balance model. A particular attention was paid to the ‘didactical cut’ (Filloy and Rojano, 1984) – which occurs when the unknown appears on both sides of the equations – from a semantic as well as from a formal point of view. Our observations show that this demarcation point was passed through successfully for the resolution of equations resulting from the balance model, with such a structure: \( ax + b = cx + d \). However, the presence of negative literal or numerical terms in the algebraic equations raised a lot of problems. In order to analyze more deeply the students reasoning in that context, we carried out several interviews with some pupils of the 8th and 9th grades.

This article reports on the results of the experiment as well as on interviews. It also presents reflections about the student cognitive processes when they are required to solve equations with negatives.

LEARNING SITUATIONS

Presentation of the situations
The whole of the activities proposed to the students of two 8th grade classes has been organized in two phases:
1. **The activities about equations with the unknown in one member** (arithmetical equations). The main objectives of these activities are to lead the students to use their arithmetical knowledge in solving equations (substitution, inversion of operations and cover-up) and to initiate the first notions related to the concepts of equation, solution and unknown. In this article, we will not discuss about the results of the first phase.

2. **The activities about equations with the unknown in both members** (algebraic equations). They are aimed to learn the formal method based on the equality properties (to perform the same operation in both members). Three situations have been designed:

   * **Situation 1 : Solving a problem**: This activity consists in solving a problem of which modeling leads to an algebraic equation. At that stage, no new solving method is introduced. In the state of the students’ knowledge, the solution can only be found by trials/errors. This situation is aimed to make students aware of arithmetic methods limits.

   * **Situation 2 : Balances**: That situation introduces the formal method based on the equality properties with balance-based activities. Students are required to find the unknown value of a weight present on both pans.

   * **Situation 3 : Formalization**: That step is aimed to systemize the formal process without the balance support. A set of 4 algebraic equations is presented without any context.

**Results and comments**

Data have been collected through observations in the classes and through students’ productions analysis. They reveal two phenomenon’s we would like to stress on:

1. **The interest of the balance model**
   Activities have been performed one after the other without raising any particular conceptual problems by the children until the formalization situation. When the balance situation has been got over, all the children were able to solve algebraic equations with additions, by performing the same operation in both members. Students productions analysis helped us to observe that the balance model offered a good mental picture of the required operations and the related concepts (sense and properties of equality). The recent interviews we propose hereafter confirm those results: after seven months of learning, students easily reactivate these techniques without needing any recall. A particular interest of using concrete models, like the balance model, is that students are able to reactivate at any moment that self-evident picture.

2. **The algebraic equations with negatives : beyond the balances**
   On the other hand, the next step of formalization (situation 3) was very difficult for a lot of students. As long as both members were composed of an addition and that the unknown value was a positive whole number, students solved it quite easily. They mentally used the balance model. But when the equation was composed of
subtractions, a lot of difficulties appeared. We identified two different error origins:

a) 'The detachment from minus sign preceding a numeral or literal term'. That type of difficulty - identified by Herscovics and Linchevski (1991) - produced the following errors:

Some students simplified like this the given equation members:

\[
\begin{align*}
-3x + 6 &= 2x + 16 \\
-2x &\downarrow \quad \downarrow -2x \\
1x + 6 &= 16 \\
2 - 3x + 6 &= 2x + 18 \\
-2x &\downarrow \quad \downarrow -2x \\
2 - 1x + 6 &= 18
\end{align*}
\]

We can see that apparently, the students do not take into account the minus sign before 3x, no matter it is presented as a number attribute (first example) or as an operation sign (second example).

b) Subtracting in order to neutralize a negative expression

In order to cancel a negative numerical (or literal) term, some students use subtraction. An equation such as \(3x - 4 = x + 9\) was solved like that:

\[
\begin{align*}
3x - 4 &= x + 9 \\
-4 &\downarrow \quad \downarrow -4 \\
3x &= x - 5
\end{align*}
\]

We can imagine two hypothesis to explain that error. The first one may come from an abusive generalization of the balance model. Stimulated by their previous success with the balance process, the children use the subtraction in order to cancel an expression, just like they did in order to withdraw some weight from the pans. The second hypothesis refers to the first type of error mentioned here above. It could be related to the inability of some students to consider the sign before the expression. For them, it is not -4 that is needed to be cancelled, but 4, the sign `-' before 4 is not taken into consideration.

Authors such as Filloy and Rojano (1984) and Linchevski and Herscovics (1996), who experimented learning situations about the same theme, also say that similar processes appear with their subjects when these are facing equations with negatives. Filloy and Rojano (1984) think that difficulty is related to the fact the students do not succeed in generalizing their knowing stemmed from their experiences with the model. These authors bring into question the use of those concrete models since they do not improve significantly the students competencies. On the basis of our analysis, we assert, on the contrary, that the balance model is a useful instrument to help students to understand notions such as the properties of equality and the related techniques.

The introduction of negatives puts the equation solving at an abstract and formal level. In that case, we can no longer consider the equation terms just as weights needing to be withdrawn from the pans (what would it mean indeed to withdraw some weights -3x or -4?). New obstacles have indeed to be overcome. Balances are not designed to overcome that type of obstacle. We have to consider transition activities in order to help students to leave the model while keeping the principles it introduces.

REST COPY AVAILABLE
CLINICAL INTERVIEW

Presentation of the interview

We interviewed 7 students: five amongst them were in the beginning of the 9th grade and had learnt during the previous school year how to solve equations in the frame of our experiments. Two other students were at the beginning of the 8th grade and had not yet learnt equation solving. They were all of average ability.

The topic of the interview was to go deeper in the analysis of the data we collected during the previous experiments. The questions concerned mainly:
- Equations with the unknown in one member: i) \( ax = b \) (with \( x < a \)); ii) \( a - x = b \) (with \( x > a \)); iii) \( -a - x = c \) and iv) \( -x = a \). Numbers were whole numbers.
- Equations with the unknown in both members.

Results

The most significant results obtained with this interview are the following:

in arithmetic equations with negatives:

Here is an example of each type of equation presented in the interview:
i) \( 12 - x = 7 \); ii) \( 4 - x = 5 \); iii) \( -4 - x = 10 \); iv) \( -x = 7 \).

1) Giving some sense to equations such ii), iii) et iv)

In order to solve those equations, all the students tried to give them some sense. No student of the 9th grade did solve spontaneously those equations through a formal method. We can reasonably assume that the numbers simplicity as well as the resolution of the first equation (i) \( 12 - x = 7 \), incited the students to use arithmetic methods based on a concrete meaning.

‘Inhibitory mechanisms’ (Gallardo & Rojano, 1994) then appeared. On the one hand, most students were amazed before an equation such as (ii): ‘It is impossible to subtract a number to 4 to obtain a bigger result!’ On the other hand, that difficulty to give some sense to those equations led to the inability to generalize the inversion of operations, even if it was widely used for (i). Either children did not think to use that method for (ii) et (iii), or they thought they were using it when adding 4 and 5 in 4 - x = 5 (ii) and adding -4 and 10 in -4 - x = 10 (iii).

After having hesitating before ‘the subtraction which makes bigger’, the students who explicitly asked the question like that: ‘By which number have I to substitute x in order to obtain a bigger result?’ succeeded in finding the solution, remembering the rule ‘minus by minus gives plus’.

Only one student solved 12 - x = 7 with the substitution method (‘which is the number which, when subtracted to 12, gives 7?’). The same student solved spontaneously and easily items (ii) and (iii) with the same method.
This observation supports our hypothesis (Fagnant & Vlassis, in press), according which the substitution process involves thinking structures that help students to conceptualize more easily the notions involved in the equations. Kieran (1988 and 1990) also supports that position.

2) Solving ‘\(x = 7\)’

That equation was the most difficult. No student could solve it spontaneously. Five of them began by giving 7 as a solution. Some of them understood it was not possible since they had then \(-7 = 7\), but they could not find the solution.

This difficulty has of course its origin in the absence of sense given by the students to an equation like \(-x = a\). But why is that particular equation more difficult to solve for the students than equations such as (ii) and (iii)? We think the main reason is that students consider \(-x\) statically, just as \(-4\), for instance. That representation leads to confusion in the minus signs. For them, the ‘\(-\)’ sign before the \(x\) is the same that the ‘\(-\)’ sign in \(-4\). In numeric cases, the numbers written behind ‘\(-\)’ are ‘naturals’, so the students consider that \(x\) can only be a natural.

Some students who proposed the correct solution \(x = -7\) explained that the solution could not be \(-7\) because if it was, it should be written \(-\)\(-7\). When we proposed to other students the solution \(-7\), they answered that the ‘\(-\)’ was already written, they refused our argument and suggested \(x = 7\) again. Cortès (1993) also indicates that in that type of equation, the unknown considered by the student is not \(x\) but \(-x\).

In order to give some sense to an equation such as \(-x = 7\), it is required the students can make the distinction between the minus sign and \(x\). Two different thinking procedures can be considered:

- Considering the expression \(-x = 7\), in a procedural manner, like \(-1 \cdot x = 7\). This raises the following question ‘Which is the number that, when multiplied by \(-1\), gives 7?’. During the interview, we tried to involve the students in that way of thinking. But none of them seemed to understand where we wanted them to go.

- The equation \(-x = 7\) can be considered with the idea of opposite numbers. That perspective leads to express the equation like this: ‘\(-x\) means it is needed to take the opposite of the number \(x\); thus, which is the number of which the opposite is 7?’. That perspective makes possible the idea that \(x\) could be a negative. Since it is required to take the opposite of a number, that number can be a negative. That second way of reasoning seems to be easier for the students. It helps them to keep their static conception of the expression while leading them to the correct solution. That method was used to find the solution by the two students who answered correctly.

in algebraic equations (for the 5 students of the 9th grade)

We were surprised to observe that algebraic equations with negatives raised fewer difficulties than the arithmetical ones. The students indeed did not try to give some sense to the algebraic equations to solve them. The presence of the unknown in both members seemed to act as a starter of the solving method consisting in performing the same operation in both members. The students did not meet any particular
difficulty in the application of that method. But the presence of negatives nevertheless produced the following errors:

4) 'The detachment from minus sign'
One student made that error. But no student did subtract a negative term to cancel it. That observation is surprising when we consider the results of our previous experiments. We'll need to interview more pupils to analyze more deeply the problem.

5) Going from $-ax=b$ to $x=-b/a$ (like in $-5x = 10$)
It is the most important difficulty we observed in the algebraic equations. We noticed two main obstacles for the students who apply completely the method consisting in performing the same operation in both members:
- Finding the right operation which links $-5$ with $x$. Whereas going from $6x = 7$ to $x = 7/6$ seems easy (the students explicitly explain they divide by 6 in each member), it is surprising to observe they do not know which operation they have to perform in order to transform $-5x$ into $x$. Some of them think they have to make $+5$ in each side. Others do not know at all what to do. It seems that the multiplication sign between $-5$ and $x$ is not evident when the coefficient of the unknown is a negative number. The students are not able to decode easily the expression $-5x$ in terms of $-5 \cdot x$.
- Dividing by a negative : Once the students succeeded in decoding correctly the expression, another obstacle appeared : they had some difficulty to accept the idea of dividing by $-5$.

in operations with numerical or literal terms

6) 'Detaching from the minus sign'
- For two students, the expression $6 + n - 2 + 5$ is simplified in $-1 + n$. They justify it by explaining that if $2 + 5 = 7$ then $6 - 7 = -1$.
- A student makes $237 + 89 - 89 + 67 - 92 + 92$ like that : he crosses out $+89$ et $-89$ and makes: $237 + 67 - (92 + 92) = 304 - 184 = 120$

7) Considering the sign which follows the numerical or literal terms
- For two students, the reduced expression of $6 + n - 2 + 5$ is '13 + n' because $2 + 5 = 7$ so $6 + 7 = 13$. They consider the sign '+' which follows 6.
- In $19n + 67 - 11n - 48 = ?$, we find the following errors, the same ones already identified by Linchevski et Herscovics (1996) (3 students):
  'Jumping off with the posterior operation': in order to reduce the expression $19n + 67 - 11n - 48 = ?$, some students grouped $19n$ and $11n$ by making an addition rather than a subtraction. The considered sign is the '+' sign which follows $19n$.
  'Inability to select the appropriate operation for the partial sum':
  For some students, $19n + 67 - 11n - 48 = 8n - 19$, because $67$ is followed by the '-' sign.
We attribute these three different types of errors to the same trend as the detachment from the minus and which consists, over all in that particular case, in
paying more attention to the sign which follows the operation rather than to the one which precedes it.

According to Linchevski and Herscovics (1991), the difficulties related to the priority rules of the operations. Our interviews do not confirm that hypothesis. The students did not propose any explanation of that kind. We tend to explain those difficulties by the arithmetical practices of the students. According to Vergnaud (1989), it seems that there is confusion between the numbers without signs (measures of size or quantities) and the numbers with signs (quantification of transformations and relations). In the primary school, over all the components of an operation, that is the numbers without signs (we make the operations with meters, francs, etc.) are stressed on, but not so often are the relations intervening in the operations. In the same way, we can also mention the ambiguity of the minus, which can be considered in a procedural way, as a sign of the operation to be performed, or in a static way, as the attribute of a number. It seems that, in this particular case, the students do not consider the second possibility.

8) Confusing the algebraic rules
A student wrote $19n + 67 − 11n − 48 = 8n − 19$ with a quite distinct justification from the other students' one. To our question ‘Why $-19$?’, he answered ‘$+67 − 48 = −19$ because plus by minus gives minus’.

DISCUSSION

The operations with the negative whole numbers present a lot of difficulties for the students. With the introduction of negatives, a formal reasoning, which goes most often into contradiction with the arithmetical knowledge, becomes necessary. In case of solving equations, that difficulty turns out to be still more important because that context makes it necessary for the students to have perfectly integrated the distinct levels of conceptualization of the negatives stressed by Gallardo (1994): subtraction, signed number (plus or minus sign is associated with the number), relative (or directed) number (idea of opposite and symmetry) and isolated number (result of an operation or solution of an equation). The consideration of the various negative dimensions is needed to give some sense to the equations with negatives themselves, as well as to the formal solving procedures. For instance, the conception of ‘relative number’ enables to give sense to an equation such as $-x = a$, or to the procedure of neutralization of a term (canceling a numerical or a literal term); the idea of ‘signed number’ is essential to avoid errors of ‘detachment of the minus sign’, ...

Moreover, with the presence of negatives, algebraic equations resolution can no longer be considered concretely: for example, it becomes impossible to maintain the ‘subtraction’ idea (withdrawing some weights from the balance pans) to neutralize a term. The letter has to be given a mathematical interpretation and no longer an intuitive one, as an object (a weight) in the meaning of Kuchemann (1981). Students have to be taught to abstract, from the concrete manipulations, the general mathematical method needed to solve all types of equations with one unknown.
Solving equations with negatives, means thus crossing the formalizing gap. This transition cannot be left in the students' hands. It needs a teaching performing explicitly the transition towards the abstract concepts involved by the formal solving methods. The data collected through the studies presented here above will help us to modify our learning sequence. Further experiments will be carried out.

In 1993, a new curriculum was established in junior secondary schools in the Netherlands, based on the principles of Realistic Mathematics Education (RME). Yet, teachers and students needed time to adjust to the new curriculum. In this article, data from the TIMSS test are studied, by distinguishing between test items that match and those that do not match the RME curriculum. Trend data (1995–1999) of Dutch students’ achievement on these two distinct sets of items and data of teachers’ approval of the test items suggest that the attained curriculum is approaching the intended curriculum at a very slow pace.

The RME core-curriculum in the Netherlands for junior secondary schools

Three decades ago Hans Freudenthal and his colleagues started to transform the mathematics curriculum with a treatise, which is generally known as Realistic Mathematics Education (RME). It is characterised by the understanding that mathematics is an integral part of real-life. Another component is the importance of enabling students to make mental images (Freudenthal, 1973, de Lange, 1987, van den Heuvel-Panhuizen, 1996).

In 1993 the “W12-16-project” established a core-curriculum based on RME for all students at Dutch junior secondary schools. The new curriculum emphasised data modelling and interpreting (through tables, graphs and word-formula), visual 3-d geometry, approximation and rules of thumb, the use of calculators and computers and other topics considered relevant to daily life of the new generation of the 21st century (Kok, Meeder, Wijers & van Dormolen, 1992). National assessment was adjusted to the new content approach. Generally, test items in the RME core curriculum describe an appealing daily life situation (often with authentic photographs to enliven imagination) followed by questions that integrate different mathematical content areas. The test items contain horizontal mathematization (Treffers, 1987) whereby realistic situations are modelled and reversibly the model is interpreted in its context. Several integrated mathematics topics can be combined and any test item is expected to keep students’ concentration alive for approximately 15 minutes (Dekker, 1993). As for the format of questioning, multiple choice items do not match RME, because the world of real-life hardly ever offers four ready-made alternatives from which to choose.

With TIMSS data, implementation aspects of this new curriculum are studied below.
The TIMSS items matching a heterogeneous set of curricula

TIMSS (Third International Mathematics and Science Study) is an international comparative study of education in mathematics and science with the important question: what can we learn from other countries? It was conducted at grade 8 level in 1995 and again in 1999. The conceptual framework for this large scale curriculum study is based on the distinction of three curriculum levels (figure 1): the intended curriculum (what society at large prescribes students to learn, curriculum experts’ opinions), the implemented curriculum (instruction at classroom level, teachers’ opinions) and the attained curriculum (what is actually learnt by students).

To study the implementation process of the RME core curriculum at the level of junior secondary schools in the Netherlands, this framework was considered useful.

At the level of the attained curriculum, the TIMSS achievement test was carefully constructed in a process that is well-documented (Garden & Orpwood, 1996). Several experts in the field developed items testing for cognitive and procedural knowledge in a wide range of mathematics topics. With 40 different nations participating, a cross section of contents and levels had to be found that would be equally unfair for all.

At the level of the intended curriculum, a Test Curriculum Matching Analysis was carried out. In each participating country curriculum experts were asked to review each test item and assess whether its content was covered by the intended curriculum for the majority of the target population. Results from this analysis are presented in table 1. For each nation participating in TIMSS-95 (testing grade 8), it shows what percentage of the TIMSS mathematics items were considered appropriate to the intended curriculum.

The Netherlands lingers at the bottom, with 71% of the TIMSS test being covered by the intended curriculum of the target population. The complement of 29% of the 157 TIMSS items was considered remote from the national curriculum. Kuiper, Bos & Plomp (1997 & 1999) already analysed this problem and their research (with a slightly different set of 150 TIMSS-95 mathematics items considered) displays a percentage of 69% of all test items that are reasonably well covered by the Dutch RME curriculum. Four years later in 1999, when curriculum experts again were asked to judge the TIMSS mathematics items, the percentage was 71% (out of 155 items), showing that no substantive change had occurred in the judgement (Bos & Vos, 2000). The minimal discrepancies (69% or 71%) can well be associated with the differences in the assessed sets of items.
It remains to be noted, that the approximately 70% portion of items that were considered to be in line with the national RME curriculum would have been much smaller if the experts also had considered the question format. With approximately 75% of all test items having a multiple choice format, there would remain very little to consider.

Dutch students’ performances on TIMSS-95 and TIMSS-99

When TIMSS-95 was carried out, serious doubts arose whether TIMSS would do justice to the Dutch target population. Additional research established that, although Dutch students were not prepared for the full set of TIMSS items by their curriculum, their abilities were well measured by TIMSS (Kuiper, Bos & Plomp, 1997, 1999). In other words: the approximately 70% of TIMSS items that matched with the curriculum gave them enough room to display their abilities. It was assumed that when learning mathematics with real-life contexts and integrated topics, students would still be able to display their abilities on isolated questions and the multiple-choice format was not to obstruct their performance.

Moreover, although it might not officially be intentional, somehow Dutch students were knowledgeable about the remote items and could attain reasonable scores on these items as well. It could be, that teachers would still follow the abandoned curriculum or mix forthcoming content of higher grades in their present teaching.
Another reason could be that students acquired their knowledge outside the mathematics classrooms, or that they just attempted the unknown tasks with an open mind.

In 1995 a sample of n=1921 students was tested, in 1999 a sample of n=2878 students was tested, according to the strict TIMSS sampling procedures (Beaton, Mullis, et.al., 1996; Kuiper, Bos & Plomp, 1997; Mullis, Martin, et.al., 2000; Bos & Vos, 2000). The tests from 1995 and 1999 were of comparable level, with half of the items being identical, and the other half being mostly clones. In the process of replacing items, only minor adjustments were made. For example item N19 in TIMSS-95 would read “shade in 5/8 of the unit squares in the grid”, and its substitute in TIMSS-99 would read “shade in 3/8 of the unit squares in the grid”.

Overall, Dutch grade 8 students performed well on both TIMSS mathematics achievement tests. In 1995 they scored an average percentage correct of 63% on the mathematics items, and in 1999 this was 65%. This small, though statistically insignificant improvement is confirmed in the international TIMSS-99 report, in which a different scale for measurement of country performances is used (Mullis, Martin, et.al., 2000). Both in TIMSS-95 and TIMSS-99 Dutch grade 8 students rank well above the international average. The new curriculum seems to have had a positive impact.

Do Dutch students show a better performance on the ± 70% portion of the TIMSS items that were considered to match their curriculum? In table 2 a trend for the average percentage correct on different sets of items is summarised. Looking at the data for 1995, the performances on the two complementary sets of items show no difference with the overall performance. On average 63% of Dutch students answered any item correctly, whether it matched the intended curriculum or not. The students performed just as proficient on the RME-matching items as on the set of items NOT covered by the curriculum.

</tr>
</tbody>
</table>

In 1999 there is a small (though not statistically significant) gap between achievements on items that match and do not match the curriculum. A larger percentage of students (68%) perform well on the test items that match the RME curriculum than on the items that are remote from it (57%). A reason for the slight discrepancy in the columns of table 2 could be that time was needed for the implementation of the new curriculum. 1993 was the year of introduction. Thus, in 1995, two years after the introduction of the RME curriculum, there was still a period of curriculum transition and the new curriculum had not yet established itself well.
Teachers might still incorporate topics from the abandoned curriculum. Four years later, in 1999, the implementation of the new curriculum was starting to show.

**Dutch teachers’ approval of the TIMSS test items**

With students’ achievement at the attained curriculum level, and the curriculum experts’ judgement at the intended curriculum level, there is still an intermediate level in the conceptual framework to analyse: the implemented curriculum. The question is whether the grade 8 mathematics teachers had covered the content of the test items and whether students would have had an opportunity to learn this content. Would teachers also cover non-RME content?

The instrument for this research question consisted of a questionnaire, disseminated to the mathematics teachers of the 126 tested classes in which they were asked to judge the TIMSS test items by the following question: if you were to set a test on all mathematics content which has been taught so far to the concerning class (tested in TIMSS), would you consider this item from its content to be suitable for this test? It was explicitly stated that teachers were to ignore the format (multiple choice) and the difficulty level, and only indicate whether the content was taught.

The instrument of 1995 covered 16 mathematics test items out of 150. This small selection was based on the intended curriculum (curriculum experts had selected these 16 to match well with the RME curriculum) and proved to be too small to provide an analysis of teachers’ coverage of the whole test. In 1999 the instrument was re-developed in a way that all 155 items were scrutinised. Yet, this number was considered too large to be included into one questionnaire, and the judgement of all items would become a tedious job for the teachers concerned. It could negatively affect their responses. Therefore, three mixed sets of items were created (of 52, 52 and 51 items), and each teacher would randomly receive one set. In this way all items would receive a judgement, although each item would only be seen by one-third of the teachers.

The response reached a satisfactory level of 89% (126 teachers were approached, 112 teachers responded). Further details on the methodology of this instrument can be found in Bos & Vos (2000). As no data from 1995 would be available to make a trend analysis, comparative data were created into two other dimensions:

- internationally, with mathematics teachers from Belgium (Flanders) judging the same mathematics items from TIMSS-99.
- cross-curricularly, with Dutch physics/chemistry teachers judging the 70 items from TIMSS-99 of their subject.

For the international comparison, Belgium (Flanders) was considered appropriate, because of similarities in economical, social and cultural aspects. Moreover their intended curriculum is very similar to the pre-RME-curriculum of the Netherlands and closely matches the TIMSS test. As can be seen in table 1, in 1995 the Belgian
Curriculum experts chose 86% of the TIMSS items to match their curriculum. In 1999 this percentage had increased to 98% (Mullis, Martin, et al., 2000).

For the cross-curricular comparison, items from science were selected. The complete TIMSS science item set (n=135 items in 1995, n=143 items in 1999) covers the subject areas physics, chemistry, life science, earth science, environmental science and nature of sciences. In the Netherlands, we do not teach integrated science like in many other countries at grade 8 level, but instead there is the combined subject of physics/chemistry, the separate subject of biology, and the separate subject of geography. From the TIMSS test, we selected 70 items that could possibly be covered in the lessons of physics/chemistry. The selection consisted of items on physics (n=38), chemistry (n=19), together with items on environmental science (n=3) and the nature of science (n=10). The curriculum experts in this field had chosen two thirds of these 70 items to match with the intended curriculum, which is just slightly less than their counterparts did for mathematics (±70%, compare table 1).

In the analysis, for each item the percentage of approving teachers was calculated, by taking those who had indicated "yes" on the question whether they would include this particular item into a test covering all taught content. It was stipulated that if an item had a high teacher' approval, many students would have had an opportunity to learn its content.

In table 3 the percentage of approving teachers is divided into categories with ranges of 20%. Items in the first approval category (0-20%) have a very low teacher approval. Items in the last category (80-100%) have ample teacher approval. In three columns the percentages of items in the five approval categories is given, for the Belgian (Fl.) and Dutch mathematics teachers, and for the Dutch physics/chemistry teachers. To visualise the comparison, figure 2 displays the same data in a bar chart.

</table>

The general profile of answers by Belgian and Dutch mathematics teachers is fairly similar. Despite differences in the intended mathematics curriculum, there seems to be a tacit cross-border understanding in approval of the TIMSS test items. Both mathematics teacher groups display a high approval of the items, with the Belgian (Fl.) teachers displaying a slightly higher approval. According to the answers in both

1 We thank the Flemish TIMSS researchers, Prof dr. J. Van Damme and drs. A. Van den Broeck (K.U.Leuven), for making these data available (Departement Onderwijs Vlaanderen, 2000).
groups, more than two-thirds of the TIMSS mathematics test items had been taught by more than 80% of the teachers, and more than 90% of the items had been taught by more than 60% of the teachers. When looking at the 70% of items matching the Dutch RME curriculum, an average 87% of the mathematics teachers indicated that it was covered in their lessons (data not in table 3). The other 30% of non-RME items were covered by an average of 71% of the teachers. This could explain, why a majority of Dutch students proved proficient on the items that were not matching the intended curriculum: their teachers would still cover these topics.

![Graph showing approval of TIMSS-99 test items by Belgian (Fl.) and Dutch mathematics teachers compared to Dutch physics/chemistry teachers.](image)

Figure 2.
Approval of TIMSS-99 test items by Belgian (Fl.) and Dutch mathematics teachers, compared to Dutch physics/chemistry teachers

Comparing the patterns of answers from the Dutch physics/chemistry teachers and the mathematics teachers proves difficult. Most physics/chemistry items receive an approval of half of the teachers, far less than the mathematics items. There are few physics/chemistry items with a high teacher's approval percentage, while in mathematics these outnumber all other items. To reach better understanding of this pattern, further cross-curricular research is needed, especially with regards to the physics/chemistry curriculum.

With the similar profiles of item approval by Belgian (Fl.) and Dutch mathematics teachers, it appears as if Dutch mathematics teachers still maintain characteristics in their instruction from the pre-RME era. Considering that their average years of teaching experience is 17 years (Bos & Vos, 2000), this means that the bulk of mathematics teachers in the Netherlands matured in their profession before 1993. It could mean that they still teach topics from the abandoned curriculum. As a consequence, it will take decades for the implemented curriculum to approach the new intended RME curriculum.

**Conclusion**

From the comparatively high performances of Dutch grade 8 students in the tests of the international comparative studies TIMSS-95 and TIMSS-99, it is obvious that the mathematics curriculum provides them with a solid foundation for doing
mathematics. Yet, the implementation of the new RME-based curriculum at this level is still in progress, six years after its introduction in 1993. To analyse the process of implementation, a distinction in TIMSS items was made with the criterion of matching the intended RME curriculum or not. The performances of Dutch students on these complementary sets of items were calculated separately. Between 1995 and 1999, a slight improvement had taken place in the performance on the RME-matching items. Dutch students also did well on items that were not part of their intended curriculum, although their score decreased from 1995 to 1999.

To analyse the intermediate curriculum level of teacher instruction in the classrooms (implemented curriculum), an instrument was developed in which mathematics teachers were asked to judge all TIMSS mathematics items. A large majority of these teachers indicated that their students had an opportunity to learn about the content covered in the TIMSS test, whether the items matched the intended curriculum or not. Comparison with their Belgian (Fl.) colleagues displayed a fair agreement between the two groups. This could imply that the process of implementing the new RME curriculum is still proceeding slowly and Dutch teachers stay attached to the abandoned curriculum and that in Dutch mathematics classrooms a mix of two curricula is carried out. Further research into the implementation of the RME curriculum is advised.

THE MICRO-DEVELOPMENT OF YOUNG CHILDREN'S PROBLEM SOLVING STRATEGIES WHEN TACKLING ADDITION TASKS

Chronoula Voutsina and Keith Jones
Centre for Research in Mathematics Education
University of Southampton, UK

The aim of this study was to determine the pathway of changes that occur in the problem solving strategies of 5-6 year old children when they are engaged in solving a specific form of addition task. Karmiloff-Smith's model of Representational Redescription (RR) suggests that higher conceptualisation and control of the employed strategy develops both before and after the achievement of an efficient solution. This paper presents evidence that tends to support this hypothesis.

INTRODUCTION

As the work of Kieren and Pirie (1994) and Lyndon and Pirie (1998), amongst others, demonstrates, mathematical understanding is always under construction. Yet very often in mathematics lessons, pupils who produce a correct answer or solution to a problem are not asked to justify or work further upon their solution. Correct answers are usually “ticked” while justifications, explanations and further work are often only asked for when errors occur. Justifying solutions is different from asking pupils to check their solutions. Indeed, Pawley and Cooper (1997) found that solution checking was not necessarily helpful for pupils, perhaps because it tends to increase cognitive load. Asking pupils to justify their solution is more akin to the “separate introduction of checking” which Pawley (1999) found led to significantly improved pupil performance on multiplicative tasks.

The aim of the research study from which the data presented in this paper comes is to try to understand the process that leads to this sort of enhanced performance. Our approach is to determine the pathways of change that occur in the successful problem solving strategies of young children as they tackle numerical tasks. This need for elaboration of a given solution after success has been addressed by some mathematics educators, notably within the theoretical framework of social constructivism. Research that has been carried out within this particular framework has used the classroom as a unit of analysis, and has shown the effectiveness of group-work and classroom discourse in promoting students’ conceptual change and understanding (see, for example, Cobb et al, 1997). Group work on problems, discussion and argumentation on different ways of solving a task are certainly beneficial. However, it may be the case that not all students benefit to the same extent by group work and whole-class discussions. Reflecting and internally working upon their own problem solving approach, and knowledge that supports their own developed, efficient strategy can be another source of learning and conceptual change for children.
A comprehensive review of the literature (Voutsina 1999) indicates that Karmiloff-Smith’s model of Representational Redescription (RR) (1984, 1992) offers the appropriate framework for this study. The model incorporates the idea of *success-based cognitive change*; that is, the possibility of conceptual change occurring after procedural success. It also suggests that higher conceptualisation and control of employed strategies develop both before and after the achievement of an efficient solution. The overall aim of the study is to determine the move 5-6 year old children make from procedural success to higher conceptualisation and understanding of the procedures they employ in the successful solution of an arithmetical task. This paper reports a typical example in order to illustrate the use of the RR model in arithmetic problem-solving, something that has not been done before.

**THEORETICAL FRAMEWORK**

The distinction between *procedural* knowledge (the ability to perform a task) and *conceptual* knowledge (the ability to understand the task) has been the subject of long debate in mathematics education (Skemp, 1971; Baroody & Ginsburg, 1986; Silver, 1987; Hiebert & Lefevre 1986; Bisanz & Lefevre, 1990). In the field of developmental psychology, Karmiloff-Smith (1992) has developed a theoretical model to account for development and learning based on the assumption that inflexible procedural behaviour rests on knowledge which is *implicit*; that is, knowledge which is not available as manipulable data. Karmiloff-Smith argues that after procedural success certain types of cognitive change may take place. In this process of change, implicit information embedded in an efficient problem-solving procedure progressively becomes more explicit, manipulable and flexible. In Karmiloff-Smith’s developmental model, the issue of cognitive change is addressed in terms of knowledge explicitation that applies in a variety of domains, including mathematics.

Within the context of problem solving this idea of knowledge explicitation has only been studied in science, and with spatial, linguistic and notational tasks, but not any area of mathematics. In the framework of this study, children’s developed strategies are seen as a product of the combination of different pieces and forms of arithmetical knowledge (conceptual, factual, procedural). Conceptual understanding, as it is built in the “micro-context” of an arithmetical task, is approached and studied on the basis of the idea of *knowledge redescription* (Karmiloff-Smith, 1992).

**THE MODEL OF REPRESENTATIONAL REDESCRIPTION (RR)**

Karmiloff-Smith argues that implicit information which is already stored in the mind, in a certain form of internal representations and is embedded in special-purpose procedures, is subject to an iterative process of redescription. The RR model is a *recurrent 3-phase model* with the following main characteristics:

**Phase 1:** “The procedural” phase
During this phase children’s behaviour is considered to be “success-oriented.” Separate units of behaviour are not brought in relation one to another. At the end point
of this phase consistent successful performance is achieved, and this is what Karmiloff-Smith calls “behavioural mastery” (ibid p. 19).

Phase 2: The “meta-procedural” phase
In this phase, an overall organisation of the internal knowledge representations takes place. As a result, children generate “organisation-oriented” behaviour. They move beyond procedural success to a phase of internal representational organisation and the generation of a unified, single approach for all the parts of the problem.

Phase 3: The “conceptual” phase
During this phase the interaction between external data and internal representations is regulated and balanced as a result of the search for both internal and external control. Representations that sustain children’s behaviour in the third phase are considered to be richer and more coherent, even though children’s behaviour in this phase can seem identical to the behavioural output at phase 1.

METHODOLOGY
The aim of the study is to describe and analyse changes in children’s strategies on the basis of the premises and explanations that the RR model introduces. The study focuses on a number of cases. Changes in children’s successful strategies are studied at a micro-developmental level. This means that the focus is on changes that occur within the context of a specific form of arithmetical task and within the boundaries of a sequence of limited-in-number-sessions. For the data collection, the micro-developmental method is combined with the clinical method of interviewing. Children are interviewed individually while working upon specially designed tasks.

The “card” task asks children to find all the possible number bonds that result in a “target” number (for example, find all the possible number bonds to make 9, or 10 etc.). A pile of identical cards with incomplete number sentences, such as the one on the right, is at children’s disposal.

\[ \square + \triangle = 9 \]

Children have to pick up one card at a time, put a number in the square and another one in the triangle in order to complete the number bond until there are no more possible ways to do so. The task is repeated with different “target” numbers. Each number bond that a child produces is considered as a step within the solution process. The hypothesis is that, in the context of this particular task, children initially approach each step of the task separately, employing different methods, and calling upon different pieces and types of knowledge. This kind of approach may well be successful. However, if appropriate motivation is given to children to keep working on the task, eventually, the different pieces of knowledge will be organised in a strategy applied consistently for every step, to the whole of the task. Similar-in-goal tasks are presented to children to test the flexibility of the new strategy, and its transferability to similar goals. One such task is the “balance” task. On a piece of paper balances, such as the one shown below are drawn.
Children have to write one number on each of the blocks at the right side of the balance. The sum of these numbers must be equal to the number written on the block at the left side.

SAMPLE

Five children from a year-1 class of a South England infant school participated in the pilot study. Because the study focuses on children's evolving strategies after success and during a relatively limited number of sessions, children most competent in addition were selected to participate so that less time would be devoted to consider arithmetical misunderstandings and errors.

A CASE STUDY

An example of changes observed while working with a child is given below. Chris was 5 years 8 months old and participated in four sessions.

Session 1

The target number was 7. Chris produced the following number combinations in the order shown in the inset below:

\[
\begin{array}{c}
\boxed{6+1} \\
\boxed{5+2} \\
\boxed{4+3}
\end{array}
\]

After writing down the first number, Chris counted on using his fingers to figure out the second. The interviewer asked Chris how he chose which number to write first. Chris replied:

Chr: Cause 6 it's just next to 7.  
C: And why did you choose 5 after that?  
Chr: Cause it's 1 more.  
C: And how did you choose 4 afterwards?  
Chr: It’s 3 more.

The first number that Chris chose was the one that was closest to the target number. This choice allowed him to count less. It was an economical in counting method. Chris completed the task and produced the following number bonds:

\[
\begin{array}{c}
\boxed{3+4} \\
\boxed{1+6} \\
\boxed{2+5} \\
\boxed{0+7}
\end{array}
\]

To produce these number combinations Chris “swapped around” the previously produced number bonds, which is how he changed their addend order. After writing the last number bond Chris seemed to keep thinking. The interviewer asked:

C: So are these all?  
Chr: There are more but I don’t know them.

In this session Chris approached the task by focusing on the production of each number bond separately. The mixture of the two methods (economical in counting method and ‘swapping’) for the production of each number bond allowed Chris to be successful. Each one of these steps in the solution process was a separate unit of behaviour which was elaborated enough to allow success. However, Chris was not aware of his success. In terms of the RR model a first level of procedural success had been achieved.
Session 2

The target number was 8. Chris produced the following number combinations:

- [7+1]
- [0+8]
- [8+0]
- [1+7]
- [2+6]
- [3+5]

After writing down the last number bond Chris took some time to look at the completed number sentences and said:

<p>| | |</p>

<tr>
<td>Chr:</td>
<td>Then it gets higher and higher and higher...</td>
</tr>
<tr>
<td>C:</td>
<td>Which one is getting higher?</td>
</tr>
<tr>
<td>Chr:</td>
<td>(shows first numbers in the last three number bonds).</td>
</tr>
<tr>
<td>Chr:</td>
<td>It goes 7, 6, 5 (shows from the top to the bottom). Oh, 5, 6, 7 (shows from the bottom to the top). The lowest numbers go down there (shows 1, 2, 3 from the top to the bottom) and then like that (shows 5, 6, 7, from the bottom to the top)…like a zigzag.</td>
</tr>
<tr>
<td>Chr:</td>
<td>How did you think of that now?</td>
</tr>
<tr>
<td>Chr:</td>
<td>I don’t know.</td>
</tr>
</tbody>
</table>

Chris noticed a pattern: a regularity of the numbers in the number bonds he had produced up to that point. He produced a new number bond following this pattern. However, this seemed to be a discovery which was not explicit enough yet to allow the formulation of verbal explanations.

Session 3

The target number was 6. Chris completed the task producing the following number bonds:

- [0+6]
- [6+0]
- [5+1]
- [1+5]
- [2+4]
- [4+2]
- [3+3]

For the production of these number combination Chris applied his initial methods. At the end of the task however, he uttered the numbers in order, to check if he had finished. The numbers that he was showing while uttering them in order appear in bold. This was the first time that Chris realised the need to put the numbers in order so that he could check. However, it was clear that he had not yet fully grasped the rationale behind this strategy because he checked the numbers by moving from one column to the other. This would not allow one to know if all the possible numbers had been used either as first or second addends and thus whether all the possible number bonds had been produced. However, at the next run with the same task Chris employed the idea of “ordering” not only to check but to solve the task. This is considered as an important change and indication of Chris’ movement away from the initial mixture of isolated though successful methods to an organisation-oriented “meta-phase” marked by the discovery of a new strategy. He applied this strategy consistently for all the steps in the task. Furthermore, he transferred the strategy to the balance task:

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Chr:</td>
<td>6</td>
</tr>
<tr>
<td></td>
<td>5 4 3 2 1 0 6</td>
</tr>
<tr>
<td></td>
<td>1 2 3 4 5 6 0</td>
</tr>
</tbody>
</table>
Chris: No more (he said right away after finishing).
C: How do you know?
Chr: 1, 2, 3, 4, 5, 6, 0 (shows second numbers from the top).
That’s all the different that you can make.

Chris produced these combinations in a few minutes by simply putting the numbers in the upper and lower boxes in descending and ascending order, correspondingly. Chris did not only transfer the “ordering” strategy to the balance-task but most importantly, this was the first time that he appeared to be certain of the completion of the task.

Session 4

In this session there were indications that Chris’ approach to the task had been subjected to a process that made it more explicit. Chris applied the “ordering” strategy in the card-task for bigger target numbers such as 19 and 25. He justified the use of the strategy by saying: “It’s easier... I know when I finish”. Moreover, a violation of constraints imposed by Chris’ initial theory of “economy in counting” was observed: Initially, in order to count less, Chris always used as first addend in the first number bond produced, the number which was closest to the “target” number. As a result, in the first number bonds the first addend was always bigger than the second. In the last session the first addend of the first number bonds produced was the smaller number. For example, when the target number was 19, Chris started the solution process producing these number bonds:

[0+19] [1+18] [2+17] This was in opposition with Chris’ initial theory of economy and probably happened because he realised that the use of the new strategy allowed him to avoid counting and any type of calculation all together. It allowed him to be successful and even more economic in effort.

DISCUSSION

Initially, Chris approached the task by applying a mixture of methods. The combination of these methods allowed Chris to complete the task successfully. However, he was not aware of his success since he kept looking for more number bonds even after all the possible number combinations had been generated. In the initial runs with the task, Chris focused his attention on each step of the solving procedure separately. He did not appear to have a whole view of the task that would allow him to relate one step with the other. Each one of Chris’ steps in the procedure can be viewed as a separate unit of behaviour elaborated enough for successfully achieving its goal. Separate units of behaviour, in the sense that there was no conceptual or causal connection established among them, were integrated into a unified solving approach. This approach was followed consistently for some time. It can be considered that at this phase, and in terms of the RR model, a first level of procedural success had been reached. A significant instance followed: Chris noticed a regularity in the numbers of certain number combinations and followed it to produce the next number bond. He found out that the new number sentence was arithmetically
correct, and maintained the regularity. Chris completed the task by applying a new strategy: the “ordering” strategy. An important change had occurred. Chris moved away from the initial mixture of isolated, though successful, methods and discovered a new strategy which he applied consistently for all the steps in the task. Within Chris’ meta-procedural approach to the task, previously isolated steps in the solution procedure were now connected into a simplified strategy. Gradually, Chris proceeded to the consistent application of the strategy in every single run. He started relying on the previous step in order to proceed to the next one. Chris treated what was previously a sequence of isolated problems as a single one. A unified strategy was generated and applied to the whole of the task. He realised the efficiency of this strategy and also the economy in its use. He verbally justified the choice to use the new strategy on the basis of this realisation. Chris had shifted from his initial success-oriented approach to a new one that allowed him to organise the different steps of the task into a consistent whole. This new approach allowed him to keep track of the number bonds that he produced and thus allowed him to develop awareness of the completion of the task and of his success. These changes in strategy employed by Chris indicate problem solving behaviour that has gone over to a meta-procedural level. Chris was now at an organisation-oriented stage where a new, simplified procedure was generated which allowed him to acquire a better control over the components of the task.

The examination of this case supports the idea that the construction of mathematical understanding is an ongoing process, as Kieren and Pirie (1994) and Lyndon and Pirie (1998) argue. However, the interpretation of the phenomena observed under the light of the RR model showed that children’s continuous search for better control and understanding of the problem situations in which they are involved is not merely restricted to, nor merely initiated by situations of difficulty, failure, or insufficient previous understanding. Stable states of success may also initiate and nurture children’s movement towards a higher conceptualisation of the problem situations and their developed strategies.

CONCLUDING COMMENTS

Overall, the data reported in this paper is an example of changes that occurred while working with a particular child in the context of a broader research project. At this stage, the data shown suggest that children introduce qualitative changes and modifications to their successful strategies. These changes indicate the passage from initial success-oriented behaviour to an organisation-oriented phase in the RR framework during which the problem solver acquired a better control over the features of the task. If this evidence is replicated in the wider study, then one theoretical implication is that the form and type of changes that the RR model accounts for, seem to pertain to the changes observed in children’s strategies within the setting of arithmetical problem solving situation. A practical implication of this for teaching is that if the process of Representational Redescription constitutes another way of
constructing knowledge, then it is worthwhile giving children the time and space they need to work upon the knowledge that supports their own successes.

Algebraic understanding and the importance of operation sense

Elizabeth Warren - Australian Catholic University

This paper examines young children's ability to generalise from their early experiences in arithmetic. A semi-structured interview was conducted with 87 children who had just completed their first three years of formal schooling. The purpose of this interview was to ascertain their understanding of 'turn arounds'. The results of the interviews indicated that many children are experiencing difficulties in reaching correct generalisations from their classroom experiences. These difficulties seem to be related to incorrect 'sense making', misleading teaching materials, and interference of new learning.

Introduction

With the recognition that students continue to experience many difficulties with algebraic concepts (Third International Mathematics and Science Study, 1998), the focus has moved to introducing algebraic ideas in the elementary grades. Kaput (1999) claims that we need to begin algebra early with an emphasis on sense making and understanding. Algebraic understanding evolves from viewing algebra as a study of structures abstracted from computation and relations, and as a study of functions (Kaput, 1999). Both these themes are believed to be appropriate for young children (NCTM Standards, 2000). As beginning algebra students progress from arithmetic thinking to algebraic thinking, they need to consider the numerical relations of a situation, discuss them explicitly in simple everyday language, and eventually learn to represent them with letters (Herscovics & Linchevski, 1994). This transition involves a move from knowledge required to solve arithmetic equations (operating on or with numbers) to knowledge required to solve algebraic equations (operating on or with the unknown or variable). It is believed that young children should be involved in making generalizations, using symbols to represent mathematical ideas, and in representing and solving problems (Carpenter & Levi 1999). This paper investigates young children's ability to generalise from their early experiences in arithmetic.

Early algebraic understanding

Two aspects are considered to be crucial in the transition from arithmetic to algebra. These are first, the use of letters to represent numbers and second, explicit awareness of the mathematical method that is being symbolised by the use of both numbers and letters (Kieran, 1992). This involves a shift from purely numerical solutions to a consideration of method and process. Yet many students experience difficulties in achieving this transition (Boulton-Lewis, Cooper, Atweh, Pillay & Wilss, 1998). Kieran and Chalouh (1992) suggest a reason for this is that most students are not given the opportunity to make explicit connections between arithmetic and algebra.
(Kieran, 1992). It seems that knowledge of mathematical structure is essential for successful transition (Boulton-Lewis, Cooper, Atweh, Pillay, & Wills, 2000).

An understanding of algebraic structure is typically derived from knowledge of the structure of arithmetic. In this instance, knowledge of mathematical structure is knowledge about the sets of mathematical objects, relationship between the objects and properties of these objects (Morris, 1999). It is about relationships between quantities (e.g., equivalence and inequality), properties of quantitative relationships (e.g., transitivity and equality), properties of operations (e.g., associativity and commutativity), and relationships between the operations (e.g., distributivity). In a beginning algebra course it is implicitly assumed that students are familiar with these concepts from their work with arithmetic. From repeated classroom experiences in arithmetic it is assumed that by inductive generalisation students arrive at an understanding of the structure of arithmetic. Thus, knowledge of structure is considered to be at a meta-level, derived from experiences in arithmetic. How do classroom experiences impact on students' ability to derive structure?

Previous research has documented ways in which students' arithmetic experiences constitute obstacles for the learning of algebra. Most of this research has focussed on the differences between the two systems, for example, differing syntax (Lodholz, 1993), closure (Kieran, 1992), use of letters as shorthand (Booth, 1989), manipulations (Booth, 1989), and equality (Wagner & Parker, 1993). Recent research has begun to focus on the development of young children's algebraic thinking (Falkner, Levi, & Carpenter, 1999), with a focus on children's understanding of equality. This paper adds to this research by considering young children's understanding of the properties of the operations.

The specific aim of this paper was to investigate young children's ability to recognise the generality of the commutative property and to discuss this property in everyday language.

**Method**

**Sample**

The sample comprised of 87 children from four elementary schools in low to medium socio-economic areas. The children are all participants in a three year longitudinal study investigating early literacy and numeracy development. The average age of the sample was 8 years and 6 months and all had completed the first three years of formal education.

**Interview**

Five tasks were developed for the semi-structured interview. The two tasks reported on in this paper probe students' understanding of the generality of the commutative
property, which is commonly referred to in our elementary curriculum as 'turn arounds'. Given the age of the sample and the number of years they had been studying mathematics, it was decided to limit the questions to addition and subtraction situations. By this stage of their schooling all children had completed their formal introduction to the concepts of addition and subtraction and could add and subtract numbers involving tens and ones. Task 1 involves probing children's understanding of 'turn arounds' for addition and Task 2 focuses on gauging whether children saw subtraction 'turn arounds' as being different from addition 'turn arounds'. For each task students were presented with 2 cards (see Figures 1 and 2).

\[
\begin{align*}
2 + 3 &= 3 + 2 \\
31 + 16 &= 16 + 31
\end{align*}
\]

*Figure 1*  Cards used for Task 1

After the completion of task 1 children were given the two cards presented in Figure 2 and were asked the same sequence of questions (see Figure 3) as for Task 1.

\[
\begin{align*}
2 - 3 &= 3 - 2 \\
31 - 16 &= 16 - 31
\end{align*}
\]

*Figure 2*  Cards used for Task 2

The script for the interview was as follows:

<table>
<thead>
<tr>
<th>Script for Task 1 and task 2</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ask</td>
</tr>
<tr>
<td>What can you tell me about the number sentences on these cards?</td>
</tr>
<tr>
<td>Are they true or not true?</td>
</tr>
<tr>
<td>(If the child says that they are true) Explain why they are true.</td>
</tr>
<tr>
<td>(If the child says that they are not true) Explain why they are not true.</td>
</tr>
<tr>
<td>Can you give me some more examples? Can you give me some examples that are true?</td>
</tr>
<tr>
<td>Describe the pattern in your own word</td>
</tr>
</tbody>
</table>

*Figure 3*  Script for the interview

The interviews were audio-taped and the scripts transcribed for analysis.

**Results**

An examination of the transcripts indicated that the responses to the two tasks fell into five broad categories. The next section describes each of the categories and includes a typical response for each.

**Category 1 (Correct generalisation)**
For task 1, the child stated that the two cards for addition were true, gave some more examples and clearly explained in their own words how to form such examples. For task 2, the child stated that the two cards for subtraction were false (not true) and gave a valid example of why they were false. A typical response was as follows:

**Task 1**

*What can you tell me about these number sentences.*

They are turnarounds.

You can really only do turnarounds with addition.

*Can you give me some more examples*

5  4
+4  +5

*Are these statements true*

Yes

**Category 2 (False generalisation)**

The child stated that all four cards for the two tasks were true, gave some more similar examples and clearly explained in their own words how to form such examples. A typical response was as follows:

**Task 1**

They mean that it is a turn around.

*Are they true or false*

True

*Can you write some more turnarounds for me*

16 + 13  13 + 16

**Explain**

It's a turn around because if you had 31 and add 16 I could turn it around so that it is 16 plus 31

**Task 2**

*What about these two?*

They are both turnarounds.

*Are they true or false? True*

*Can you give me some other examples of turnarounds?*

Wrote 18-6

6-18

*How would you explain that to someone else?*

Now it is take away and if I had 18 over there and 6 over there I would turn it around so that I would have my 6 over there and my 18 over there.

*Could you give me a subtraction example?*
Subtraction means you take away.
Subtraction is like a give away - If I had 12 bricks over there 8 bricks over

**Category 3 (Interference of question’s format)**

For this category the child stated that all four cards for the two tasks were false. A very common reason for this stance was that there should only be one number after the equal sign. A typical response was as follows:

**Task 1**

Not true
Because the = is meant to go last and the plus first
Because = is in the middle and there is another plus after the equal and it doesn't equal 3 + 2 it is meant to equal one number. You can have 2+3=5

*After the equals how many numbers do you think there should be? one*

Should be 31+16= should be 47 - you have to take away the plus sign

**Category 4 (Interference of new learning)**

The category represents responses where children seem to be experiencing some confusion due to over generalisations of new learning. For example, two children could now take 3 from 2 as they had recently been introduced to 'trading'. Another two posited responses as follows:

**Task 1**

True
Because you can add them up
*What do you mean - can you write another one that is true*
A plus or a take away
(wrote) 32+17=
The biggest number is at the top
*What about this one here (16+32)*

That's not true - you have to add more

**Task 2**

Not true
Because 31-16= 15 and they have a take away sign there and the number 31 at the end of the sum so it should be 31-16=15. It meant to be 2 take away 3 is one but they have 2 take away 3 equals 3 take away 2. But if it was three take away two it would equal one.

Has the first number always have to be the biggest Yes
Is 2 plus 3 true No

**Task 3 true**

16 take away 31 and 2 take away 3 are not true because 2 can't take away 3
Because it is too small it is below 3

*What about if I wrote down the plus one*
16+4 =

Can I do the second one - NO

2 + 28 =

Because 2 is too small.

Can I do the first one - YES

**Category 5** (unable to respond to the task)

Each response was coded according to the five categories. Table 1 summarises the frequency of responses in each category.

**Table 1 Frequency of response for each category**

<table>
<thead>
<tr>
<th>Category</th>

<td>5</td>
</tr>
<tr>
<td>5</td>
<td>No response</td>
<td>4</td>
</tr>
</tbody>
</table>

The majority of children failed to reach the correct generalisations.

**Discussion and conclusion**

The results of this study present three differing themes. First young children certainly seem capable of reaching generalisations, even if these generalisations are mathematically incorrect. Most are engaged in sense making and understanding (Kaput, 1999). For example, Mitchell until recently could not make 'sense' of 2-3. Children in his class have recently been introduced to the notion of trading. He stated *I can now do these. 2 take away 3 you can't do so you cross that one out (2) and put the 12 up there and then 12 take 3 is 9.* While this is not mathematically correct he felt very satisfied with his response. Young children are also capable of expressing their generalities in simple everyday language, a necessary step for progressing from arithmetic to algebraic thinking (Herscovics & Linchevski, 1994) and in most instances can offer further examples.

Second the types of classroom experiences that children are engaging in seem to interfere with them reaching valid generalisations. In this instance, teaching materials appear to be acting as cognitive obstacles to abstracting the underlying mathematical structure of arithmetic. A number of instances of these obstacles were presented in the data. The format of the cards themselves caused difficulties for some children. Samantha stated *I've never seen them written like this before. I write 31 take 16 = (and mimed the vertical algorithm). I don't know if they are true or false,* indicating that she had never seen expressions written in a horizontal format. The position of the
equal sign also caused difficulties (see the response for category 3). Children's understanding of "=" also caused difficulties. Many of the responses in category 3 stated that 2+3 doesn't equal 3 and offered 2+3=5+2=7 as how the first card for Task 1 should be written. This confirms Anenz-Ludhow and Walgamuth's (1998) claim that many children in elementary grades generally think that the equal sign means that they should carry out the calculation that proceeds it and the number following the equal sign is the answer to the calculation. Again, this misunderstanding seems to be caused by teaching materials that predominantly involve getting answers to problems. In another section of the interview many children stated that 'equal means altogether, the answer'.

Third children's misunderstandings also seem to be based on intuitive assumptions about applying new ideas to other familiar situations and interference from new learning in mathematics. Most of the children in the sample had had some classroom experiences with 'turn arounds' but, as indicated by the responses, these experiences seemed to be limited to addition situations. When presented with the subtraction task man simply applied their new understanding to this situation. Some tried to make sense of this intuitive assumption and changed their response during the interview. For example, Lucas stated 2-3=3-2 is true. 31-16=16-31 is true as well. I am thinking that they may not be true. Because 2 is not higher than 3 and 3 is higher than the 2. But 36% were convinced that their intuitive assumption was correct. As indicated by the response to category 4, new learning seemed to also cause difficulties for some children. The introduction of subtraction interfered with their understanding of addition and the introduction of trading interfered with their understanding of subtraction.

From this research it seems from their classroom experiences with addition and subtraction young children have already developed misunderstandings with regard to the commutative property. When developing curriculum materials for the early years we must take into account that young children are engaging in sense making. We need to ensure that the ideas and materials we are presenting at this level help children abstract the structure of arithmetic rather than act as cognitive obstacles to future learning. From this study it seems that the misunderstandings these children are experiencing are based on pragmatic reasoning about new notions, the effects of misleading teaching materials and classroom experiences, and interference from new learning in mathematics.

A MATTER OF PERSPECTIVE: VIEWS OF COLLABORATIVE WORK IN DATA HANDLING

Jane M. Watson
University of Tasmania

Helen L. Chick
University of Melbourne

Abstract: This paper reports on a study of students' collaborative group work in a grade 5/6 classroom using an open-ended task from the chance and data part of the mathematics curriculum. It considers (a) students' beliefs about collaborative group work compared to their actions; (b) observations of student knowledge, learning, and outcomes during collaboration compared to understanding displayed in individual interviews after work was completed; (c) students' accounts of events that took place in their groups compared with what was recorded on videotape; and (d) students' perceptions of the task and their beliefs about the mathematics curriculum.

Introduction

This study is one of a series examining students' collaborative work using an open-ended data handling activity. Earlier studies identified factors associated with small group collaboration in a near-classroom situation, examined the use of an open-ended mathematical task in that environment, and documented help asked for and provided during the collaborative sessions (Chick & Watson, 1998; Watson & Chick, 2000, in press). In the grade 5/6 class used for this research, the teacher claimed to employ collaborative work in mathematical problem solving. She also said that the students knew the expectations, which included that everyone in the group understood how the result was obtained. For the current study, students were video-taped working in groups, and were also interviewed after the collaborative activity about their beliefs and understanding. These two sources of data provided an opportunity to observe and compare students' actions, beliefs, and potential contradictions in behaviour. This allowed the investigation of four key themes.

Views on collaboration. With the use of collaborative activities in the mathematics classroom becoming more common, it is recognised that students need to appreciate the benefits, be willing to work with others, and (sometimes) be taught necessary skills. It is also acknowledged that whereas some students see the benefits of collaboration (e.g., Watson & Chick, in press), others would prefer to work alone (e.g., Barnes, 1998). Ross and Cousins (1994) observed that students' intentions to seek and give help were not necessarily associated with their behaviours when participating in group work.

Did students learn what it appeared they did? Decisions about what students have learned in classroom settings may be made based on output produced (e.g., Chick & Watson, 1998), test scores (e.g., Webb, Troper, & Fall, 1995), comments recorded on videotape (Cobb, 1999), questions asked or answered (e.g., Watson & Chick, 2000), or post class interviews (e.g., Clarke, 1998; Frid, 1994). In this study transcribed
videotapes were used to examine understanding during collaboration. This was compared to the understanding exhibited in individual follow-up interviews.

Recollection of events. During individual interviews students were not specifically quizzed about what happened in their groups, however they recounted what had occurred when asked to explain their group’s poster and when asked if there was anything else that their group might have considered. Of interest were discrepancies in the accounts given by students and the actual events as recorded on videotape.

Is this maths? Students’ negative views of mathematics and lack of confidence in the subject are well documented (e.g., Leder, Pearn, Brew, & Bishop, 1997). The introduction of chance and data to the curriculum had the potential to assist in softening the perceived profile of mathematics through the use of concrete materials, the inclusion of social applications, and the need for students to make personal judgements in decision-making. Of interest is what effect this has had on students’ ideas of what mathematics is and its usefulness in everyday life.

Research Questions

In light of the above considerations, four questions were addressed. (i) Were students’ beliefs about the value of collaboration as expressed during individual interviews consistent with their behaviour observed on the videotape? (ii) Were the observations of student knowledge, learning, and task outcomes consistent with that displayed in later individual interviews? (iii) Were students’ accounts of events that occurred during their group work consistent with what was observed on videotape? (iv) To what extent did students question the mathematical nature of the task set?

Methodology

Procedure. Twenty-seven students in a combined grade 5/6 classroom in a suburban Australian primary (elementary) school took part in three 45-minute collaborative problem solving sessions involving an open-ended task from the chance and data part of the mathematics curriculum. The teacher assigned the students to groups of three, all with mixed gender. Seven groups had a mix of grades. Although the class had participated in group work on other occasions, the groups assigned for this activity were different from previous groups. The groups of three students were distributed around the classroom, half of the class at a time, with a video camera trained on each group. Except for a few initial instances of showing off for the cameras, the students ignored their presence. The task set for the students was to study a set of 16 data cards that contained the following information on each of 16 imaginary students: name, age, eye colour, favourite activity, weight, and number of fast food meals eaten per week. The students were asked to prepare a group poster displaying what they had learned about the 16 students. More details of the task are provided in Watson and Callingham (1997). After the three sessions, each group showed and explained its poster to the rest of the class, the two teacher/researchers who conducted the sessions (one of whom was the second author), and the classroom teacher. A week later the first author, who had not been previously involved with the class, interviewed all 27
students individually with a sequence of questions related to what occurred during the collaborative sessions, what the students understood of the task, and their views of working in groups. All students were happy to talk about the activity and none appeared to show any nervousness.

Analysis. The research team that analysed the data included, at various times, the authors, the second teacher/researcher present in the classroom, the transcriber of the videotapes, and a research assistant. The analysis of the data from interviews and videotape of the group sessions was similar to that advocated by Clarke (1998), adapted to meet the aims of the research questions. His *complementary accounts methodology* combines various sources, includes the reflective voice of the student, and employs a multifaceted analysis by a team of researchers. He asserts that an individual’s learning process is embedded in a complex social context, and is “an integration of not just the obvious social events that might be recorded on a videotape, but also the individual’s construal of those events, the memories invoked, and the constructions that arise as a consequence” (p. 100). In Clarke’s approach students viewed classroom videotape during their interviews. This was not done here because it was felt important to make comparisons of the students’ memories and beliefs about what had happened in the collaborative setting.

Data. There were 15 boys and 12 girls in the class; 5 boys and 4 girls were in grade 5. The data that were collected for each student included: gender of student, grade of student, assigned group, statements made about the activity and mathematics itself, understanding exhibited during group work and during the interview, descriptions of events occurring during group work that differed from that observed on videotape, description of collaborative or non-collaborative actions observed on videotape, and stated beliefs on collaboration during the interview. Where subjective decisions had to be made, these were decided by three or four members of the research team.

Results

Contradictions of belief and action on collaboration. Students were classified according to (a) whether their behaviours during group sessions were collaborative (or non-disruptive) or non-collaborative, and (b) whether the beliefs expressed during the individual interview supported collaborative work or not. Eleven students displayed predominantly collaborative behaviour, whereas 15 were classified as non-collaborative. In interviews 12 students said that, in general, collaboration is good, 12 had a negative view of collaboration, and 3 expressed both views with justifications (see Table 1). Some students expressed mixed views: they usually liked working in groups but not in this one, or they did not mind this group but did not always like working in groups. Of the three who strongly expressed both views, one girl showed both types of behaviour. She gave the boy in the group a dig with her elbow and hid the group’s work from him so he could not collaborate, but she also gave him a great deal of help drawing graphs. In her interview she said she liked working in this group but did not always enjoy group work. This student was not classified in Table 1.
Table 1. Association of expressed belief in collaboration with observed behaviour
during group work (n = 261).

1One girl displayed both positive and negative beliefs, and collaborative and non-
collaborative behaviour. She is not included in the table.

2Two boys expressed both positive and negative views of group work, with justification.

Two boys, judged to display non-collaborative behaviour, also expressed mixed beliefs in relation to group work. One, who hoarded cards and flicked pencils and rubber bands, said that although “sometimes some of the people in the group were a bit silly, a bit uncooperative,” the group worked quite well as “I got to know my partners better” and “[I’m] glad I worked with the group.” The other boy was not disruptive but was often non-collaborative, ignoring questions from the other boy in his group and making all group decisions himself. In the interview he said “Yeah, we cooperated ... and I learned ... I guess with a group you just have to cooperate,” but he also liked working alone because he could follow his own ideas. This boy was judged by the research team to be one of the brightest students in the class.

Four students who were judged to behave in a collaborative or non-disruptive fashion and who said that they liked to work in groups, were, in fact, observed to be ignored or abused by other group members. The other four students in the “collaborative-positive” cell of Table 1 were from the two most cooperative groups. The three students who generally behaved collaboratively but had negative views of group work were observed to be quiet students. In the case of one girl, one of the boys in her group was particularly disruptive. The third group member, a collaborative boy, noted that he would rather have worked on his own, as “sometimes when you needed the card another person had it, you couldn’t get the card when you needed it.”

Of students showing non-collaborative behaviour, 4 expressed positive views and 9 negative views, with, as noted above, 2 expressing both. Overall the groups from which these students came were judged among the least collaborative. There was a high representation of boys in the group displaying non-collaborative behaviour and having negative views of group work. Overall, about two-thirds of the class showed consistent behaviour and beliefs. No effect for students’ grade level was noted.

Discrepancies in understanding. When the responses from the individual interviews were compared with the understanding displayed during group work sessions and the poster presentation, 16 of the students appeared consistent in their understanding of the task and what they had done. However, explanations from 11 students appeared quite different from those originally observed. Of these students, 6 (3 boys, 3 girls)
had difficulty explaining what they had done in the group work sessions. One helped
the others in her group construct their graphs during the group sessions but had
trouble explaining her own graph during the interview. The other 5 students (of the
11) appeared to verbalise better understanding than they showed during group
sessions. Three were girls, of whom one missed the final session and so did not
contribute to her group’s poster. One could state hypotheses about relationships
among variables of which she appeared unaware during the group sessions, and one
discussed a larger number of variables (for example differences between boys and
girls) than during the group work where she appeared to consider only one,
“hobbies”. The two boys appeared to concentrate on the interview questions in
contrast to their classroom behaviour, and provided better explanations than they had
produced earlier.

Discrepancies in fact. In recounting events that occurred during group sessions, five
students’ descriptions differed markedly from events as recorded on videotape. One
boy who hypothesised about the relationships among the variables claimed he did not
graph any of these. He did graph at least one but due to the domineering attitude of
the older girl in his group, he threw it away. He also claimed that all three had
contributed to the group’s graph, when in fact he and the other boy were only allowed
to do “colouring in”. Another boy explained why his graphs, rather than those of the
other boy in the group, were used on the poster by saying a teacher/researcher told
the group not to put “wrong data” on it; hence the other boy’s graph was not used.
Nothing said by the teacher/researcher on the videotape could be construed this way.
The three girls with contradictory accounts of what happened were all dominant
individuals in their groups. One said she wanted to graph eye colour, whereas during
the group sessions she repeatedly stated that she did not like the idea at all. The
second stated that her group had produced another graph that did not get on the final
poster. Although a different graph was suggested by another group member, this was
not even started. The third said her group discussed which graph to produce when in
fact there was no discussion, she just demanded that her idea be carried out.

Is this maths? During group work 4 of the 27 students actively questioned whether
the activity had anything to do with mathematics. Three boys and a girl asked
variations on the theme: “What does this have to do with maths?” Another girl asked
the second author in the course of the group work, “How can you like maths?” These
five students’ responses reflect some of the stereotypical views still present in the
classroom. Students were not purposely questioned on these beliefs during their
individual interviews, as the ideas were not part of the original research brief and
because of the possibility of influencing responses to other interview questions.

Discussion

This class was not selected because it contained highly able students trained in a
specific regime of collaborative behaviour. It was selected to observe what happens
in a typical classroom in a typical school where collaboration is at least superficially
known to be part of the teacher’s program. The class was judged by its teacher to be “average”, but she was confident students understood how to work collaboratively. The research team agreed with the teacher about the students’ ability level and considered that the cognitive outcomes did not reach the level of other grade 6 children using the same task (e.g., Watson & Callingham, 1997). This study provides information for those who wonder how collaboration works in the “real world”.

With some students indicating that sometimes they liked group work but not this time, or that they liked this group but not all group work, it may be that the specific make up of the group determines its success. It is interesting to note the differing experiences of the eight students who behaved collaboratively and expressed positive views about group work. Half were from groups judged to be the most disruptive and half were from the least disruptive groups. For the four students who had experienced abuse or been ignored, the contrast between views and experienced behaviour was not discussed in the interview. It is possible that they had experienced other more positive collaborative environments that compensated for this unpleasant experience or were reflecting a view they thought that the teacher wanted them to express. For the other four students, whose beliefs matched their behaviour, it might be expected that since their beliefs and behaviours coincided this contributed to relative harmony in their two groups. Whether these attitudes and actions were engendered by previous events in the classroom or the influence of the teacher is impossible to determine.

Of the 56% of students judged to have behaved in a non-collaborative fashion, a third were supportive of group work. Two of the girls in this category were among three dominant females who dictated terms within their groups. The research team suspected that some comments from students supporting collaboration—such as “It was easier to work together because you worked as a team”—closely resembled the opinions of their teacher. It is, however, impossible to determine if the students were speaking from genuine belief or from a “politically correct” position they had learned in the classroom. Of the two-thirds who were consistent in showing non-collaborative behaviour and negative beliefs most (9 of 11) were boys, including two whose views were equivocal. It is interesting that all members of one group were in this cell of Table 1, including the only two girls. This group comprised two grade 6 girls and a grade 5 boy and it appeared to the researchers that the grade and gender mix of this group, with a dominant but mathematically inept girl, was particularly unproductive.

The difference in understanding displayed at individual interviews from that observed during the group work sessions, particularly for the six students unable to explain the work done previously, is disturbing. Several possibilities exist to explain the apparent decline. Although all students appeared completely at ease during the individual interview with the first author, it may be that some were confused by the presence of the camera and a new researcher. It is also possible that in the intervening week students had forgotten what they had done. All appeared to remember the sequence of events but details may have been lost. Alternatively it is possible that students picked up comments and language from other members of their groups, which they utilised
during group sessions and quickly forgot. The research team felt confident in the attribution of understanding during these sessions, certainly in several cases where the students appeared able to help others in their groups. The five students whose understanding of relationships appeared better at the time of the individual interview may have gleaned further information from the poster presentations made after the group sessions but before individual interviews, and further digested comments made by other group members. The fact that 41% of students displayed discrepancies in two apparently reliable settings, points to the need to collect information on student understanding from several sources.

The five students who gave discrepant accounts of events that occurred during group work were all in the non-collaborative category in terms of observed behaviour on the videotape. Two of the girls' beliefs about group work contrasted with their behaviour and one boy was equivocal about group work. Although it is impossible to be certain, it may be that these students wanted to make their own positions look more positive by describing events differently from the way they actually occurred.

The observation of student comments on mathematics and its relationship to the task was a serendipitous outcome of comments captured on videotape. The comments may reflect the fact that these children had had no graphing or other data handling activities in this class. They point to a need to include data handling activities at all levels and to connect them to the goals of the mathematics curriculum.

**Conclusion**

Overall the results of this small study of students' behaviour, in what was claimed by the teacher to be a collaborative environment, were disappointing to the research team. Critics of this study would undoubtedly say that the students had not been properly trained in the techniques of cooperative group. Given the social conditions and time available in many schools, however, it is fair to ask what is realistic in terms of training time for cooperative group work. Good, Mulryan, and McCaslin (1992)—who considered the role of teachers in preparing students, classroom management, age of students, and the role of explanations—concluded, "It is doubtful that there is a common shared experience of small group learning ... Experiences ... are better thought of as probabilistic than as predictable” (p.190).

If collaborative group work is an aim for teachers, then it would appear that in "typical" classrooms such as the one studied, more preliminary work is required to create the proper expectations in students. It is also necessary to consider carefully the assignment of students to mixed-gender and mixed-aged groups. The teacher of the class in this study believed her students would work cooperatively in the groups she assigned, yet the groups appeared to display many shortcomings.

The Teacher's and Students' Important Roles in Sustaining and Enabling Classroom Mathematical Practices: A Case for Realistic Mathematics Education

Joy W. Whitenack, Nancy Knipping & Ok-Kyeong Kim
University of Missouri-Columbia

Abstract

This paper is a preliminary report of a second-grade classroom teacher experiment. The primary aim of this paper is to address the important role the classroom teacher and the students play in sustaining the classroom mathematical practices. To advance our ideas, we use excerpts from one discussion to illustrate the teacher's keen ability to consider aspects of the children's self-generated models. By capitalizing on such instances, the teacher not only provides possible learning opportunities for individual students but also makes it possible for the researchers to anticipate the emergence of subsequent more sophisticated practices.

In this paper, we provide a preliminary report of a second-grade classroom teaching experiment that was conducted during the 2000-01 academic year. The overall aim of this project was to support the children's flexible, mental reasoning with two-digit quantities. In particular, we explored the possibility of accounting for the children's learning as they moved from using informal to more formal ways of interpreting problems and recording their thinking. As a secondary goal, we hoped to refine an instructional sequence, Aunt Mary's Candy, to support the children's arithmetical reasoning. Our reasons for doing so were quite pragmatic. Because the classroom teacher was also using a newly adopted curriculum (that was compatible with the instructional sequence), the teacher needed to determine how she could infuse the sequence with the regular curriculum without threatening the integrity of either.

In our discussion here, we elaborate the significant role the classroom teacher and students can play in sustaining and the classroom mathematical practices. The teacher, for her part, must recognize important aspects of the students' interpretations and associated representations as they work individually, with partners or when they engage in whole class discussions. As she does so, she must employ strategies to make these interpretations explicit for the students. More generally, she must develop ways to infuse the children's idiosyncratic methods with the collective ways of interpreting and communicating mathematical ideas. At the same time, she must be flexible enough to advance ideas that support the emergence of new mathematical practices. As such, the teacher is faced with enormous challenges as she supports her students' mathematical learning. The students, for their part, must make sense of their activity and develop ways to notate and communicated their ideas to others. Before we address these issues, however, first we couch our discussion in theoretical assumptions and methodological issues that framed our efforts. We then provide examples from one classroom discussion to illustrate how the teacher and students can sustain and enable the classroom mathematical practices.

Theoretical Considerations

Instructional Design Theory of Realistic Mathematics Education. With regard to Realistic Mathematics Education [RME], Gravemeijer (1999) makes a strong case for the role curriculum might play in supporting children's formal mathematical reasoning. In particular, he elaborates several heuristics for developing and implementing instructional activities. One such heuristic is the role students' models can play in supporting their mathematical learning. These models are thought to emerge from the students' own understanding of a problem situation that is couched in a rich context. As students engage in problem solving within this context, they develop informal ways of representing their interpretations and solution methods. Eventually their models take on a life of their own and can be used to reason mathematically without referring to the original problem context, that is, these models are transformed into more formal ways of reasoning.

In our view, mathematical meanings are socially accomplished by reflective individuals (Lave & Wenger, 1991; Cobb & Bowers, 2000). These meanings are negotiable as individuals reflect on their own and others' actions. That is, these meanings become social objects as individuals mutually orient themselves to one another's activity. One the other hand, these meanings have their roots in individual students' sense-making as they participate in mathematical activity that is valued by the teacher, the school district and the community at large. As such, we assume that the individuals' sense-making activity and the social situations in which they engage are inseparable and situated in various communities of practice. Although we acknowledge that social situations contribute to what constitutes knowing and doing mathematics in various communities, because our interest is that of mathematics learning in classrooms, our primary focus here is to elaborate the socially-situated nature of mathematics learning within this particular classroom microculture. (e.g., Cobb & Bowers; Lave & Wenger).

By coordinating RME with this situative view, the models that the students manipulate, adapt, or transform, although idiosyncratic per se, contribute to sustaining and enabling the taken-as-shared mathematical practices that emerge during whole class discussions.

Aunt Mary's Instructional Sequence. As one of the goals of the project, in collaboration with the classroom teacher, Ms. Wilson, we developed a series of activities to support the students' flexible manipulation of two-digit quantities for addition and subtraction situations. We adapted tasks from previous classroom teaching experiments conducted by the Purdue Problem Centered Mathematics Curriculum Project (Cobb, Yackel, Wheatley, Wood, NcNeal, Preston, & Merkel, 1992) and the Mathematizing, Modeling and Communicating in Reform Classrooms Project (Cobb, Yackel & Gravemeijer, 1995). Using some of these previously developed materials, we collaborated with Ms. Wilson to design an ongoing context about candy that her Aunt Mary made and distributed at various community...
functions, or gave to family members and friends. As the students worked in this context, they first created physical collections (with multilink cubes) to represent packages (collections of ten) and pieces of candy (collections of ones) and later drew pictures to reason about addition and subtraction situations involving Aunt Mary's candy. Making physical and pictorial collections allowed the students to engage in informal problem solving situations. These experiences, in turn, eventually allowed them to develop ways of notating and symbolizing that fit with more formal ways of notating and interpreting addition and subtraction situations (cf. Gravemeijer, 1999).

The activities Ms. Wilson introduced were designed so that the students could develop their own notational methods to explain their thinking about collections of tens and ones. Yet, certain ways of speaking about and notating how they broke apart and recombined collections of tens and ones became commonly used by many of the students. Typically, students drew rectangles to represent packages of ten candies and small circles to represent individual, loose candy. When solving subtraction situations, they usually crossed off loose pieces and subtracted additional pieces to take away the amount they needed to subtract. Whereas there was some variation in how they marked the packages, their notational methods and accompanying interpretations appeared to be understandable to the other students.

Methodology

Data Collection and Analysis. Data collection techniques included videotaping the daily lessons, making field notes, and collecting samples of the students' independent and small-group work. We gathered additional information as we talked to children each day and observed their mathematical activity. In addition to these data collection techniques, we conducted clinical interviews with each child at the beginning and end of the project to document their progress.

To analyze the data, we first perused our field notes to identify key lessons. After watching videotape recordings of several daily lessons, the videotape recording of one representative lesson was transcribed so that we could conduct further analysis. We also analyzed the children's written work samples to characterize their notational methods. Analysis of the children's written work was then triangulated with the whole-class discussion to reconstruct to the events of the lesson.

Classroom Episodes

The example we use here was taken from a lesson that occurred several weeks into the instructional sequence. The example is part of a whole class discussion that occurred after the children worked on several addition and subtraction tasks. After the children had completed several of the problems, Ms. Wilson asked them to join her in the front of the room to share their ideas. To begin the discussion, Ms. Wilson asked two children to come to the blackboard at the same time and show how they solved the following problem:
Aunt Mary has 11 pieces of candy on the counter. Uncle Johnny eats 0 pieces of candy. Show how much candy she has now.

Each child then explained his or her drawings on the board. We enter the discussion as Alice, the first child, explained how she solved the problem. She had drawn two packages showing each of the pieces of candies and four loose pieces (See Figure 1a). She then labeled each package with the numeral ten, the four loose pieces, and circled the six candies that she needed to take away. Interestingly, she also wrote two number sentences (20 + 4 = 24, 24 - 4 = 20). As her sentences indicated, she did not include the two loose pieces that she took away as she recorded her answer of 20. We enter the discussion as Ms. Wilson asked Alice to explain her drawing:

Teacher: Alice would you tell us about your drawing?

Alice: Yeah. Well first of all, I knew that if I had a package of ten (points to one of her packages) well um, what I did, I writed out and separated them and circled the ten and put a ten at the bottom. And then I made another package of ten...over here and then I circled that and put a ten and I added this ten with this ten and that made it twenty. And then I knew that I had to add the four [pieces] on (points to the four loose pieces) so I put the four over here and I got twenty-four.

We infer from Alice's explanation that telling about her drawing meant to describe what she had drawn. As the discussion ensued, Ms. Wilson asked Alice about her picture. In doing so, Ms. Wilson prompted Alice to provide a rationale for her drawing.

Teacher: And what you are showing is what Aunt Mary has on the counter right now. Right?

Figure 1. (a) Alice's and (b) Luke's written records for 24 - 6 = ?

We infer from Alice's explanation that telling about her drawing meant to describe what she had drawn. As the discussion ensued, Ms. Wilson asked Alice about her picture. In doing so, Ms. Wilson prompted Alice to provide a rationale for her drawing.
Alice: (Nods yes.)
Teacher: Can I ask you a question before you go on to explain?
Alice: (Nods yes.)
Teacher: You said that you laid them out as pieces that and you circled them so that we would know that they were packages. What made you lay them out in pieces like that?
Alice: Because I knew if I did it the other way, that it would be harder. [It would be harder] to draw it to make the package torn apart.
Teacher: Okay, so you did it so that you could see the packages when you wanted to tare them apart. Okay. So you have your twenty-four sitting out there, so now what are you going to do?

Ms. Wilson's question to Alice about why she showed loose pieces in each package is very important. By asking this question, "What made you lay them out in pieces like that?," Ms. Wilson made it possible for Alice to explain why she needed to show all the individual pieces. In essence, Ms. Wilson implicitly communicated to Alice and the other students that her drawing was valued. By making all the pieces visible, Alice could easily manipulate the pictorial collections to reason sensibly. When we consider the fact that Alice predominantly used counting strategies during her interview session and had difficulty solving tasks involving numbers over 20, her rationale seems quite fitting. Further, by asking this question, Ms. Wilson made it possible for the other students to understand why Alice chose to show the packages this way. The students had an opportunity to consider the particular details of Alice's drawing.

Following this exchange, Alice explained how her number sentences fit with her pictures but did not notice that her answer would be 18, not 20. As the discussion continued, Ms. Wilson prompted Alice to explain her answer:

Teacher: Okay and then you circled some other pieces there. Um, what did you circle those pieces for?

Alice: Oh because, um, remember I said that Uncle Johnny ate six [pieces]
Teacher: Okay. And show where those six are that you [circled].
Alice: Well, I knew I had four, and then I knew that I had to use another package. So that I can get six because there is no other, um, there's no other way to get to six. So I took the four and put a line, and then I circled the four, I mean two, and then I counted them and figured out four, (points to the two pieces in the package and counts) and then five, and then six.

At this juncture, Alice moved beyond merely describing her drawing to giving a reason for why she circled the six loose pieces. We suspect that Ms. Wilson's question about the circled pieces was particularly significant in helping Alice explain.
her thinking. Initially, Alice may not have realized that she needed to use her picture
to explain her thinking. However, at this point in the exchange, she explained in
some detail her thinking using the drawing.

Following this exchange, Ms. Wilson asked Alice to determine how many pieces of
candy Aunt Mary had left. After counting the remaining candy, Alice changed her
answer to 18. She then changed her number sentence $24 - 6 = 18$.

As the discussion continued, Ms. Wilson redescribed Alice's picture to the class. As
she did so, she communicated to the students that Alice had made an important
contribution to the class. We share part of her comment to illustrate how Ms. Wilson
capitalized on aspects of Alice's drawing:

Teacher: This is a really neat way of looking at it. [This is] something I hadn't
really thought about, Alice. But it really makes a lot of sense to me. She
knew that Uncle Johnny ate more loose pieces than she had loose pieces
sitting on the counter. So what she decided to do is to go ahead and
show the pieces loose, and then she could work with them real easily.
But she wanted to make sure we knew that she still had two packages.
So she just drew the candies as if Aunt Mary had not yet quite packaged
them up yet. She [Aunt Mary] had them in rows of what she was going
to package. So you can see the loose pieces (points to the two packages
Alice has drawn)...

Ms. Wilson’s comment here addressed to two important points. The first point relates
to representing Aunt Mary’s packages as loose pieces. Alice had a reason for drawing
the loose pieces in each package. It was easier for her to work with the packages if
she drew all the pieces. Also, by making the loose pieces, her pictures were
understandable to the rest of the class. Second, we note that Ms. Wilson and Alice,
together, made it possible for certain mathematical ideas to emerge during the
discussion. For Ms. Wilson’s part, she aligned Alice’s reasoning with how the class
thought about and represented Aunt Mary’s candy. Alice also contributed to this
process when she provided a rationale for making her packages as loose pieces and
explained her solution process.

After redescribing Alice’s drawing, the second child, Luke, came to the blackboard
and explained his drawing (see Figure 1b):

Luke: I crossed off the two pieces to make six and so, um, so that that would
then be eight little pieces. And then those x's are for showing that Uncle
Johnny had already had eaten them. And then I did that [drew the 8
pieces] so that you could see that there were eight more pieces (points to
the eight loose pieces he has drawn on the blackboard)...And, and that’s
how I got the number eighteen (points to the numeral 18).

Luke, interestingly, used his drawing to explain how he solved the problem. In
response to Luke’s explanation, Ms. Wilson again underscored the significance of his
as well as Alice’s drawings and associated interpretations:
Teacher: What Luke did was a really, really neat thing. Because what he did was he went ahead and drew what Aunt Mary had on the counter, okay? And kind of like Alice, he imagined this [package] (points to the package that Luke has used to cross off two pieces) being broken up into pieces I think. And he said (points to the fours loose pieces that are crossed out) "I have four pieces that I can take away for what Uncle Johnny eats plus I need two more from this package" (points to the two pieces crossed out from one of the packages). And then he shows us (makes a circle with her hand around the eight loose pieces left) the eight pieces what he has left when he takes them away.

As Ms. Wilson redescribed Luke’s picture, she specifically indicated how his picture was different from Alice’s. Luke did not show the individual pieces contained in each package. As she indicated, he “imagined” that he could break apart a package to subtract the two additional pieces. By making this distinction explicit, Ms. Wilson communicated that she particularly valued how he reasoned with his drawing. By redescribing his explanation, Ms. Wilson also implicitly communicated that Luke had offered what constituted an acceptable explanation. Liam, for his part, contributed to this process by explaining his thinking using the pictorial collections.

Final Remarks

As we revisit our classroom example, we note that this discussion constrained and enabled the classroom mathematical practices. On the surface of it, the children’s contributions were not mathematically different—both children offered very similar methods for solving the task. However, as we consider the quality of the children’s explanations, their drawings point to different ways they participated in these practices. Whereas both children subtracted the loose pieces by taking away two pieces from one of the packages, how they made their pictorial collections signified very different ways of reasoning with the packages. Alice needed to count individual pieces, whereas Luke appeared to act with the packages as abstract collections (Cobb & Wheatley, 1988). The challenge then for the classroom teacher was to align the students’ idiosyncratic interpretations with the emerging practices. As in our example, by juxtaposing these two children’s explanations on the blackboard, Ms. Wilson could highlight the different interpretations the children might give as they decomposed and recomposed pictorial collections of tens and ones.

This example also points to the possible learning opportunities that arise during classroom discussions. Children like Alice might curtail how they made packages as pictorial collections. As a consequence of participating in this discussion, Alice had the opportunity to understand how other children reasoned with the packages. As such, she may develop interpretations that fit with how Luke acted with the pictorial collections. Luke could act with the collections without having to remake the individual pieces that composed each package. Further we clarify a collective conceptual shift that the class may make as they begin to act with their drawings in ways that are similar to how Luke solved the task. They may move from counting to
making pictorial collections to reason with pictorial collections of abstract tens and ones.

These situations could also be learning opportunities for students like Luke. As they reflect on aspects of their drawings, they may curtail their methods by no longer needing to mark off individual pieces from a package. They may begin to reason mentally about the packages and use numerals to show how they partition collections of ten solve subtraction situations.

Finally, we note that the classroom mathematical practices are socially accomplished as the teacher and the students participate in these discussions. Whereas they contribute in different ways, it is clear that their contributions are equally important in advancing the mathematical practices. This is particularly the case in classrooms where children’s self-generated models are valued and capitalized on. Such accounts as the one we have reported here remind us of the necessary role students’ models play in learning mathematics with understanding.

References

We describe a procedure for developing pedagogical knowledge about the potential argumentation space of groups of children in a conceptual locale. The method used involved the collection of small groups of children who had made significantly different responses to diagnostic test items, and the recording and analysis of their subsequent researcher-managed arguments in discussion. An example of the method is presented which shows how groups of 11-year old children developed arguments about the ordering of decimals, in response to a classic diagnostic item involving the ordering of 185, 73.5, 73.32, 57, 73.64. The analyses of these discussions led to a chart of the key elements of argument that arose, as well as general strategies for managing such discussions that were productive. These are considered as devices for helping teachers to plan argumentation in their classrooms.

Introduction

The identification and characterisation of the way children understand the mathematics presented to them in the curriculum has long been the focus of research in the psychology of mathematics education and continues to be a source of empirical and theoretical investigation. While much of this work was, and is still, conducted within a 'misconceptions' or 'alternative frameworks' paradigm, there is continuing development of work on children's mathematical thinking which elaborates on contextual, social and socio-cultural factors, and on the significance of inquiry discourse. (See for instance, Kirschner & Whitson, 1998, Forman & van Oers, 1998, Cobb & Bauersfeld, 1995 and Cobb et al, 2000.) In this study we are interested in how children may reveal and develop their understanding through collaborative argument in group discussion. We are particularly interested in discovering and describing productive lines of argument in relation to particular content conceptual locales, which may help teachers to develop productive discussions in their regular classrooms.

It has long been 'known' that children's errors and misconceptions can be the starting point for effective diagnostically-designed mathematics teaching. The key mathematical work on this in the UK was done in the 1980s by the ESRC Diagnostic Teaching Project (Bell et al, 1983), in which cognitive conflict was seen as the route to developing understanding. Argument in discussion between conflicting positions is seen as one important source of such conflict. The TIMSS video study reported that Japanese mathematics teaching typically makes use of a diagnostic approach: teachers are prepared with notes on a variety of likely responses to a key lead question, with guidance as to the thinking these responses indicate, and constructive teaching suggested related to each (Schmidt et al, 1996). This was related to the success of Japanese children's mathematical learning and particularly their problem solving capabilities. Dialogic methods involve the characteristics of conversation
and the rigours of reason and persuasion: sustained talk and listening, statements of understanding or thinking-in-progress, the use and consideration of evidence, cognitive conflict and the making of new connections (Andrews et al, 1993; Costello et al, 1995; Inagaki, Hatano & Morita, 1998; Ryan and Williams, 2000).

**Charting argumentation space: a methodology**

There can be no genuine discussion or argument without a ‘problematic’, i.e. an unresolved or not trivially-resolvable problem. This induces some purpose and some tension that sustains a discussion. The problematic for a particular group of children was established through prior testing which provided a range of student responses and methods of solution. The children were set the task of persuading each other by clear explanation and reasonable argument of the answer. The giving of clarifications, reasons, justifications and informal ‘proof’ was the rationale for the discussion. We use the term ‘argumentation space’ to describe the collection of relevant arguments likely to be used productively in children’s arguments about a particular problematic. In this paper we show how we are beginning to chart argumentation spaces in ways which may help teachers to plan classroom discussions to develop productive arguments. In addition we outline the main strategies which we found supported productive argument in group discussions.

In this study a primary school cohort of 74 ‘year 6’ (i.e. 11-year old) children was screened with a test that was designed to reveal common errors that had already been identified as relevant to their mathematics curriculum and level (Ryan & Williams, 2000). Essentially this involved identifying the most important common errors on tests for which we had collected a National sample of data (N = 1759) covering the entire mathematics curriculum for Key Stage 2 (end of UK primary school). From these errors, which had been coded and entered into a Rasch analysis (Ryan, Doig & Williams, 1998), we identified the most interesting errors based on the criteria that they should be: (a) common enough to reward a teacher’s attention, (b) relevant to a significant locale of the curriculum being taught at the given age level in focus and (c) significant in terms of the literature on the psychology of learning.

The result was a diagnostic pencil and paper test of some 30 items lasting about 30 to 40 minutes and (later) a 20 minute mental test. The test items were drawn from the whole primary school curriculum. By way of an example, we will cite the case of an item called ‘Ordering’, which asked children to sort the numbers 185, 73.5, 73.32, 57, 73.64 from smallest to largest. In the National sample we found two common errors as expected: 57, 73.5, 73.32, 73.64, 185 (‘decimal point ignored’) and 57, 73.32, 73.64, 73.5, 185 (‘longest is smallest’). These errors had been identified in the APU study of the early 1980s (Assessment of Performance Unit, 1982). The ‘decimal point ignored’ error is believed to have an important bearing on the development of children’s number concept, and is typical of children’s over-generalisation of whole number conceptions to the wider field of rational numbers. From each of the three year 6 classes, we selected 4 children for each discussion group on the basis that they had provided a range of responses on the test items.
There were 9 groups (36 children). The children from each group were from the same class and knew each other well, though were not necessarily from the same friendship group. Their teachers advised us on the likely successful dynamics for each group. They were mixed groups of boys and girls. Each group was withdrawn for discussion and videotaped in sessions lasting from between 30 to 50 minutes. Most children were involved in two sessions of taping. They recalled their test item response (an interval of a few days only) and were invited to present an argument for their response to the group. We, as researchers, adopted the teacher’s role in discussion: generally four students at a time. All discussions were transcribed and analysed.

The analysis of argument follows Toulmin’s scheme in general (developed by Cobb & Bauersfeld, 1995 and Cobb et al, 2000; Krummheuer, 1997, and others). Propositions relevant to the issue are ‘backed’ by arguments that are then subject to testing. In general children find it unnecessary to argue propositions which are believed to be shared, (i.e. taken-as-shared) so any particular discourse reflects the presumed shared points of departure, including the rules of argument in such situations. In this, the Researcher as a quasi-teacher, assumes the authority and seeks to ensure reasonableness, the need for the inquiry to persuade by good thinking and argument, and so on (Costello et al, 1995). An important role in productive argument may be played by tools in practice, which may provoke the formulation of connections between components of mathematical knowledge, new constructions and hence productive backing. The number line has been shown to play a significant role in many such contexts, and does so in the following example.

**Results**

Here we present part of one transcript for an argument about the ordering of decimals. Some commentary and analytical categories used are shown in bold to the right:

Kim: **OK.** I put 57 there – .... Then I put 73.5, ... Then I put 73 point thirty-two, then I put 73.64 point sixty-four, then I put 185. **Everyday language**

Natalie: Well, I got 57 at the beginning too. And then I got 73.5. Then I got 73 point three- two Then I got 73 point six- four. Then I got 185. **Mathematical language**

RES: Could you explain why you put 73.5 before 73.32 (three, two)? **Focus**

Natalie: Because 73.32 (three, two) has got two digits after the decimal point and 73.5 has only got one. **Backing: separating decimal as wholes**

Elise: I’m not so sure, because 73.5 is basically 73 and a half. 73.64 (six, four) is, I’m not sure if it would be over a half or under...Actually I think the same as Kim... because, like Natalie said, there are two digits there, and two digits there, and only one digit there. **Intro fraction referent: conflict, backing**

RES: What do you think Richard? **Check alternatives**

Richard: Same as Elise.

RES: The same... If I had a number line... Are you used to seeing a number line? (children nod). And I had 72. 72 would be back there. 73 would be there. 74 would be there. Where would you put 73.5? Do you want to do that Richard? **Intro tool: number line**
Richard: *(puts 73.5 halfway between 73 and 74)*
RES: Can anybody put any other numbers in between 73 and 74?
Kim: Yeah *(puts 73.64 above 73.5)*
RES: Why have you put in bigger than 73.5?
Kim: Because it’s over a half.
RES: Any other numbers you could put on that number line? Do you want to have a go Natalie?
Natalie: 73 point two-five
RES: 73.25 (?), where would that go?… Could you tell us why you put 73.25 just there?
Natalie: It’s a quarter of the number.
RES: Do you agree with that? *(children nod.)* So, it’s gone… why has it gone exactly there? Is that because it is halfway towards a half?
Natalie: Yeah.
RES: Could you put a number on that number line Richard?
Richard: Erm, 73.45…*(places it between 73.25 and 73.5… places 73.75 between 73.5 and 74).*
RES: 73.75, right? That’s …?
Richard: Three-quarters.
RES: So you put that halfway between 73 and a half, and 74… Where do you think 73.32 should go
Kim: Before 73.5
RES: Why?
Kim: Because 73.5 is a half and 73.32 (?) is just after a quarter.
RES: Could you say why it’s just after a quarter?
Kim: Because a quarter is 73.25 (?) and 73.32 is bigger than 73.25 *(All agree)* I now think 73.32 is there, and 73.5 is there.
RES: You all want to change your minds now? Now why did we go wrong in the first place?
Kim: Because we saw them as two-digit numbers, and we thought that the two-digit numbers were more than a one-digit number
Elise: I would say that 73.25 is a quarter, and it’s less than 73.5 because that’s a half, and 73.32 is just over a quarter, so it would be just under 73.5

Extracting the most productive and essential elements of this and other arguments about ‘decimal point ignored’ allow us to make a summary chart (Fig 1 below). This summarises the lines of argument we found that we think teachers will find useful in preparing for a particular discussion about ‘ordering’.

Note the arguments advanced are ‘backed’ in Toulmin’s sense *(Toulmin, 1969)* by the introduction of three key tools and references, without the introduction of these by the teacher/researcher or by a child, the arguments may critically follow different lines. These were:

- the placing of known decimals and fractions on a number line (e.g. 0.5 at ½, 0.25 at ¼).
- the equivalence or cancelling of fractions (e.g. 50% = 50/100 = 5/10 = ½)
- the equivalence of metric measures (e.g. 500mm = 50cm = 0.5m).
Decimal point ignored (DPI): … point five is less than point thirty-two because five is less than thirty-two.

BUT, compare fractions:

... putting known fractions and decimals on a number line

1/4 1/2

0.25 0.5

and 0.32 is a bit bigger than 0.25

DPI: …but point five and point fifty aren’t really the same … because if you add zero after the five you get fifty…

“Adding a zero” may not change the value… 50% or 50/100 cancels down to 5/10 and ½.

DPI: But column headings are tenths and unit-ths… why do you have two different ways of writing a single number?

but

50 millimetres is the same as 5 centimetres and 2 kilograms is 2000 grams.

Fig 1: A chart of argumentation space for ‘Decimal Point Ignored’

The difference between numbers with one decimal place and two decimal places is particularly critical here, as was evident in this episode when 0.25 was placed at ¼ on the number line. In another discussion the critical difference was manifest in argument about the value of 0.5 and 0.50, which were considered by some children to represent different numbers, even with different places on the number line. One child actually suggested that ‘nought point five’ should perhaps be written as 0.05 when ordered with ‘other’ two decimal place numbers. This discourse manifests a conceptual world of whole numbers extended to decimal numbers which consists of pairs of numbers separated by a point, ( i.e. x point y) and that the number after the point is, or should be, a fixed length of string digits. This is the root of DPI errors and their backing arguments.
In the next stage of the analysis we sought to categorise the researchers’ inputs to the discourse and influence on the discussions in general. Being aware of the children who made the common errors in advance, the researcher manifestly sought to ensure that the arguments for the error were clearly voiced, as well as to ensure that potentially productive tools and referents were introduced at some point: hence the significance of the particular conceptual locale to pedagogical content knowledge.

However, we examined general teaching strategies that seemed generally productive across problem contexts and conceptual locales. In eliciting and sustaining argument, we include the eliciting of variety of ‘answers’ and arguments, asking children to listen and sometimes paraphrase others’ views, seeking further clarification of arguments, (sometimes helping to formulate and encourage a minority point of view), seeking alternatives and dissent, and seeking reasons and ‘backing’. These are all strategies that forestall closure and encourage productive conflict. In the final post-resolution stage of discussion, strategies that encouraged reflection included asking children whether and why they had changed their mind, what the argument or misconception had been, and how they would summarise what they had learnt.

Conclusions and discussion

We have shown that it is possible to use dialogue generated in research to chart an argumentation space which describes the children’s arguments in response to provocative diagnostic items in a conceptual locale. The concept of an argumentation space located around a diagnostic item is designed to be helpful in supporting teachers’ pedagogical content knowledge. We interpret these spaces as providing potential classroom discourses structuring potential zones of proximal development of individuals within a class. The dialogues teachers might generate in replication of the research setting might thereby provide opportunities for individuals to learn by testing their responses against those of their peers, and being given an opportunity to evaluate and shift their position accordingly.

We are currently investigating and evaluating how helpful these ‘charts’ can be to teachers in practice, and whether the resulting dialogues will be successful in helping children learn. The next step in the project involves a study with teachers delivering, marking and interpreting the diagnostic test and observation of their subsequent teaching through discussions based on these argumentation spaces. We will present some evaluation of its effectiveness in helping teachers to develop their practice at the PME presentation.

We believe that the approach adopted here has certain conceptual strengths and weaknesses. Clearly, desirable pedagogical content knowledge with respect to a conceptual field or even locale cannot be altogether encapsulated in one chart. In fact, even the literature in diagnostic teaching – a conflict-based method – is far from solely based on conflicting students in discussion: the use of particular tools and representations in particular have a most significant role. Furthermore there is a danger in peer discussion, often cited by teachers and in the literature, that students will be persuaded by the weakest of arguments.

1852
However, the strength of developing this methodology for teachers as a tool in their practice is that it has certain general features as well as the particularities in the locally structured chart for a locale. Thus, we would hope that this approach as a teaching method will help teachers to improve their practice very generally. We are optimistic that the method will encourage at least some teachers to see themselves as teacher-researchers, and that they will wish to extend these or begin constructing their own charts for locales we have not yet explored.

Learning to Teach Mathematics Differently: Reflection Matters
Terry Wood
Purdue University

The nature of mathematics teaching, influenced by constructivist and social theories, is better understood as the result of investigations of accomplished teachers, but questions still remain as to how teachers' learn this complex form of teaching. This research reports an investigation of the interplay between beginning elementary teachers' reflective thinking and changes made in their mathematics teaching. The findings reveal teachers who change in teaching progressively increase in depth of reflection on their teaching and in appropriately interpreting their students' intentions and mathematical thinking. Reflections of teachers with little change in mathematics teaching consist of descriptions, evaluations, and rationalizations of events; moreover, they are unable to view circumstances from the students' perspective.

It is widely accepted that changes in perspectives on students' learning and the development of knowledge in mathematics reflect trends in cognition and the nature of knowledge influenced by post-modern philosophies. Together these trends have significantly changed the view of mathematics teaching to a more complex pedagogy that represents a major shift from the long-standing emphasis on single computational procedures (MSEB, 1989). Although, the nature of teaching, influenced by constructivist and social theories, is better understood as the result of investigations of accomplished teachers (e.g., Jaworski, 1994; Schoenfeld, 1998; Wood, Nelson & Warfield, in press), questions still remain about how teachers' learn this complex form of teaching.

A significant body of research exists which indicates teachers have learned as evidenced by changes in their practice, beliefs and knowledge. But the question still remains, how do we know if teachers are learning? To answer this question it is necessary to investigate the process of reflection which is thought to be central in teachers' learning (Schön, 1987). The purpose of this research is to examine how teachers used both their reflective thinking as a process in pedagogical reasoning and their classroom practice to transform their mathematics teaching in ways advocated (e.g., National Council of Teachers of Mathematics [NCTM], 1989, 2000).

OVERVIEW

Several studies have shown that teachers develop the pedagogy necessary to create reform-oriented mathematics classes as they reflect on events that occur in their classrooms (Fennema, et al., 1994; Cobb, Wood, & Yackel, 1990; Simon & Schifter, 1995). Research reported in this paper is supported by the National Science Foundation under award number RED 925-4939. All opinions are those of the author.
Fundamental to the thinking about teacher learning is the contention that "attempts to influence teachers' knowledge and beliefs will not be at their most effective unless they draw on teachers' first-hand experiences of interacting with their students during mathematics instruction" (Cobb, Wood, & Yackel, 1990, pp. 141-142). Although these studies identify changes in teaching and teachers' beliefs, other studies have shown that while some teachers develop complex forms of teaching, others make little change (e.g., Vacc & Bright, 1998). Furthermore, among teachers who make changes, some teachers continue to develop in their teaching while others do not (Franke, et al., 1998). This raises questions about the commonly accepted notion that elementary classrooms are a source of opportunities for teachers' learning.

Along with classrooms as sites for teachers' learning, reflection is thought to be an essential process in teachers' learning and central in their capacity for pedagogical reasoning (Shulman, 1987). Subsequently, reflective thinking is viewed as central to much of the thinking in mathematics education about teacher learning. Studies, such as that of Mewborn (1999), have investigated what teachers' found problematic in classroom situations as a means to examine their reflective thinking. In her study, Mewborn found that teachers' reflective thought followed Dewey's (1933) five phases; moreover, to be a reflective thinker required teachers to hold relativistic beliefs. Although this research contributes to an understanding about the reflective thinking of teachers, it is still not well understood how teachers use reflective thinking to make sense of their work and how reflection influences the changes they make in their teaching.

Thus, the purpose of this research is to investigate how teachers use reflective thinking in their pedagogical reasoning and how their thinking relates to changes in teaching. It is contended that substantial change in teaching occurs as teachers reflect on their lessons, examining how classroom events that occurred compare with their intentions, and making alterations based on their reflections. In this study, the process of reflection was examined by investigating what teachers' notice when observing their classrooms, the interpretation they make of events, and the changes they propose in their practice. These findings about the process of reflection were then compared with analysis of the teachers' videotaped classrooms with regard to their development of socially interactive learning environments and the mathematics that occurred during the lessons.

THEORETICAL ORIENTATION

Cognitive and social context theoretical perspectives guide the research on the processes of teachers' learning. Both of these perspectives hold the view that the human mind is generative, creative, proactive, and reflective and that humans interpret and give meaning to events and things in their lives. Social environment provides opportunities for learning and differences in social context are thought to affect the nature of what is learned. Therefore, the social context teachers create for student learning affects their own opportunities for learning within the classroom. Thus, from a
social interactive perspective the teachers' creation of classroom social structures important to students' participation in the discourse of inquiry is of central interest.

From a cognitive perspective the construct reflection drawn from the work of Dewey (1933) is used to describe the process by which teachers give meaning to their own and students actions and is used to examine teachers' learning. Reflection, in this study, is defined as the distancing of one's self from the object of reflection. Borrowing from Dewey's (1933) notion of that reflective thinking; consists of "a state of doubt, hesitation of perplexity in which thinking originates," and "an act of searching, hunting or inquiring to find material that will resolve the doubt" and "dispose of the perplexity" (p.14). The early work of Shulman (1987) on pedagogical reasoning and the recent research of Mewborn (1999) on the characteristics of reflection are used to further delineate the process of teacher reflection. Using both cognitive and social interactive perspectives allow for an explanation of teachers' learning that considers the interplay between teachers' reflection as a central process in pedagogical reasoning and their the development of classroom learning environments.

The characteristics of teaching follow conceptualizations of Jaworski (1994) that describes a teaching triad that consists of three dimensions, management of learning, sensitivity to students, and mathematical challenge. In addition, the interactive dimensions of participation and questioning from Wood (Wood & Turner-Vorbeck, in press) further characterize teaching.

DATA SOURCE, METHODOLOGY AND ANALYSIS

Approach to Teacher Development

The study reported in this paper is part of a larger 2-year research and development project in which the research goal was to investigate how elementary teachers' develop their classroom teaching in accordance with reform schemes. The development aspect of the project consisted of creating an approach to inservice teacher education for elementary teachers that utilized three central themes that incorporated tenets of constructivism, social constructivism and sociology. Taken together, these themes reflected a stance toward working with teachers that placed importance on individual development of teaching in conjunction with the formation of public or common knowledge of teaching through the generation of a community of professional practitioners. In order to promote teachers' learning and yet attempt to develop an approach to development that would be less labor intensive for teacher educators, certain aspects of technology were used as support (cf. Wood, 1999 for further detail about the approach).

For the purpose of promoting teacher personal reflection, a component was created in the professional development approach that required teachers' to reflect on their teaching activity in conjunction with their students' mathematical thinking during

---

\footnote{The project is "Recreating Teaching Mathematics in the Elementary School" funded by the National Science Foundation.}
mathematics lessons. Teachers made video recordings of their lessons and then later used these videotapes to examine the events that occurred during their lessons. However, in order to engage in investigation of their instruction, teachers needed support in developing their skills in making observations and reflecting on videotaped classroom events. As a means of support, a 3-step procedure was created, following Jaworski (1988), for responding to the tapes by writing in “reflective journals.” These steps were to: write their expectations for the lesson prior to teaching; make detailed records of the discourse during class discussion; and, compare and contrast the records of the events described with their expectations. Following this, they were to write a “plan of action” to carry out in the classroom based on the results of their reflections.

**Teachers and Data Source**

Seven beginning (2 years of previous teaching experience) elementary teachers participated in the 2-year research and development project that involved an intensive investigation of their learning to teach. The seven teachers taught in the same school district in first through fifth grades (6-11 year-olds).

The reflective journals and the class videotapes served as the primary data sources for the research on individual teacher reflection and learning to teach. Each teacher made written comments following the format described above for the purpose of recording their reflections before, during, and after watching their classroom videotapes. Secondary data sources were each teacher’s written journal responses to specific questions asked by researchers during the group working sessions and e-mail exchanges between the teachers and research team.

The primary source of data for analysis of classroom teaching consisted of videotape recordings of mathematics lessons recorded by each teacher twice per month. Each lesson videotaped was viewed and logged by the research staff as a detailed record to be used in the analysis.3

**Methodology and Analysis**

The methodology and analysis followed a qualitative research paradigm and procedures similar to those of Glaser and Strauss (1969) and Strauss & Corbin (1990) in which categories were developed from the data, examined for confirming and disconfirming evidence and revised. The specific methodology and analysis for examining reflection and classroom practice are described next.

**Processes of Reflection**

For the teachers’ journal entries a written running record of each entry was compiled by one member of the research team of each teacher’s: a) expectations, b) description of events, and c) reflections on the lesson. The three entries were analyzed and refined, analyzed again, and a running record for each teacher written by the same member of the research team. The teachers’ responses were categorized as description, reflection or rationalization. The section of the journal that consisted of reflections on

---

3 Research team members were Luiza de Souza, Caroline Van Tuinen, Michael Palm, Janet Warfield, and myself.
the lessons was additionally categorized in terms of depth of reflection. These categories revealed not only the nature of what aspects of students' thinking teachers reflected on but also the quality of their reflection. The categories for quality of reflection consisted of thought on action, thought on thought, to thought on thoughts of children. The teacher journal responses to researcher-asked questions and the content of the e-mail messages provided supporting evidence for the running records. Each member of the research team individually analyzed each teacher's written journal entries and then met to discuss their analyses with the other members of the research group. Differences in interpretations were discussed and resolved by looking within the data for confirming or disconfirming evidence.

**Classroom Practice**

The classroom videotapes and logs were used to investigate each teacher's practice. The videotape logs for each of the classroom lessons were coded by the research team following an extension of the coding scheme developed and used in previous studies of teaching (Wood & Turner-Vorbeck, in press). The research team individually coded each lesson log for one teacher at a time and then met to discuss their analysis. Differences in interpretation were discussed and resolved by looking within the logs for confirming or disconfirming evidence. Certain videotaped lessons collected at the beginning and end of each year served as baseline data. The baseline videotapes were used to gauge changes in teaching over the duration of the project. Following a discussion of the coding of the baseline tapes, each member wrote a summary for each teacher of the interaction patterns, discourse, teacher questions and mathematical topics discussed.

**Integration of Teacher Reflection and Classroom Practice**

The remaining coded logs, along with the baseline lessons, were matched with journal entries in order to integrate teacher reflections on their classroom practice with video recordings of the lesson. The analysis of the data consisted of comparing and contrasting journal entries of teacher reflection with the log of the lesson being reflected up on. In addition, subsequent lessons were analyzed in order to match instances of teacher insight from reflection and proposed plans for change with video recorded observations of teaching.

**RESULTS AND DISCUSSION**

**Teacher Reflection**

The findings from the analysis of the data on teacher thinking and instances of reflection revealed differences among the teachers in terms of the content and depth of their reflection on children's mathematical thinking in the context of their class. Additionally, teachers differed in the intensity or quality of their reflection. That is, from the beginning one group of teachers on reflection saw aspects of their classroom interaction as problematic and gave thought to how their role as teacher influenced the situation (e.g., “I need to listen more & not lead children to what I want to hear. I need..."
to just let them explain their thinking."") Later, these same teachers’ reflections became ‘thoughts about their thoughts’ (e.g., “...solve the problem by subtracting at the very beginning so I knew she knew how to solve the problem.”) And still later, these teachers’ thoughts were about what children’s thinking or intentions might be in the situation (e.g., “The other children were busy coloring to find the answer I felt that they thought they were going to find the answer quickly (or faster) than it took them!”) Over the 2-year period, these teachers appeared to deepen in their understanding of children’s mathematical thinking and their view of the problem, solution, or both.

Another group of teachers’ responses consisted of summaries of events (e.g., “all students were on task”) or evaluations of students’ behavior (e.g., “the students are all doing a much better job of sharing responsibilities.”) When these teachers’ did reflect, these primarily consisted of rationalizations (e.g., “I feel we never have a good discussion when the camera is rolling” and “I feel the problem lies before in earlier grades, parental involvement, and many students just being lazy.” Moreover, they often attributed to children’s action reasons that were inherent in the child (e.g., “I had a hard time with the lower math students. They failed to build on other, earlier problems.”) Thus, they seemed not to think about how their children might be thinking about or making sense of a problem or solution; they were seemingly unable to view the situation from the child’s perspective. Additionally, they seldom considered how their role, as teacher, might influence the situation.

**Classroom Practice**

Analysis of the teachers’ classroom practice also revealed differences in the growth of their teaching. The analysis of the first baseline classroom videotape revealed that all of the teachers initially taught mathematics conventionally. That is, the focus was on computational procedures, interaction and discourse that consisted of the typical IER pattern described by Mehan (1979) and others. The teachers who substantively changed in their teaching created classroom environments similar to those advocated by reform in mathematics education (NCTM, 1989; 2000). These classes involved teachers and children in discussion that was characterized as inquiry and argument (c.f., Wood & Turner-Vorbeck, in press). The teachers that made little change in their teaching continued their conventional interaction characterized by teachers’ ‘test questions’, students’ answers, followed by teacher evaluation.

**SUMMARY AND IMPLICATIONS**

Taken together, the findings revealed two distinct groups of teachers existed that differed in the nature of their reflection and in their development of the pedagogical skills necessary to create interactive learning environment and the mathematics advocated in the reform agenda. Teachers who made changes in their mathematics classrooms progressively increased in the depth of their reflection. They also differed in their interpretation of their students’ intentions and thinking—what Jaworski (1994) refers to as “student sensitivity.” Conversely, the reflections of teachers who made
little change in their teaching consisted of quite different content. Their responses consisted of descriptions, evaluations, and rationalizations of the events that occurred and they were seemingly unable to view the situation from the child’s perspective.

Reflection has long been considered as an essential process in teachers’ learning and central in their capacity for pedagogical reasoning, both of which are necessary if teachers are to develop and continue to generate more sophisticated forms of pedagogy. These findings provide further insights into how teachers’ do or do not learn to teach differently and the role of reflection in the process that are important for mathematics teacher education.

EXPLORING MULTIPLICATIVE AND ADDITIVE STRUCTURE OF
ARITHMETIC SEQUENCES

Rina Zazkis and Peter Liljedahl
Simon Fraser University

Arithmetic sequence is used in this study as a means to explore preservice elementary school teachers' connections between additive and multiplicative structures as well as several concepts related to introductory number theory. Vergnaud's theory of conceptual fields is used and refined to analyze students' attempts to test membership of given numbers and to generate elements that are members of a given infinite arithmetic sequence. Our results indicate that participants made a strong distinction between two types of arithmetic sequences, sequences of multiples (e.g. 7, 14, 21, 28, ...) and sequences of "non-multiples," (e.g. 8, 15, 22, 29, ...). Students were more successful in recognizing the underlying structure of elements in sequences of multiples, whereas for sequences of non-multiples students often preferred algebraic computations and were mostly unaware of the invariant structure linking the two types.

An arithmetic sequence is a sequence of numbers with a common difference. The topic of arithmetic sequence, along with other sequences, is usually introduced in high school and the standard approach utilizes algebraic representation and manipulation. Despite being a part of a high-school, rather than elementary school, curriculum the topic of arithmetic sequence is frequently approached in mathematics courses for preservice elementary school teachers. This is mainly because arithmetic sequences surface in the discussions of pattern recognition and understanding relations, generalization, and problem posing techniques (Brown and Walter, 1990; Principles and Standards for School Mathematics, 2000). However, little research has been done on students' learning of this topic. In this study we explore preservice elementary school teachers' understanding of the structure underlying arithmetic sequences.

THEORETICAL FRAMEWORK

Vergnaud's Theory of Conceptual Fields

In several publications over the last two decades Vergnaud developed, proposed and elaborated on the theory of conceptual fields (Vergnaud, 1988, 1994,
1996, 1997). The development of the theory of conceptual fields was motivated by the need to establish connections between explicit mathematical concepts, relations and theorems and between students' at times implicit, dynamic conceptions and competencies related to these mathematical concepts, relations and theorems. The following are among the established terms of reference:

- **Conceptual field** (1996, p. 225) is a set of situations, the mastering of which requires several interconnected concepts. It is at the same time a set of concepts, with different properties, the meaning of which is drawn from this variety of situation.

- A **scheme** (1996, p. 222; 1997, p. 12) is the invariant organization of behavior for a certain class of situations.

- A **theorem-in-action** is a proposition that is held to be true by the individual subject for a certain range of the situation variables (1996, p. 225).

**Cognitive Development in a Conceptual Field - Theory Extension**

Vergnaud claims that the theory of conceptual field is "a theory of representation and cognitive development" (1996, p. 220). Problem situations serve as triggers in generating and promoting cognitive development. When students are faced with a new situation, "they use the knowledge which has been shaped by their experience with simpler and more familiar situation and try to adapt it to this new situation" (Vergnaud, 1988, p. 141). This description is similar to Piagetian accommodation and assimilation. We elaborate further on the mechanism for the development of a particular scheme.

Theorems-in-action are identifiers of students' knowledge, as they describe mathematical relationships, either correct or incorrect, that are taken into account by students when they choose a path to solve a problem. Vergnaud suggests that "theorems-in-action have the potential to be the links among situations in the conceptual fields" (1988, p. 145). We add that theorems-in-action may also serve as separators, rather than links, and recognizing either could serve as a stepping-stone to learning.

Scheme development may occur in two ways: A student may recognize differences in two seemingly similar classes of situations. As an outcome, different theorems-in-action will be invoked, and, as a result, different routes will be taken by a student in dealing with each of the two classes of situations. A student may also recognize invariant structure in two classes of situations that were formerly perceived as "different". This may lead to an adaptation of two previously used theorems-in-action into one more general theorem-in-action that is applicable for both classes of situations. Furthermore, identifying invariant structure in situations may serve as a bridge that takes a student from one conceptual field to another.
METHODOLOGY

Participants

Participants in this study were preservice elementary school teachers enrolled in a core mathematics course. Students' work with arithmetic sequences in this course included pattern recognition, generating sequences given the first element and the difference, and developing and implementing formulas for calculating the \( n \)-th element as well as the sum of the first \( n \) elements of the sequence. Students also worked with elementary number theory topics, including divisibility, factors and multiples, and the division algorithm. Twenty out of 64 students enrolled in the course volunteered to participate in a clinical interview, which was the main source of the data collection.

Situations

Situation is a key feature in Vergnaud's definition of a scheme and a conceptual field. In this research we take a broad interpretation of situations, and classify as situations not only contextualized word-problems, but also mathematical problems and questions that are "abstract" or "decontextualized"; that is, not rooted in "real world" context. The following interview questions represent the core of the situations that were presented to participants.

1. Describing and exemplifying. Give several examples of arithmetic sequences. Can you think of an example that is different from others?

2. Testing membership.
Consider the following sequence of numbers
(a) 2, 5, 8, 11, 14, ...
Is it arithmetic? Is the number 360 (or 440) an element in this sequence (assuming it is infinite)? Why? Is there another way to verify this?

(b) The same question with respect to sequence 3, 6, 9, 12, ...
(c) The same question with respect to sequence 17, 34, 51, ... and number 204
(d) The same question with respect to sequence 8, 15, 22, 29, ... and number 704.

3. Generating examples of members. Can you think of a "large" number that is an element in sequence 2, 5, 8, ... (If necessary, "large" was described as a 3- or 4-digit number). Can you think of a large number that is definitely not an element in this sequence?

The same questions were posed with respect to sequences listed in 2(b), (c) and (d) above.
Objectives

We explore students' attempts to deal with the situations, specifically aiming to:

(1) identify and describe strategies (rules of action) used as participants encounter problem situations related to arithmetic sequences,
(2) analyze students' strategies and uncover underlying theorems-in-action,
(3) suggest a path for a development of individual's scheme within the context of presented situations, and
(4) test empirically the (above) extension of the theory.

STUDENTS' SCHEMES: RESULTS AND ANALYSIS

Listing the elements in a given arithmetic sequence by adding the common difference will eventually generate "large" elements and determine whether a given number is the element in the sequence. In light of Vergnaud's theory the common difference can be seen as an invariant identifying a class of situations. For participants in this study listing the elements was not the preferred choice, however, this strategy was mentioned by 8 participants as a verifying strategy or as a default for not being able to generate a better strategy.

Using the formula $a_n = a_1 + (n-1)d$ was a popular choice of strategy. The formula is applied in routine questions to find the n-th element when the first element and the common difference are known. Furthermore, it can be used to calculate any one of the four variables when the other three are known. Application of formulas was the exclusive strategy suggested by only one of the participants. However, 17 participants used formulas for situations similar to 2a and 2d, whereas they applied considerations of form and pattern for sequences similar to 2b and 2c. This fact, taken together with the significant amount of prompting and invitation to think of "another way" during the interview, suggests that participants preferred formulas when the pattern in the sequence was not obvious to them; that is, when they weren't aware of the multiplicative invariants in the structure of the elements. Therefore, participants invoked a scheme previously established to deal with arithmetic sequence related questions, the scheme of plugging numbers into the formula.

Multiples and non-multiples. It became apparent from participants' responses to question 1 (request to provide examples of several arithmetic sequences) that there is a class of arithmetic sequences preferred by students. Each participant provided between 4 and 8 examples of arithmetic sequences. Most of these examples were sequences of multiples of a small natural number, such as 3, 6, 9, 12 or 5, 10, 15, 20, ... with a possible exception of a sequence of odd numbers.
When the interviewer explicitly asked for "something different", the usual reaction was to provide sequences of multiples of "large" numbers, such as 50, 100, 150, 200, ... etc. or list multiples in a descending order. Though participants readily accepted other sequences, such as 2, 5, 8, 11, ..., as "arithmetic", they were not a part of their immediate repertoire of examples.

Realizing that some arithmetic sequences are "sequences of multiples" provides a tool for testing membership or generating "large" elements without relying on formulas. However, 8 participants overgeneralized the observation that every element in an arithmetic sequence is a multiple of the common difference $d$ to hold for any arithmetic sequence. This tendency is exemplified in the following excerpt from the interview with Leah.

Interviewer: Would you please consider the following sequence: 8, 15, 22, 29, so far it’s an arithmetic sequence, how would you continue?
Leah: 36, 43?
Interviewer: Okay. And how about the number 704? Is it an element in this sequence?
Leah: I’m going to check and see if 7 is a factor of 704, (pause) no ...
Interviewer: No for what?
Leah: Um, 704 is not going to be in this sequence because 7 is not a factor of 704.
Interviewer: Okay. How about 700?
Leah: Yeah, um, 7 is a factor of 700, so I think it’s going to be in the sequence. 7 x 100 is 700.

Leah claims that the number 700 is an element in a sequence 8, 15, 22, ... because 7 is a factor of 700. In such cases the student’s theorem-in-action was challenged by the interviewer by pointing out contradictory evidence. As a result of these types of challenges some participants refined their scheme by limiting it to certain kind of situations. Once the difference between the two classes – multiples and non-multiples – was realized, it became apparent that the same scheme cannot be used to accommodate both. As a result the scheme of considering multiples of $d$ was restricted to sequences of multiples only.

In the following excerpt Sally considers the sequence 8, 15, 22, ... and the number 704.

Interviewer: So 704 is not divisible by 7, none of these elements in this sequence you believe will be divisible by 7, so can you draw conclusions from what you have now?
Sally: It’s, it’s um very possibly in this set.
Interviewer: Um hm. What, what will convince you?
Sally: (laugh) Well just because it's not divisible by 7, doesn't mean it's in the set, right?
Interviewer: Can you give me an example of a number that you know for sure that is not in this arithmetic sequence?
Sally: Um hm, um 700...
Interviewer: Another one...
Sally: Um, 77.
Interviewer: Okay. And how about 78?
Sally: It may be in the set, but it's not divisible by 7...
Interviewer: (laugh) So 77 you're sure is not, 78 you're not sure.
Sally: Right.
Interviewer: 79?
Sally: Could be...
Interviewer: Could be. 80?
Sally: Could be...

Sally is confident that multiples of 7 are not elements in the given sequence, but she believes that any number that is not a multiple if 7 "could be" in the sequence. At this stage students are able to differentiate and note that previously generated theorems-in-action are not fruitful in a new situation. However, they have not yet revised their theorems-in-action to generate rules-of-action for the new class of situation. Whereas a number's property of "being a multiple" gives a clear indication of its belonging to a sequence of multiples and non-belonging to a sequence of non-multiples, the property of "being a non-multiple" identifies that a number doesn't belong to a sequence of multiples, but gives no explicit hint with respect to the number's membership in a given sequence of non-multiples.

It was a common observation that sequences of multiples have two identifying features (invariants), multiples of $d$ and a common difference, whereas sequences of non-multiples have only one identifying feature of common difference. Identifying a class of situations as "multiples" often left participants without appropriate tools to deal with non-multiples. In 17 cases the participants took advantage of multiples in considering situations 2(b) and 2(c), but regressed to the use of formulas for 2(a) and 2(d).

A further development was to realize that any arithmetic sequence of whole numbers can be considered as a translation along the number line of a corresponding sequence of multiples. Therefore, the next important step in developing individual's scheme is to recognize the invariant multiplicative structure of elements in an arithmetic sequence of non-multiples, often referred to by participants as "multiples adjusted".
Interviewer: Let’s take one more. 8, 15, 22, 29 another sequence.
Lily: Okay, so this is a difference of 7...
Interviewer: How about the number 704?
Lily: (pause) 704, no (pause) this is, these numbers are plus 1 of multiples of 7, multiples of 7 plus 1...

Consideration of multiples and "adjustment" where necessary clearly equips Lily with a powerful scheme. Such an "adjustment" is expressed by Megan in a more mathematical way as she considers division with remainder.

Interviewer: And what about 704?
Megan: No, because that’s got a remainder of (pause) 4, not 1... it needs to have a remainder of 1.
Interviewer: So can you please describe for me your general strategy? How would you decide whether a number I give you does belong to this sequence or doesn’t belong to it?
Megan: Um, if it’s divisible by 7, with the remainder of 1 then it does belong to the set.

Six participants eventually succeeded in suggesting some adjustment of either multiples or numbers divisible by $d$, and 2 explicitly mentioned the common remainder in division by $d$ thereby identifying the multiplicative structure in a sequence of non-multiples.

Towards a Unified Scheme. Although the invariant of "multiples" in the sequences of multiples and the invariant of "multiples adjusted" in the sequences of "non-multiples" are analogous, the learner may still see multiples and non-multiples as two separate classes of situations having a different invariant structure. Therefore different schemes are invoked in dealing with these situations. The identification of a multiplicative invariant within non-multiples is essential for the development of a unified scheme. Identifying similarities, other than lexical, between the two classes, can be a next step in scheme development. It is a further sophistication to consider multiples with adjustment (that can be zero) or common remainder (that can be zero) in division by $d$ as the invariant that unifies both classes of situations and allows an individual to invoke the same scheme for any arithmetic sequence. Recognizing invariant structure in two previously-treated-as-different multiplicative invariants supports the development of a unified more mature scheme. However, the interview situations provided little opportunity for participants to extend their scheme in a way that it could accommodate both classes.
CONCLUSION

Greer (1992) proposed that the analysis of the relationship between the conceptual fields of additive and multiplicative structures is a long-term objective on the agenda for further research in mathematics education. Our research is a step in this direction. Furthermore, this study contributes to prior research on preservice elementary school teachers understanding of elementary number theory (Zazkis & Campbell, 1996), specifically the concepts of multiples, divisibility and division with remainder. In addition, analysis of students' development of a specific problem related scheme leads to a more profound understanding of scheme development in general and in such provides an extension of Vergnaud's theory of conceptual fields. Furthermore, our research points at a possible direction for a pedagogical approach to the topic, an approach that capitalizes on the common structure of elements in an arithmetic sequence.

OPEN-ENDED TASKS: THE DILEMMA OF OPENNESS OR AMBIGUITY?

Robyn Zevenbergen
Griffith University, Australia

Open-ended tasks have been shown to offer considerable potential for learning in mathematics. They have substantial benefits for learning and assessment. However, when using open-ended tasks, questions need to be posed as to how open can they be. In making tasks “open” there is some chance that the task can become ambiguous. This paper reports on a small study of students’ responses to open-ended tasks where some tasks were clear in their goals whereas others were more open, and hence open to greater interpretation by the students.

Tirosh (1999) notes that questions and questioning have a significant role in reform in mathematics education since new movements in mathematics education compel teachers and teacher educators to move away from the traditional forms of teacher-directed and closed questioning techniques that have dominated mathematics classrooms in the past. One tool that has been recognized as having significant value is that of open-ended questions or tasks. The work of researchers and teachers across a range of nations has been particularly valuable in identifying the features of open-ended tasks and how these are of benefit to teaching and learning (Becker & Shimada, 1997; Boaler, 1998; Chappell & Thompson, 1999; Sullivan, Warren, & White, 1999). While such research has been particularly useful in demonstrating the value of open-ended approaches to teaching mathematics, it has been limited in its analysis of the questions being posed. This paper explores the use of open-ended tasks across three classrooms, noting the ways in which language influences the interpretations of the given tasks. It is proposed that the tasks are useful in facilitating greater responses from the students, and hence, making assessment more authentic. However, it is noted that there is some need for concern when tasks become so open as to become ambiguous.

Open-ended Tasks

Sullivan et al (1999) define open-ended tasks as having more than one possible response (goal) and where there are multiple pathways for resolution (activity). They propose that such openness in activity and goal “fosters some of the more important aspects of learning mathematics, specifically, investigating, creating, problematizing, mathematizing, communicating and thinking” (p. 250), which they see as being substantially different from the more restrictive processes associated with recall and rote learning. Closed tasks have typically and predominantly been used in mathematics classrooms and examinations and can be seen as having one answer, for example, “What is the area of a rectangular piece of paper with the dimensions of 4 cm and 6 cm?” Clearly, there is only one correct answer, $24 \text{ cm}^2$. While there may be a number of ways in which the answer can be calculated, such as repeated addition ($6+6+6+6=24$), using a diagram marking the rectangle into small squares, or multiplying 4 by 6, in most cases there is a preferred activity for resolution. In contrast, an open-ended task is one that allows for a range of
“correct” responses and a range of ways of achieving those responses. An open-ended task would be one such as: "If the area of a rectangular piece of paper is 24 cm\(^2\), what might be its dimensions?" This type of question offers greater scope for teachers in assessing students’ understanding of area, and also allows students’ greater scope in demonstrating what they know about area.

Chappell and Thompson (1999) note that the advantages of using open-ended tasks in mathematics are that they encourage students to move beyond the skills-based approaches typical of mathematics classrooms. They demand that they students think more deeply about the concepts; and that they make connections between concepts. This point is reinforced by the work of Boaler (1998) who found that the students who used open-ended approaches in mathematics developed deeper and more connected forms of knowing than their peers in traditional classrooms. She argues that the learning in the open-ended classrooms was more like the learning that occurs in the world beyond school and hence there is greater transfer from school to beyond school.

Sullivan et al (1999) raise the issue of content specificity of open-ended tasks as this allows the mathematics to be made transparent to the students so enabling their learning to be more directed. An example these authors cite is "A number is rounded off to 5.6. What might the number be?" (Sullivan et al., 1999, p. 250). In these tasks, the content is specific to mathematics and students are able to answer it according to the current levels of understanding—some may use two decimal places whereas others use three or more decimal places. The rationale behind open-ended tasks is that they are to be seen as open enough for interpretation so that students answer them in ways that they understand.

The Project

This paper reports on the analysis of a number of tasks given to students in the upper primary school in Queensland, Australia. A set of five open-ended tasks was given to 115 students, but only two of the tasks will be discussed in this paper. The tasks were all open-ended and were designed to cover a range of areas of the mathematics curriculum. Students were given the tasks during a mathematics lesson, and conversation was allowed. Two multi-age classrooms participated in the study, with each classroom having approximately 60 students and two teachers. The students were in the final two years of primary schooling and aged 11–13. The students were given the tasks to complete and later a number of interviews were conducted with selected children in order to gain some appreciation of their thought processes when undertaking the tasks. These students were selected on the basis of the responses that they had offered in the tasks.

Task 1: Data Handling Task

The first task to be discussed involved the interpretation of statistics. The context was a real one to the students whose school was close to a major road that lead to an island where there was only a very small bridge to cover the main thoroughfare of traffic. There had been substantial reports on the need for a bridge or alternative thoroughfare to cater for the increasing traffic.
Task: At the Chevron Island Bridge, the average number of people per car is 2.5. Draw what this might look like if there are 16 cars on the bridge.

The task was open in its goal and method of resolution. It allowed the teachers to access students’ understanding of what the statistics meant in the world beyond school mathematics. Frequently, the mean is something that is calculated: “Forty people in 16 cars, what would the mean be?” However, this task asked what this might look like when posed in the context beyond school. Similarly, it assessed whether or not students understood what a mean of 2.5 meant, and how this is manifested in the everyday. It also allowed for further information to be posed by students that would not otherwise be possible through a closed question. This type of task provided a rich source of information about students’ understanding of measures of central tendency, interpretation of data, and application of data.

The responses to this task fell into a number of categories. Many of the students were able to work through the task so that they could provide a range of cars that would have different number of people in them and where the average number of people was 2.5 per car (see Fig 1a).

Other responses indicated that students realised that there needed to be a total of 40 people in the 16 cars (see Fig 1b). In noting explicitly the need for a total of 40 people, students used a range of strategies, including those listed below, to arrive at 40 people.

Others took a more systematic approach and had alternate cars with two and three people in each (see Fig 2). While this produced a mean of 2.5, it did not show the depth of understanding evident in the responses above. Students appear to have calculated a simple method of means of 2.5 using a pairing strategy of 2 and 3 and then applied this to the 16 cars.
Another strategy used involved the translation of “half”. Some students (see Fig 3a) showed three people per car with one person being smaller than the others. This would suggest that these students interpreted the 0.5 to mean a “small” or “half” person, as was confirmed through the interviews. One student commented that a child was “half an adult so there are two adults and one child in each car.” Others showed a similar representation, but with a code to show that there were two adults per car and one child whereby the one child represented “half a person” or “0.5 people”.

Figure 3a and 3b: Cars showing representations of “half”

Others (see Fig 3b) showed “half a person” by only drawing half a body so that there was literally a “half person” in each car. This representation indicates a literal translation of the data and hence would suggest that there is a need for further work to be undertaken with these students.

As can be seen from these responses, the open-ended task allowed for considerable diversity in responses and a range of representations. This offers potential for effective diagnosis of students’ understandings. While the goal was restricted in some sense (in that there needed to be 16 cars on the bridge), the ways in which people were represented in these cars was open. The responses offered by the students varied in both the goal (by having different amounts of people in each car) and the activity through which they solved the task. Students had varying degrees of success with the task but all were able to produce some documentation of their understanding of the task and the concepts involved. This allowed for the teacher to make a range of judgements about students’ levels of understanding.

**Task 2: Estimation and Rounding Task**

The role of language and openness need to be considered with open-ended tasks. The use of language in open-ended tasks may make them “open” to interpretation as well as open mathematically. Consider the following task:

**Task**: My dog weighs about 20 kilograms. How much could she weigh?

This task was designed to assess the estimation and rounding skills of students so that the words of “about” and “could” were central to the notion of estimation and rounding. However, the responses of the students indicated a number of possible interpretations of the task. Many of the responses were difficult to categorize since
there would need to be some unsubstantiated interpretation of the results, so only those that clearly fell into a category are considered in the calculations.

Around half of the students interpreted the question to be one of estimation of weights. There was some degree of variability in responses with 38% of the students offering responses around the 20kg measure, as was the expected response. These responses centred on what would normally be considered those typical of a mathematical context. These students offered responses that were either a single weight such as 18.5kg, or a range of weights such as 18-22kg; or between 22.5 and 19.8, while others constructed a list of weights such as 17, 18, 19, 20, 21, 22. Others (16%) offered responses that were weights around 30-40kg that may be considered too high for estimation purposes but may indicate some conceptualization of estimation. Some of the students interviewed thought that this weight was close to 20kg while others thought that this is what their dog (at home) weighed. Hence, it is difficult to classify the answers as being correct or otherwise without further information as to the rationale behind the responses offered by these students.

What was interesting was the cluster of responses whereby students interpreted the task to be futures-orientated, where the task was translated as meaning “If my dog weighs 20 kg now, what might she weigh in the future?” Typical of this group of responses are the following answers:

"When she’s bigger, she’ll get to 25kg.”
“A puppy could be a weight of 20kg but when it’s older it could weigh 40 to 45 kg.”
“If I had a Husky that weighed 20 kg as a puppy, it might weigh 60–70kg.”
“My puppy is half grown. He weighs about 20kgs. When he is fully grown, he will way [sic] about 70kgs.”

These responses indicate that the language of the task created a different interpretation from that intended. When asked about the response he made to this task, one boy offered the following comment. “In our group one of the girls who is good at maths said that we really needed to estimate that if a puppy would weigh 20 kgs, what might is be when it was fully grown.” This comment indicates two important issues, the first being that of interpretation of the task, and second, that the role of group work also impacts on the translation of the task. While it is not possible to say how many students followed group dynamics in their responses, it is possible that in some groups dominant personalities were able to sway particular students in proposing answers of a particular type.

The use of “My dog” may cause students to personalize the task. Some students interpreted the question to be highly contextual and related to their own dog so that little or no mathematizing was undertaken. This group consisted of 17% of the student responses. Typically the responses were written in a way that suggested that the students were interpreting the question as if it were about their own dogs, real or imagined. Responses in this category were typically:

“My dog is an obese German Shepherd who weighs 60kg.”
“My dog Wally weighs about 20kg. It is very old. The vet said it should weigh 40kgs at least.”
“I think my dog is a bit fat. She could weigh about 15-17kgs.”
Included in this group of responses was a cluster of responses that seemed to estimate what a dog might weigh and tried to think about which dogs might weigh particular weights around 20 kg such as:

"A cocker spaniel might weigh 30 kgs"

"A Labrador would weigh about 40-50kgs."

There seems to be some transfer from the context of the question to the context beyond the mathematics classroom as if the question being posed asks the students to consider what types of dogs may weigh round 20kgs. While they could not accurately guess a dog that would be about 20 kgs, their reasoning is exemplified by the comment made by one girl—"I tried to think about what dog might weigh about 20 kgs. A foxy [fox terrier] is only little so I think they would not even be 10kgs. Dogs like Rottweilers and Great Danes are really big and would weight lots. I could not think of a dog that would be about 20 kgs. A Labrador would be more than 20 kgs but it was the closest that I could guess that would be near to 20kgs."

With this question, there is some sense that the question could have been worded so that it would be less ambiguous. As Sullivan et al (1999) argued, the content specific nature of open-ended tasks can provide support for learners. This task may have been ambiguous and hence open to too much interpretation when the intention of the task was to assess/access students’ understanding of estimation and rounding of mass. The task might have been better worded if it were “If a vet has rounded a dog’s weight to 20 kgs, what might the dog have weighed?” However, such wording raises a dilemma as to the openness of the task. The use of signifiers such as “rounded” can serve as a key word and as such may provide the cue for what the students need to do to undertake the task. Where a key word approach has been used, it is difficult to ascertain whether or not students have understood what the task is asking or where there has been a reliance on key words. As a strategy, using key words to solve word problems has been found to be successful. Schoenfeld (1992), reporting on a text book series widely used in the USA, found that most word problems (approx. 90%) in the series could be solved using superficial key words rather than requiring any mathematical understanding or interpretation. Using tighter or more explicit wording may have resulted in more students being able to answer the question “correctly”, it raises the issue as to the purpose of questioning in mathematics classrooms.

One of the advantages of the open-ended tasks is that they allow students to see the application of tasks to contexts beyond the classroom. While tighter wording of the problem may have meant that students were then able to provide estimates of the pre-rounded weight, it raises issues as to whether or not students understand the transfer between contexts. As Boaler (1998) argues “It seemed that the act of using mathematical procedures within authentic activities allowed the students to view the procedures as tools that they could use and adapt. The understandings and perceptions that resulted from these experiences seemed to lead to increased competence in transfer situations” (p. 59). In this instance, the wording of this question was akin to what would be heard in many beyond-school contexts, such as a veterinarian’s surgery where the weight of the dog determines the dosage of a medicine. Following Boaler’s contention, it would suggest that such openness may be useful for its links, and hence transfer, to the non-school contexts.
Openness Versus Ambiguity

While the first example highlights the value of open-ended tasks for assessment, some questions regarding the value of the second task as an assessment item need to be raised. In contrast, the second task could be seen as being poorly worded due to the ambiguity of the task. As noted earlier, however, this ambiguity can also be of value insofar as creating an openness to the task. By tightening the wording of the task in order to reduce ambiguity, it is possible that the task becomes too prescriptive due to key words defining what is to be undertaken—in this case, the use of rounding would reduce ambiguity insofar as the goals of the task but would also provide a cue as to what needed to be done. Durkin and Shire (1991) have shown that ambiguity is a part of mathematics education. Words such as rational, odd, base and so on have particular meanings in mathematics that are very different from their in non-mathematical contexts. Similarly, homophones such as pi and pie; two and too; or whole and hole also produce ambiguities for students. Walkerdine (1982) has argued that students often identify a particular word as being key in a sentence or task and as a consequence select the wrong discourse in which to locate and respond to the task. For example, in the second task, the students have interpreted the word “could” to mean a futures perspective and have responded in this sense, rather than as a rounding context as intended by the teacher. They have identified a futures discourse and responded correctly in this context.

As has been recognised within the mathematics education community, there are particular social and cultural norms that work with mathematics classrooms that students must become conversant with. Part of such competency is recognizing the unspoken rules of interactions with mathematics and what are seen to be valid and legitimate forms of responding. Students need to become familiar with what are socially legitimate forms of knowledge within the classroom and what are not. Ambiguity in wording, for example, can confuse students in what are socially acceptable responses. In the case cited here, the potential for inclusion of futures-perspectives can be a legitimate part of the mathematics classrooms, so the responses can be seen as appropriate. However, many other tasks need to be considered carefully as the ambiguous wording may cause students to offer inappropriate responses as a consequence of misinterpretation of the words and their relevant contexts. For example, the use of “odd” numbers can result in students perceiving such numbers as being “strange” due to the ambiguity of the term between the mathematics and non-mathematics contexts. Students must make the transition from one context to another. Indeed, many of the errors made by students can be seen to be linguistically related rather than mathematical.

While the value of open-ended tasks has been shown in this and other studies, there is a need for support for students when beginning open-ended approaches to teaching. In the case cited here, these students had little or no experience with open-ended tasks. Their responses to the first task suggest that they are able to deal with the tasks, but as the second task indicates, some explicit teaching maybe of value in contexts where there is some ambiguity in the task. In this case, the ambiguity can be a feature of the openness of the task but also a hindrance, particularly if there is some assessment associated with the tasks. Coming to know mathematically and pedagogically, means coming to understand the expectations of
the social and cultural norms that are embedded in such tasks. In the second task, where the ambiguity may be seen as a valuable characteristic, it may be of value to make this ambiguity an explicit teaching feature so that students come to know the unspoken rules or norms of the mathematics classroom.
